Foreword

Foreword for *Nurse Anesthesia*, First Edition

Preface

Acknowledgments

Unit I Professional Issues

1 Nurse Anesthesia

The Problem of the Occasional Anesthetists

Historical Antecedents of the Nurse as Anesthetist
Anesthesia: Medicine, Nursing, Dentistry, or What?
Organization: “We Who Are Most Interested”
World War II and Nurse Anesthetists
A Short-Lived Peace for Nurse Anesthetists and the Nation
The New Age of Nurse Anesthesia: the 1960s
The 1970s: A Turbulent Decade
Federal Legislative Initiatives in the 1980s
CRNA Achievements of the 1980s
The Call for Health Care Reform in the 1990s
Doctoral Preparation of Nurse Anesthetists Achieved
CRNA Practice Today
International Federation of Nurse Anesthetists
Progress in Anesthesia
Summary
References

2 Nurse Anesthesia Specialty Practice and Education in the United States

Nurse Anesthesia Educational Requirements
Certified Registered Nurse Anesthetist Practice
AANA Organizational Structure and Function
Summary
References

3 Patient Centered Care, Cultural Competence, and Nurse Anesthesia Practice

Patient-Centered Care: What It Is and Why Is It Important

Measurement of Health Care Quality in Anesthesia

Summary

References

Unit II Scientific Foundations

4 Nurse Anesthesia Research

Methods of Knowing

The Nature of Research

The Eight Critical Stages in the Research Process

Evidence-Based Practice: Empowering Decision Making Through Research

Evidence-Based Practice in Nurse Anesthesia

Summary

References

5 General Principles, Pharmacodynamics, and Drug Receptor Concepts

Receptor Structure

Drug Response Equation

Pharmacogenetics

Population Variability

Drug Dose Response

Drug Receptor Interactions

Drug Antagonism

Summary

References

6 Pharmacokinetics

Properties That Influence Pharmacokinetic Activity

Other Factors That Influence Pharmacokinetics

Pharmacogenetics and Pharmacogenomics

Summary

References

7 Pharmacokinetics of Inhalation Anesthetics

Primary Factors Controlling Uptake, Distribution, and Elimination of Anesthetics

Pediatrics

Other Factors

Summary

References

8 Inhalation Anesthetics

Relationship Between Chemical Structure and Agent Characteristics

Pharmacodynamics

Minimum Alveolar Concentration

Influence of Inhalation Agents on Organs and Systems

Inhalation Anesthetics and Pregnancy

Summary

References

9 Intravenous Induction Agents

Nonbarbiturate Intravenous Anesthetics

Benzodiazepines

Anesthetic Neurotoxicity

Summary

References

10 Local Anesthetics

Anatomy of the Peripheral Nerve

Neuron Electrophysiology and the Action Mechanism of Local Anesthetics

Chemical Structure of Local Anesthetics

Pharmacodynamics and Pharmacokinetic Concepts

Local Anesthetic Systemic Toxicity

Clinical Use of Local Anesthetics

Summary

References

11 Opioid and Non-opioid Analgesics

Opioids

Individual Opioids

Summary

References

12 Neuromuscular Blocking Agents, Reversal Agents, and Their Monitoring

History

Monitoring of Neuromuscular Blockade

Depolarizing Agents
Nondepolarizing Agents
Reversal of Neuromuscular Blockade
Cholinesterase Inhibitors
Anticholinergics
Summary
References

13 Autonomic and Cardiac Pharmacology

Autonomic Drugs—Sympathomimetic Amines
Direct-Acting α -Agonists
Mixed Function Agonists
Selective β_2 -Agonists
 α -Receptor Antagonists
 β -Adrenergic Blocking Agents
Statins
Antiplatelet Drugs
Cholinergics
Anticholinergics
Direct Vasodilators
Calcium Channel Blockers
Angiotensin-Converting Enzyme Inhibitors
Angiotensin II Receptor Antagonists
Anesthesia Management of Patients Taking Angiotensin Axis Blockers
Catecholamine-Depleting Agents
Tyrosine Hydroxylase Inhibitors

Catechol-O-Methyltransferase Inhibitors

Cardiac Glycosides

Management of Specific Diseases

Preoperative Administration of Cardiac Drugs

Summary

References

14 Additional Drugs of Interest

Perioperative Antibiotics

Antiemetics and Perioperative Nausea and Vomiting

Psychiatric Drugs and Anesthesia

Summary

References

15 Chemistry and Physics of Anesthesia

General Chemistry: Matter and Energy

Newtonian Physics

Thermodynamics

Quantum Physics

References

Unit III Technology Related to Anesthesia Practice

16 Anesthesia Equipment

Organization of the Anesthesia Gas Machine

Supply

Processing

Delivery

Disposal

Risk Management

Summary

References

17 Clinical Monitoring I

Electrocardiogram Monitoring

Central Venous and Arterial Hemodynamic Measurements

Arterial Pressure Monitoring

Transesophageal Echocardiography Monitoring

Summary

References

18 Clinical Monitoring II

Monitoring Standards

Alarm Fatigue

Systematic Approach to Monitoring

Airway Monitoring

Additional Monitoring Issues

Anesthesia Education and Patient Monitoring

Summary

References

19 Clinical Monitoring III

Electroencephalogram

Processed EEG Waveforms

Monitors for Assessing Central Nervous System Blood Flow and Oxygenation

Evoked Potentials

Bispectral Index

Summary

References

Unit IV Preoperative Preparation

20 Preoperative Evaluation and Preparation of the Patient

Preanesthesia Assessment Clinic

Chart Review

Patient Interview

Patient Evaluation: Overview of Systems

Diagnostic Testing

Fasting Considerations

American Society of Anesthesiologists Physical Status Classification System

Preventing Operative Errors

Summary

References

Unit V Intraoperative Management

21 Fluid Administration, Perioperative Goal-Directed Fluid Therapy, and Electrolyte Disorders

- Fluid Volume, Types of Fluids, and Overview of Fluid Management
- Normal Physiologic Distribution and Regulation of Fluids
- Composition and Relative Advantages of Various Intravenous Fluids
- Impact of Surgery and Anesthesia on Vascular Flow and Organ Perfusion
- Historical Approach to Fluid Management
- Perioperative Goal-Directed Fluid Therapy
- Electrolyte Balance
- Summary
- References

22 Blood and Blood Component Therapy

- Estimation of Blood Volume and Loss
- Transfusion Thresholds and Indications
- Patient Blood Management
- Conservation Strategies
- Transfusion Compatibility
- Emergency Transfusion
- Massive Transfusion Protocols
- Fractionation
- Best Practice Transfusion Guidelines
- Blood Storage
- Complications of Blood Transfusion
- Summary
- References

23 Positioning for Anesthesia and Surgery

Physiologic Effects of Surgical Positions

Pathophysiology of Nerve Injury

Factors Contributing to Nerve Injuries

Patient-Related Factors Contributing to Nerve Injuries

Perioperative Neuropathies

Brachial Plexus Injuries

Spinal Cord Injury

Postoperative Visual Loss

Other Position-Related Injuries

Surgical Positioning

Closed-Claims Studies

Summary

References

24 Airway Management

Anatomy and Physiology of the Airway

Airway Evaluation

Tracheal Intubation

Management of the Difficult and Failed Airway

Airway Blocks

Cricoid Pressure

Adjunct Airway Equipment and Techniques

Tracheal Extubation

Complications of Airway Management

Summary

References

25 Cardiovascular Anatomy, Physiology, Pathophysiology, and Anesthesia Management

Cardiovascular System

Vascular System

Hypertension

Mitral Stenosis

Mitral Regurgitation and Insufficiency

Aortic Stenosis

Aortic Insufficiency

Mitral Valve Prolapse

Cardiomyopathy

Summary

References

26 Anesthesia for Cardiac Surgery

Anesthetic Management of General Cardiac Surgery

Anesthetic Considerations for Specific Cardiac Diseases and Surgical Procedures

Summary

References

27 Perioperative Management of Cardiac Implantable Electronic Devices

Review of Pacemakers

Review of Implantable Cardioverter Defibrillators

Perioperative Period

Summary

References

28 Anesthesia for Vascular Surgery

Peripheral Vascular Disease

Abdominal Aortic Aneurysms

Abdominal Aortic Reconstruction

Thoracic Aortic Aneurysms

Aortic Dissection

Descending Thoracic and Thoracoabdominal Aneurysms

Endovascular Aortic Aneurysm Repair

Cerebrovascular Insufficiency and Carotid Endarterectomy

Carotid Artery Angioplasty Stenting

Summary

References

29 Respiratory Anatomy, Physiology, Pathophysiology, and Anesthetic Management

Anatomy and Physiology of the Respiratory System

Respiratory System Pathology

References

30 Anesthesia for Thoracic Surgery

Preoperative Preparation

Lateral Decubitus Position

One-Lung Ventilation

Anesthetic Management During One-Lung Ventilation

Thoracic Surgical Concerns

Complications After Thoracotomy

Summary

References

31 Neuroanatomy, Neurophysiology, and Neuroanesthesia

Organization of the Central Nervous System

Anatomy of the Central Nervous System

Peripheral Nervous System

Vasculature of the Central Nervous System

Electrophysiology

Neurotransmitters

Sensory Pathways

Motor Pathways

Neuroanesthesia

Intracranial Pressure

Neurophysiologic Monitoring

Anesthetic Considerations for Specific Procedures

Summary

References

32 Renal Anatomy, Physiology, Pathophysiology, and Anesthesia Management

Structure of the Kidney

Renal Physiology

Effects of Anesthesia on Normal Renal Function

Acute Kidney Injury

Chronic Kidney Disease

Preoperative Renal Assessment

Anesthetic Management of Patients With Advanced Renal Disease

Intravenous Fluid Management

Cystoscopy

Extracorporeal Shock-Wave and Laser Lithotripsy

Percutaneous Nephrolithotomy

Transurethral Resection of the Prostate

Laparoscopic Urologic Surgery

Robotic Urologic Surgery

Renal Transplantation

Open Nephrectomy

Summary

References

33 Hepatobiliary and Gastrointestinal Disturbances and Anesthesia

Liver Disease

Diseases of the Biliary Tract

Diseases of the Esophagus

Diseases of the Stomach

Pancreatic Disease

Diseases of the Intestinal Tract

Splenic Disease

Carcinoid Tumors and Carcinoid Syndrome

Summary

References

34 Anesthesia for Laparoscopic Surgery

Creation of the Pneumoperitoneum

Physiologic Effects of the Pneumoperitoneum

Complications of Laparoscopic Surgery

Anesthetic Management

Postoperative Concerns

The Future of Laparoscopic Surgery

Summary

References

35 Anesthesia for Robotic Surgery

History of Robotic Surgery

Robotic Systems

General Anesthetic Considerations

Considerations for Surgical Subspecialties

Summary

References

36 Musculoskeletal System Anatomy, Physiology, Pathophysiology, and Anesthesia Management

Overview of Neuromuscular Transmission

Muscle Physiology

Musculoskeletal Pathophysiology and Anesthesia

Summary

References

37 The Endocrine System and Anesthesia

General Principles of Endocrine Physiology

Pituitary Gland

Parathyroid Gland

Pancreas

Diabetes Mellitus

Adrenal Glands

Thyroid Gland

Summary

References

38 Hematology and Anesthesia

The Normal Vessel Wall

Vessel Injury

Cell-Based Theory of Coagulation

Fibrinolytic System

Anesthetic Implications

Specific Disorders

Other Considerations

Summary

References

39 Thermal Injury and Anesthesia

Classification of Burn Injury

Etiologies of Burn Injuries

Treatment of the Burn Patient

Summary

References

40 Trauma Anesthesia

Etiology of Traumatic Injury

Coordinated Management of Care

Early Evaluation of the Trauma Patient and Common Injury Patterns

Blunt Versus Penetrating Trauma

The ABCDs of Trauma Anesthesia

Special Topics in Trauma Anesthesia

Summary

References

41 Anesthesia for Organ Transplantation

History of Organ Transplantation

Renal Transplantation

Pancreas Transplantation

Liver Transplantation

Lung Transplantation

Intestinal Transplantation

Anesthetic Considerations for the Organ Donor

Summary

References

42 Outpatient Anesthesia

Features of Outpatient Surgery

Patient Selection

Patient Evaluation and Preparation

Premedication

Anesthetic Considerations

Postoperative Considerations

Summary

References

43 Anesthesia for Ear, Nose, Throat, and Maxillofacial Surgery

Functional Anatomy of the Head and Neck

Preparation and Considerations for Ear, Nose, and Throat Procedures

Specialized Equipment for Ear, Nose, and Throat Procedures

Special Considerations for Ear, Nose, and Throat Procedures

Select Techniques Commonly Used in Ear Nose and Throat Procedures

Procedures Involving the Face, Ear, Head, and Neck

Summary

References

44 Anesthesia for Ophthalmic Procedures

Ophthalmic Anatomy

Pharmacology: Ocular Medications and Anesthetic Agents

Select Ocular Anesthesia Techniques

Ocular Regional Anesthesia
Positive Orbital Pressure
Anesthesia Management
Ophthalmic Anesthesia Complications
Summary
References

45 Anesthesia for Orthopedics and Podiatry

Pneumatic Tourniquet
Non-Pneumatic Tourniquets
Patient Positioning
Arthroscopy
Arthroplasty
Spinal Surgery
Foot and Ankle Surgery
Forearm and Hand Surgery
Arthritic Syndromes
Summary
References

46 The Immune System and Anesthesia

The Immune System
Active and Passive Immunity
Hypersensitivity
Alloimmunity
Autoimmunity

Immunodeficiency Disorders

Cancers of the Immune System

Surgery and the Immune System

Anesthesia and the Immune System

Anesthetic Management of the Immunocompromised Patient

Summary

References

47 Anesthesia and Laser Surgery

Introduction

Basic Principles of Lasers

Laser Effects on Biologic Tissues

Surgical Lasers

Laser Safety

Surgical Fires

Anesthesia for Laser Procedures

Summary

References

48 Obesity and Anesthesia Practice

Overview

Adipose Tissue

Causes of Obesity

Pathophysiology of Obesity

Pediatric Obesity

Maternal Obesity

Treatment of Obesity

Pharmacologic Considerations

Anesthetic Management: Preanesthetic Evaluation

Anesthetic Management: Preparation

Anesthetic Management: Maintenance

Anesthetic Management: Postoperative Care

Summary

References

49 Regional Anesthesia

Applied Anatomy and Physiology of the Central Neuraxis

Spinal Anesthesia

Epidural Anesthesia

Combined Spinal and Epidural Anesthesia

Caudal Anesthesia

Summary

References

50 Regional Anesthesia

Selection of Regional Anesthesia Techniques

Complications of Peripheral Nerve Blockade

Electrical Stimulators in Regional Anesthesia

Ultrasound-Guided Regional Anesthesia

Intravenous Regional Anesthesia (Bier Block)

Intercostal Nerve Blocks

Transversus Abdominis Plane Block

Lower-Extremity Block

Summary

References

51 Obstetric Anesthesia

Anatomic and Physiologic Changes During Normal Pregnancy

Labor and Delivery

Analgesia for Labor and Vaginal Delivery

Anesthesia for Cesarean Section

Complications of Regional Anesthesia

Obstetric Complications

Anesthesia for the Pregnant Patient Undergoing a Nonobstetric Procedure

Neonatal Resuscitation

Summary

References

52 Neonatal Anesthesia

Developmental Considerations

Growth and Development

Anesthetic Pharmacologic Considerations in the Neonate

Drugs Used to Provide Neonatal Anesthesia

Fluid Management

Anesthetic Equipment

Preoperative Assessment

Anesthetic Considerations for Selected Cases

Summary

References

53 Pediatric Anesthesia

Pediatric Anatomy and Physiology

Pediatric Pharmacologic Considerations

Preoperative Preparation

Anesthetic Management

Postoperative Care

Regional Anesthesia

Outpatient Anesthesia

Pediatric Anesthetic Morbidity and Mortality

Summary

References

54 Geriatrics and Anesthesia Practice

Preoperative Assessment

Age-Related Physiologic Changes in the Older Adult

Issues of Specific Importance in the Older Adult Preoperative Assessment

Age-Related Pharmacologic Implications in the Older Adult

Comorbidity in the Older Adult

Ethical Issues in the Treatment of the Older Adult

Postoperative Delirium

Postoperative Cognitive Dysfunction

Summary

References

55 Postanesthesia Recovery

Postanesthesia Care Unit Admission

Anesthesia Report

Initial Postanesthesia Care Unit Assessment

Ongoing Assessment

Discharge From the Postanesthesia Care Unit

Summary

References

56 Acute Pain

Pain

Physiologic Consequences

Pharmacology

Acute Pain Management in Special Populations

Summary

References

57 Chronic Pain

Anatomy and Physiology of Pain

Pain Pathophysiology

Types of Chronic Pain

Treating Chronic Pain

Pharmacology

Targeted Pain Management

Age-Related Considerations

Patient-Centered Approach

Failure to Treat Pain

Summary

References

58 Nonoperating Room Anesthesia

Administration of Anesthesia in Remote Locations

Anesthesia for Specific Procedures in Remote Locations

Remote Anesthetic Monitoring Using Telecommunication Technology

Summary

References

59 Anesthesia Complications

Mortality in Anesthesia

Morbidity in Anesthesia

Perioperative Mortality and Mortality Related to Human Error

Perioperative Mortality and Morbidity Related to Obstetrics

Perioperative Mortality and Morbidity Related to Pain

Perioperative Mortality and Morbidity Over 70 Years of Age

Anesthetic Complications Related to the Growth and Development of Pediatric Brain

Perioperative Cardiopulmonary Complications

Intraoperative Awareness

Complications Associated With Sedation and Anesthesia Outside of the Operating Room

Management of Complications

The Second Victim

The Human Factor in Complications

Foreword

We are reprinting the forward written by John F. Garde from the first edition of *Nurse Anesthesia*, which was published in 1997. John encouraged the publication of the first edition of this text, two decades ago, as an important milestone in the evolution of the specialty of nurse anesthesia. He felt it showcased the breadth and depth of nurse anesthetists' contributions to research and clinical care. John conveyed his enthusiasm for the unique role of nurse anesthetists to everyone he encountered. He believed that anesthesia excellence was manifest when a clinician made a difference in the everyday lives of patients. He was without question the most consequential nurse anesthesia leader of his time. We present the foreword that he wrote for the first edition of this textbook in his honor.

Foreword for *Nurse Anesthesia, First Edition*

As a new century dawns, nurse anesthetists continue to provide the highest quality anesthesia services to their patients. To put this into perspective, consider that nurse anesthetists safely and compassionately administered anesthesia throughout the entire last century and even prior to that. The writings of Alice Magaw, published between 1899 and 1906, provide a noteworthy benchmark. Magaw detailed the use of chloroform and other anesthesia with the open-drop technique in more than 14,000 surgical cases without a single fatality attributable to anesthesia. She was the first nurse anesthetist to publish articles on the practice of anesthesia and was considered “the mother of anesthesia” during a time when surgeons selected nurses to specialize in anesthesia to provide greater safety for patients requiring anesthesia.

Many pharmacologic and technologic changes in anesthesia have occurred, however, since those noble beginnings. The chapter titles of this textbook serve as an atlas to this expanded knowledge base: “Clinical Monitoring in Anesthesia,” “Anesthesia Equipment,” “Pharmacokinetics,” “Inhalation Anesthetics,” “Intravenous Induction Agents,” “Local Anesthetics,” “Opioid Agonists and Antagonists,” and “Neuromuscular Blocking Agents, Reversal Agents, and Their Monitoring,” to name a few. Look at the specialty components of anesthesia contained in this book: “Cardiac Anesthesia,” “Respiratory Anesthesia,” “Thermal Injury and Anesthesia,” “Trauma Anesthesia,” “Outpatient Anesthesia,” “Regional Anesthesia,” “Anesthesia for Ophthalmic Procedures,” “Anesthesia and Orthopedics,” “Anesthesia for Ear, Nose, Throat, and Maxillofacial Surgery,” “Anesthesia and Laser Surgery,” and the list goes on. The continuum for practice in the twenty-first century is that of professionals learning anew how to ensure the best possible care for their patients.

When Agatha Hodgins and other nurse anesthetist pioneers

gathered in a classroom in the anesthesia department of the University Hospital of Cleveland on June 17, 1931, they established what was to become the American Association of Nurse Anesthetists (AANA). This group sought to place better-qualified people in the field, to keep those already in nurse anesthesia abreast of modern developments, and to give protection and recognition to this group of professionals.

When the AANA values statement was adopted in 1995, it was not surprising that it reflected this earlier philosophy. The AANA values the following:

- Its members and the advancement of the profession of nurse anesthesia
- Quality service to the public through diverse practice settings based on collaboration and personal choice
- Integrity, accountability, competence, and professional commitment
- Scientific inquiry and contributions to the fields of anesthesiology, nursing, and related disciplines
- Participation in the formation of healthcare policy.

These value statements are supported by knowledgeable practitioners ever in pursuit of their craft.

Nurse Anesthesia is a textbook that builds on a formidable knowledge base and draws on the expertise of CRNAs and other professionals practicing in today's fast-paced, ever-changing environment. I look upon this volume as a means to demonstrate the profession's growth and encourage CRNAs and student nurse anesthetists to read it and reflect upon the dynamic field they have chosen.

I would like to close with one of my favorite quotations from Ralph Waldo Emerson, which I believe reflects all professionals on their prospective journeys:

To laugh often and much; to win the respect of intelligent people ...;

to earn the appreciation of honest critics ...;

to find the best in others ...;

to leave the world a bit better. ... Bon voyage.

John F. Garde MS, CRNA, FAAN

Preface

Nurse anesthesia education and clinical practice continues to evolve at a rapid pace. Our professional degree has moved to the doctoral level, and the requisite knowledge needed to provide safe patient care is increasing exponentially. Due to the complexity of modern surgical procedures, ensuring the highest-quality outcomes requires the need for lifelong learning. Anesthesia practice has expanded beyond the traditional surgical settings to include interventional procedures, pain management, and non-operating room anesthetics. The objective of this new edition is to integrate the vast amount of current knowledge to help guide clinical practice.

Technological innovations that allow this textbook to be used in traditional, as well as various electronic formats, are now commonplace. We approach the sixth edition of *Nurse Anesthesia* with a clear intent to bridge these platforms while remaining true to our educational objectives. Since the conception of the first edition of this text more than two decades ago, we continue to be guided by our original vision to fill the need for scientifically-based, clinically-oriented work on which anesthesia practitioners and learners can rely to deliver excellent patient care.

Our intent is to harness the vast knowledge that nurse anesthetists bring to clinical practice and provide a comprehensive, evidence-based resource for continuous learning. We are tremendously gratified that this textbook has become the seminal work for our specialty. This book is included among the Library of Congress's essential nursing textbooks for medical libraries throughout the United States and in national digital resource databases such as Elsevier's ClinicalKey for Nursing. We reach an international audience of nurses and nurse anesthetists and are always pleased when we hear of the positive impact we are having on anesthesia practice worldwide.

We are especially grateful to all of our new and returning authors

who bring a wealth of expertise and experience to their respective areas. The majority of clinical anesthesia continues to be provided by nurse anesthetists, and this textbook is a testament to the leadership we bring to academic and clinical nursing. Each chapter has been extensively reviewed and revised to contain the most salient information available. The newest concepts, techniques, and areas of controversy in anesthesia are discussed in detail. This is the first edition to contain full color, which greatly enhances the readability of the hundreds of new tables, figures, and boxes. Effective anesthesia must be viewed as part of a therapeutic continuum of care. For this reason, we have been especially sensitive to include the latest medical and surgical information available from the specialties that impact our practice. Integrating new technology and knowledge in the basic sciences into clinical practice has allowed nurse anesthetists to continue to evolve as leaders in providing safe and comprehensive care. We have included additional new chapters on a wide variety of topics, including patient-centered care; cultural competence and nurse anesthesia practice; additional drugs of interest, including antibiotics, psychiatric drugs, and antiemetics; goal-directed fluid therapy; blood and blood component therapy; anesthesia management for patients with cardiac devices; anesthesia for robotic surgery; anesthesia for transplant surgery and organ procurement; and chronic pain: physiology and management. The chapter dedicated to research in nurse anesthesia has been reconceptualized to focus on the integration of evidence-based research into practice.

Producing an educational resource of this size and complexity would not be possible without the tireless efforts of our authors and a broad array of experts. We would like to express our sincere gratitude to Retta Smith, who assisted in the production and editing of this textbook, and Clinton Lee for designing graphics. We proudly carry over from the previous editions hundreds of anatomic figures that were specially hand drawn for this text by the renowned medical illustrator, William E. Loechel. We would like to express our gratitude to the staff at Elsevier who work tirelessly to produce this textbook. This book would not exist without their knowledge, expertise, and enthusiasm. A special thank you to

Tamara Meyers, Executive Content Strategist; Laura Selkirk, Senior Content Development Specialist; and Lisa Bushey, Project Manager.

We would also like to acknowledge the contributions of Karen Plaus, PhD, CRNA, FAAN, as the coeditor of the first five editions of this text. Dr. Plaus has devoted her career to educating nurse anesthetists and advancing our specialty. Her decades-long achievements on the national and international level continue to be instrumental in making nurse anesthesia a vital specialty for delivering high-quality healthcare.

Professional Issues

OUTLINE

1 Nurse Anesthesia A History of Challenge

2 Nurse Anesthesia Specialty Practice and Education in the United States

3 Patient Centered Care, Cultural Competence, and Nurse Anesthesia Practice

Nurse Anesthesia

A History of Challenge

Bruce E. Koch

It is fitting to open a text on nurse anesthesia with a history chapter. Nurses were the first professional anesthetists in the United States; the vast majority of anesthetics provided in this country are administered by nurses. And nurses have contributed to progress in clinical anesthesia, patient safety, and the science, education, and public policies supporting anesthesia. By teaching what nurse anesthetists in the past have accomplished, oftentimes against great odds and with few or none of the resources available to us today, we fix in the pupil's mind the fact that anesthesia is a practice of nursing.

People have known since the late 18th century that inhaling nitrous oxide or diethyl ether produces euphoria. The English scientists Joseph Priestley and Humphrey Davy experimented on themselves and even partied with these substances. Davy famously speculated that nitrous oxide “may probably be used with advantage during surgical operations.”¹

At the same time, American medical students used ether and nitrous oxide recreationally. But almost 40 years would pass before they attempted to use these agents as adjuncts to surgery. Crawford Long, a Georgia physician, used diethyl ether for the removal of a small cyst in 1842, but he did not report his findings. At least two other men, the Massachusetts physician Charles Jackson and the Connecticut dentist Horace Wells, experimented with ether or nitrous oxide. Four years after Long's use of ether, on October 16, 1846, the Boston area dentist William T.G. Morton conclusively demonstrated the use of ether for surgical anesthesia in an operating room (now memorialized as the “Ether Dome”) at

Massachusetts General Hospital. So important was the event that the surgeon John Collins Warren, who had witnessed many prior failed attempts, reportedly exclaimed, "Gentlemen, *this* is no humbug." Another eminent surgeon who had been in attendance stated, "I have seen something today that will go around the world."² From their vantage point, optimism seemed justified; however, another half century would pass before the promise of painless surgery would be substantially fulfilled.

From the outset, Morton's discovery caused problems. People realized its monetary and historic value, and wanted a piece of the action. Morton attempted to disguise ether so he could profit from it. He named the substance Letheon and applied for a patent. Long, Jackson, and Wells all claimed credit for Morton's discovery. The four men battled for years. The physician and writer Oliver Wendell Holmes, Sr. (father of the Supreme Court Justice) wrote to Morton: "Everybody wants to have a hand in a great discovery.... All I want to do is give you a hint or two as to names." Holmes suggested "anesthesia from the Greek for insensible." But it seems Holmes too wanted something for himself. The term *anesthesia*, according to historian Julie Fenster, "had been in use before to denote parts of the body benumbed but not paralyzed." She added that, "Holmes only borrowed the word for the new state of being, though he has received credit for coining it."³ As Robert Dripps dryly noted, "anesthesia was placed under a cloud."⁴

Nineteenth century anesthesia was problematic in other more important ways. The related infections and careless anesthetists vexed surgeons, plagued patients, and delayed progress in the field of anesthesia for decades. They led the historian Ira Gunn to term this era "the period of the failed promise."⁵

The Problem of the Occasional Anesthetists

In the 19th century, physicians developed surgery, but not anesthesia, as a medical specialty, although there were calls for them to do so.⁶ James Gather, the pioneer physician anesthetist, gave one explanation for this medical disinterest: “So intense had been the interest in surgery that anesthetics had been used only as a means to an end, and this fully explained the attitude of the profession on this subject in America at the present time.” But money was also an issue. One physician commentator, S. Simon, doubted whether a physician “taking the work up as a specialty could make a living at it alone; and especially is this true in the smaller cities.”⁷ The historian Marianne Bankert agreed: “Apart from the few physicians who had a genuine intellectual interest in anesthesia, it would also take years for the economics of anesthesia to make it an attractive area for their colleagues—if at first, only as a supplemental source of income.”⁸ The Philadelphia surgeon J. M. Baldy thought anesthesia unworthy of a physician's intellect: “Every physician obtains his medical education with the idea of practicing medicine, and it is only dire necessity which will compel him to give up such a future for the narrow one of anesthesia.” Anesthesia remained a medical stepsister to surgery until well into the 20th century.⁹

The work of anesthesia was relegated to others: “Students, nurses, newly graduated physicians, specialists in other fields, and even custodians were called upon to be *etherizers*.”¹⁰ “Anesthesia could be anybody's business,” wrote Virginia Thatcher.¹¹

Lack of attention led to a degradation of knowledge and technique: “Within a few months (of the discovery) at the Massachusetts General Hospital, Morton's inhaling apparatus (which had worked well) was abandoned in favor of a small bell-shaped sponge, which was saturated with ether and applied directly over the nose and the mouth of the patient.”¹¹ Not surprisingly, ether pneumonia resulted. Some surgeons therefore turned to chloroform, which had been discovered to have

anesthetic properties by James Simpson in England in 1847. "But, very soon, a death occurred from chloroform, then another and another in quick succession. This led to its more careful and restricted use by some surgeons, to its total abandonment by others, but in 1855, the general mass of surgeons and physicians still continued its use..."¹² Thatcher cited one physician who, in 1859, wrote: "In some cases Dr. M. had seen chloroform administered by young gentlemen rather in a careless manner....In fact, he believed that most of the fatal cases can be traced to a careless administration of the remedy."¹³

Careless anesthesia persisted for decades. A cogent example was recorded in 1894 by Harvey Cushing, the founder of neurosurgery. Almost fifty years after the discovery of anesthesia, Cushing was a student at Harvard Medical School:

My first giving of an anaesthetic was when, a third-year student, I was called down from the seats and sent in a little side room with a patient and an orderly and told to put the patient to sleep. I knew nothing about the patient whatsoever, merely that a nurse came in and gave the patient a hypodermic injection. I proceeded as best I could under the orderly's directions, and in view of the repeated urgent calls for the patient from the amphitheatre it seemed to be an interminable time for the old man, who kept gagging, to go to sleep. We finally wheeled him in. I can vividly recall just how he looked and the feel of his bedraggled whiskers. The operation was started and at this juncture there was a sudden great gush of fluid from the patient's mouth, most of which was inhaled, and he died. I stood aside, burning with chagrin and remorse. No one paid the slightest attention to me, although I supposed I had killed the patient. To my perfect amazement, I was told it was nothing at all, that I had nothing to do with the man's death, that he had a strangulated hernia and had been vomiting all night anyway, and that sort of thing happened frequently and I had better forget about and go on with the medical school. I went on with the medical school, but I have never forgotten about it.

Not surprisingly, surgeons began to appreciate the need for professional anesthetists. The need, as Thatcher defined it, was for

anesthetists who would “(1) be satisfied with the subordinate role that the work required, (2) make anesthesia their one absorbing interest, (3) not look on the situation of anesthetist as one that put them in a position to watch and learn from the surgeon's technic [*sic*], (4) accept the comparatively low pay, and (5) have the natural aptitude and intelligence to develop a high level of skill in providing the smooth anesthesia and relaxation that the surgeon demanded.” Some surgeons, particularly in the Midwest, “accepted in this capacity a class of persons for whom they had learned to have deserved respect and from whom they had obtained commendable assistance and service—the Catholic hospital Sister.”¹¹ And so as a result of medical disinterest, poor delivery of anesthesia in general, and an overwhelming need, nurses were asked to give anesthesia.

Historical Antecedents of the Nurse as Anesthetist

The Civil War provided the first opportunity for nurses to assume the duties of anesthetist. Evidence is found in three different accounts. Mrs. Harris from Baltimore, Maryland, took chloroform and stimulants to the Battle of Gettysburg. Harris “penetrated as near as possible to the scene of the conflict, ministering as much as in her power to the stream of wounded that filled the cars...”¹⁴ It is not known whether Mrs. Harris was a nurse. A second report connects a nurse with administering chloroform: “Private Budlinger of the 76th Ohio Unit, after breathing it for a few minutes without any apparent effect, more chloroform was added and reapplied by a nurse in attendance.”¹⁵

But the most convincing example was written by a nurse. Catherine S. Lawrence, a native of Skaneateles, New York, wrote a 175-page autobiography in which she recorded administering anesthesia as a Union Army nurse. Lawrence described her duties at a hospital outside Washington, D.C., during and after the Second Battle of Bull Run (1863). She administered medications, resuscitated with restoratives like ginger, tied sutures around arteries, and administered chloroform. “I rejoice that the time has arrived that our American nurses are being trained for positions so important. A skillful nurse is as important as a skillful physician.”¹⁶⁻¹⁸

The early use of nurses as anesthetists was mostly an American phenomenon. However, a 1911 article revealed that “(In) the European hospitals female as well as male nurses...were taught how to give anaesthetics [*sic*] in the... (Franco-Prussian War of 1870–71). Only the nurses gave anaesthesia in the ambulatory hospitals on the field.”¹⁹

The First Civilian Nurses to Practice Anesthesia

Civilian nurses began to practice anesthesia at the behest of surgeons during the 1870s in the Midwest. Sister Mary Bernard founded the Sisters of St. Joseph of Wichita, Kansas, and in 1877

entered St. Vincent's Hospital in Erie, Pennsylvania to train as a nurse. A year later, she took over the anesthesia duties of the hospital. This practice was repeated by surgeons throughout the Midwest. The Franciscan Sisters, who were active in the building and staffing of St. John's Hospital in Springfield, Illinois, were particularly successful in preparing hospital Sisters as nurse anesthetists and sending them out to other Midwestern hospitals. Having been prepared by another community of the Sisters of St. Francis (Syracuse, New York), Sister Mary Erhard went to Hawaii in 1886, where she administered anesthesia and performed other nursing duties on the island of Maui for approximately 42 years.

The St. Mary's Experience

In the summer of 1883, a very destructive tornado swept through Rochester, Minnesota. In its wake, wrote Helen Clapsattle, the tornado "left an idea in the mind of the mother superior of the Sisters of St. Francis." During rescue efforts, Mother Alfred paid a visit to Dr. W.W. Mayo and asked: "Did he not think it would be well to build a hospital in Rochester?" Dr. Mayo thought the town too small to support a hospital, but "Mother Alfred had made up her mind. Quietly she overruled the Old Doctor's objections and said that if he would promise to take charge of a hospital, the sisters would finance it." St. Mary's Hospital was built and opened, and although hospitals ranked low in the public's mind, the venture was a huge success. By 1904, it had expanded twice in order to keep up with demand, and has endured until today as the Mayo Clinic. The Mayos (William Sr., William Jr., and Charles) won international acclaim for their surgery.

But how did the Mayos handle the administration of anesthesia? Like many surgeons, they were aware of its dangers, but unlike their colleagues on the East Coast, they were quick to embrace the open drop method of ether when it was brought to the United States from Germany. They also differed from East Coast physicians in one other respect: "In employing a permanent full-time anesthetist, and that a nurse, the Mayos were unusual if not unique. In other hospitals anesthetizing was one of the duties of the interns."

Why would they give the job to nurses? The Mayos had given the

job to a nurse “in the first place through necessity; they had no interns. And when the interns came, the brothers decided that a nurse was better suited to the task because she was more likely to keep her mind on it, whereas the intern was naturally more interested in what the surgeon was doing.”²⁰

Nurses won the Mayos' admiration by improving anesthesia care. Alice Magaw could discuss “a hundred and one details as to signs of sufficient anesthesia and ways of recognizing and preventing impending disaster.” Magaw, along with her pupil Florence Henderson, refined and advocated the dripping of ether. Ether anesthesia required vigilance and careful attention to detail and to the psychological care of patients to minimize the agitation that often led to disasters like the one previously described by Harvey Cushing.

Florence Henderson described how this was done: “A modified Esmarch inhaler, which is covered with two layers of stockinet, is used.... With the mask held about an inch from the face the ether is dropped upon it, slowly at first, and the patient is asked to breathe naturally through the nose. Then the mask is gradually lowered, and the rapidity of the dropping increased, care being taken not to give the ether fast enough to cause a sensation of smothering or suffocation. As soon as the jaw relaxes the head is turned to one side, because the patient usually breathes more easily with the head in this position.” This was quite a contrast to the “crude” methods of most early anesthetizers, and it was successful. Nancy Harris and Joan Hunziker-Dean, who investigated Florence Henderson's life, concluded that “through a delicate balance of interpersonal skills and technical expertise, (Henderson) was able to essentially eliminate the excitement phase of ether anesthesia and consistently used a fraction of the usual ether dose. She demonstrated to all who observed that the administration of ether anesthesia could be elevated to an art form.”²¹

Magaw and Henderson improved the safety of anesthesia care. Magaw accounted delivery of over 14,000 anesthetics “without an accident, the need for artificial respiration or the occurrence of pneumonia or any serious results.”²²⁻²⁶ Included were anesthetics for abdominal, intraperitoneal gynecologic, urologic, orthopedic, ophthalmic, head and neck, and integument operations. Some were

even conducted with the patient in the prone position.²³

Thatcher wrote that it was Alice Magaw who “brought to the profession of nurse anesthetist as well as to the Mayo Clinic no little fame at a time when poor anesthesia was the major worry of most surgeons.” Charles Mayo was so impressed by Magaw that he named her “The Mother of Anesthesia.” Surgeons who visited from Minneapolis, Iowa, Baltimore, Chicago, and England “sent selected nurses to Rochester to observe Alice Magaw and other nurse anesthetists at St. Mary's Hospital at their work.”¹¹

Magaw and Henderson introduced better teaching methods too. Early anesthesia education has been described by A.J. Wright as “on the spot training of any person available.” At Mayo, sometimes the “nurses stayed for 2 or 3 months and learned to give ether under supervision.”²⁷

The Lakeside Experience

A second “Mecca” of nurse anesthesia developed in Cleveland, Ohio. In 1900, Agatha Hodgins (Fig. 1.1), a Canadian nurse, went to Cleveland to work at Lakeside Hospital. Dr. George Crile chose her to become his anesthetist in 1908, and as such she became perhaps even more renowned than Alice Magaw. Together with Crile, Hodgins pioneered the use of nitrous oxide/oxygen anesthesia, introduced it in World War I, and opened and led a prominent school for nurse anesthetists that endured the first major challenge from physician anesthetists. In 1931, Hodgins alone founded the American Association of Nurse Anesthetists (AANA).

FIGURE 1.1 Agatha Hodgins, an educator and founding president of the AANA, reintroduced (with other American nurse anesthetists) the use of nitrous oxide for battlefield surgery during World War I in Europe.

Hodgins' primary interest was in education. Like the St. Mary's Hospital in Rochester, Minnesota, the Lakeside Hospital was the recipient of many requests for anesthetist training from both physicians and nurses. According to Thatcher, "Visiting surgeons eager to emulate the Lakeside methods, customarily bought a gas machine (the Ohio Monovalve) and then sent a nurse to Cleveland to find out how it worked."¹¹ Hodgins recalled, "The number of applicants increased so rapidly that we felt some stabilizing of work necessary and the matter of a postgraduate school in anesthesia presented itself." In 1915, Hodgins opened a school at Lakeside Hospital. The Lakeside School was not the first formal postgraduate anesthesia educational program; that honor belongs to St. Vincent's Hospital in Portland, Oregon. But the Lakeside School is the only program for which original records still exist. There were admission requirements, the course included both clinical and didactic components, tuition was charged, and a diploma was granted. "The department of anesthesia encompassed the school, both being under the charge of Agatha Hodgins as chief anesthetist. She, in turn, worked under the jurisdiction of the superintendent of the hospital and the chief surgeon. For the supervision of the students she had 1 or 2 assistants until 1922 when the number was increased to 3."¹¹ The evolution of nurse anesthesia education into a more formalized, scientifically based discipline can thus be seen.

Although records do not exist, the Lakeside Hospital School prompted the establishment of 54 similar programs at major hospitals in Chicago, Illinois; Worcester, Massachusetts; Milwaukee, Wisconsin; New Orleans, Louisiana; Baltimore, Maryland; Ann Arbor, Michigan; St. Louis, Missouri; Detroit, Michigan; Poughkeepsie, New York; Tacoma, Washington; and Minneapolis, Minnesota.²⁴

The Proliferation of Nurse Anesthetists

Prior to World War I, the administration of anesthesia grew more sophisticated. Nitrous oxide was reintroduced, and with it came the first anesthesia machines capable of pressurizing, regulating, and delivering a gas. Surgeons and hospitals sought nurse anesthetists who were capable of using the machines. The first recognition of the value of formalized education also occurred at this time. Four postgraduate programs were developed: at St. Vincent's Hospital in Portland, Oregon (1909),²⁵ at St. John's Hospital in Springfield, Illinois (1912); at New York Postgraduate Hospital in New York City (1912); and at Long Island College Hospital, Brooklyn, New York (1914).¹¹ Other nurse anesthesia programs were developed as a part of the undergraduate nursing curriculum as a specialty option. Isabel Adams Hampton Robb, a leading pioneer in nursing and the first superintendent of the Johns Hopkins School of Nursing, which opened in 1889, had, in 1893, published a nursing textbook titled *Nursing: Its Principles and Practices for Hospital and Private Use*; this textbook included a chapter titled "The Administration of Anaesthetics." By 1917, as a result of the "superior quality of anesthesia performed by nurse anesthetists,"²⁴ they were given the responsibility for surgical anesthesia at Johns Hopkins Hospital in Baltimore, where a training program was established under the direction of Ms. Olive Berger.

But success bred resistance. Thatcher wrote that, "The rapid growth of postgraduate schools of anesthesia in which nurses were trained, as well as the increasing enthusiasm for the trained nurse anesthetists during World War I, did not escape the attention of physician specialists in anesthesia, and during the 1920s resentment against the nurse anesthetist culminated in attempts to legislate her out of existence."¹¹

The Great War, a Small Battlefield

Nurse anesthetists played a very large role during World War I. Their involvement began in 1913, four years before the United States became involved militarily, and lasted until the armistice in 1918.

When America entered the war, the Army Nurse Corps numbered 233 regular nurses; it would grow to 3524 nurses by 1918. The number of nurses who actually practiced anesthesia is unknown, because at the time nurse anesthetists formed part of the general nursing staff.²⁷ However, nurse anesthetists were credited with introducing nitrous oxide/oxygen and teaching its administration to the English and the French.²⁸ As a result of the superior performance of nurse anesthetists, both the Army and the Navy sent nurses for anesthesia training for the first time.

Several outstanding World War I-era nurse anesthetists have been remembered because they wrote of their work. Nurse anesthetists spent countless hours etherizing wounded soldiers as they arrived in “ceaseless streams for days at a time after battles,” wrote Mary J. Roche-Stevenson. “Work at a casualty clearing station came in great waves after major battles, with intervals between of very little to do.... Barrages of gun fire would rock the sector for days, then convoys of wounded would begin to arrive by ambulance. Night and day this ceaseless stream kept coming on.... The seriously wounded, especially the ones in severe shock, were taken to a special ward, given blood transfusions and other treatments in preparation for surgery later. From the receiving tent, the wounded were brought to the surgery, put on the operating tables stretcher and all, given an anesthetic, operated upon, picked up on their stretcher, and loaded on hospital trains for evacuation to base hospitals.”²⁹ Terri Harsch,²⁷ who described the works of Roche-Stevenson and others such as Sophie Gran Winton, reported that 272 nurses were killed during the war.

In a paper about Miss Nell Bryant, who was the sole nurse anesthetist from the Mayo Clinic stationed at Base Hospital Number 26,³⁰ we learn that chloroform and ether were in use, the physiology of shock was poorly understood, oxygen and nitrous oxide were given without controlled ventilation, and venipuncture involved a surgical cutdown.

Anne Penland was a nurse anesthetist with the Presbyterian Hospital of New York unit at Base Hospital Number 2. She had the honor of being the first US nurse anesthetist to go officially to the British front, where she so won the confidence of British medical officers that the British decided to train their own nurses in anesthesia, ultimately relieving more than 100 physicians for medical and surgical work. Several hospitals were selected for this training of British nurses, including the American Base Hospital Number 2, with Penland as the instructor.⁸

Commenting in the *Bulletin of the American College of Surgeons*, Frank Bunts wrote: "The (First) World War demonstrated beyond any question the value of the nurse anesthetist."³¹ George Crile speculated that "if the Great War had gone on another year, the British army would have adopted the nurse anesthetists right in the middle of the war."³² Looking back after World War II, Lt. Colonel Katherine Balz, Deputy Chief of the Army Nurse Corps, credited nurse anesthetists for the fact that 92% of "battle wounded who reached Army hospitals alive were saved."³³

Anesthesia: Medicine, Nursing, Dentistry, or What?

Although few physicians chose to specialize in anesthesia before World War II, one who did, Francis Hoeffler McMechan—a Cincinnati native—began a crusade around 1911 to claim the field solely for physicians. McMechan had become disabled shortly after entering the field of medicine, and did not practice. He and his wife undertook his mission through writing, publishing, and speaking. McMechan's first target was the high profile Lakeside School and its famous surgeon George Crile. He alleged that anesthesia was the practice of medicine, and he petitioned the Ohio Medical Board to take action. McMechan considered Ohio a “pivotal state in the national fight for the preservation of the status of the anesthetist as a medical specialist.”³⁴

The board acted. In a letter to Crile in 1916, the board claimed that no one other than a registered physician was permitted to administer anesthesia. Essentially, the board ordered Lakeside Hospital's School of Nursing to cease its anesthesia program or lose its accreditation. Not wanting to be responsible for the loss of the school's accreditation, Crile obeyed the order, pending the outcome of a hearing conducted in 1917. At the hearing, Crile took the position that Lakeside Hospital was only following the lead of many of the major clinics in the country. Crile managed to persuade the board of medicine to lift its order, and he was able to reinstitute his nurse anesthesia educational program and his use of nurse anesthetists.

But to protect nurse anesthetists, Crile took an additional step. In 1919, together with supporting physicians, he “introduced a bill into the (Ohio) legislature to legalize the administration of anesthetics by nurses.”^{4,11} An amendment to the legislation stated that nothing in the bill “shall be construed to apply to or prohibit in any way the administration of an anesthetic by a registered nurse *under the direction of and in the immediate presence of* (emphasis added) a licensed physician,” provided that such a nurse had taken a prescribed course in anesthesia at a hospital in good standing.³⁵

Physician supervision of nurse anesthetists would recur many times over.

A second attempt to legislate nurse anesthesia out of existence occurred in 1916. The Louisville (Kentucky) Society of Anesthetists passed a resolution proclaiming that only physicians should administer anesthesia. The attorney general concurred, and the Kentucky State Medical Association followed with a resolution stating that it was unethical for a physician to use a nonphysician anesthetist or to use a hospital that permitted nurses to administer anesthesia. These events prompted the surgeon Louis Frank and his nurse anesthetist Margaret Hatfield to ask the state board of health to join them in a suit against the Kentucky State Medical Association. They lost in the lower court, but on appeal, they won. In 1917, Judge Hurt of the Kentucky Court of Appeals not only confirmed the right of nurses to administer anesthesia, he also enunciated clearly that state licensure was meant to protect consumers, not professionals.

These two cases showed physicians that they could not rely on the courts to end nurse anesthesia. But still, they were not deterred. Physician anesthetists in California brought suit against Dagmar Nelson, a nurse anesthetist. The *Chalmers-Francis v. Nelson* case was decided in favor of Dagmar Nelson at each level of the California civil court system. The California Supreme Court ruled again that the functioning of the nurse anesthetist under the supervision of and in the direct presence of the surgeon or the surgeon's assistants was the common practice in operating rooms; therefore, the nurse anesthetist was not diagnosing and treating within the meaning of the medical practice act.^{36,37}

At the time, nurse anesthetists welcomed and embraced the concept of physician supervision. Gene Blumenreich, who has written extensively on the legal history of anesthesia, noted that "A number of states adopted statutes recognizing the practice of nurse anesthetists. Typically, these statutes followed the formulation in *Frank v. South* and provided that nurse anesthetists were to work under the 'supervision' or 'direction' of a physician." However, the statutes did not define supervision. "It is clear that the legislation was not attempting to create new duties and responsibilities but merely to describe what was already occurring practice...to explain

why nurse anesthetists were not practicing medicine.”³⁸ Decades later, however, supervision would be misconstrued by anesthesiologists and turned into a battleground.

Organization: “We Who Are Most Interested”

In 1926, Agatha Hodgins called together a small group of Lakeside Hospital alumnae to form a national organization. Hodgins had been an educator since World War I, and she sought strength in numbers to address problems related to education. One hundred thirty-three names were submitted, and tentative bylaws were drawn up. But according to Ruth Satterfield, who was an eminent Certified Registered Nurse Anesthetists (CRNA) educator and the first nurse appointed as Consultant to the Army Surgeon General, “much of what she (Hodgins) said fell on deaf ears.”³⁹ The association failed to thrive. The national organization of nurse anesthetists would only come to life after several problems coalesced in 1931.

Physician opposition to nurse anesthetists was one such factor in this development. For example, California nurse anesthetists organized in 1929 after the Board of Medical Examiners alleged that nurse anesthetist Adeline Curtis was practicing medicine illegally. Curtis, a natural public speaker, went on the road with this refrain: “...we can get nowhere without an organization. We're in the minority of course but we must organize.”⁴⁰ California held its first meeting February 3, 1930.⁴¹ Other states followed suit, and by the end of the 1930s, 23 had established organizations.

Economics brought nurse anesthetists together as well. This era of organization occurred during the Great Depression, and Hodgins noted in 1935 that “the strongest objection of physicians during this period was against those nurse anesthetists who were working on a fee for service basis.”⁴² Hanchett,⁴³ who examined the *Chalmers-Francis v. Nelson* case (1933), concluded that plaintiff California physicians were motivated by economic factors. And Thatcher observed that “Miss Hodgins' concept (of an organization) might never have been sparked into action, and organizations of nurse anesthetists might have stayed at the local level if the collapse of the nation's economy had not revived the physician anesthetist's interest in protecting his income by eliminating competition from

nurses..."¹¹

But it was the poor state of anesthesia education that most motivated Agatha Hodgins. In 1931, she wrote the following to Adeline Curtis, who was embroiled in the California dispute: "My chief interest is in education."⁴⁴ And with the factors noted previously compounding each other, Agatha tried again.

The National Association of Nurse Anesthetists (NANA) was born on June 17, 1931. Its name would be changed to the American Association of Nurse Anesthetists in 1933. The first meeting was held in a classroom at Lakeside Hospital and was attended by 40 anesthetists from 12 states.⁴⁵

Right away, the new association set its sights on improving the quality of anesthesia by raising educational standards. The new president, in a letter to Marie Louis at the American Nurses Association, wrote: "It is because of the increasing number of nurses interested in the particular work and growing realization of difficulties existing because of insufficient knowledge of, and proper emphasis on, the importance of education, that we who are most interested are taking the steps to insure our ability to define and help maintain the status of the educated nurse anesthetist."⁴⁶ An education committee was formed. Chaired by Helen Lamb, the committee crafted "recommended" curriculum standards for schools and ratcheted them up in 1935 and again in 1936.

But the fledgling association was weak. With few members and little money, it could not hold its first national meeting for three years, much less advance an agenda of education reform. In that period, Agatha Hodgins sustained a heart attack and "for all practical purposes bowed out as administrative leader." Gertrude Fife (Fig. 1.2) took over the day-to-day affairs. There grew the realization, attributed by Bankert to Helen Lamb and the Education Committee, that the problems were of such magnitude that an alliance with a more influential professional association would be required. But which one?

FIGURE 1.2 Gertrude Fife and Helen Lamb were among the highly motivated group who built the profession. Fife served as second president of NANA in 1933–35 and as treasurer from 1935–50, and edited the AANA Journal from 1933–50.

Forming an alliance with a major professional organization would likely prove problematic, as divergent interests could collide and trust would be tested to its limit. The small, young NANA would have to fight to maintain its independence, while at the same time obtain much-needed support. According to historian Rosemary Stevens, the AANA “made overtures to the American Board of Anesthesiology (ABA) in 1938 which might have enabled the two movements to combine and the anesthesiologists to take on the responsibility of the nurses' training.” But at the time, the ABA was struggling to emerge from under the wing of surgery, and “the nurses were summarily rejected.”⁴⁷

So, instead, with the guidance and support of the American Hospital Association, Gertrude Fife and Helen Lamb planned the first meeting, which was held in Milwaukee in 1933. They also crafted a highly centralized organization to efficiently address the association's concerns. Thatcher listed those concerns: “(1) building up the membership so that there would be a creditable showing at the Milwaukee meeting; (2) arranging a program; (3) getting a constitution and the bylaws revised; and (4) launching the association's educational program.”

Membership was to be a privilege, a mark of distinction. The bylaws required that an active member have graduated from an

accredited school of nursing, have passed the required state board examination, and maintain an active license. Importantly, an applicant must “have engaged for not less than three years in the practice of the administration of anesthetic drugs prior to 1934, and must be so engaged at the time of making application for membership.”⁴⁸

As membership surpassed 2500, a survey of schools, using on-site surveyors, evaluated courses being taught. An Anesthesia Records Committee was formed to create a standardized anesthetic record, and the credential “Member of the American Association of Nurse Anesthetists” was implemented. These strides served to show that the profession had left its infancy. Then World War II erupted and stalled further progress.

World War II and Nurse Anesthetists

When World War II began, nurse anesthetists once again distinguished themselves. They served at home and in all theaters of operations. Mildred Irene Clark, who was originally from North Carolina, joined the Army in 1938. Under Army auspices, she graduated from Jewish Hospital in Philadelphia, where Hilda Salomon was program director. Clark was on assignment as a nurse anesthetist at the Schofield Barracks Hospital in Hawaii when Pearl Harbor was struck. Clark was among other nurse anesthetists on active duty who set up educational programs for preparing additional nurse anesthetists. Clark completed her career in 1967 as the Chief of the Army Nurse Corps, the first nurse anesthetist to hold this position.

Annie Mealer, another notable Army nurse anesthetist, was sent from Walter Reed Army Medical Center to the Philippines in 1941. She served as chief nurse and chief nurse anesthetist of the hospital on Corregidor. For three years, Mealer was held as a prisoner of war. Among the nurse anesthetists imprisoned with her were Denny Williams, Doris Keho, and Phyllis Arnold Iacobucci. They and 62 other Army nurses were imprisoned until February 3, 1945.

Marianne Bankert quotes at length a letter Annie Mealer later wrote in which she described her experiences. Mealer recalled housing President Quezon and his family, dodging “Jap bombs,” and “giving anesthetics to one casualty after another” who “all needed help that only a nurse could give them.” In Japanese custody aboard a troop ship, and sick with dengue fever, Mealer wrote, “I threw my cape down on the deck to lie on it and prayed that the wind would blow the fumes of the stale fish in another direction. I looked around at the nurses in the various uniforms of coveralls and skirts. They had grown slender as reeds, but were smiling over some secret rumor about liberation—not realizing they had nearly three more years of hard work and starvation.”⁸

Wartime greatly expanded the need for anesthetists in both military and civilian hospitals. Lt. Col. Katherine Balz, the Education Consultant to the Army, estimated that “approximately 15,000,000 patients were admitted to Army hospitals during the

war, and something had to be done to provide the anesthesia services needed for these patients' care." Rosemary Stevens reported that in 1942, nurse anesthetists outnumbered anesthesiologists by 17 to 1.⁴⁹ By the end of World War II, the Army Nurse Corps had educated more than 2000 nurse anesthetists, most (though not all) of whom were given an abbreviated 4- to 6-month curriculum patterned after that required by the AANA (Fig. 1.3).⁵⁰ Lt. Col. Balz recalled a situation in which some volunteer nurses were placed into anesthesia service after only 90 days of training! "At the end of that time, these volunteers were thrown into a situation in which 100 operations were being performed every 24 hours...there were not enough hours in the day to care for the patients and at the same time provide for formal instruction. In this hospital, over 5,000 anesthetics were given during a six months' period, and not one death or complication occurred as a result of anesthesia."⁵¹

FIGURE 1.3 This recruitment brochure was disseminated to schools of nursing to counteract the negative effect of anti-nurse anesthetist public relations.

The increased needs and the shortened training period posed "extraordinary complications" for the AANA. The quality of newly-minted graduates had to somehow be addressed. To maintain

standards, the AANA implemented a temporary “program of certification by exam and certification by waiver.”⁸ Accreditation of programs was postponed entirely. In 1943, the Annual Meeting was reduced to just one day; a quorum could not be met, so already-elected officers remained on the board.

From her sick bed, Agatha Hodgins sent these words of encouragement: “The immense and vital part all branches of medical service will play in this continuing task can—because of its greatness—be now only dimly conceived. They will in very truth be a ‘green island’ in ‘the wide deep sea of misery’ now encompassing the earth.” These were among her last words. Hodgins passed away in 1945. Her gravesite is located on Martha's Vineyard.⁵²

As World War II drew to a close, the AANA's plans for instituting a certification examination for civilian membership were at last realized. The first examination was given in June 1945. It was completed by “90 women in 39 hospitals in 28 states, plus one in the Territory of Hawaii.”⁶⁶ It would be hard to conclude that their “high type of service” during the two world wars did not account for this accomplishment.

Nationally, World War II was also associated with bringing about certain human rights advances. President Truman integrated the armed forces in 1948, and the first male nurse was commissioned in 1955, a step attributed to nurse anesthesia. The AANA admitted its first African-American member in 1944 and its first male member in 1947. The first two male nurses commissioned in the Army Nurse Corps were nurse anesthetists: Edward L.T. Lyon of New York, and Frank Maziarski of Washington, who later became the sixtieth president of the AANA.^{11,53}

A Short-Lived Peace for Nurse Anesthetists and the Nation

After the war, the number of physicians in anesthesia greatly increased. In 1940, there were only 285 full-time anesthesiologists, 30.2% of whom were certified; in 1949 there were 1231, 38.3% of whom were certified.⁶⁹ Ira Gunn attributed the increase to wartime medical experiences “alerting physicians to the potential of anesthesia as a specialty.”⁵⁵ Bankert listed as causes “the increased complexity of anesthetics, but also...a military structure that encouraged medical specialization and a GI Bill that supported medical residencies.”⁸ The country produced more physicians, and many were drawn to anesthesiology.

An “old problem” reappeared. For upon returning from military service, “medical (physician) anesthetists—*many of them trained in the Armed Services*—(in an effort) to establish themselves in a civilian economy, brought about a resurgence of activity against the nurse anesthetist.”¹¹ One activity was to render “historically invisible” the contributions of nurses. For example, the centennial celebration of ether at the Massachusetts General Hospital made no mention of nurse anesthetists (it would, in fact, be the impetus for Virginia Thatcher's seminal history book). Bankert listed other similar efforts: “a myth is launched of the early superiority of British anesthetists—a land, so the story goes, which was never so foolish as to allow nurses to administer anesthetics; the national association of physician-anesthetists backdates its founding (from 1936) to 1905; a new word (*anesthesiologist*) is coined in the 1930s to distinguish the work of physician-anesthetists from nurse-anesthetists; ‘historical’ studies are published with titles such as *The Genesis of Contemporary Anesthesiology*, as though nothing of significance occurred in the field until the 1920s, when physician-anesthesia began to be effectively organized.”⁸

Then anesthesiologists launched a public relations effort to denigrate nurse anesthetists. Bankert reported that, in 1947, several “major articles” appeared in *Look Magazine*, *Hospital Management*, *Reader's Scope*, and *This Week*. One excerpt railed: “Bad anesthesia

causes more operating-room deaths than surgery. Now many hospitals have physician-anesthetists to protect you." And fear was a part of this campaign: "Until the operating rooms of our hospitals are brought into line with the clear requirements of modern anesthesiology, hundreds of Americans will continue to die needlessly on operating tables, sacrificed to ignorance and incompetence."⁸ It is not known what, if any, evidence was offered to support this opinion.

These efforts did not accomplish their goal. Surgeons, the public, and "often the anesthesiologist himself" were not dissuaded from trusting nurse anesthetists. However, they did "discourage many capable nurses from entering the field," prompting the AANA to promote the profession and recruit nurses who had been frightened away.¹¹ Soon thereafter, the first quality of care study in anesthesia took place. The results, according to Gunn, "shocked and dismayed many anesthesiologists."

In 1954, Beecher and Todd published a prospective analysis of anesthesia outcomes collected between 1948 and 1952. Ten university hospitals contributed data for approximately 600,000 anesthetics. The nurse anesthetists' treated patients death rate was one half that of anesthesiologists. Furthermore, there was no difference in physical status of the patients between groups of providers. However, that did not stop the authors from surmising (without evidence) that anesthesiologists were anesthetizing more complex surgical cases.⁵⁶ Not surprisingly, more quality comparisons would be conducted in the coming decades.

In fact, as Gunn pointed out, nurse anesthetists at that time were second to no one. In 1948, for example, Olive Berger at Johns Hopkins reported 480 anesthetics for repair of cyanotic congenital heart disease, including tetralogy of Fallot.⁵⁷ Betty Lank at Boston Children's Hospital pioneered the use of cyclopropane in pediatric anesthesia.⁵⁸ After the United States committed troops to South Korea, the National Women's Press Club named the Army nurse as its Woman of the Year (1953). An Army nurse anesthetist, Lieutenant Mildred Rush from Massachusetts, was designated to accept the award on behalf of all Army nurses.

It was the Korean War that ultimately led to the accreditation of all nurse anesthesia education programs. During the war itself, the

AANA had begun accrediting programs, but it had little clout, and within each state the Veteran's Administration had its own standards concerning "so-called" accredited schools. To enforce proper standards, the AANA successfully appealed to the Department of Health, Education, and Welfare for recognition as the sole accrediting agency.⁸ For a returning GI to obtain education benefits, he had to attend an accredited school of anesthesia. Within a few years, civilian schools either brought themselves into compliance with AANA standards or quietly closed.

The New Age of Nurse Anesthesia: the 1960s

When the 1960s began, the AANA had evolved into a more fully-fledged professional organization under the influential leadership of its first full-time executive director, Florence McQuillen, who was hired in 1948. John Lundy, the chairman of anesthesiology at the Mayo Clinic, worked with McQuillen and referred to her as “the best-read person on the literature of anesthesia.” McQuillen exerted such a powerful influence at the AANA⁸ that in 1965 she was named association executive of the year by the journal *Hospital Management*.

During McQuillen's tenure, certification of graduates and accreditation of programs placed the association firmly within the regulatory and educational spheres of American health care. Membership grew considerably, and exceeded 10,000. All 50 states had associations affiliated with the AANA. In addition, the members had approved the beginnings of a continuing education program in anesthesia.⁵⁹

But the decade of the 1960s was a transitional period for everyone in health care, including nurse anesthetists. The United States, which had increasingly relied on employer-based health insurance since WWII, extended coverage to elderly and poor people through Medicare and Medicaid in 1965. These programs led to a greater need for health care providers. Educational programs for all health care professionals, including nurse anesthetists, increased accordingly.

Growth was embraced by anesthesiologists in ways that were not entirely welcomed by CRNAs, as they had been known since 1956. Gunn recounted that “Anesthesiologists held meetings to define the future.” Some sought an all-physician specialty. Others knew such a goal was unattainable, because nurse anesthetists were “providing the majority of anesthesia care in the United States.”⁶⁰ To resolve the manpower issue, two ideas gained prominence. Some advocated for the support of nurse anesthesia educational programs.⁶¹ Adherents of the second idea proposed another type of

anesthesia practitioner based on a physician assistant model that the anesthesiologists could control.^{62,63} Either option would be problematic.

Clearly, there would be value in communication between the two groups. But since 1947, an American Society of Anesthesiologist (ASA) bylaw precluded anesthesiologists from communicating with the AANA. According to Marianne Bankert, ASA President Albert Betcher (1963) initiated efforts to establish relations with nurse anesthetists, in light of the reality presented by “present and projected personnel needs.”⁸

In 1964, the ASA and AANA established a liaison committee that met twice a year. Florence McQuillen articulated the AANA's goals. Through dialogue, the AANA sought “no interference with the progress of educational programs of the Association, and a curbing of anti-nurse anesthetist activity and publicity.”⁶⁴ After three years of meetings, the *AANA News Bulletin* and the *ASA Newsletter* published a joint statement that read in part: “It is, therefore, highly desirable that continued close liaisons be developed between these organizations for enhancing the quality and quantity of available personnel, for advancing educational opportunities, for determining ethical relationships and for the overall improvement of patient care.” C.R. Stephens, a noted anesthesiologist who had worked with nurse anesthetists for many years, wrote in a 1969 report to the ASA: “Progress has not been rapid, but the dialogue has enhanced understanding.”^{8,65} That progress and understanding would be tested severely during the next decade.

The 1970s: A Turbulent Decade

Long-term American involvements, such as the Vietnam War (Fig. 1.4), and an era of progressive reforms became part of this country's history during the 1970s. As federal expenditures for health care rose, the government engaged in greater scrutiny of health services. In 1974, the US Commissioner of Education revised the criteria governing nationally-recognized accrediting agencies, of which the AANA was one. The new criteria were intended to protect the public's interests by completely separating the professional obligations of a professional association from its proprietary concerns.⁵⁴ The AANA would have to give up its roles in accrediting programs and certifying graduates, roles it had nourished and cherished since 1931. To divest itself of these operations, AANA undertook a wholesale reorganization. In 1975, largely through the work of Ira Gunn, assisted by Ruth Satterfield, Mary Cavagnaro, and Ed Kaleita, autonomous councils were established and granted accrediting and certifying functions.⁶⁶

FIGURE 1.4 First Lieutenants Jerome Olmsted (A) and Kenneth Shoemaker (B) were killed in 1967 following the crash of a C47 transport plane carrying wounded soldiers from Pleiku to Qui Nhon, Vietnam.

The process of governmental review and revision provided an

opportunity for physicians to attempt to take over control of CRNA education. The ASA proposed a competing accrediting organization, the Faculty of Nurse Anesthesia Schools, and it misused both the Joint Statement issued by the AANA/ASA Liaison Committee (1972) and a manpower study to justify its activities. After many tense months of strategizing, however, the Councils on Accreditation and Certification ultimately won the government's approval.

The struggle over accreditation and certification had several important outcomes. By separating out the accrediting and certifying functions, the AANA was free to pursue laws and policies that would protect CRNAs without fear of creating a conflict between its private interests and its public duties. Second, it revived the AANA's relationship with the American Nurses Association, but it "increasingly strained relations between the AANA and ASA."⁸

Ira Gunn (Fig. 1.5) recalled that some nurse anesthetists saw this episode as an opportunity to upgrade educational programs and move into universities and colleges. John Garde, Ira Gunn, Joyce Kelly, and Sister Mary Arthur Schramm were the CRNAs who pioneered programs in the baccalaureate, and then graduate, frameworks in the early 1970s.⁶⁷

FIGURE 1.5 Ira Gunn.

In another outgrowth of this era, state nurse anesthetist

organizations sought explicit legal recognition, either within the state nurse practice act or as a separate law. Gunn traced this phase of licensure to a Department of Health, Education, and Welfare committee report from 1971 that “supported an extended scope of function for registered nurses.” Other factors influencing its development included higher educational standards, increased complexity of practice, the women's movement, and the increased presence of men in nursing.⁶⁸

Nurse anesthetists were soon addressed in one or more places within state statutes or regulations in all 50 states. However, according to Mitchell Tobin, the former Director of State Government Affairs for AANA: “Although it is clear that legitimacy of nurse anesthesia as a profession is widely accepted, the manner, type, and frequency of statutory and regulatory recognition of CRNA practice varies considerably.”⁶⁹ In the following decade, the AANA would have to issue position statements to influence the ways in which CRNAs were treated under state nurse practice acts and boards of nursing rules.

And last, the AANA, in a rare offensive legal maneuver, sought direct reimbursement for CRNA services within the Medicare program (1976). President John Garde spoke of the rationale in his 1973 report to the members: “If a physician is paid for a procedure or care, and that same procedure or care is provided by the CRNA, why should it not be reimbursed through health insurance programs?”⁷⁰ The effort failed. However, coupled with the other challenges of the 1970s, this attempt alerted CRNAs to the need for an increased presence in Washington, D.C.

Federal Legislative Initiatives in the 1980s

By the end of the 1970s, American medicine had “suffered a stunning loss of confidence”—so wrote Paul Starr in “The Transformation of American Medicine.” “Slower economic growth and persistent inflation in the seventies undoubtedly lay behind the shift from a redistributive to a regulatory politics in health care.” But, although the economy declined, medicine “seemed to pass from stubborn shortages to irrepressible excess.” From 1970 to 1980, health care expenditures had grown from \$69 billion to \$230 billion, and “the reimbursement practices for hospitals and doctors were peculiarly designed to encourage higher costs.⁷¹ Conservatives and some liberals in Congress aimed to cut that back.

Gunn described how cost control played out within anesthesia: “Anesthesiologists billed for services when they were not present in the hospital or even in town. Some chose not to come out at night or on weekends to supervise care provided in emergencies, yet they billed as if they had been present. Anesthesiologist supervision or billing capability for concurrent cases was not limited to any specific fixed numbers, permitting abuse. During this time, some surgeons were openly critical of the number of fees being paid to anesthesiologists for two or more concurrent services, particularly when the anesthesiologists were not available. A number of these surgeons and other providers complained to both private insurers and Medicare. As a result, some private payers began limiting reimbursement to not more than two concurrent procedures, and Medicare's Inspector General focused on anesthesia reimbursement in the search for potential fraud. Around this time, Richard Verville, the AANA's Washington counsel, stated that a source in the Inspector General's office of what was then the US Department of Health, Education, and Welfare had told him that approximately 25% of Medicare fraud and abuse investigations concerned anesthesia services.”⁷² Two federal efforts to control anesthesia costs and accountability had their genesis in these peculiar reimbursement practices.

TEFRA

The first federal effort to control anesthesia costs and accountability was the Tax Equity and Fiscal Responsibility Act (TEFRA), enacted in 1982. TEFRA was designed to control costs and “ensure that an anesthesiologist demonstrated that he or she provided certain services as part of a given anesthetic to qualify for payment. Among other things, TEFRA limited payment to anesthesiologists for no more than four concurrent cases, and stipulated seven conditions that anesthesiologists must fulfill as part of a given anesthetic procedure to qualify for payment.”⁷³

However, TEFRA had some adverse implications for CRNAs. The seven conditions were misconstrued by the ASA as standards of practice. Its *Guidelines to the Ethical Practice of Anesthesiology* (adopted October 25, 1978; effective February 12, 1979) made this clear.⁷⁴

These guidelines separated reimbursement for anesthesiologists based on supervision or medical direction, and specified payments on the basis of direction to be limited to not more than two concurrent procedures. Payment took two forms. When the CRNAs were employed by the anesthesiologist, each service was billed as though the anesthesiologist had administered each case. When the CRNAs were hospital employees, the time units for the anesthesiologist were cut in half. When the anesthesiologist's service was supervision and not direction (i.e., supervising three or more CRNAs), the payment was to be made under Part A of Medicare on the basis of a “reasonable charge.” The hospital could still bill for the CRNA services of their own employees under Part A if the services were provided within the hospital and under Part B of Medicare if the services were provided in a surgical center.

An Existential Threat Leads to Direct Reimbursement

In early 1983, while the AANA was still dealing with TEFRA, without much fanfare and with less media exposure than usually accompanies such legislation, Congress passed a second cost control bill, the prospective payment system (PPS). The PPS revised the means of calculating Medicare payment from a cost-plus fee for

service basis to prospective pricing based on diagnosis-related groups. This measure posed a much greater threat to CRNAs than did TEFRA.

The PPS legislation was a powerful disincentive to the hiring of nurse anesthetists, for the following reasons: (1) it would be impossible for the anesthesia component of payment to cover the full cost of hospital-employed CRNAs; (2) unbundling of services and payment was prohibited; and (3) anesthesiologists who had been billing for CRNA services under Medicare Part B could no longer do so. Taken together, these caveats meant that “CRNA services were, for all practical purposes, nonreimbursable.”⁷³ If this legislation was enacted, hospitals would terminate CRNAs and rely entirely on anesthesiologists.

The very real threat posed by PPS mandated action. Either the reimbursement for both anesthesiologists and CRNAs would need to be placed under the same source, Medicare Part A, or AANA would have to seek direct reimbursement rights for CRNAs under Medicare Part B.

In the 1980s, CRNAs were heavily-recruited health care professionals. Most CRNAs were employed by hospitals or anesthesiologists, but a growing number of CRNAs practiced privately. Private practice CRNAs were unable to obtain reimbursement directly from Medicare, Medicaid, and many private insurance companies.

After a 3-year-long effort that Bankert described as “one of the greatest lobbying achievements not only of the AANA, but of the whole of nursing,” President Reagan signed into law the Omnibus Budget Reconciliation Act of 1986.⁸³

Since then, Medicare and Medicaid have paid directly for all CRNA services, making nurse anesthetists the first nursing specialty to be so accorded. Of its importance, Dr. Judith Ryan, the executive director of the American Nurses Association, said that “The American Association of Nurse Anesthetists' achievement to secure direct reimbursement for CRNAs is a singular, notable contribution to identification and payment of the nurse as a provider of care, and nursing services as covered health benefits.”⁷⁵

Non-Legislative Legal Problems Arise

In the same decade, events of no less significance took place in civil law pertaining to anesthesia. The courts tested whether a surgeon is liable for the actions of a nurse anesthetist. Traditionally, surgeons have been considered “Captains of the Ship,” and were therefore thought to be responsible for everything that occurred inside an operating room. Logically, this theory was extended to mean that “nurses (and nurse anesthetists) become the temporary servants or agents of the attending surgeon during the course of an operation, and liability for their negligent acts may thus be imposed upon the surgeon under the doctrine of *respondet superior*.”⁸ Blumenreich explained the danger to CRNAs of this theory: “When surgeons work with nurse anesthetists, the surgeons become liable for their mistakes—but when surgeons work with anesthesiologists, the surgeons do not have to worry about what happens at the head of the table.” But, in fact, the theory is fallacious. Blumenreich went on to say, “First, surgeons are not always liable for the negligence of nurse anesthetists. Second, surgeons may also be liable for the negligence of anesthesiologists. Third, because a surgeon's liability, whether working with nurse anesthetists or anesthesiologists, depends on the particular facts of the situation, as a practical matter, the surgeon is likely to be included in the suit whether the surgeon is working with a nurse anesthetist or an anesthesiologist.” In fact, no surgeon has been held liable in a court of law for the negligence of a nurse anesthetist. Courts have apportioned liability according to the specific facts of a case.^{76,77}

A second area of civil law that effected anesthesia in the 1980s was antitrust. Nurse anesthetists, like other professionals, are subject to antitrust laws. However, they can also use those laws when they allege that others have conspired to restrict CRNA practice. Two cases filed by CRNAs, Vinod Bhan (*Bhan v. NME Hospitals, Inc.*, 84-2256, DC No. CV-S-83-295 LKK [October 2, 1985]) and Tafford Oltz (*Oltz v. St. Peter's Community Hospital*, 861 F2d 1440, 1450 [9th Cir 1988]), illustrate these points.

Oltz had held clinical privileges and had worked as a private practitioner at St. Peter's Community Hospital in Helena, Montana. His privileges were terminated when the hospital gave an exclusive contract to a group of anesthesiologists. Oltz alleged, and the court ultimately agreed, that the hospital and the anesthesiologists had

conspired to terminate his privileges so that the anesthesiologists would have access to his cases. The verdict turned on the fact that St. Peter's Community Hospital had significant enough market shares within its service area to exert a monopoly, and that by awarding the exclusive contract to the anesthesiologists, the hospital damaged competition. By August 1994, more than 12 years and numerous appeals later, Oltz prevailed. The court awarded Oltz (the plaintiff) \$1.6 million in attorney fees.⁷⁸

A second antitrust case involved Vinod (Vinnie) Bhan, who practiced anesthesia in California. When his hospital terminated his privileges and replaced him with anesthesiologists, Vinnie sued. The defendants (both the hospital and the anesthesiologists) challenged Bhan's standing—that is, his legal right to file suit. They asserted that Bhan, as a nurse and nurse anesthetist, did not, in the eyes of the law, compete with physicians because of their different licensure. Bhan lost the case because the hospital that terminated his privileges did not have sufficient market share in the community to restrain competition. One essential element of antitrust laws is that they exist to protect competition, not competitors. Bhan's ability to compete was not adversely effected, because there were plenty of other local hospitals where he could seek to practice.

However, the appellate court ruling that gave Bhan and CRNAs standing to sue anesthesiologists as competitors set a significant legal precedent for the profession. The Circuit Court concluded, *“No doubt the legal restrictions upon nurse anesthetists create a functional distinction between nurses and MD anesthesiologists. They do not, however, necessarily preclude the existence of a reasonable interchangeability of use or cross-elasticity of demand sufficient to constrain the market power of MD anesthesiologists and thereby to affect competition”* (emphasis added). The court continued, stating that “as a matter of law, Bhan's allegations are sufficient to establish that he is a proper party to bring this antitrust action.”^{79,80}

And Blumenreich said, “The Bhan case was important because it gave to some extent the protections of the antitrust laws to nurse anesthetists. Hospitals could not boycott nurse anesthetists.” Its results would be more “long-lasting.”

Hyde v. Jefferson Parish Hospital District No. 2

A third antitrust case, *Hyde v. Jefferson Parish Hospital District No. 2* (1983; New Orleans, Louisiana), centered on whether an exclusive contract by a group of anesthesiologists was by itself (*per se*) a violation of the antitrust laws. At East Jefferson Parish Hospital, a group of anesthesiologists held an exclusive contract with the hospital and worked with hospital-employed CRNAs. Dr. Hyde was denied privileges solely on the basis of the exclusive contract. Hyde sued, claiming that a patient who was admitted for surgery in effect had no choice but to buy anesthesia from the hospital's exclusive group of anesthesiologists. He alleged that this situation represented a tying arrangement, which had previously been deemed in violation of the antitrust laws. (A tying arrangement would be similar to going to a store to buy bread but being unable to buy it by itself. Rather, one would be required to buy butter to get the bread, whether or not the purchaser used butter on bread.)

The Jefferson Parish Hospital District won the case at the lower court level, but Hyde appealed all the way to the US Supreme Court.

The ASA also filed an *amicus curiae* brief, but in support of Dr. Hyde. The ASA opposed exclusive contracts, but attempted to link its opinion to the quality of care, stating that “the elimination of competition through a classic tying arrangement is not simply a matter of dollars and cents. It can adversely affect the quality of medical care. ASA believes that in this setting, it is particularly important that competition be allowed to reward superior performance and innovation, while exposing the indifference to quality that may too often be the hallmark of a monopoly.”⁸¹

The Supreme Court ruled unanimously in favor of the hospital's right to award an exclusive contract for anesthesia services. The ruling was favorable to CRNAs in what Blumenreich recalled was a “footnote in the court's opinion to the effect that ‘there has been no showing that nurse anesthetists provide a lesser quality of care.’ So we feel like we accomplished what we set out to do.”⁸² Shortly afterward, the AANA appointed Blumenreich General Counsel, a post he held until 2011. Gunn wrote that “the Hyde case alerted the AANA to the need to revitalize its public relations program, continue its watch for attempts to discredit CRNAs, and take action

either to correct or to prevent further damage.”

CRNA Achievements of the 1980s

Although much attention focused on events taking place on the legal front, other important areas of practice were advanced in the 1980s. For example, liability insurance coverage, first offered to CRNAs in 1974 by outside brokerages, was skillfully brought in-house when the AANA bought the Glen Nyhan Agency. Renamed A+, and now called AANA Insurance. The agency has provided a steady stream of insurance to CRNAs since 1988, without which CRNAs would be subject to outside insurance companies, some controlled by physicians.

The AANA Education and Research Foundation was established in 1981; it would be renamed the AANA Foundation in 1995. The Foundation has enjoyed enormous support. A current report lists scholarships, grants, and workshops in excess of \$3.43 million given to 2900 individuals.⁸⁴

The Conductor

No review of the 1980s would be complete without mentioning the ascendance of John Garde (Fig. 1.6), who served the profession from 1957 through 2009. Mr. Garde's career at the AANA stemmed from being an educator. From 1964 to 1975, John was Program Director, Associate Professor, and then Chairman of Anesthesia at Wayne State University. Mr. Garde joined the AANA in 1980 as the Education Director, and then in 1983 was appointed Executive Director. This was the post he held until retiring for the first time in 2000, and the post that made him an "iconic figure in the health care community."⁸⁴

FIGURE 1.6 John Garde.

Under Mr. Garde's executive leadership, the profession prospered. Evidence for this includes the previously described legal and regulatory victories and educational advancements. The AANA also expanded to include AANA Publishing, AANA Insurance Services, AANA Management Services, the AANA Foundation, a Government Relations Office in Washington, D.C., and (not least) the AANA Archives. (John was “steeped in history.”)

Because John “knew everyone,” relations between the AANA and outside organizations flourished. According to Rita Rupp, a nurse who served as Special Assistant to the Executive Director at AANA, “John facilitated and led in the formation of the National Federation of Nursing Specialty Organizations and later a national nursing executive directors group.”

Nurse anesthesia even globalized during this era: the International Federation of Nurse Anesthetists was formed, and the AANA supported volunteerism in developing nations through Health Volunteers Overseas.

With characteristic modesty, John later recalled that he saw himself as “the conductor of a great orchestra.” Past President Larry Hornsby elaborated: “The president was the soloist. John used the orchestra to make the soloist sound the very best...(as president) you could not fail... He catered to each president's needs and strengths to make you the leader that the organization needed at the time” (Personal communication, 2011).

The Call for Health Care Reform in the 1990s

Cost Containment in Health Care

Bill Clinton (whose mother Virginia Kelly was a CRNA)⁸⁵ was elected president in 1992 with a promise to reform health care. The president's health care reform package was aimed at universal coverage, and reflected a major shift in health care delivery toward managed care.

For a variety of reasons, Clinton's health care plan was defeated. In its place, the health insurance industry, in conjunction with the major businesses that provided health insurance to their employees, forced a form of “managed care” on a large portion of the insured population. Managed care, in theory, was intended to (1) move the health care system from a disease treatment to a health maintenance system; (2) do away with incentives found in the fee-for-service system—that is, the more services provided, the more money made—and thereby reduce unnecessary health services^{86,87}; (3) promote a cost-effective workforce by emphasizing primary care providers and nonphysician professionals; and (4) promote a shift from independent practice patterns to greater use of salaried personnel. Some anesthesiologist groups found that, under managed care, their workload declined by 40%.⁸⁸ Physicians thus scrambled to protect autonomy and income, while patients sought to preserve some choice of provider.

When CRNAs won direct reimbursement rights in 1986, they agreed to accept no more than the amount Medicare assigned for the service as payment in full. In other words, CRNAs would not “balance bill.” Payment schedules were then devised for anesthesiologists working alone, CRNAs working alone, and anesthesiologists medically directing CRNAs in team practice settings. In the early 1990s, a Government Accounting Office (GAO) study⁸⁹ revealed that payments for anesthesia services under the medical direction arrangement were 120% to 140% greater than payments for CRNAs or anesthesiologists working alone. This payment scheme served as a strong incentive for anesthesiologists

to employ CRNAs, but it was not budget-neutral, which had been the intent of Congress. The GAO recommended payment of only one anesthesia fee, totaling no more than when an anesthesiologist performed the service alone. Furthermore, the study recommended that payment for anesthetic procedures under the medical direction model be split 50% for the CRNA service and 50% for the anesthesiologist service, a significantly reduced portion for both the anesthesiologists and the CRNAs. The AANA chose to support the single-payment plan. The ASA opposed it. The single-payment reimbursement plan was implemented, and tension between the two groups was exacerbated again.

Attempts to Measure Quality of Care

In the second half of the 20th century, first physicians, and then nurses, attempted to evaluate the quality of anesthesia care by measuring death rates. The first attempt was published in 1954 by Beecher and Todd.⁹⁰ The Beecher and Todd study looked at nearly 600,000 cases gathered from university medical centers nationwide. This study was notable for shedding light on the “not yet entirely clear, nor completely appreciated” cardiovascular dangers of curare, with which there was an associated “sixfold difference, unfavorable to curare” in the death rate.

As mentioned earlier, Beecher and Todd compared outcomes between physician specialists, residents in anesthesia, and nurse anesthetists. Although there was “comparability of good and poor risk cases in the three groups,” and “although the physician specialist anesthetizes only half as many patients as the nurse, he is charged with an equal number of anesthesia deaths.” In other words, the anesthesiologists' outcomes were far worse.

Two decades later, amid complaints about the Veterans Administration (VA) health care system, the US House of Representatives mandated a study by the National Science Foundation regarding the care given to veterans. At the time, CRNAs provided much of the anesthesia administered at VA facilities. The reviewers reported back to Congress in 1977 that there were no significant differences in anesthesia outcomes based on the providers of that care.⁹¹

In 1980, an anesthesiologist named W. H. Forrest published a

portion of an institutional differences study conducted by the Stanford Center for Health Care Research. Forrest divided the institutions between those predominantly served by nurse anesthetists and those predominantly served by anesthesiologists. He concluded—using conservative statistical methods—that there were no significant differences in anesthesia outcomes between the two anesthesia providers.⁹² (Ira Gunn wrote that she “spoke with Dr. Forrest regarding his study, and he mentioned that he had been castigated by his colleagues for reporting these results.”)

A North Carolina retrospective study of anesthesia-related mortality from 1969 to 1976 (performed by a committee from the North Carolina Society of Anesthesiologists) was published in 1981. The findings were similar for all providers (e.g., CRNAs working alone, anesthesiologists working alone, and CRNAs and anesthesiologists working together as a team); however, no test of significance was made in this study.⁹³

Subsequent studies deserve attention because they were used to support the claim that CRNAs should be supervised by anesthesiologists.

Between 1992 and 2003, studies by Abenstein and Warner; Silber et al.; Wiklund and Rosenbaum; and Vila et al. were published and promoted as evidence that the “the utilization of anesthesiologists improves anesthesia outcomes.” These studies and their rebuttals were summarized in “Quality of Care in Anesthesia,” a 2009 publication by AANA.⁹⁴ The article by Abenstein and Warner “purported to analyze the quality of care...but failed to mention the key conclusion.” For example, the authors claimed that there were “differences in the outcomes of care based on type of provider, *notwithstanding that the actual researchers came to the opposite conclusion*” (emphasis original). The Silber study “examined the death rate, adverse occurrence rate, and failure rate of 5972 Medicare patients. One analyst concluded that these data were, in fact, not “specific to anesthesia staffing,” and “the type of anesthesia provider does not appear to be a significant factor in the occurrence of potentially lethal complications.” Two studies attributed to Wiklund and Rosenbaum were also found to be irrelevant. The AANA reviewer pointed out that Wiklund and Rosenbaum, by attributing safer anesthesia to a federal decision to

“support training in clinical anesthesiology” had left “the path of unbiased review of the specialty to make unsubstantiated or misleading comments about the unilateral contributions of anesthesiologists to the advancements achieved.”

The Silbur study stirred up “serious questions of objectivity.” “Reportedly, both the *Journal of the American Medical Association* and the *New England Journal of Medicine* declined to publish” it. The timing of its publication led to questions about its motivation. “The abstract was published in the midst of the controversy between anesthesiologists and nurse anesthetists over HCFA's [Health Care Financing Administration] proposal to remove the physician supervision requirement for nurse anesthetists in Medicare cases.” The AANA reviewers concluded, “The timing of the publication in the ASA's own journal was politically motivated” to influence the HCFA (now known as the Centers for Medicare and Medicaid Services [CMS]). However, CMS ultimately “dismissed all claims” made by the authors in this study.

The Vila study compared outcomes at ambulatory surgery centers (ASCs) with those in office operating rooms (a practice for many independent CRNAs). It claimed that “the risk of adverse incidents and deaths was approximately 10 times greater in the office setting than in an ASC, and that if all office procedures had been performed in ASCs, approximately 43 injuries and six deaths per year could have been prevented.” It concluded with the hopeful remark that “the presence of anesthesiologists in ASCs “may be a factor in more favorable outcomes.”

But the AANA analyst pointed out flaws in both the methodology and conclusions of this study. The study “does not specifically mention CRNAs,” yet it “makes the unsupportable assertion that office surgery may not be as safe when an anesthesiologist is not present.”

Misuse of outcomes research was extensive during this era. Gunn wrote that “in the medical literature in the 1990s, serious questions were raised regarding the quality and relevance of published research, the peer review system, and the selection of articles for publication.”⁹⁵ A 1993 review concluded that 95% of the medical research being published in journals was either flawed or irrelevant.⁹⁶

The Federal Supervision Regulation

In what Past President Larry Hornsby described as a “message from the grave,” Alice Magaw commented that, during the 1890s at the Mayo Clinic, physicians oversaw nurse anesthesia in a “general way.” In other words, Magaw and her colleague Florence Henderson were on their own. In the next twenty years, as the acceptance of nurse anesthetists grew, a few physicians sought control over the women who practiced anesthesia. The 1915 challenge to the Lakeside Hospital School made this trend clear, and prompted surgeon George Crile and some of his colleagues to seek legislation in Ohio that for the first time codified the practice of nurse anesthesia in law.¹¹ An amendment to that legislation made mention of physician supervision: “the administration of an anesthetic by a registered nurse *under the direction of and in the immediate presence of a licensed physician.*”²⁵ Nurse anesthetists welcomed this development and sought similar legislation in other states, because it legitimized their practice.^{35,97}

In the 1980s, there emerged physician oversight regulations within the Medicare Rules for Participating Hospitals. The regulations stemmed from the aforementioned TEFRA of 1982, and pertained only to anesthesia, not to other areas of health care where physicians and nurses overlapped. Because they were federal, these regulations preempted any state laws that permitted CRNAs to practice without supervision.⁷³

At the same time TEFRA took effect, the number of anesthesiologists tripled. Increased competition in the anesthesia marketplace prompted Blumenreich to write that supervision became

the springboard for yet new attacks. In 1985, H. Ketcham Morrell, president of the American Society of Anesthesiologists (ASA) wrote: “...the operating surgeon or obstetrician who purports to provide medical direction of the nurse, in the absence of an anesthesiologist, carries a high risk of exposure, on a variety of legal theories, for the acts of the nurse.”⁹⁸

An unknown number of surgeons opted for anesthesiologists as a result. Imagined liability among surgeons became such a crisis that

Blumenreich wrote” “no subject has received more of my attention.”

For CRNAs, removing supervision from the Medicare Rules was an obvious remedy, because it would impact practice across the country. From 1994 to 2001, HCFA and AANA attempted to do just that. The enormous struggles that ensued were chronicled briefly by Patrick Downey in the AANA Journal⁹⁹ and in spellbinding detail by Sandra Larson in a PhD thesis.¹⁰⁰ Legislation was introduced in both houses of Congress that would remove the supervision requirement and address reimbursement issues. Both the AANA and ASA responded with grassroots public relations campaigns, and the legislation went nowhere. Then, in December 1997, HCFA proposed a major change in its *Hospital Conditions of Participation*, including the elimination of physician supervision of CRNAs. Nursing organizations lined up in support of the change, but medical opposition was fierce. Nullifying legislation was proposed, as were safety studies to delay its consideration. More public relations were deployed, and the controversial claims of the Silbur study (that outcomes are better when CRNAs are supervised by anesthesiologists) were invoked. In March of 2000, HCFA ruled that CRNAs could practice without physician supervision, and in its ruling, HCFA deemed the Silbur study “irrelevant.” But the new rule was not implemented until the final days of the Clinton administration, and the Bush administration, as all new administrations do, placed a moratorium on late-term regulations. In November 2001, the Bush administration, in response to vigorous and costly lobbying by the ASA, “allowed political favoritism” to prevail over rigorous policy-making. The new administration restored the earlier rule containing supervision.

However, the “final” rule contained an escape clause, a proviso allowing state governors to opt out. Between 20 and 31 states (opinions varied) had no laws specifying supervision of CRNAs, which meant governors might be inclined to provide an opt-out. Before long, some governors did. Iowa was the first, and then a number of rural Western states opted out. To date, governors in 17 states have done so. These include Iowa, Nebraska, Idaho, Minnesota, New Hampshire, New Mexico, Kansas, North Dakota, Washington, Alaska, Oregon, Montana, South Dakota, Wisconsin,

California, Colorado, and Kentucky. Depending upon one's interpretation, this includes at least 50% of eligible states.

Two prominent health economists, Brian Dulisse and Jerry Cromwell, studied Medicare data between 1999 and 2005.¹⁰¹ They found “no evidence that opting out of the oversight requirement resulted in increased inpatient deaths or complications.” This came as no surprise to the AANA and CRNAs. The authors concluded: “We recommend that CMS return to its original intention of allowing nurse anesthetists to work independently of surgeons or anesthesiologist supervision without requiring state governments to formally petition for an exemption.”

Other contemporary studies supporting this assertion were collected in the publication *Quality of Care in Anesthesia*.¹⁰² Studies conducted by Simonson, Ahern, and Hendryx (2007), and Needleman and Minnick (2008) found no significant differences between CRNAs and anesthesiologists with respect to obstetric anesthesia outcomes. Pine, Holt, and Lou (2003) studied Medicare outcomes for patients in 22 states between 1995 and 1997. They found similar mortality rates for CRNAs and anesthesiologists working individually; no statistically significant difference in the mortality rate for team versus solo practice; and no statistically significant difference in mortality for hospitals without anesthesiologists versus hospitals where anesthesiologists provided or directed anesthesia care. And last, the Institute of Medicine—the health arm of the National Academy of Sciences—weighed in with a report entitled “The Future of Nursing: Focus on Scope of Practice.”¹⁰³ The report came as a powerful endorsement of nurses as high-quality clinicians. Its conclusion reads, in part:

Now is the time to eliminate the outdated regulations and organizational and cultural barriers that limit the ability of nurses to practice to the full extent of their education, training, and competence. The U.S. is transforming its health care system to provide quality care leading to improved health outcomes, and nurses can and should play a significant role. The current conflicts between what APRNs can do based on their education and training and what they may do according to state and federal regulations

must be resolved so that they are better able to provide seamless, affordable, and quality care. Scope-of-practice regulations in all states should reflect the full extent not only of nurses but of each profession's education and training. Elimination of barriers for all professions with a focus on collaborative teamwork will maximize and improve care throughout the health care system.

Doctoral Preparation of Nurse Anesthetists Achieved

Upgrading Nurse Anesthesia Educational Requirements

The upgrading of academic credentials for CRNA educators and their graduates has always been closely tied to the goals of the professional association to advance the art and science of anesthesia.¹⁰⁴ Nurse anesthesia leaders have been responsible for increasing requirements for curricular content, faculty qualifications, and academic credentials for graduates since the early 20th century. Over time, schools of anesthesia have changed from apprenticeships at hospitals into degree-granting institutions fulfilling the vision of early anesthesia leaders for a university education for nurse anesthetists. This movement into academia required identifying the location of schools of anesthesia throughout the nation, determining the essential characteristics of better schools, agreeing on curricular requirements, inspecting schools, and developing a school approval process.

Doctoral Degrees

Beginning in the mid-1980s, the AANA and the Council on Accreditation (COA) assessed the need for and feasibility of practice-oriented doctoral degrees for nurse anesthetists. In June 2005, the AANA board of directors convened an invitational summit meeting to discuss interests and concerns surrounding doctoral preparation for nurse anesthetists. Following the summit, the Task Force on Doctoral Preparation of Nurse Anesthetists (DTF) was formed and charged with developing options related to doctoral preparation of nurse anesthetists for the AANA board to consider.¹⁰⁵ The DTF's final report and options were presented to the AANA board of directors in April 2007, and in June 2007 the board unanimously adopted the position of supporting doctoral education for entry into nurse anesthesia practice by the year 2025. This decision was based on more than two years of investigation to

thoroughly explore the interests and concerns surrounding doctoral preparation of nurse anesthetists.

Setting a requirement for doctoral education followed in October 2009, when the Council on Accreditation of Nurse Anesthesia Education Programs adopted a position that “The COA will not consider any new master's degree programs for accreditation beyond 2015: and that students accepted into an accredited program on January 1, 2022, and thereafter must graduate with doctoral degrees.” The position became part of the Standard on Accreditation of Nurse Anesthesia Educational Programs and the basis for drafting new standards for clinical doctorate programs.¹⁰⁵

CRNA Practice Today

Demographic information collected from CRNAs by AANA in 2015 indicated there are approximately 48,000 members of the AANA. CRNAs are 58% female and 43% male. Their average age is 48.6 years. Ninety-one percent of currently practicing CRNAs consider themselves white/Caucasian, with only 9% reporting being nonwhite. Ninety-six percent of CRNAs reported that they practice clinical anesthesia, whereas only 2% work in either management/administration or education. The median annual total compensation for CRNAs, including salary and benefits, is \$170,000, up from the \$165,571 reported in 2010. CRNAs work in all states and in every clinical setting, using every anesthetic modality (general, regional, sedation, pain management). The data point out that American CRNAs are very productive and make an enormous contribution to the care of patients under anesthesia. And CRNAs are fulfilled by their work; only 10% expressed job satisfaction of 3 or less on a scale of 1 to 5.

The United States military is engaged around the world. CRNAs deploy to trouble spots as members of the US Army, Navy, and Air Force. Others work within the Department of Health and Human Services for the US Public Health Service and the VA. CRNAs are proving to be very versatile, fulfilling more than clinical duties in today's military: they are also leaders and, in some cases, soldiers on the line. CRNAs Major Steve McColley and Captain Mitchell Bailey earned Bronze Star Medal nominations for acts of courage in Iraq. Major Jeffrey Roos, a CRNA stationed at Fort Benning, Georgia, earned a Bronze Star from the Army for his lifesaving efforts during Operation Anaconda, the first major US offensive launched in Afghanistan after the September 11, 2001, attacks on the World Trade Center. A CRNA was in the news for extricating Private Jessica Lynch from a hospital in Iraq.

In past wars, CRNA deployments reduced anesthesia staff at stateside hospitals. No figures exist to describe the overall impact of the latest escalation on anesthesia services in stateside hospitals. However, the impact of deployments has been mitigated somewhat following a recent policy change in the Navy. Navy CRNAs are

now considered “licensed independent practitioners” (LIPs), a term coined by The Joint Commission (TJC). According to Captain Annette Hasselbeck, NC USN, LIP status has enabled the Navy's medical planners to use global sourcing of CRNAs. In other words, CRNAs are used interchangeably with anesthesiologists, based on skills, seniority, and availability. This had always been the pattern in practice, but defining CRNAs as LIPs has kept practice in compliance with TJC policy. According to Captain Ron Van Nest, NC USN (retired), the policy was changed in 2000 to reflect the fact that CRNAs very often deploy alone and capably make independent clinical decisions that affect anesthetic management. Recognizing CRNAs as LIPs has also kept morale high; all billets are filled, and retention of Navy CRNAs is at 100% as of this writing.

International Federation of Nurse Anesthetists

The International Federation of Nurse Anesthetists (IFNA) is a coalition of national associations of nurse anesthetists. It is an affiliate member of the International Council of Nurses and a Nursing Partner of the World Health Organization. The IFNA represents more than 50,000 nurse anesthetists worldwide, and is a growing organization with members in both developed and developing countries (S. Quellette and J. Rowles, written communication, January 21, 2012). The first organizational meeting was held in September 1988, and 11 countries were admitted as charter members in 1989. A World Congress is held every 2 years and is hosted by a member country.

To date, there are 36 member countries. The IFNA has developed international standards for education, standards of practice, standards for patient monitoring, and a code of ethics for nurse anesthetists.³⁴ An anesthesia approval process for entry level programs was launched in 2010, offering three levels of awards: Registration, Recognition, and Accreditation. The goal of the Anesthesia Program Approval Process is to encourage programs to comply with the IFNA's *Educational Standards for Preparing Nurse Anesthetists* through an approval process that takes cultural, national, or regional differences into consideration.¹⁰⁶

Progress in Anesthesia

Since the 1890s, nurse anesthetists facilitated the advancement of modern surgery. Their expertise with early ether anesthesia made possible the first successful intracranial, thoracic, adult and pediatric cardiac, and trauma operations.⁹⁸

Nurse anesthetists lifted the quality of anesthesia education available to nurses by implementing certification and recently recertification by examination, accreditation of schools, mandatory continuing education, and progressively higher degree standards for entry into practice.

Progress in anesthesia attributable to CRNAs has occurred in other areas of the discipline as well. The AANA Foundation lists and describes hundreds of recent and ongoing CRNA-led research projects.¹⁰⁷ These projects range from basic and applied sciences to clinical anesthesia, education, and economics.

A *Special Research Edition* of the *AANA Journal* published in August, 2011 featured a “select and eclectic” group of articles, all based on applied and basic research. The *Special Edition*, and some of the research, was funded by the AANA Foundation, whose president, Louise Herschkowitz, CRNA MSHA, wrote: “As our profession evolves, and as more CRNAs grow through doctoral education, the quantity and quality of both clinical and basic science research is rapidly expanding.”

The editor-in-chief of the *AANA Journal*, Chuck Biddle, CRNA PhD, wrote in an editorial: “Of great pride to me is the quality and diversity of work that I see emerging from colleagues nationwide, research that is altering the landscape of anesthesia care. I believe that strongly held views based on belief rather than sound evidence still exert too much influence on health care decision making. The age of evidence-based practice is upon us, and we should actively embrace the opportunity that it provides to merge research, skill, intuition, and humanitarianism.”

Summary

Nurses were recruited into the field of anesthesia by surgeons in the latter half of the nineteenth century because inexperienced clinical anesthesia administration by others often resulted in morbidity and mortality. The Civil War was the earliest documented use of nurses as anesthetists, and it became a trend afterward. By the 1890s, nurse anesthesia was well established, having spread from Midwestern Catholic hospitals to cities on both coasts. Before the turn of the twentieth century, nurse anesthetists provided gratuitous training to others. The first hospital-based anesthesia educational program opened in 1909. During World War I, nurse anesthetists were widely credited with significantly reducing combat-related surgical morbidity and mortality. By 1920, nurse anesthesia had become well established and well accepted.

Nurse anesthetists formed a national organization in 1931. Dedicating themselves to advancing anesthesia education and patient safety, nurse anesthetists implemented a number of firsts: annual meetings, a monthly bulletin, and a journal. In 1945, the first certification examination for graduates was implemented. As a result of service in the mid-century wars, nurse anesthetists earned officer's status, and men gained the right to join the military's nurse corps. When the military demanded that its nurse anesthetists pass the AANA certification examination, civilian hospitals soon followed suit. By the 1950s, nurse anesthetists worked with surgeons and engineers to pioneer anesthesia machinery, ventilators, and anesthesia for pediatric cardiovascular surgery. During this era, accreditation of anesthesia training programs was achieved.

The second half of the twentieth century was marked by a closer involvement between the profession and government. As Medicare paid for a larger proportion of clinical anesthesia services, the government in turn exerted increasing control over how those services were rendered and at what cost to taxpayers. Because federal dollars also went for nursing education, the government exerted a measure of control over accreditation. Independent councils on accreditation, certification, recertification, and public

interest evolved from this.

In the 1960s and 1970s, state governments modernized nurse practice acts to account for new subspecialties in advanced practice nursing. CRNAs had to participate, even though they had long predated other advanced practice nurses. The 1980s and 1990s brought about governmental efforts to “reform” health care by extending services and containing costs. Quality of care entered the debate, and CRNAs ultimately proved what had been shown 50 years earlier: anesthesia outcomes are no worse and perhaps better when a CRNA administers the anesthetic. For CRNAs, constant vigilance and a presence in federal and state government centers were essential because each of the aforementioned policy changes presented organized anesthesiologists with an opportunity to threaten nurse anesthesia. As a result, state nurse anesthetist associations became stronger, and the AANA established an office in Washington, D.C.

Progress in nurse anesthesia has occurred over many decades and resulted in an extraordinary record of patient safety. CRNAs have undertaken hundreds of clinical, scientific, and policy research projects to further professional and public understanding of nurse anesthesia.

Nurse Anesthesia Specialty Practice and Education in the United States

Francis Gerbasi, Lynn Reede

The specialty practice of nurse anesthesia is one of the most challenging and rewarding roles of Advanced Practice Registered Nursing (APRN). Nurse anesthetists, together with their professional association, the American Association of Nurse Anesthetists (AANA), have been role models for members of the other APRN roles (i.e., nurse practitioners, clinical nurse specialists, and certified nurse midwives) and advanced practice professional organizations. This chapter describes the educational requirements necessary to become a Certified Registered Nurse Anesthetist (CRNA), the practice roles of the CRNA, and changes in the Council on Accreditation of Nurse Anesthesia Educational Programs (COA) and their role along with the AANA in advancing the nurse anesthesia profession.

Nurse Anesthesia Educational Requirements

Nurse anesthesia educational requirements form the foundation for the nurse anesthesia profession. The upgrading of educational requirements ensures graduates have the knowledge, skills, and abilities to enter into practice and provide safe anesthesia care. In 1933 the National Association of Nurse Anesthetists (NANA) was established. A primary goal of NANA was to develop nurse anesthesia educational objectives.¹ Accreditation standards and processes were established to ensure high quality nurse anesthesia programs. The accreditation function for nurse anesthesia programs was performed by the AANA until the COA was established in 1975 and assumed responsibility for establishing the standards and accreditation of nurse anesthesia programs. The COA is the only accrediting agency recognized by the US Department of Education (USDE) and the Council for Higher Education Accreditation (CHEA) to accredit nurse anesthesia educational programs in the United States and Puerto Rico. The scope of the COA's accreditation includes nurse anesthesia programs that award post-master's certificates, master's, or doctoral degrees, including programs offering distance education. The standards (i.e., master's, doctoral, and fellowships) are measures used by the COA to assess the quality of nurse anesthesia education. The COA has been responsible for increasing the requirements for curricular content, faculty qualifications, and academic credentials for graduates. This includes the requirement that all COA-accredited nurse anesthesia programs award a master's degree, which occurred in 1998 and award doctoral degrees to students entering programs on January 1, 2022, and thereafter.

Nurse Anesthesia Education Today

As of January 2015, nurse anesthesia programs are governed by two sets of standards based on the degree the program is awarding. Programs awarding master's degrees are governed by the 2004 *Standards for Accreditation of Nurse Anesthesia Educational Programs*.²

Programs awarding doctoral degrees are governed by the Standards for Nurse Anesthesia Programs: Practice Doctorate.³ The processes used to accredit programs are focused on ensuring compliance with the *Standards* and the *COA Accreditation Policies and Procedures*.⁴

Accreditation provides a means to assure and improve higher education quality.⁵ Revisions to the *Standards* and the accreditation policies occur periodically to ensure they continue to reflect the current requirements to prepare graduates for entry into practice, meet USDE and the CHEA recognition requirements, and promote improvement in nurse anesthesia education. In 2011, the COA initiated a major revision of its standards with the purpose of establishing new practice doctorate standards. In 2015, the COA approved the practice doctorate standards.⁶ In 2016, the COA established the Programs' Transition to the Doctoral Level policy.⁴ The policy reinforces the requirement that all accredited programs must offer a doctoral degree for students entering programs on January 1, 2022, and thereafter.

General Educational Requirements for Nurse Anesthesia Programs

Nurse anesthesia programs are required to demonstrate compliance with the *Standards* and the *Accreditation Policies and Procedures*. Programs are required to assess their integrity and educational effectiveness through ongoing evaluation and assessment. Programs must continually monitor and evaluate their didactic and clinical curriculum, including, but not limited to, curricular content, admissions policies, faculty, and clinical sites used for student educational experiences. In addition to programs' internal assessment processes, programs must submit annual reports to the COA, complete self-studies and host onsite COA visits. The COA monitors programs' indicators of success and the attainment of their stated outcomes. This includes programs' pass rates on the National Board of Certification and Recertification for Nurse Anesthetists' (NBCRNA) National Certification Examination (NCE), programs' attrition, and employment rates of graduates.

Programs must demonstrate that graduates take the NCE

examination and pass it in accordance with the COA's pass-rate requirement. The COA first established a policy and procedures for monitoring programs' NCE pass rates in 2003. The COA made major revisions to the policy in 2006, 2013, and 2016. The most recent revised policy establishes a mandatory pass rate of 80% of all programs' first-time takers when considering the three most recent graduation cohorts.⁷ Programs must meet or exceed the COA mandatory pass rate. Programs that fall below the mandatory pass rate will be monitored and must demonstrate improvement. If improvement is not demonstrated within the established timeframe, programs' accreditation is subject to an adverse accreditation action.

Programs are also required to accurately post their first time NCE pass rates, attrition rates, and employment rates of its graduates on their websites and to link their websites to the COA's list of accredited programs.⁴ These stringent requirements help ensure the effectiveness of nurse anesthesia clinical and didactic education, as well as ensuring that the public is being provided with accurate information related to student achievement.

To assess the overall quality of nurse anesthesia programs, the COA conducts periodic assessment of recent graduates' preparedness for entry into practice. The most recent assessment was conducted from August 2011 to February 2012. The results indicated that 98% of graduates and 97% of employers identified that graduates were prepared for entry into practice. Ninety-six percent of the employers indicated they would hire the same graduates again.⁸

High quality educational programs must have sufficient resources. At its May 2013 meeting, the COA approved a "Program Resources and Student Capacity" policy.^{4,9} The policy requires programs verify there are adequate resources to support the size and scope of the offering to appropriately prepare students for practice and to promote the quality of graduates. The process programs must use to establish their class size is identified in the policy. Programs can submit requests to the COA to increase their assigned class size. Requests to increase class size must be approved prior to the enrollment of additional students.

The COA has requirements related to the administration of nurse

anesthesia programs. The requirements include programs' management of faculty and students, fiscal management, maintenance of COA accreditation and other higher-education accreditation requirements of the universities, faculty continuing education, and program evaluations. The Practice Doctorate Standards require nurse anesthesia programs to employ CRNAs with doctoral degrees in the roles of program administrator and assistant program administrator by January 1, 2018.

Programs are required to enroll only students who are of quality appropriate for the profession and who have the ability to benefit from their education. Minimum admission requirements include graduation from a school of nursing, a baccalaureate or graduate degree in nursing or an appropriate major, current unencumbered license as a registered nurse, and a minimum of 1-year full-time work experience as a registered nurse in a critical care setting. The critical care experience must have provided the registered nurse with the opportunity to develop as an independent decision-maker capable of using and interpreting advanced monitoring techniques based on knowledge of physiological and pharmacological principles. Programs determine what types of work experience are acceptable for admission to meet this requirement. Examples of critical care areas include but are not limited to surgical, cardiothoracic, coronary, medical, pediatric, and neonatal intensive care units.

Nurse Anesthesia Education Program Curriculum

The didactic curricula of nurse anesthesia programs are governed by the master's and doctoral standards and help ensure students are provided with the scientific, clinical, and professional foundation upon which to build sound and safe clinical practice. Programs must demonstrate that they provide an extensive educationally sound curriculum combining both academic theory and clinical practice. The curricula must include three separate courses in advanced physiology/pathophysiology, advanced pharmacology, and advanced health assessment. This requirement is consistent with the educational requirements identified in the APRN

Consensus Model.¹⁰ The curricula must also include content areas in anatomy, chemistry, biochemistry, physics, professional issues, equipment, technology, pain management, research, clinical correlation conferences, radiology, ultrasound, chemical dependency, and wellness.^{2,3} Courses ensure graduates have the knowledge to provide safe, high quality anesthesia care. Course content includes the induction, maintenance, and emergence from anesthesia; airway management; anesthesia pharmacology; and anesthesia for special patient populations such as obstetrics, geriatrics, and pediatrics.

Programs awarding doctoral degrees most commonly award either a Doctor of Nursing Practice (DNP) or Doctor of Nurse Anesthesia Practice (DNAP). Doctoral programs are required to provide additional content in ethical and multicultural health care, health policy, health care finance, informatics, leadership, and management. All programs must evaluate students' knowledge and skills to ensure they are meeting the programs' stated objectives as they progress in the program. All programs must develop and implement policies and procedures that use objective criteria to promote student learning while simultaneously enhancing the programs' quality and integrity.

The methods used to deliver nurse anesthesia curricula are changing as new technologies are being applied in higher education. Based on COA 2015 Annual Report data, 69% of nurse anesthesia programs use some form of distance education in their provision of didactic instruction.¹¹ Programs' distance education offerings vary from several core courses to programs in which the majority of the didactic curriculum is provided using distance education. In addition, 98% of programs report having access to some form of simulation (e.g., simple models, computer, full-body patient simulation).¹¹ The involvement of individual programs ranges from the use of simulation to supplement traditional content delivery methods to the utilization of simulation to entirely deliver curricular content.

The clinical curriculum of nurse anesthesia education provides students with an opportunity to apply didactic knowledge in clinical practice. Programs prepare graduates with the knowledge and skills to administer all types of anesthesia, including general,

regional, and selected local and moderate sedation to patients of all ages for all types of surgeries. Students use a variety of anesthesia drugs, manage fluid and blood replacement therapy, and interpret data from sophisticated monitoring devices. Additional clinical responsibilities include the insertion of invasive catheters, the recognition and correction of complications that occur during the course of an anesthetic, the provision of airway and ventilation support during resuscitation, and pain management. Students enrolled in nurse anesthesia programs on January 1, 2015, and thereafter must have performed a minimum of 600 anesthetics, which must include specialties such as pediatric, obstetric, cardiothoracic, and neurosurgical anesthesia.^{2,3} The anesthesia experiences include the care of not only healthy but critically ill patients of all ages for elective and emergency procedures. In most programs, the minimum number of clinical experiences is surpassed early in their clinical practicum. Based on FY2015 certification transcript data, nurse anesthesia programs provide an average of 865 cases, 1703 hours of anesthesia clinical experience, and 2620 total clinical hours for each student.¹²

During students' clinical experiences, they must be supervised by CRNAs or anesthesiologists who provide instruction in the administration and monitoring of various techniques, including both general and regional anesthesia. The clinical faculty evaluates the technical and critical thinking skills of students. The entry into practice competencies for the nurse anesthesia professional are those required at the time of graduation to provide safe, competent, and ethical anesthesia care to patients for diagnostic, therapeutic, and surgical procedures.^{2,3} The entry into practice competencies should be viewed as the structure upon which the nurse anesthetist continues to learn new facts, obtain and refine knowledge, and develop skills along the practice continuum that starts at graduation (proficient), and continues throughout their entire professional career (expert).

Councils' Configurations and Relationships

In the 1970s, the AANA bylaws were revised to allow for the establishment of four separate autonomous councils under the corporate structure of the AANA: the Council on Accreditation of

Nurse Anesthesia Educational Programs (COA), the Council on Certification of Nurse Anesthetists (CCNA), the Council on Recertification of Nurse Anesthetists (COR), and the Council for Public Interest in Anesthesia (CPIA). The councils were established with the intention of informing and assuring the public that accreditation, certification, and recertification activities are within the discipline of nurse anesthesia and are separate from and not unduly influenced by the AANA. In the 2000s, there were significant changes in the councils' structure. In 2007, the CCNA and COR incorporated to form the National Board of Certification and Recertification for Nurse Anesthetists (NBCRNA). The COA separately incorporated in 2009; in 2010 the AANA members voted on an AANA bylaws change at the August 7, 2010, AANA annual business meeting to not continue to recognize the CPIA. Subsequent to that action, the CPIA chose to not continue its activities and has since been dissolved. The COA and the NBCRNA are solely responsible for their own internal affairs, including the election of officers and the direction of their financial activities. A CRNA Chief Executive Officer serves the COA, NBCRNA, and the AANA. In accordance with their bylaws, membership on the COA and NBCRNA boards include CRNAs (educators and practitioners), hospital administrators, and members of the public. Membership on the COA also includes university and student representatives. To enhance communication between the organizations, liaisons were established for the AANA, NBCRNA, and the COA in 2013. Liaison representatives attend select sessions at the organizations' boards meetings. In addition, communication between the AANA, COA, and NBCRNA is facilitated through regularly scheduled leadership meetings that include discussions on issues of mutual concern. More information on the AANA, COA, and NBCRNA can be found at <http://www.aana.com>, <http://www.home.coa.us.com>, and <http://www.nbcrna.com>, respectively.

Current and Future Specialization

At the COA's January 2014, meeting, the specialization of nurse anesthesia practice took a major step forward when the COA adopted Standards for the Accreditation of Post Graduate CRNA

Fellowships and procedures for the accreditation of postgraduate CRNA fellowships.¹³ CRNA fellowships contain advanced education and training in a focused area of specialty practice or concentration. The first fellowship accredited by the COA was established in advanced pain management. In 2008, the AANA assembled a group of CRNA practitioners who devoted most of their clinical practice to pain management. Through the input and guidance of this group of leaders, a theoretical foundation for pain practice was operationalized and work was subsequently initiated to formalize the content for nurse anesthetists expressing an interest in advanced pain management. The AANA first developed a partnership with Hamline University in St. Paul, Minnesota to offer a postgraduate certificate in advanced pain management. The inaugural class of students enrolled in this fellowship started their program of study in 2012. In 2014 the Hamline University fellowship was the first fellowship accredited by the COA. In 2016 the AANA changed the academic affiliation from Hamline University to Texas Christian University (TCU), Fort Worth, TX. The TCU Postgraduate Advanced Pain Management Fellowship is a partnership between the AANA and TCU. It consists of a three-semester/12-month postgraduate educational program in advanced pain management.¹⁴ This fellowship is in the area of nonsurgical (chronic) pain management. Whereas other specialty groups could eventually avail themselves of this education, the commitment is to focus on the nurse anesthesia community and to expand enrollment to other practice disciplines over time, based on demand and the adequacy of educational resources.

An important development for the practice of APRNs was the APRN Consensus Model, approved in 2008.¹⁰ This is a model for licensure, accreditation, certification, and education. The APRN Consensus Model identifies areas of educational specialization within advanced practice nursing that occur beyond the levels of role and/or practice foci and are not to be used as sources for regulation of practice, but rather to serve the individual nursing practitioners in their delivery of care and services.¹⁰ Therefore future examination for specialty areas of practice by the CRNA, above the role of nurse anesthetist, should not be utilized as a gate-keeping mechanism to prevent any CRNA from engaging in any

subspecialty practice. As long as a CRNA can demonstrate they have obtained the knowledge, skills, and abilities necessary to engage in a specialized area, the individual practitioner should not undergo regulation via additional professional licensure. In 2015, the NBCRNA established a specialty credentialing process in nonsurgical pain management.¹⁵

Other academic institutions that offer programs in nurse anesthesia are now considering development of other subspecialty fellowship programs. As mentioned previously, these programs should not be regulated by the state boards of nursing; rather the NCSBN Consensus Model recommends that professional nursing organizations provide professional oversight and that accreditation and subspecialty certification are the quality metrics that should be used to insure graduates of these subspecialty programs provide safe and quality care to patients. As health care in the United States continues to expand under the Patient Protection and Affordable Care Act of 2010, the need for more subspecialty care providers is projected to increase. Subspecialty programs in nurse anesthesia will help bridge this gap.

Certified Registered Nurse Anesthetist Practice

CRNAs are advanced practice registered nurses, licensed as independent practitioners who provide holistic, patient-centered anesthesia, analgesia, and pain management services for patients across their lifespan, no matter the complexity of their health.¹⁶ As leaders and decision makers, CRNAs work in collaboration with the interprofessional team that includes the patient, other health care professionals and qualified practitioners, such as physicians (e.g., surgeons, obstetricians, or anesthesiologists), dentists, and/or podiatrists, to provide high quality anesthesia services.¹⁶⁻¹⁸

There are several nurse anesthesia-related practice roles as defined by the NBCRNA; they include clinical practice, administration, education, and research, or a combination of two or more of the areas of practice.^{16,19} In their clinical practice role, nurse anesthetists administer approximately 40 million anesthetics annually for patients in the United States.¹⁹ CRNAs provide comprehensive, patient specific anesthesia services using anesthesia and analgesia techniques for surgical, obstetric, procedural, diagnostic, and chronic pain management procedures. CRNAs are the direct provider of all elements of anesthesia services in academic and community hospitals, critical access hospitals, ambulatory surgical centers, clinics, and offices, as well as the US military, public health services, and Veterans Administration health care facilities. In some states, CRNAs are the sole anesthesia providers in almost 100% of all rural hospitals, providing patients and families access to excellent obstetric, surgical, diagnostic, and trauma stabilization services in their community.²⁰

CRNAs are consulted on a 24-hour basis and are an integral part of the health care team, lending their expertise in perioperative management that may include preanesthesia patient optimization, airway management, critical care, pain management, resuscitation, and other related clinical activities.^{16,20} In addition to their clinical practice role, CRNAs are business owners, administrators, or practice in other leadership positions; participate with the team in

quality improvement processes; lead research activities; are educators; collaborate in interdepartmental activities including policy development; and participate in various state and federal governmental agencies.^{16,20} CRNAs meet the health care competency needs of their patients and are also didactic and clinical educators of nurse anesthesia students and teach other health care professionals specific skills related to their profession (e.g., flight nurses, medical students, respiratory therapists).

Today, market pressures are causing consolidation of health care facilities in local markets and across the country, as well as the growth of health care employment management companies.²¹⁻²³ As health care transitions from a reimbursement model based on fee for service to one grounded in value-based care and outcomes, the CRNA offers value and excellence in leadership, holistic patient care, quality, and cost effective care.²³ To meet the needs of their community, the CRNA may practice in a single or a variety of employment arrangements, such as self-employed, employed by a health care facility, anesthesia group, health system, practice management company, university, military or clinic, or health care system.

CRNA Professional Credential

Professional certification indicates that the individual has met predetermined criteria that measure the knowledge, skills, attitudes, and judgments necessary for entry into the specialty of nurse anesthesia practice. Certification affords the public and employers an awareness of the qualifications and capabilities of health care providers. The CRNA credential indicates that the individual who holds it has met prescribed criteria and is qualified to provide the services described within a CRNA's scope of practice.^{16,19}

In order to enter practice as a CRNA, an individual must:

1. Comply with all state requirements for current and unrestricted licensure as a registered professional nurse in all states in which he or she currently holds an active license;
2. Complete a nurse anesthesia educational program accredited by

the COA or its predecessor within the previous 2 calendar years;

3. Successfully complete the NCE administered by NBCRNA or its predecessor;¹⁸ and

4. If applicable, apply for licensure as a CRNA in the state(s).

The NCE eligibility requirements are available in the NBCRNA National Certification (NCE) Handbook that can be found at <http://www.nbcrna.com>>Publications/Events>Handbooks.

To maintain the CRNA credential, an individual must meet the requirements set forth by the NBCRNA in the Continued Professional Certification (CPC) Program. The comprehensive and rigorous CPC Program promotes professional development and lifelong learning to address changing accreditation requirements, the evolving health care environment, increasing autonomy of nurse anesthesia practice, and to integrate new technology into practice regardless of practice setting, patients, and conditions. The CPC Program is being phased in with all certificants participating by August 1, 2017. The program is comprised of two 8-year periods over 16 years and will continue to be revised to meet the needs of patients and health care. The program's 8-year periods are comprised of two 4-year cycles. In addition to documentation of practice and licensure, the program components include Class A and Class B credit requirements, completion of the four core modules, and the CPC examination. In addition to completion of the CPC Program 4-year cycles for maintenance of certification, the CRNA must document his or her anesthesia practice, maintain current state licensure, and certify that he or she has no conditions that could adversely affect the ability to practice anesthesia.¹⁹ Additional information regarding the CPC program may be found at www.nbcrna.com>CPC/Recertification.

CRNA Scope of Practice

The AANA promulgates nurse anesthesia evidence-based practice standards and guidelines. The AANA *Nurse Anesthesia Practice Standards, Scope of Nurse Anesthesia Practice* and *Code of Ethics* provide the foundation for nurse anesthesia professional

practice.^{16,24,25} The *Scope of Practice and Nurse Anesthesia Practice Standards* are the foundation for the *COA Standards for Accreditation of Nurse Anesthesia Education Programs* as shown in [Table 2.1](#).^{3,16} The 2013 *Scope of Nurse Anesthesia Practice* addresses the responsibilities associated with clinical anesthesia practice working collaboratively with other health care providers, but is not limited to, the following^{16,24}:

TABLE 2.1
Crosswalk Between AANA Scope of Nurse Anesthesia Practice & COA Standards for Accreditation of Nurse Anesthesia Programs: Practice Doctorate

Element of Scope of <i>Nurse Anesthesia Practice</i>	Standard(s) That Address Element
Perform a comprehensive history and physical	D8
Conduct a preanesthesia evaluation	D15
Obtain informed consent for anesthesia	D25, D28, D32, D35
Develop and initiate a patient-specific plan of care	D5, D17
Select, order, prescribe and administer drugs and controlled substances	D5, D9, D10, D11, D13, D14, D17, D19, D20, D21, D22
Select and insert invasive and noninvasive monitoring modalities	D5, D9, D10, D11, D13, D14, D17, D19, D20, D21, D22 & clinical experience requirements
Provide acute, chronic and interventional pain management services	E2.2, E2.3
Provide critical care and resuscitation services	D1, D5, D12, D13, D14, D16, D19, D21, D22
Order and evaluate diagnostic tests	D8, D16, D19
Request consultations	D1, D17, D26, D32
Perform point-of-care testing	C2.3, D19, E2.2
Plan and initiate anesthetic techniques, including general, regional, local, and sedation. Anesthetic techniques may include the use of ultrasound fluoroscopy and other technologies for diagnosis and care delivery, and to improve patient safety and comfort	D9, D10, D11, D2, E2.2, E2.3 & clinical experience requirements
Respond to emergency situations using airway management and other techniques; facilitate emergence and recovery from anesthesia	D12, D21, D22, D26, E2.3, E10
Provide post-anesthesia care, including medication management, conducting a post-anesthesia evaluation, and discharge from the post-anesthesia care area or facility	D5, D29

From Council on Accreditation of Nurse Anesthesia Educational Programs (COA). *Standards for Accreditation of Nurse Anesthesia Programs: Practice Doctorate*, Park Ridge, IL: 2015; American Association of Nurse Anesthetists: *Scope of Nurse Anesthesia Practice*. 1. Performing a comprehensive history and physical
2. Conducting a preanesthesia evaluation and assessment
3. Obtaining informed consent for anesthesia
4. Developing and initiating a patient-specific plan of care
5. Selecting, ordering, prescribing, and administering drugs and controlled substances
6. Selecting and inserting invasive and using noninvasive monitoring modalities
7. Providing acute, chronic, and interventional pain management services
8. Providing critical care and resuscitation services
9. Ordering and evaluating diagnostic tests
10. Requesting consultation
11. Performing point-of-care testing
12. Planning and initiating anesthetic techniques, including general, regional, local, and sedation
13. Using anesthetic techniques that may include ultrasound, fluoroscopy and other technologies for diagnosis and care delivery, and to improve patient safety and comfort
14. Responding to emergency situations using airway management and other techniques
15. Facilitating emergence and recovery from anesthesia
16. Providing post-anesthesia care, including medication management, conducting a post-anesthesia evaluation, and discharge from the post-anesthesia care area or facility

In addition, the *Scope of Nurse Anesthesia Practice* and the *Standards for Nurse Anesthesia Practice* are the authoritative statements that describe the minimum rules and responsibilities for which the nurse anesthetist is accountable. The standards apply to all anesthetizing locations and are intended to offer guidance for safe and high quality anesthesia care.²⁴ Individual state or facility rules and regulations may influence CRNA scope of practice. Anesthesia services evolve and change over time as research, evidence, technology, and new medications offer modification of existing or new anesthesia techniques. As the CRNA considers the addition of new skills to their practice, he/she may access AANA *Considerations for Adding New Activities to Individual CRNA Scope of Practice* to address any decision points that may be necessary.²⁶ It is also the responsibility of the CRNA to acquire the knowledge, skills, judgment, and experience necessary to safely practice within the scope of practice specific to state and facility policy.²⁵ More information regarding CRNA practice is available on the AANA website at <http://www.aana.com>

AANA Organizational Structure and Function

The AANA is a professional membership association that represents 49,000 CRNAs and student registered nurse anesthetists nationwide. According to August 2015 AANA data, more than 90% of CRNAs in the United States are members of the AANA.²⁰ The AANA was first incorporated in Ohio on March 12, 1932, as the National Association of Nurse Anesthetists (NANA). It was reincorporated in the state of Illinois on October 17, 1939, and was designated as a tax-exempt organization in accordance with subsection 501(c) of the Internal Revenue Code and, that same year, the organization's name was changed to the American Association of Nurse Anesthetists.²⁷

AANA bylaws, policies and guidelines are the governance documents of the Association and are available at <http://www.aana.com>. The bylaws address the different classes of membership, decision-making procedures, responsibilities of the AANA's elected officials, the role of the Executive Director/Chief Executive Officer, the configuration of committees, functions of committee members, and the AANA's relationship with state nurse anesthesia associations.²⁸

The AANA Board of Directors (BOD) is elected by voting-eligible members of the AANA and serves as the governing body for the AANA. The BOD includes the president, president-elect, vice president, treasurer, and seven directors from seven regions in the United States. The BOD is responsible for the leadership and governance of the AANA.²⁸ The Board adopts organizational policy and strategic framework; oversees the budget and related financial affairs; adopts clinical standards and guidelines; directs legislative advocacy activities; and serves as a liaison with external governmental and professional organizations. In addition, the BOD collaborates with and considers recommendations for activities that align with the AANA strategic priorities from the AANA staff, the committees of the association, COA, NBCRNA, AANA Foundation, and adopts recommendations as appropriate.

The AANA resides in two offices in Park Ridge, IL, and one office in Washington, DC, and employs over 128 staff members. The AANA Chief Executive Officer leads and manages the daily activities of the Association with the assistance of the Chief Operations Officer and the Senior Directors of the various divisions. Collectively, the AANA staff carries out objectives as adopted by the elected AANA BOD and consistent with the AANA's mission statement to “advance patient safety, practice excellence, and its members' profession.” With this in mind, the AANA supports advocacy activities at the local, state, and federal levels on behalf of its members and the public. The AANA's organizational structure and more information regarding the AANA divisions and its advocacy efforts are available at <http://www.aana.com> About Us.

AANA Foundation

The AANA Foundation serves as the philanthropic arm of the American Association of Nurse Anesthetists. The AANA Foundation is a charitable organization devoted to anesthesia research, education, and development. The Foundation funds scholarships, doctoral fellowships, postdoctoral fellowships, research grants, general poster sessions, oral “State of the Science” poster sessions, and doctoral mentorships. Additional information regarding the AANA Foundation may be found at <http://www.aana.com/aanaaffiliates/aanafoundation/Pages/default.a>

AANA Association Management Services, Inc.

The AANA owns one subsidiary, the AANA Association Management Services, Inc. (AAMS), which provides non-dues-related sources of revenue, as well as services for the general membership. There are currently two divisions within the AAMS. These divisions provide services related to malpractice insurance and housing (hotel rooms and lodging arrangements in association with meetings and events of the AANA) for both internal and external clients. Additional information is available at <http://www.aana.com/insurance>.

Summary

With the continued dedication and engagement of its members, volunteer leaders, and staff, the nurse anesthesia profession and the American Association of Nurse Anesthetists has grown and evolved for well over a century. As patient and health care delivery complexity continues to evolve, CRNAs are health care leaders well positioned to address the challenges of complex patients and systems of care well into the future.¹³ CRNAs in partnership with the AANA have the professional responsibility and opportunity to take an active role to secure their future, because a profession and professional organization is only as successful as its members.

Patient Centered Care, Cultural Competence, and Nurse Anesthesia Practice

Henry Talley, Costellia Talley

The nature of health care is transforming, driven in part by landmark recommendations from the National Academy of Medicine (formerly known as the Institute of Medicine) for quality and safety in health care systems and health professions.¹

According to the National Academy of Medicine's report, health care systems do not consistently provide high-quality care to all Americans, frequently do not translate knowledge into practice, often do not apply new technology safely and appropriately, and do not make the best use of their resources.^{1,2} The efforts to become more responsive to improving patients' outcomes have resulted in a paradigm shift from the traditional paternalistic provider-centered approach of care delivery to a shared decision-making patient-centered approach of care delivery. With the new model of health care delivery (patient-centered care), patients are active participants in the decision-making process about their care. Studies have shown that patient-centered care is associated with improvement in care processes, health care utilization, patient satisfaction, self-management, and health outcomes, including decreased mortality.³⁻⁵

Increasingly, anesthesiologists are caring for patients who make decisions about health care services based on personal needs and preferences, as well as the advice they receive from physicians, nurses, other care providers, internet, peer support groups, and a variety of information and communication technologies designed to support care. As anesthesiologists, it is important that we engage our patients throughout the spectrum of anesthesia care. The provision of quality care is a team activity and, as a member of a team, we

must all work well together and efficiently.⁶ In this chapter, we will discuss (1) patient-centered care as one of the six domains of health care quality and why it is important; (2) the status of health care quality and health disparities in the United States; and (3) offer considerations for the integration and evaluation of quality patient-centered care into the provision of anesthesia care.

Patient-Centered Care: What It Is and Why Is It Important

There is a growing demand from patients, policy makers, insurers, regulators, and accreditors to improve health care quality and safety, requiring anesthetists to persistently evaluate the quality of care that they provide.⁷ Patient-centered care has been recognized as an effective and efficient health care delivery method that has the potential to improve quality, patient safety, and patient outcomes at both the individual and system level.⁸ For this reason, patient-centered care is advocated as a key approach to the design and delivery of services provided by health care professionals (independently or collaboratively) across the health care continuum. Globally, patient-centered care is considered to be the gold standard of health care.⁹ Patient-centered care is critical to improving quality, improving safety, and reducing health care cost.¹⁰ However, there is a lack of consensus on what constitutes patient-centered care and how it should be delivered. Although there is disagreement on how patient centered care is defined, most conceptualizations include the following attributes: (1) education and shared knowledge; (2) involvement of family and friends; (3) collaboration and team management; (4) sensitivity to nonmedical, cultural and spiritual dimensions of care; (5) respect for patient needs and preferences; and (6) free flow and accessibility of information.¹¹ According to the American Association of Nurse Anesthetist (AANA), “patient-centered care is based on the concept of shared decision-making by establishing a patient partnership through sharing information and evidence, acknowledging patient preferences and ideas, identifying choices, and negotiating decisions and agreeing upon an action.”¹² Within this context, Certified Registered Nurse Anesthetists (CRNAs) should engage patients in the shared decision-making process, while being respectful of patients' ideas and preferences in the design of a safe, high-quality anesthetic experience. Patients are increasingly demanding a greater input into decision-making about their health. Additionally, patients have access to their health information and

available options.¹³

Patients report that there is a difference between the care they are seeking and the care that they receive.¹⁴ For example, patients often report significant problems in gaining access to critical information, understanding treatment options, getting explanations regarding medications, and receiving responsive, compassionate service from their providers.^{11,15-17} Outcomes that matter to the patient and that are feasible should guide the delivery of care. In one study, lack of understanding, fear, and anxiety about anesthesia caused one in four patients to postpone surgery, despite anesthesia's long history of quality care and safety.¹⁸ There has been a 97% decrease in anesthesia-related deaths since the 1940s (64/100,000 versus 1/100,000).^{19,20}

The Concept of Patient-Centered Care

Most current conceptualizations of patient-centered care are based on research commissioned by the Picker Institute (formerly, Picker Commonwealth Program for Patient-Centered Care).²¹ The research identified eight dimensions of patient-centered care:

- respect for patients' preferences and values
- emotional support
- physical comfort
- information, communication and education
- continuity and transition
- coordination of care
- the involvement of family and friends
- access to care

This research influenced the landmark National Academy of Medicine report conceptualization and policy initiative.¹ The National Academy of Medicine adopted these categories, but added additional layers of responsibility for health systems, linking quality to patient-centered care.²² Patient-centered care is one of the six dimensions of high-quality health care identified by the National Academy of Medicine that are essential to the improvement of health care quality. The other dimensions are: (1) safety, (2) timeliness, (3) effectiveness, (4) efficiency, and (5) equity

(Table 3.1).¹ Patient-centered care is considered to be the most important dimension of all because of its close association with safety. The core concepts of patient-centered care are:

TABLE 3.1

Six Dimensions for Improving Health Care Quality as Defined by the Institute of Medicine

Dimensions	Definition of Dimensions
Safety	The avoidance, prevention, and amelioration of adverse outcomes or injuries stemming from the processes of healthcare (errors, deviations, and accidents). Patients should not be harmed by the care that they receive; no harm should come to health care providers. The goal is that <i>no patient is caused any injury or complication from the effects of the overall anesthesia encounter.</i>
Timely	There should not be significant delays in treatment or long wait times, especially those that may be harmful.
Effective	Refers to the use of evidence-based care to guide best practices. This includes the underuse of effective care and overuse of ineffective care
Efficient	The avoidance of waste, including waste of equipment, supplies, ideas, and energy.
Equitable	The provision of care that does not vary in quality based on personal characteristics such as gender, ethnicity, geographic location, or socioeconomic status.
Patient-centered	The provision of care that is respectful of and responsive to patient preferences, needs, and values. Making certain that clinical decisions are based on patient values.

Adapted from Longnecker DE, Brown DL, Newman MF, et al. *Anesthesiology*. 2nd ed. New York, NY: The McGraw-Hill Companies, Inc. 2012; Varughese AM, Hagerman NS, Kurth CD. Quality in pediatric anesthesia. *Pediatric Anesthesia*. 2010;20(8):684–696.

- *Dignity and Respect:* Anesthetists must listen to and respect the patient's point of view and choices. The anesthesia plan should incorporate the patient and family knowledge, values, beliefs, and cultural background.
- *Information Sharing:* Anesthetists should communicate and share complete and unbiased information with patients and families in a useful and affirming way. The information should be timely, complete, and accurate so that shared decision-making can occur.
- *Participation:* Patients and families should participate in decision-making at the level of their choice.
- *Collaboration:* Patients, families, health care professionals, and health care leaders should collaborate on all aspects of health care (delivery of care, policy and program development, implementation and evaluation, professional education).²³

Berwick et al. further developed these concepts designed to

improve health outcomes into the Triple Aim.²⁴ The Triple Aim includes improving the patient experience (including quality and satisfaction), improving the health of the population, and reducing per capita costs. These aims have been adopted by the Institute for Healthcare Improvement (IHI) and several other organizations. The IHI Triple Aim concept design includes (1) focus on individuals and families; (2) redesign of primary care services and structures; (3) population health management; (4) cost control platform; and (5) system integration and execution.²⁵ Other components of patient-centered care that have been identified are coordination and integration of care, holistic care, enhanced provider-patient relationship, health information systems, and socio-cultural competence.²⁶

The integration of patient-centered care into health care delivery is continuing to evolve and the methods used to implement patient-centered care into practice vary. The integration of patient-centered care into practice requires a change in organizational culture. At the organizational level, seven key factors contribute to patient-centered care¹¹:

- *Leadership*: CEOs and boards of directors have to be committed and engaged to sustain patient-centered care.
- *Strategic vision/plan*: This must be clearly communicated to members of the organization. The vision should be consistently communicated. The organization's vision and values should be placed in a high traffic area to remind health care providers of the patient-centered behaviors expected and to let patients and families know what they can expect.
- *Involvement of patients and families*: This should happen at all levels, from care to key committees of the organization.
- *Supportive work environment for employees*: This includes engagement of employees in all aspects of process design and treating employees with dignity and respect.
- *Systematic measurement and feedback*: Monitoring the impact of changes and interventions.
- *Quality of the built environment*: The provision of a supportive and nurturing physical environment.
- *Supportive technology*: Technology that engages patients and

families by facilitating information access and communication.

Policy makers also advocate patient-centered care as a way to improve quality. The three main policy drivers of patient-centered care are:

- Mandatory government requirements for providers to collect and publish patient experience data
- Having information publicly available to enable consumers to choose between service providers
- Incentives for providers who achieve high measures of patient-centeredness

The Centers for Medicare and Medicaid Services (CMS) and the Agency for Healthcare Research and Quality (AHRQ) routinely collect data on patient experiences. The Patient Protection and Affordable Care Act of 2010 expanded data collection. The CMS provide financial incentives to health care providers and hospitals that provide information on quality. The Consumer Assessment of Healthcare Providers and Systems (CAHPS) developed standardized surveys to obtain information on patient's experiences. Hospitals use CAHPS to assess communication with doctors; communication with nurses; responsiveness of hospital staff; communication about medicines; pain control; cleanliness and quietness of physical environment; and discharge information.

Patient Engagement

Patient engagement is a strategy used to improve patient-centered care, and it is critical to achieving high quality care.²⁷ Patient engagement involves a meaningful participation by patients in different aspects of care (e.g., clinical encounters, guideline development, and research); the health care provider is the expert on medical care and the patient is an expert on his/her life values and status.^{28,29} An important goal of patient engagement is to foster the patient-anesthesia provider relationship through communication, clinical guidance, emotional support, and tailored provision of information. Shared decision-making is specifically suited for times when two or more treatment options are available and both have equally acceptable outcomes.

Patient engagement for anesthesiologists includes education, risk assessment, intervention, patient questions, and ultimately, shared decision-making.³⁰ This type of communication empowers patients to participate in decision-making, ask questions, and express feelings and/or concerns. Early patient engagement promotes better outcomes by identifying risks, educating patients and encouraging shared decision-making.

Traditionally, health care information has been exchanged in a face-to-face format. However, health information technology such as eHealth (including web-based interventions, smart phones, and equipment), telephone coaching, and telehealth are dramatically changing how information is exchanged. These changes have led to the development of clinical decision support tools. Clinical decision support is a process designed to provide timely information (usually at the point of care) to assist in clinical decision-making for health care providers, staff, patients, or other individuals with knowledge and person-specific information.³¹ Greene defined clinical decision support as “the use of information and communication technologies to bring relevant knowledge to bear on the health care and well-being of a patient.”³²

Tools to assist with decision-making include computerized alerts and reminders to providers and patients; clinical guidelines; condition-specific order sets; focused patient data reports and summaries; documentation templates; diagnostic support; and contextually related reference information.³¹ Anesthesia clinical decision support tools are characterized as (1) enhancing reimbursement or reducing costs^{33,34}; (2) increasing adherence to clinical, compliance, or regulatory protocols^{35,36}; (3) improving documentation^{37,38}; and (4) monitoring physiologic data in near real time and providing intraoperative recommendations at the point of care.³⁹⁻⁴¹ Studies show that in anesthesia, clinical decision support tools improve compliance and billing.^{42,43}

Shared Decision-Making

Shared decision-making is a strategy to improve patient engagement and is used as a health care quality tool to examine variation in diagnostic procedures. Shared decision-making occurs when an anesthesia provider and a patient (and family) work

together to make a quality decision about the anesthesia plan that is best. The decision-making process takes into account evidence based information about available risk and benefits of each anesthetic option, anesthesiologists' experience and knowledge, and the patient's values and preferences.

Shared decision-making has evolved to include interprofessional models of health care delivery.⁴⁴ Interprofessional care is defined as “the development of a cohesive practice between professionals from different disciplines to provide an integrated and cohesive answer to the needs of the client and family.”⁴⁵ The inclusion of an interprofessional model enhances communication among team members, increases patient safety and job satisfaction, and improves patient and process outcomes.⁴⁶ Interprofessional collaboration is supported by the AANA.⁴⁷

Shared decision-making is a priority of the Affordable Care Act. The Affordable Care Act established standards for the development of decision-making aids to assist in educating patients.

Barriers to shared decision-making include health literacy, lack of familiarity and/or experience with shared decision-making, lack of desire to participate in the process, provider lack of knowledge about evidence based practice, resources, and time.^{48,49} Health literacy refers to the skills needed to access, understand, and use information to make an informed decision. Providers will need to take into account the patient's ability to understand and apply information.

Health care providers in a fee-for-service environment organization may have a financial disincentive to participate in shared decision-making because it may reduce the use of high-cost procedures.⁵⁰ Health care providers may also resist the integration of shared decision-making into their care because it may interfere with patient workforce.

Benefits of Patient-Centered Care

Patient-centered care has clinical and operational benefits and improves the care experience. When patients and families, providers and administrators collaborate and partner, patient and provider satisfaction increase, quality and safety of health care increases, and health care costs decrease.^{23,51,52} Other benefits

associated with patient-centered care include decreased mortality, decreased emergency department visits, fewer medication errors, lower infection rates, higher functional status, improved clinical care, and improved liability claims experience.^{53,54} Patient-centered care improves efficiency through a reduction in diagnostic tests, unnecessary referrals, and decreased hospital admission.^{55,56} Patient-centered care improves patient satisfaction and trust, which improves provider satisfaction and provider retention rates.¹⁰

Extensive resources have been allocated to attaining a high value, high quality health care system at the national, state, and local level. The US Department of Health and Human Services is promoting patient-centered care as a way to improve health care quality through the provision of information about local health providers (Value Driven Healthcare Initiative).⁵⁷ Health care value is defined as the health care outcomes based on the dollars spent.⁵⁸ The mantra of value driven health care is “the right care for every person every time.” The focus of value driven health care is to make care safe, effective, efficient, patient-centered, timely, and equitable.

Patient-Centered Care and Cultural Competence

Providing high quality care to all citizens is the goal of health care reform, but the quality of health care in the United States has drawn concern for many. Although the Institute of Medicine (National Academy of Medicine) and the AHRQ have made efforts to reduce health disparities, gaps continue to persist.⁵⁹ Some populations experience inequality in health care, decreased patient safety, and poorer health outcomes based on race, ethnicity, socioeconomic status, language, gender, religion, immigrant and refugee status, disability, geography, insurance status, and sexual orientation.^{60–63} The National Academy of Medicine report “Unequal Treatment: Confronting Racial and Ethnic Disparities in Healthcare”⁶⁴ found that even with the same socioeconomic status and insurance, and when comorbidities, stage of presentation, and other confounders are controlled for, minorities often receive a lower quality of healthcare than do their white counterparts. The root cause of health disparities is complex and multifactorial and varies across regions and/or populations.

The National Academy of Medicine report⁶⁴ identified a set of

root causes of racial and ethnic disparities that included, among others:

- *Health system factors*: Focuses on issues related to the complexity of the healthcare system. Minority patients, those with limited English proficiency, low health literacy, mistrust, and limited familiarity with the health care system may find it disproportionately difficult to navigate the system.⁶⁵ The presence or absence of interpreter services to assist patients with limited English proficiency can also cause disparities.
- *Care-process variables*: Includes issues related to healthcare providers' communication, including stereotyping of patients which may lead to differences in recommendations for treatment and diagnostic procedures, as well as limited skills in communicating with diverse populations, which impacts clinical decision-making.
- *Patient-level variables*: Includes difficulty navigating the health care system such as mistrust of health care provider, refusal of services, poor adherence to treatment, difficulty voicing concerns and asking questions, and delay in seeking care.⁶⁵

Cultural competence of health care providers and the health care systems is a strategy to address disparities and improve outcomes. Culturally competent patient care requires health care providers to be respectful and responsive to the health beliefs, practices and needs of diverse populations. As health care systems are redesigned to meet the patient-centered care initiative, health care organizations must integrate cultural competence strategies to achieve equity (culture of equity). Cultural competency in health care delivery affects outcomes among diverse populations; therefore, it is important that health care professionals understand disparities and take steps to become culturally competent. Increased levels of cultural competency have the potential to improve patient-provider communications, improve the accuracy of diagnoses, prevent patients from exposure to unnecessary risk diagnostic procedures, enable providers to better obtain true informed consent, and enable patients to participate in shared decision-making.⁶⁴ Additionally, cultural competency training has also been shown to improve the knowledge and attitudes of

healthcare professionals who care for racial/ethnic and linguistic minority patients.⁶⁶

Patient-centered care and cultural competence have been identified as methods to improve health care quality and reduce disparities.⁶⁷ Although these concepts have different foci; they have similarities. The premise is that patient-centered care is culturally competent and culturally competent care is patient-centered. The difference in the two concepts has been defined:

*Both patient-centeredness and cultural competence aim to improve healthcare quality, but each emphasizes different aspects of quality. The primary goal of the patient-centeredness movement has been to provide individualized care and restore an emphasis on personal relationships. It aims to elevate quality for all patients. Alternatively, the primary aim of the cultural competence movement has been to increase health equity and reduce disparities by concentrating on people of color and other disadvantaged populations. Nevertheless, there is significant common ground between the two.*⁶⁸

Since publication of the National Academy of Medicine report, several approaches have been used to improve quality, eliminate health care disparities, and improve equity. A Robert Wood Johnson Foundation⁶⁹ report outlined six steps involved in the long-term integration and sustainability of efforts to reduce disparities and improve equity:

- *Linking quality and equity:* Focuses on achieving optimal outcomes for all groups of patients, although optimal outcomes of care may differ from person to person and group to group. Linking quality to equity requires implementing a basic quality improvement infrastructure and making equity an integral component of quality improvement. Quality improvement efforts must be tailored to each patient population and target the root causes of inequities, and the inclusion of equity into routine quality improvement processes.

A quality improvement infrastructure is essential for the reduction and elimination of disparities.

This includes the development of metrics and goals to monitor improvement, shared commitment and engagement in continuous improvements across all levels of staff, and a process for continuing improvement that supports ongoing adjustment of care. The collection of health care process and demographic variables (race, ethnicity, and language) is vital to individual quality improvement efforts and efforts to reduce disparities. Equity in the development of quality improvement focuses on improving health outcomes for everyone.

- *Creating a culture of equity:* “A culture of equity means recognizing that disparities may exist in an organization, and taking responsibility for reducing them.”⁵⁹ Cultural competency training improves the patient-provider relationship. The foundation of a culture of equity depends on health care providers and staff recognizing that disparities may exist and taking responsibility for its reduction. Health care organizations must make sure that equity is explicitly reflected in the organizational mission and vision statements. Examples include (1) designating specific leaders who are responsible for disparities reduction; (2) identifying equity champions, individuals who are willing to tackle inequalities in care (passionate and willing to go the extra distance); (3) recruiting and maintaining a diverse workforce that reflects the patient population that is served; (4) creating and maintaining an active patient/community or patient advisory board that is representative of the patient population; and (5) creating and maintaining strong working and consulting relationships with community-based groups and organizations who serve priority populations.
- *Diagnosing the disparity:* An equity lens is used to assess and diagnose health disparities. When using an equity lens,

considerations are given to examining the difference between quality of care and outcomes between different populations. Once a disparity is identified, the organization must analyze why the disparity exists. A root cause analysis is often used to explore a disparity and to identify its underlying cause. When conducting a root cause analysis, the focus should be on issues that are pertinent to the priority population and that contribute to the differences in care. A helpful mnemonic coined by the National Academy of Medicine can be used when conducting a root cause analysis is the 3-C's (culture, communication, and context). The data can be collected using a standard quality improvement tool. Once the data is collected, tools such as the fishbone diagram are often used to provide a visual display of the causes and effects of the disparities. At the end of the root cause analysis, a priority matrix is done to determine the disparity that is most important and feasible to address.

- *Designing the intervention:* Best practices should be used to design the intervention and the intervention should be based on the findings from the root cause analysis. To be successful, the intervention must be multilevel and target multiple players within the health care system. The Finding Answers Intervention Research (FAIR) database⁶⁹ provides a customized list of interventions that address disparities and can be used to facilitate the designing of the intervention. The site has an interactive format and the interventions are categorized by disease area, racial/ethnic population, organizational setting and intervention strategy.
- *Securing buy-in:* Buy-in is a critical component for a health disparities intervention to be successful. Buy-in entails a pledge of support/commitment and the provision of resources for interventions and activities from all stakeholders.
- *Implementing change:* If the organizations have analyzed the causes of a targeted disparity (root cause analysis), designed a tailored intervention to address the health disparity identified as most relevant to the patient population, and secured buy-in from all involved stakeholders, then they have laid a strong foundation for success. The implementation process should include regular evaluation of the impact of the intervention. Three types of

measures should be used to evaluate the intervention: data evaluation process, outcome, and intervention tracking measures. The long-term goal of an intervention is sustainability.

The increased emphasis on cultural competence is driven in part by the increase in minority populations, as well as the passing of the Patient Protection and Affordability Act⁷⁰ that increased the number of the newly insured, health care reform, findings indicating that sociocultural differences between patients and providers influence communication and decision-making, and the push for value based health care. These all provide opportunities to reduce disparities and improve equity. The Patient Protection and Affordability Act has components that specifically address disparities and it created Accountable Care Organizations (ACOs), whose aim is to ensure that patients receive the right care at the right time, avoid unnecessary duplication of services and prevent medical errors. Accountable Care Organizations include a groups of doctors, hospitals, and other health care providers that voluntarily come together to provide coordinated high quality care. Similarly, the Department of Health and Human Services released the “Action Plan to Reduce Racial and Ethnic Disparities,” which focuses on making the “a nation free of disparities in health and health care.”⁷¹

There is overlap between patient-centered care and cultural competence. Patient-centered care and culturally competent care are both needed to improve health outcomes and achieve equity. Every patient and family that has an interaction with health care systems brings with them a subculture that guide their understanding, interpretation, and outcomes of the interaction. Culturally competent care requires that health care systems and health care professionals have the knowledge, attitude, and skills to meet the needs of a diverse population. [Table 3.2](#) provides the key features of a culturally competent health care system and personal interactions. To effectively integrate culturally competent care into a system requires that individuals embrace the differences of populations and consider ways that we are the same, while being respectful of the individual differences. By designing services to a patient's culture and language preference, health professionals can help improve positive health outcomes for diverse populations. As the health care system is redesigned, it is important that health care

organizations provide culturally competent care, provide high quality care to all, eliminate disparities and assure equity.

TABLE 3.2

Key Features of Cultural Competence of Health Care Systems and Interpersonal Interactions

Culturally Competent Health Care Systems	Culturally Competent Health Care Interpersonal Interactions
Diverse workforce that reflect the population	Explores and respects patient's values, preferences, and needs
Having language assistance available	Find common ground
Ongoing training regarding culturally and linguistically appropriate services	Is aware of own biases and assumptions
	Is aware of health disparities and discrimination
	Effectively use interpreters as needed

Patient-Centered Care as a Dimension of Safety and Health Care Quality

Patient safety is the foundation of high quality health care. There is a growing recognition of the importance of maintaining a culture of safety and quality. The Joint Commission describes a culture of safety as “the summary of knowledge, attitudes, behaviors, and beliefs staff shares about the primary importance of the well-being and care of the patients they serve, supported by systems and structures that reinforce the focus on patient safety.” Health care systems that have a culture of safety and provide high quality care are guided by three principles: trust, reporting, and improvement.

Widespread efforts to reduce surgical site infection, adverse drug events, and other preventable events resulted in 1.3 million fewer incidents between 2010 and 2013. These changes are partially due to heightened awareness, increased accountability, and changes in reimbursement patterns. For example, reimbursement for some hospital-acquired infections has been eliminated and some carry a penalty.

Although the safety of health care has improved, there is still room for improvement. One of the most common types of hospital-acquired infection occurs at the surgical site surgical site, accounting for up to 40% of the all hospital-acquired infections.^{37,72,73}

Surgical site infections increase economic burden (length of stay and hospital cost) and disability-related outcomes. Health care cost doubles for patients with surgical site infection.⁷⁴ The Surgical Care Improvement Project, launched by the CMS and the Centers for Disease Control and Prevention aimed to reduce perioperative complications (i.e., surgical site infection, perioperative myocardial infarction, postoperative pneumonia, and venous thromboembolism). The initiative mandated that antibiotics prophylaxis be administered within incision, administration of the appropriate antibiotic, and discontinuation of antibiotic within 24 hours. Studies have shown that this initiative has been successful in reducing infection; however, compliance rates range from 60% to 100%.⁷⁵⁻⁷⁷ Hospitals are given incentives to increase compliance and are required to audit and release Surgical Care Improvement Project data to the CMS and insurance companies.

Measurement of Health Care Quality in Anesthesia

The main goal of health care quality improvement is to continue what is good about the present health care system while at the same time focusing on the areas that need improvement.⁷⁸ The measure of healthcare quality is not new; however, defining the importance of any given measure is problematic.⁷⁹ As established by the Affordable Care Act, the National Quality Strategy (NQS) was created in March 2011 to provide greater clarity on how health care providers and delivery systems could meet the goals of individual experience improvement of care, improved population health, and decreased costs.^{24,79} With input from more than 300 stakeholders, the ultimate aim of the NQS is to provide the framework to help focus on the alignment of quality measures and quality improvement activities.⁸⁰

As anesthesia practice enters a new crossroads, patient satisfaction, as a measure of health outcomes and delivery, has emerged as a valuable metric in the evolving system of health care.^{81,82} Anesthesia practice has been undergoing change over the last decade; however, in the future, our roles and responsibilities may be called into question and the sustainability of the practice may be in jeopardy if our focus does not continue to evolve. In the era of health reform, it is imperative that nurse anesthesia practice models drive the future of this clinical specialty. Remodeling practice represents a disruptive improvement in which the benefits offered are simpler, less costly, and of equal or higher quality than existing fee-for-service models.⁸³ As such, clinical practice and patient outcomes will be a more important measure of success as the Affordable Care Act continues to link pay with high quality care, population health, and reduced expenditures.^{83,84}

Decision Making and Patient Centered Care in Anesthesia

Shared decision-making is nothing new in anesthesia practice; it has

always been one of the hallmarks of the profession. Anesthesia practice has historically used a form of shared decision-making by including physician generalists, physician specialists, nurses, and auxiliary personnel in the course of the perioperative experience. The perioperative experience is successful when it is approached in a way that involves clinicians and patients sharing the best available evidence when making choices that will achieve the most informed decisions regarding the course of the anesthesia experience. The use of interdisciplinary teams is an essential element in the development of quality care measurements. Consensus building between appropriate stakeholders will ensure that risk-benefit trade-offs are thoroughly evaluated.

Health Care Quality and Safety in Anesthesia

Any organization, whether public, private nonprofit, or private for-profit can develop a measure; however, getting organizational and provider buy-in to adopt a given measure is critical if health plans and payers are to endorse them. Currently, the National Quality Forum (NQF) is the leading organization that reviews and endorses measures. The NQF is a not-for-profit, nonpartisan, membership-based organization whose measures and standards serve as a critically important foundation for initiatives to enhance health care value, make patient care safer, and achieve better outcomes.⁸⁵

NQF's endorsement process is geared to be a transparent, consensus-based practice that brings together diverse health care stakeholders from the public and private sector to foster quality improvement. At time of writing, approximately 300 NQF-endorsed measures are used in more than 20 federal public reporting and pay-for-performance programs, as well as in private sector and state programs.

By setting the example for safe, quality care, the anesthesia professions have been cited as leading the way in patient safety and outcomes. Reductions in anesthesia mortality have been accomplished through the use of new technologies, standardizing processes, simulation, championing patient safety and quality, and the formation of the Anesthesia Patient Safety Foundation.⁸⁶

Healthcare is a shared effort between providers and patients. In 1996, The National Patient Safety Foundation (NPSF) began as an

idea at a conference on medical error. The conference was organized by the American Association for the Advancement of Science, the American Medical Association, and the Annenberg Center for Health Sciences at Eisenhower Medical Center in California. At that meeting, representatives announced plans to form a foundation that would be “a collaborative initiative involving all members of the health care community aimed at stimulating leadership, fostering awareness, and enhancing patient safety knowledge creation, dissemination, and implementation.” NPSF is broader in scope, but similar in concept and mission to its predecessor, the Anesthesia Patient Safety Foundation, which focuses on the perioperative arena.

The AANA is continually developing informational sources to aid CRNAs in understanding the complex relationship between quality and value outlined in many of the CMS quality initiatives. These quality initiatives will affect reimbursement. Therefore, it is important for CRNAs to build their knowledge base about and become more familiar with these initiatives. The Physician Quality Reporting System (PQRS) Program is a CMS quality initiative that affects eligible providers' (EPs') reimbursement rates for covered Physician Fee Schedule (PFS) services furnished to Medicare Part B Fee-For-Service (FFS) beneficiaries. Although technically a voluntary program, nonparticipation in the PQRS program has financial implications for future Medicare Part B FFS reimbursement. Financial implications exist in the form of payment adjustments based on satisfactory reporting of PQRS measures. Compliance with PQRS reporting requirements also has repercussions beyond the PQRS program; therefore understanding this program is essential to CRNAs' ability to safeguard their Medicare billings.⁸⁷

There are several PQRS reporting mechanisms for single practitioners and group practices. Depending on their specialty, setting, and practice, EPs may choose from the following methods to submit data to CMS: Claims-based; Electronic Health Record (EHR); Qualified Registry; Qualified Clinical Data Registry (QCDR); or the Group Practice Reporting Option (GPRO).⁸⁷ With the passage of the Patient Protection and Affordable Care Act (PPACA), there is an increased demand for health care providers to

accelerate quality improvement and promote transparency through the reporting of clinical quality measures. The CMS, via different quality reporting programs, has been collecting a number of metrics, including performance measures and patient experiences, and is now using them to report on healthcare provider and group practice performance.⁸⁷ A list of Qualified Clinical Data Registries that support anesthesia measures are available through the AANA.⁸⁸

Summary

Patient-centered care and cultural competence is essential to providing high quality care in nurse anesthesia practice. The importance of viewing the patient as a unique individual with distinct attitudes, values, beliefs, and behaviors exceeds generalizations that can be assumed about various cultural groups. The goal of patient-centered, culturally competent care is to create an environment free of discrimination, where patients are recognized for their individuality, without regard to race, national origin, color, age, religion, sex (including pregnancy and gender identity), sexual orientation, disability (physical or mental), status as a parent, genetic information, or other factors.

Nurse Anesthesia Research

Empowering Decision Making Through Evidence-Based Practice

Elisabeth Cole McConnell, Chuck Biddle

The nurse anesthetist brings a wealth of knowledge and experience to every patient encounter. Evidence-based practice (EBP) guides the safe and effective application of this knowledge in clinical practice by providing the tools necessary to translate high-quality research into successful patient care. EBP provides a systematic and efficient means of assessing the quality of research and applying empirical findings to the clinical setting. Whether selecting an antiemetic, administering an intravenous fluid, deciding on mechanical ventilator settings, or planning postoperative pain control, the nurse anesthetist relies on EBP to guide clinical decision making and improve patient outcomes.

Although there are many approaches to EBP, the essential components common to all include the following:

- Defining the patient's problem
- Proficiently searching the relevant literature
- Critically appraising the discovered literature
- Rationally applying the relevant literature in the context unique to the patient

At the core of EBP is the notion of critical thinking. Critical thinking is applied to the appraisal of the pertinent literature and balanced with clinical experience as the clinician determines whether the evidence is applicable to a particular patient's situation. However, the nurse anesthetist's ability to critically appraise the relevant literature is contingent on the extent of his or her

understanding of clinical research. Thus EBP requires the nurse anesthetist to develop a thorough grasp of the process of conducting and evaluating clinical research studies. Such an understanding begins with an exploration of the nature of research and the research process. Mastering these concepts of clinical research is a critical step in practicing successful evidence-based anesthesia.

Research represents a rational approach to making practice choices among initially plausible alternatives and provides a direction and means for validating these choices. The impact of research on the day-to-day activities of the nurse anesthetist has become an especially relevant topic. Before the mid-1970s, the vast majority of nurses functioned without much consideration of research or publication of their ideas. In the late 1970s, nurse anesthesia experienced a period of punctuated evolution. Major driving forces behind this evolution included the movement to a graduate educational framework, a more sophisticated appreciation of the scientific underpinnings of our specialty, national attention to issues of patient outcomes and patient safety, and a growing self-awareness of nurse anesthetists not only as providers of excellent clinical care but also as active participants as scholars in the field. Recognition of the importance of EBP was especially influential in this progression.

Nurse anesthetists primarily function with a practice-oriented perspective, and therefore the recommendations of Brown et al. seem especially relevant.¹ These scholars suggest that four characteristics of research are essential for the development of a scientific knowledge base for a discipline such as nurse anesthesia. First, research should be actively conducted by the members of the discipline. Second, research should be focused on clinical problems encountered by members of the discipline. Third, the approach to these problems must be grounded in a conceptual framework—that is, it must be scientifically based, emphasizing selection, arrangement, and clarification of existing relationships. And finally, the methods used in studying the problems must be fundamentally sound.¹

Methods of Knowing

The term *research* can be broadly defined as the application of a systematic approach to the study of a problem or question. However, we do not know all the things we claim to know on the basis of systematic inquiry. Other sources of knowledge include authority, personal experience, and logical reasoning.

Perhaps the most advanced way of knowing is reflected in the scientific method. Although it too is fallible, the scientific method is more reliable and valid than other methods. It provides for self-evaluation with a system of checks and balances that minimizes bias and faulty reasoning. In essence, it is a systematic approach to solving problems and enhancing our understanding of phenomena. It is, at its foundation, the gathering and interpretation of information without prejudice.

The Nature of Research

Research is by definition a dynamic phenomenon. Whether it is directed purely at the acquisition of knowledge for knowledge's sake (basic research) or at the specific solution of problems (applied research), it is a process that can be conceptualized in terms of at least four characteristics.

First, research can assume many different forms. Second, research must be valid, both internally and externally ([Box 4.1](#)). Internal validity is necessary but not sufficient for ensuring external validity. Third, research must be reliable. *Reliability* refers to the extent to which data collection, analysis, and interpretation are consistent and to which the research can be replicated. Fourth, research must be systematic. The elements of a systematic approach include the identification of the problem or problems, the gathering and critical review of relevant information, the collection of data in a highly-orchestrated manner, an analysis of the data appropriate to the problem or problems faced, and the development of conclusions [Box 4.1](#) the study's framework.

Research Scenario: Internal Versus External Validity

Internal Validity

- The extent to which results can be accurately interpreted and the degree to which the independent variable (that which is manipulated) is responsible for a change in the dependent variable (that which is measured). For example, the patient's blood pressure is measured. A combination of propofol, midazolam, isoflurane, and a new muscle relaxant is used for induction of anesthesia. A postinduction blood pressure is recorded, and the researcher concludes that the new muscle relaxant lowers blood pressure.

Questions

- Has the researcher isolated the effect of the muscle relaxant from

those of the other agents?

- Are there plausible or competing alternative explanations?

Analysis

- Internal validity is low because the results cannot be interpreted with any degree of certainty.

External Validity

- The extent to which the results can be generalized; this issue relates to the question “To whom can the results be applied?” For example, 35 obese men who are nonsurgical volunteers are anesthetized with a standard dose of a new induction drug. The clinical half-life of the drug is determined with plasma drug sampling and brain wave activity monitoring. The researcher concludes that future patients receiving the standard dose of the new drug will experience a clinical half-life of 11 minutes.

Questions

- Is it reasonable to assume that obese patients might respond differently than their nonobese counterparts?
- Might women respond differently than men?
- Could surgical manipulation or other drug therapy have an impact on the pharmacokinetics of the new drug?

Analysis

- External validity is low because the results cannot be generalized to any other individuals except those similar to the subjects in the study.

Scientific knowledge emerges from an enterprise that is intensely human; as a consequence, it is subject to the full spectrum of human strengths and limitations. The scientific discovery and

understanding that attend participation in research and its results can be professionally exhilarating and satisfying.

The Eight Critical Stages in the Research Process

Research accords several personal freedoms to those who engage in it: the freedom to pursue those opportunities in which one is interested, the freedom to exchange ideas with other interested colleagues, and the freedom to be a deconstructionist, that is, one who challenges existing knowledge. Yet, despite these freedoms, research must be logical, must progress in an orderly manner, and ultimately must be grounded within the framework of the scientific method. If research is a way of searching for truths, uncovering solutions to problems, and generating principles that result in theories, we must come to understand the process of research.

The research process can be described in many different ways. For purposes of simplicity, this process is defined as consisting of eight distinct stages:

1. Identification of the problem
2. Review of the relevant knowledge and literature
3. Formulation of the hypothesis or research question
4. Development of an approach for testing the hypothesis
5. Execution of the research plan
6. Analysis and interpretation of the data
7. Dissemination of the findings to interested colleagues
8. Evaluation of the research report

Stage 1: Identification of the Problem

The selection and formulation of the problem constitute an essential first step in the research process. The researcher decides the general subject of the investigation, guided principally by personal

experience and by inductions and deductions based on existing sources of knowledge. The researcher makes the general subject manageable by narrowing the focus of the problem. The following criteria must be met at this phase of the research process:

- The problem area should be of sufficient importance to merit study.
- The problem must be one that is practical to investigate.
- The researcher should be knowledgeable and experienced in the area from which the problem has emerged.
- The researcher should be sincerely motivated and interested in studying the problem.

We constantly encounter problems and situations that can be studied. At clinical anesthesia conferences, one might hear remarks such as the following:

“It seems to me that a small dose of intravenous lidocaine given just before propofol alleviates virtually any pain on injection.”

“Do you think there is less nausea and vomiting in outpatients who are deliberately overhydrated?”

“I find that the use of the waveform generated by my pulse oximeter gives me valuable information about depth of anesthesia.”

“I believe that the inspiratory pause mechanism on the Ohmeda 7810 ventilator significantly improves arterial oxygen tension in patients with chronic obstructive pulmonary disease.”

“I am convinced that sleepiness is a major cause of anesthesia accidents.”

A study could emerge from each of these situations, built on ideas, hunches, or curiosity. A problem that lends itself to research often materializes from personal observations and in the sharing of ideas and experiences among those who are familiar with the phenomenon in question.

Once identified, the problem should be stated in terms that

clarify the subject and restrict the scope of the study. Defining the terms involved in the problem statement is also critical, as **Box 4.2** demonstrated in **Box 4.2**.

Research Scenario: Stating the Problem

Poor

- I am unsure of the effectiveness of etomidate in patients.

Better

- I am unsure at what dose etomidate induces unconsciousness in patients undergoing hysterectomy and what impact it has on heart rate, blood pressure, and vascular resistance.

Comments

- The problem should be focused.
- The terms should be clarified.
- The relationships should be understood.
- The problem should not be so narrow as to be trivial.

The wording of the problem statement sets the stage for the type of study design used. Each step in the research process subsequently influences later steps, and this should be kept in mind at all times. A mistake made early inevitably creates difficulties at some later stage in the process.

Common Mistakes

At this stage of the process, pitfalls can include an overly ready acceptance of the first research idea that comes to mind, as well as a selection of a problem that is too broad or vague to allow effective study.

Stage 2: Review of the Relevant Knowledge and Literature

Once the problem has been identified, information is needed for putting the problem into proper context so that the research can proceed effectively. A well-conducted literature review provides the researcher with:

- an understanding of what has already been accomplished in the area of interest;
- a theoretical framework within which the problem can be optimally stated, understood, and studied;
- an appreciation for gaps in current understanding of the phenomenon;
- information for avoiding unanticipated difficulties;
- examples of potentially useful or poorly constructed research designs and procedures; and
- a background for interpreting the results of the proposed investigation.

Effective search strategies are discussed later in the chapter.

Common Mistakes

At this stage in the research process, mistakes include hasty review of the literature, overly heavy reliance on secondary (book) rather than primary (journal) sources, lack of critical examination of the methods by which conclusions were reached, and incorrect copying of references. For example, a mistake in noting the volume number or misspelling an author's name makes it more difficult to locate them again with ease.

Stage 3: Formulation of the Hypothesis or Research Question

In its most elemental form, a hypothesis is either a proposed solution to a problem or a stated relationship among variables. It establishes and defines the independent variable (the variable that is to be manipulated or is presumed to influence the outcome) and

the dependent variable (the outcome that is dependent on the independent variable). The hypothesis is declarative in nature and assumes one of three forms:

1. A *directional hypothesis*: Patients premedicated with midazolam have less anxiety on arrival to the operating room than do those who were not premedicated.
2. A *nondirectional hypothesis*: Patients premedicated with midazolam experience a difference in anxiety on arrival in the operating room when compared with those who were not premedicated.
3. A *null hypothesis*: Patients premedicated with midazolam experience no difference in anxiety on arrival in the operating room compared with those who were not premedicated.

Research questions are generally reserved for investigations that are descriptive or exploratory in nature or for when the relationships among the variables are unclear. A research question might be more appropriate than a hypothesis in a study that proposes to determine the beliefs of anesthesia providers who interact with patients under specific circumstances. For example, consider the following research question: what are the attitudes of nurse anesthetists in the northeastern United States who care for patients with acquired immunodeficiency syndrome (AIDS)?

Common Mistakes

At this point in the process, mistakes include use of a vague or unmanageable hypothesis and development of a research question that cannot be answered reasonably.

Stage 4: Development of an Approach for Testing the Hypothesis

After the research idea has taken shape in the form of a formal hypothesis or research question, a plan of attack is developed. The research proposal represents the stage at which the ideas of the

project crystallize into a substantive form. The proposal includes:

- a problem statement and clarification of the significance of the proposed study;
- the hypothesis or research question;
- a sufficient review of the literature for justification of the study;
- a description of the research design;
- a careful explanation of the sample to be studied; and
- the type of statistical analysis to be applied.

A research proposal is a useful and efficient way for the researcher to determine the completeness of the plan and is usually required if the researcher is to obtain departmental or institutional approval or is applying for financial support.

Research Methods

The research method is the way the truth of a phenomenon is coaxed from the world in which it resides and is freed of the biases of the human condition. A variety of research methods are at our disposal, and researchers are not inflexibly wedded to any particular approach. Researchers do not follow a single scientific method but rather use a body of methods that are amenable to their fields of study.

Some of the methods available are highly recognizable, permanent components of the researcher's armamentarium, whereas others have evolved not only with respect to time but also in response to the specific needs of a particular problem or discipline. The research method can be influenced by the way a researcher views a problem. For example, a researcher can test a hypothesis, search for a correlation, ask "why" or "how" questions, or probe a phenomenon on the basis of "what would happen if" suppositions. Research methods in the context of EBP will be discussed later in the chapter.

The researcher can view the method on the basis of the fundamental task that it will accomplish. For example, two broad categories into which research efforts can be divided are basic research and applied research. Basic research adds to the existing body of knowledge and may not have immediate, practical use.

Applied research is oriented toward solving an immediate, specific, and practical problem.

The research method can be characterized in terms of its temporal relationship to the problem. A retrospective study is the process of surveying the past; the thing in which we are interested has already occurred, and we are simply looking to see what did occur. In contrast, a prospective study looks forward to see what will happen in a given situation; here, the collection of data proceeds forward in time.

It is important to understand several terms fundamental to the research process. As mentioned previously, the dependent variable is the object of the study, or the variable that is being measured. The independent variable is the one that affects the dependent variable and is presumed to cause or influence it. Another way of looking at this relationship is that variables that are a consequence of or are dependent on antecedent variables are considered dependent variables.

Another set of variables consists of control variables, also known as *organismic*, *background*, or *attribute* variables. Control variables are not actively manipulated by the researcher, but because they might influence the relationships under study, they must be controlled, held constant, or randomized so that their effects are neutralized, **Box 4.3** carried out, or at least considered by the researcher (**Box 4.3**).

Research Scenario: Understanding the Types of Variables

Study Group

A new intravenous drug that may be associated with fewer cardiovascular effects than thiopental during induction in pediatric patients is being studied. Fifty children aged 3 to 6 years, undergoing intravenous inductions for hernia repair or eye muscle surgery are randomized to either the propofol group or the new drug group. Blood pressure, heart rate, and rhythm are measured by a dedicated observer who is unaware of which drug the patients are receiving.

Analysis

The dependent variables are blood pressure, heart rate, and heart rhythm. The independent variable is the drug the child receives, either the propofol or the new drug. A number of control variables are present, including sex, fluid status, time of day, underlying medical history, and concurrent drug therapy. With randomization, such control variables should be equated or neutralized for the two groups, but even randomization is not an absolute guarantee.

The term *blinding* or *masking* refers to the process of controlling for obvious and occult bias arising from subjects' or researchers' reactions to what is going on. In a single-blind design, the patients are unaware of which treatment or manipulation is actually being given to them. In the double-blind design, neither the researcher nor the subject is aware of which treatment or manipulation the subject is receiving. Whereas randomization attempts to equalize the groups at the start of the study, blinding equalizes the groups by controlling for psychological biases that might arise apart from any effect of the treatment. Many factors influence the decision to use a single-blind or a double-blind design. For example, in some situations, it may not be feasible to disguise a particular treatment or intervention.

Operationalization is defined as the process of precisely defining a given variable, condition, or process so that it may be replicated in future studies. If researchers do not operationalize the terms, phrases, and manipulations in the study, the net effect could be an ambiguous study. In a study examining the effects of epidural anesthesia in critically ill patients, it would be essential to operationalize the terms *effects* and *critically ill patients*. Without operationalizing these terms, future researchers would not know whether effects referred to patient mortality, paralysis, infection, therapeutic benefit, or some other consequence of epidural anesthesia. Similarly, in a study comparing the quality of inhalation induction with isoflurane and sevoflurane in pediatric patients, it is essential that the researcher operationalize the terms *inhalation induction* and *quality*. Operationalization of terms clearly designates performable and observable acts or procedures in such a way that they can be replicated immutably.

Classifying Research on the Basis of Methodology

There are many classification schemes for research design. Ultimately, the research design is one that is dependent on and inextricably wedded to the study's purpose, scope, and the nature of the problem at hand. [Table 4.1](#) offers a simplified approach to classifying research design. Much weight is applied to the type of research method used when assessing its rigor and its relevance to EBP. [Table 4.2](#) provides a brief synopsis of commonly used study designs.

TABLE 4.1
Classifying Research by Method

Type	Qualities and Purpose	Example
Experimental	At least one variable manipulated Random assignment to groups Dependent variable is measured Good for determining cause and effect Prospective in nature	Is there more or less pain on injection of one or the other drug? What did the manipulation do?
Ex post facto	Independent variable has already occurred Examines relationships by observing a consequence and looking back for associations Retrospective in nature (Latin for "from a thing done after")	Looking back over 5 years, does a relationship exist between the rate of myocardial infarction and the inhaled anesthetic that was administered?
Descriptive	Describes something as it occurred Incidence, relationships, and distributions are studied Deals more with "what-is?" than "why-is-it-so?" questions	What are the attitudes of nurse anesthetists regarding the care of patients who have AIDS?
Historical	Describes "what was" rather than what effect variables had on others Events are described as accurately as possible through a process of critical inquiry	A test of the hypothesis is that Sister M. Bernard was the first nurse anesthetist.
Qualitative Phenomenology Grounded theory Ethnography	Experiences lived by people Perception is viewed as our access to that experience Discovers and conceptualizes the essence of complex processes	What is the nature of the relationship between nurse anesthetists and surgeons in private and in academic settings?

TABLE 4.2
Synopsis of Major Study Designs

Study Design	Advantages	Disadvantages
Survey	<ul style="list-style-type: none"> • Generally inexpensive and simple • Low risk of ethical problems 	<ul style="list-style-type: none"> • Establishment of association at best; no demonstration of cause and effect • Susceptible to recall bias • Possible unequal distribution of confounders between or among groups • Possible unequal group sizes
Case-control study	<ul style="list-style-type: none"> • Generally quick and inexpensive • Feasible method for studying very rare disorders or disorders with long lag between exposure and outcome • Fewer subjects needed than cross-sectional studies • Ethically safe • Matched subjects 	<ul style="list-style-type: none"> • Reliance on recall or records to determine exposure status • Confounders difficult to identify and control • Possible difficulty in selection of control groups • Large risk of bias: recall, selection
Cohort study	<ul style="list-style-type: none"> • Can establish timing and directionality of events • Can standardize eligibility criteria and outcome assessments • Administratively easier and less expensive than randomized controlled trials 	<ul style="list-style-type: none"> • Possible difficulty identifying control subjects • Exposure possibly linked to a hidden confounder • Difficulty in blinding • Lack of randomization • For rare disease, large sample or long follow-up necessary
Randomized controlled trial	<ul style="list-style-type: none"> • Unbiased distribution of confounders • Blinding more likely • Statistical analysis facilitated by randomization 	<ul style="list-style-type: none"> • Costly in terms of time and money • Volunteer bias—not all patients willing to be “randomized”
Observational study	<ul style="list-style-type: none"> • No random assignment • Generally inexpensive 	<ul style="list-style-type: none"> • Loss of control over the intervention • Loss of control over potential (known and unknown) confounders
Retrospective design	<ul style="list-style-type: none"> • Cheaper and generally easier to perform than prospective studies • Highly useful for discerning the nature of phenomena, especially in describing associations between or among variables • Improved techniques and statistical methods have made these methods more defensible • Data often housed in existing manual or electronic databases, making access convenient 	<ul style="list-style-type: none"> • Independent variable has already occurred • Loss of control over variables • Cannot ascertain cause-and-effect relationships • Determining which variable is dependent and which variable is independent not consistently possible when a relationship is revealed
Crossover design	<ul style="list-style-type: none"> • Smaller sample needed because subjects serve as own controls and error variance is reduced • All subjects receive treatment (at least some of the time) • Statistical tests assuming randomization can be used • Blinding can be maintained • Ethically problematic at times 	<ul style="list-style-type: none"> • All subjects receive placebo or alternative treatment at some point • Lengthy or unknown washout period (recovery from a given intervention) • Not usable for treatments with permanent effects

Research designs can be classified into two broad domains: experimental and observational. Observational studies do not

involve an investigator-controlled manipulation or intervention, but rather simply track the subjects for a defined period, recording events defined by the researcher's objectives. The independent variable (e.g., a clinical intervention such as a patient who received or did not receive a blood transfusion for aortic valve surgery as part of routine care) is simply a matter of record, and a dependent variable (e.g., an outcome such as the rate of wound infection or fever) is recorded. Such a study can progress forward in time (prospective) or, in the case of a study looking back in time (retrospective), examine an institutional database. Another type of observational study is the cross-sectional study, in which well-defined measures are recorded at predetermined points in time.

Case reports are commonly seen in the anesthesia literature and provide an opportunity to vicariously experience the care provided to a patient. These reports describe perioperative events, characteristics of an individual patient (or of a series of similar patients in a case series), and the successes or failures associated with a described management regimen. However, the subjective nature of case reports and studies introduces substantial bias. Due to this bias and because the study design does not allow for the controls necessary for hypothesis testing, this type of design is often used solely to generate a hypothesis.

The case-control study is a type of observational study in which a researcher examines a group of patients (the cases) to identify factors that seem to be associated with a past outcome (e.g., blindness following anesthesia). A key component of the design is the identification of a similar group of patients who did not experience the negative outcome (the controls). This component is called *matching*, and is usually conducted with respect to the patients' gender, age, surgical procedure, and other factors. Matching allows the researcher to minimize differences in patient characteristics between the case and control groups that obscure the effect of the variables of interest. For example, in a study of blindness following anesthesia, if the case group contained more patients with type II diabetes mellitus than the control group, a higher incidence of blindness in the case group may be due to complications of diabetes rather than anesthesia. In this example, diabetes would be considered a confounding variable, or

confounder. Balancing confounding variables between study groups minimizes the risk that extraneous factors are responsible for the association between the variables of interest and the outcome. Traditionally, this type of study is considered sufficiently powered if the ratio of cases to controls is 1 : 2 or greater (1 : 3 or 1 : 4 is optimal). Case-control studies are useful for identifying associations between a variable or variables and an outcome but are not powerful enough to allow for cause and effect to be determined.

Observational studies are limited by their inability to control factors that influence the study outcome. In an observational study, the researcher has no control over the treatment assigned to a patient or the numerous variables likely to affect the outcome of interest. As a result, many forms of bias are introduced to the study. At best, the researcher can use observational studies to make associations between described variables. One tool used to improve the validity of conclusions reached by observational studies is the use of propensity score analysis, discussed later in the chapter.

Experimental research designs minimize potential bias by allowing the researcher to control for confounding variables. These studies are prospective and measure the effect of manipulating the independent variable on the dependent variable. Generally, the goal is to describe and assess an intervention for its safety or efficacy or to determine if one approach offers benefits over existing interventions. A cohort study is a prospective study that compares a group of patients either receiving a treatment or having a condition of interest with a control group. Over time, data for the two groups is collected and compared. Cohort studies work well for experiments that might otherwise be unethical or dangerous. For example, such a study might identify two groups of patients scheduled to receive laparoscopic gallbladder surgery: a group of people who are morbidly obese and a comparison group of people who are not. Although researchers cannot randomly assign patients to undergo surgery, cohort studies allow researchers to minimize variability between study groups to compare outcomes of interest. Assessing outcomes such as drug requirements, duration of surgery, positioning-related injury, and ventilator requirements would allow some general conclusions to be reached regarding considerations in caring for patients of different body types

undergoing a similar procedure.

The gold standard of clinical experimental research is the randomized controlled clinical trial (RCT). Clinical trials, by definition, involve the use of humans as subjects and require a specific set of criteria (Fig. 4.1). Because powerful controls are established and the influence of bias is reduced, RCTs are better able to reveal the true effect of an intervention on selected measured outcomes. Because of the high quality of the evidence they produce, randomized trials are heavily relied on in EBP. Randomized controlled trials are discussed in more detail later in the chapter.

FIGURE 4.1 The randomized controlled trial (RCT) is a prospective, longitudinal experimental study in which representative members of the population of interest are randomly assigned to either a treatment group (also called an *experimental group*) or a control group. Study conditions are carefully controlled so that the only functional difference between the treatment and control groups is the intervention being studied. Ideally, both the subjects and the researchers should be “blinded” to the type of group (treatment or control) to which the subject has been assigned. A sufficiently powered RCT ensures that the study design facilitates the accurate detection of a treatment effect and the size of that effect. Carefully following the study participants and measuring the treatment effect with the appropriate statistical techniques is also essential to a quality RCT. Finally, a randomized controlled trial should be able to be reproduced by other researchers to confirm the study's findings.

Quasi-experimental research differs from experimental research in that it is missing one or more of the key elements required for an experimental design. Either a control group or a randomization procedure may be absent from the design. For example, a practitioner at an institution regularly prescribes ondansetron whereas a fellow practitioner does not. A prospective quasi-experimental trial in which both practitioners use a standard anesthetic technique would allow the two practitioners to use or not use ondansetron as they normally would. The incidence of nausea and vomiting in the first 6 postoperative hours can then be compared between each practitioner's patient groups. Although randomization is not achieved, a study that may not otherwise have been possible because of the inflexibility of the clinicians involved is successfully accomplished. Quasi-experiments, by yielding to one or more of the rigid criteria of the experimental design, offer an attractive alternative in certain circumstances.

Qualitative Research: An Alternative Paradigm

Up to this point, the traditional approach to a problem has been characterized by deductive reasoning, objectivity, manipulation, and control. An alternative approach involves a group of methods characterized by inductive reasoning, subjectivity, exploration, and process orientation. These methods fall under the rubric of qualitative research techniques.

Qualitative techniques include philosophic inquiry, historiography, phenomenology, grounded theory, and ethnography. Generally speaking, *qualitative research* refers to systematic modes of inquiry directed principally at observing, describing, analyzing, interpreting, and understanding the patterns, themes, qualities, and meanings of specific contextual phenomena. Qualitative research seeks to gain insight by discovering the meanings associated with a given phenomenon and exploring the depth, richness, and complexity inherent in it. The treatise on qualitative approaches by Marshall and Rossman is recommended to interested readers.²

Sampling

Under most circumstances, studying everyone who might be affected by a particular study is impractical, if not impossible. For example, if we want to know how effective intravenous nitroglycerin is in minimizing the rise in blood pressure associated with laryngoscopy in hypertensive patients, we cannot realistically study all hypertensive patients who undergo laryngoscopy. Rather, we would hope to find a smaller group of subjects who are representative of the relevant population at large. By accessing certain information in the sample, we can credibly make inferences or generalizations regarding the population at large.

Similarly, if we want to know how often anesthesia machines in small community hospitals receive preventive maintenance, we cannot visit all the community hospitals in the nation. Instead, we might randomly select a number of hospitals in a number of different states, visit those locations, and inspect the maintenance records. By studying this representative sample, we can make some reasonable and safe generalizations regarding the phenomenon of preventive maintenance at large.

Consider the anecdote about the four blind people who encountered an elephant during one of their daily walks. Each person felt a different part of the elephant. When asked to describe what they had encountered, the first person replied, “a tree trunk” (the elephant's leg). The second reported feeling “a large snake” (the elephant's trunk). The third reported that it was “most definitely a wall” (the elephant's torso). The last person reported that it was “a large, frayed rope” (the elephant's tail). This analogy illustrates that a few discrete sampling points may not be adequate for describing a complex phenomenon. Not only is a random sample best, it should also be large enough and sample a sufficient number of points in the population that a truly representative perspective is gained.

Different sampling techniques can be used, depending on the research design. In a true random sample (also known as *probability sampling*), all members of the population at large have a similar chance of being included in the study. This is rarely the case in clinical research, in which we are confined to dealing with those individuals who present themselves. In this situation, the sample is called a *convenience sample*. When a convenience sample is used in

an experimental study, it is important to ensure that the subjects selected for the study are at least randomized when assigned to treatments or groups. In the ideal situation, the researcher aims for both random selection (from the population at large) and random assignment (to the different groups in the study).

Obtaining a random sample, especially in clinical research, is often a complicated process. Most important is the realization that the concept of randomness is essential to minimizing human biases associated with both selection and assignment. Randomization is discussed in detail later in the chapter.

Instrumentation and Measurement

Two important concepts essential to measurement are validity and reliability. Instrument validity is the degree to which an instrument, such as a blood pressure cuff or a personality inventory, accurately measures what it is intended to measure. Instrument reliability refers to the degree of consistency with which an instrument measures whatever it is measuring, that is, whether the same result is obtained on repeated trials.

Validity and reliability are often easily established for measures of certain physiologic phenomena, but may be troublesome in behavioral or psychological evaluations. Imagine trying to determine reliability and validity for a thermometer. Contrast this to trying to establish validity and reliability for a psychological tool that professes to measure a nurse anesthetist's attitude toward euthanasia; obviously, the latter is a much more difficult undertaking. Although a measure must be reliable to be valid, it can be reliable without being valid. For example, a skin temperature probe might reliably (consistently) measure temperature even in a variety of extreme settings, although it would not be viewed as a valid indicator of core temperature. Both reliability and validity are discussed in degrees rather than in "all-or-nothing" terms.

Many published instruments have reliability and validity testing reported. When choosing an instrument for a study, it is critical to consider whether the instrument's reliability and validity have been established. For example, if an instrument measures evoked responses in the esophagus as an indicator of depth of anesthesia, it must be determined whether the reliability and validity of the

instrument have been established under the conditions of the anesthetic protocol being used in the proposed study. Coefficients of reliability and validity are presented on a scale of 0 to 1, with 1 being perfect.

Occasionally, the researcher may encounter no reasonable measures to use for a study. Instruments for measuring such phenomena as arterial oxygen tension, end-tidal anesthetic concentration, and opioid metabolic by-products are well established. However, a researcher may need to develop a totally new instrument (questionnaire) to determine perceptions regarding the propriety of a given manufacturer's high-pressure promotional campaigns for newly released pharmaceutical products. In developing such a tool, it is helpful to have an expert in the discipline look over the instrument and provide feedback to ensure that the instrument is appropriate.

Researchers have a variety of instruments for measuring phenomena. These include:

- Written tests
- Rating scales
- Questionnaires
- Chemical tests
- Physical tests
- Electrical tests
- Visual observation
- Auditory observation
- Psychological inventories

Levels of Measurement.

In designing a study, the researcher must decide how to measure a phenomenon such as anxiety level, blood pressure, attitude toward health care, or rate of complications. There are four levels or degrees of measurement: nominal, ordinal, interval, and ratio. The type of data measured determines the kind of statistical analysis that can be done. [Table 4.3](#) characterizes the four levels of measurement.

TABLE 4.3**Characteristics of the Four Categories of Measurement**

Category	Characteristics	Examples
Nominal	Identifies	Male or female
		Diagnosis
Ordinal	Identifies	American Society of Anesthesiologists (ASA) class
	Orders	Order of race finish
Interval	Identifies	Intelligence
	Orders	Calendar years
	Equal intervals	Degrees Fahrenheit or Celsius
Ratio	Identifies	Blood pressure
	Orders	Reaction time
	Equal intervals	Weight
	Has a true zero	Distance
		Degrees Kelvin

Nominal level measurement allows data to be divided into categories, but the only quantifiable measures are the frequencies with which the data fall into each category. For example, in a study assessing the educational level of nurse anesthetists, only the number of nurse anesthetists who fall into each category (certificate, bachelor degree, master degree, doctorate) can be reported. No numerical value can be assigned to represent the type of degree received by nurse anesthetists.

Ordinal level measurement allows for data to be ordered or ranked. For instance, the American Society of Anesthesiologists' (ASA) Physical Status system provides for a relative ranking system for patients on the basis of their pathophysiologic status. Although pathophysiologic status cannot be assigned a numerical value, the relative standing of patients can be determined.

Interval level measurement uses numeric data that are ordered and spaced equally, such as temperature on the Fahrenheit or centigrade scale, calendar years, or intelligence quotients derived from an intelligence performance test. Here, the distance between adjacent scores is highly meaningful.

Ratio level measurement uses numeric data that can be ordered and equally spaced. It is based on a scale with an absolute zero point, such as temperature on the Kelvin scale, reaction time, height, and blood pressure. Both interval and ratio level measures can be referred to as *continuous* in nature.

Measurement can also be defined in terms of four broad categories: cognitive, affective, psychomotor, and physiologic. Each

can manifest as one of the levels noted earlier. Cognitive measurement addresses the test subjects' knowledge or achievement. For example, what actions should be taken in the face of unexplained bradycardia? Affective measurements determine interests, values, and attitudes, thereby providing behavioral insights. For example, how do nurse anesthetists in different locations feel about anesthetizing patients with AIDS? Psychomotor measurements test the subjects' ability or skill in performing specific tasks, such as evaluating performance with a new laryngoscopic design. Physiologic measurements look at the biologic functioning of the organism, for example, heart rate differences in men and women at basal conditions.

Although researchers sometimes develop unique instruments which must be tested for reliability and validity, many published and acceptable instruments can be located in any number of sources.^{3,4}

Measurement of Treatment Effect.

Effect size is a measure of the magnitude of the observed relationship between a study treatment and its outcome. Two common measures of effect size are the odds ratio and relative risk. These effect size measures assess the likelihood of an event occurring in two comparison groups. Consider the following fictional data set of all-cause mortality of middle-aged smokers and nonsmokers living in a rural locale. In the modestly sized sample are 462 nonsmokers and 851 smokers. An epidemiologic study tracked these two cohorts for 15 years and reported overall mortality in each group at the end of the study period. The follow-up reveals that 308 nonsmokers were alive and 154 had died. Of the 851 smokers, 142 were alive and 709 had died (Table 4.4).

TABLE 4.4

Outcome for Smokers vs Nonsmokers in a 15-year Study

	Alive	Dead	Total
Nonsmokers	308	154	462
Smokers	142	709	851
Total	450	863	1313

The data in the table suggest that smokers were more likely to

have died during the study period than were nonsmokers. Although it is clear that statistical significance would be demonstrable, the fundamental question is “How much more likely is a smoker to die than a nonsmoker?” The odds ratio and relative risk can be used to shed light on this question. In a patient population, the odds for a group are calculated by the number of patients who achieve the stated outcome divided by the number of patients who did not. In the current example, the outcome is death. Nonsmokers have 1 : 2 odds of dying ($154/308 = 0.5$) during the study. For smokers, the odds of dying are 5 : 1 ($709/142 = 4.993$). The odds ratio is the ratio of the odds of the exposure group to the odds of the nonexposure group. In our example, the “exposure” is smoking. The odds ratio ($4.993/0.5 = 9.99$) indicates that smokers have almost tenfold greater odds of dying than nonsmokers in our fictional population.

Relative risk (sometimes called *risk ratio*) is a measure of probability rather than odds. A group's probability of a stated outcome is measured by the number of patients in the group who achieve the outcome divided by the total number of patients in the group. In our study, nonsmokers have a 33% probability of dying during the study period ($154/462 = 0.3333$). For smokers, on the other hand, the probability of death is 83% ($709/851 = 0.8331$). The relative risk ($0.8331/0.333 = 2.4995$) indicates that the probability of death is 2.5 times greater for smokers than it is for nonsmokers.

The magnitude of these measures is quite different in this example. Although both revealed that smokers were more likely to die during the study period, which of the measures is a more accurate representation of reality? This is not always an easy question to answer, but an important one to consider as one weighs the evidence. In general, relative risk measures events in a way that reflects the directionality of the outcome. For example, if the risk is 1, the exposure is not associated with the outcome—the likelihood of the outcome happening in either the exposure or nonexposure populations is equal. With an increased risk, the ratio is greater than 1. The likelihood of the outcome happening in the exposure population is greater than in the nonexposure population. Conversely, if there is a decreased risk, the ratio is less than 1. These two measures are suitable for different purposes and appeal to

different people in different ways. The odds ratio is better suited when the outcome of interest is relatively rare, as it tends to overestimate risk in a manner similar to the preceding example.

The Pilot Study

A pilot study is the implementation of a study on a small scale. It includes only a few subjects who will generally not be included in the formal study. Its purpose is to troubleshoot the methodology for any anticipated design problems. The pilot study allows the researcher the opportunity to perform a dry run, ultimately facilitating the progression of the study.

Common Mistakes

At this point in the process, mistakes include failure to adequately operationalize definitions, failure to define the population or sample adequately, unrealistic expectations for subject recruitment and participation, underestimation of the difficulty of design execution, failure to establish instrument reliability and validity, and failure to appreciate the ethical dimensions of the investigation.

Stage 5: Execution of the Research Plan

Up to this point, the research process has involved the acquisition of knowledge regarding the subject, planning the project, and critical thinking about what is to occur. The next stage of the process involves actual data collection and the organization of the data into a format that facilitates data analysis.

Data collection must precisely follow the procedure the researcher previously specified. The real payoff in research comes with the drawing of useful and bona fide conclusions once the data have been collected and precisely analyzed within the framework of the research design. The goal of the previous step—namely, maximization of both internal and external validity—would not be achieved if the researcher were to deviate from the plan.

Maintaining careful records of what was done and what results were recorded is essential. The labeling and sorting of data into the respective categories or chronologies should be extremely precise.

No data should be discarded until the researcher knows that they are absolutely unnecessary. Many researchers “stockpile” raw data and their notes, because additional uses for the information may not manifest for months or even years after the initial project's completion and publication.

Common Mistakes

The mistakes associated with this stage include drifting from the stated methodology for convenience or administrative purposes, placing excessive demands on subjects, allowing personal bias to creep into the research plan, using observers or research assistants who are improperly trained, failing to obtain a sufficient sample size, and improperly using measurement instruments.

Stage 6: Analysis and Interpretation of the Data

Not only is proper data analysis essential to the design, analysis, and interpretation of the investigation, it is also necessary for understanding and evaluating research studies conducted by other investigators. Analysis has three general phases: the initial mechanical manipulation of the data, the analysis, and the thoughtful formulation of conclusions on the basis of the analysis.

For the purposes of this discussion, the following two questions are posed:

1. What is the rationale for the use of statistical analysis in research?
2. What are the more common statistical procedures used, and under what circumstances are they appropriate?

Descriptive Statistical Techniques

Once the data on the phenomenon under study have been collected, they are often categorized and described. For example, if the goal of a study is the determination of the incidence of headache and the change noted in blood pressure in 50 patients undergoing spinal anesthesia, the researcher would describe the number of patients who reported headaches and experienced changes in blood pressure, as well as the pain score and blood pressure values. The

study would also report the demographics of the sample of patients in terms of sex, height, weight, or any other relevant variable.

The group or set of all the observations of the variable is called a *distribution*. The distribution yields information about the overall dispersion of the phenomenon within the sample, as well as the exact location of a given measure relative to the group as a whole. In the case of an interval- or ratio-level measurement, such as blood pressure, the distribution of values is probably Gaussian or bell-shaped in nature (i.e., some pressures are low, most are intermediate, and some are high). By studying the distribution, the researcher can compare a particular measured value with all the values obtained for the phenomenon.

Alternatively, the researcher might use a technique that clusters data into rational blocks or intervals. For example, in the spinal anesthesia study, instead of listing all 50 initial blood pressures individually, the researcher could tabulate them according to frequency relative to a given interval. In this case, each measured blood pressure falls within a range, and the frequency of presentation in the sample is tabulated as shown in [Table 4.5](#). Instead of using the tabular form, the researcher could arrange the same data in graphic form, indicating the frequency of the phenomenon on the vertical (y) axis and the blood pressure values on the horizontal (x) axis. In histograms and bar graphs, the width of each bar corresponds to the limits of the interval, and the height of the bar corresponds to the frequency or percent of the cases occurring in a specific interval. A frequency polygram is also a commonly used tool for displaying data. Points are plotted directly over the midpoint of each of the intervals. The data given in [Table 4.5](#) are presented in [Fig. 4.2](#) as a frequency polygram.

TABLE 4.5
Frequency Distribution for Initial Systolic Blood Pressure

Interval (mm Hg)*	Frequency†
0-60	1
60-90	8
91-120	15
121-150	15
151-180	8
>180	3

*Interval equals the range or band into which a given measure is placed.

†Frequency equals the number of observations falling into that interval.

FIGURE 4.2 The frequency polygram. Note the bell-shaped configuration the plotted data have assumed; this is typically the “normal” distribution of biologic data (e.g., blood pressure, weight, heart rate, minimum alveolar concentration, intelligence.)

Other descriptive statistics include the mean (the arithmetic average of the sample); the median (the point below which one half of the measurements lie); and the mode (the value occurring most frequently). The range shows the dispersion data from the highest to the lowest value. Variance and standard deviation (SD) must be computed and are based on the concept of deviation (the difference between an observed score and the mean value in the distribution). Variance is the square of the sum of all of the deviations divided by the number of scores, and the SD is the positive square root of the variance. Because of variation, investigators describe the data not only in terms of the typical or average value but also the amount of variation that is present. With respect to quantitative data such as blood pressure, number of attempts at intubation, or amount of blood loss, this task is generally a matter of characterizing the distribution of the attribute in terms of its central tendency and dispersion. This is achieved by providing the mean and the SD.

The SD is a tool for describing the variation of individual observations around the mean. Standard error of the mean (SEM) is

linked to the SD by the following simple mathematical formula:

$$\text{SEM} = \text{SD} / \sqrt{n}$$

where \sqrt{n} is the square root of the number of observations in the sample.

The SEM describes the variation of the sample mean (that for the actual data collected) around the true, but unknown, population mean (that for all possible observations). The difficulty with using the SEM is that as the number of subjects or observations increases, the standard error of the mean decreases. In theoretic terms, as n approaches infinity, SEM approaches 0. Researchers are urged to consult with a biostatistician and to develop a rationale before deciding to use the SEM or SD.

In general, the higher the level of measurement used (i.e., ratio > interval > ordinal > nominal), the greater the flexibility in selecting a descriptive statistic. Using the data from the spinal anesthesia study noted earlier, it would be appropriate to compute the SD for initial systolic blood pressure (ratio-level data). However, such a computation would be meaningless for nominal-level information, such as whether subjects are male or female.

Correlational Statistical Techniques

The correlation coefficient is generally used for describing the extent to which two variables are related to each other or for quantifying the degree of that relationship. For example, it would be useful if one were studying the extent to which the level of carbon monoxide in the blood is related to cigarette smoking. Calculated correlations vary from +1.0 (a perfect direct correlation) to -1.0 (a perfect inverse correlation). A correlation of 0 indicates no relationship. Researchers often display the correlations visually in the form of a scattergram, which shows the shape of a relationship between two variables. There are many types of correlational techniques (Table 4.6).

TABLE 4.6

Correlation Techniques Appropriate to Data Type

Correlation	Variable No. 1	Variable No. 2
Product-moment	Interval or ratio	Interval or ratio
Spearman rank	Ordinal	Ordinal
Point biserial	Nominal or ordinal	Interval or ratio
Phi	Dichotomy	Dichotomy
Contingency	Nominal	Nominal

In the hypothetical study of carbon monoxide level and cigarette smoking, a researcher might decide to use the product-moment correlation technique. The numeric value for carbon monoxide in the blood has a true 0 (ratio-level data). A numeric value can also be used to describe daily cigarette smoking (ratio-level data). The correlation between these variables would probably be positive and very high (e.g., 0.8 or even higher), which suggests that heavy use of cigarettes is associated with a high carbon monoxide level in the blood.

Conversely, assume a study examines the relationship between gender (a nominal-level variable) and anesthetic minimum alveolar concentration (a ratio-level variable). In this example, the researcher using the point biserial correlation technique would expect to see a very low correlation, because gender has been found to not be associated in any meaningful way with anesthetic requirements.

Inferential Statistical Techniques

Inferential statistical procedures provide a set of techniques that allow the researcher to infer that the events observed in the sample will also occur in the larger unobserved population from which the sample was obtained. There are two basic reasons for using inferential techniques. First, they can assist the researcher who is testing a hypothesis and must decide whether to accept or reject it. For example, a researcher, having a particular value in mind, poses the question, "Is this value reasonable in light of the evidence from the sample?" Second, inferential techniques can be used for estimation. For example, a researcher may have no particular value in mind but wants to know what the population value is. The researcher draws a sample, studies it, and makes an inference about the population characteristic (Fig. 4.3). These two classic situations that are addressed by inferential techniques are as follow:

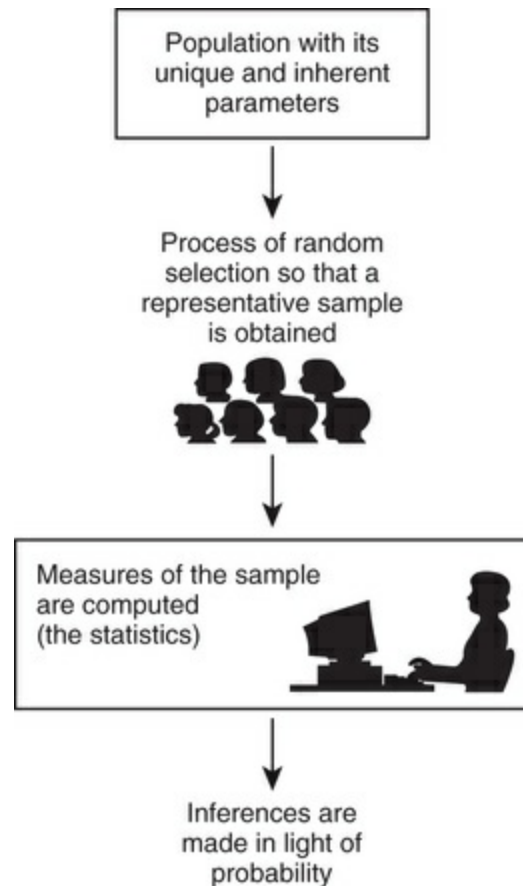

FIGURE 4.3 Conceptual model of inferential statistics.

1. *Testing a hypothesis* (Table 4.7). Is there a significant difference in the incidence of nausea between those patients given thiopental and those who receive propofol?

TABLE 4.7

Statistical Methods Used for Testing Hypotheses

Type of Experiment					
Scale of Measurement	Two Treatment Groups Consisting of Different Individuals	Three or More Treatment Groups Consisting of Different Individuals	Before and After a Single Treatment in the Same Individual	Multiple Treatments in the Same Individual	Association Between Two Variables
Interval (and drawn from normally distributed populations)*	Unpaired <i>t</i> -test	Analysis of variance	Paired <i>t</i> -test	Repeated-measures analysis of variance	Linear regression and Pearson product-moment correlation
Nominal	Chi-squared analysis of contingency	Chi-squared analysis of contingency table	McNemar test	Cochrane Q	Contingency coefficient

	table				
Ordinal	Mann-Whitney rank sum test	Kruskal-Wallis statistic	Wilcoxon signed rank test	Friedman's statistic	Spearman rank correlation

*If the assumption of normally distributed populations is not met, the observations should be ranked, and the methods for data measured on the ordinal scale should be used.

Adapted from Glantz SA: *Primer of Biostatistics*. 3rd ed. New York: McGraw-Hill, 1992; Biddle C. *Evidence Trumps Belief: Nurse Anesthetists and Evidence-Based Decision Making in Nurse Anesthesia*. Chicago: AANA Publishing, 2010.

2. *Making an estimation*. What percentage of nurse anesthetists perform a thorough machine check at the start of each day?

Researchers are seemingly preoccupied with the concept of significance. The level of significance (also designated as alpha level or p value) is a criterion used in making decisions regarding a hypothesis. If p is less than 0.05, the probability that the difference observed between the samples was the result of chance alone is less than 5%. Accordingly, the probability that the difference between the samples was real (i.e., it resulted from the treatment) and was not just the result of chance is greater than 95%. The type of statistical test used determines the test value that corresponds to a p value of less than 0.05 and indicates a statistically significant result. Statistical tables report these significant test values for each type of statistical test. It is conventional to establish the alpha level before the data analysis is begun; however, there seems to be an increasing trend toward reporting calculated p values after hypotheses have been tested. Commonly used levels in research are $p < 0.05$ and $p < 0.01$; p is less than 0.10 is sometimes used in preliminary or descriptive studies. There is also a trend to simply report the calculated p value and leave the interpretations up to the reader.

In recent years, there has been growing resistance to the exclusive use of the p value in interpreting research findings, despite the still widespread use of the p value in interpreting hypotheses. Fundamentally, the p value was never intended to be a substitute for scientific reasoning. Consumers of the clinical research literature should keep these guidelines in mind:

1. The p value can be distorted by the data's incompatibility with a

specific statistical model.

2. P values do not measure the probability that the studied hypothesis is true, or the probability that the data were produced by random chance alone.

3. The p value does not measure the size of an effect or the importance of a result.

4. By itself, the p value does not provide a good measure of evidence regarding a model or hypothesis.

The p value is a dimensionless value that is, at best, only an indicator of the direction of the effect, and in no way speaks to the clinical meaningfulness of the relationship.

Confidence intervals provide greater detail about the measured outcome than p values. The purpose of any research study is to provide an estimate of the effect the study treatment would have if it were applied to the entire population of interest, what many call the “true value” of a treatment effect. The confidence interval, or CI, is the range within which the true value of the treatment effect is expected to fall 95% of the time. In other words, if the study treatment was applied to the entire population of interest, 95 out of 100 times the size of the treatment effect would be within the specified confidence interval range. 95% CI is most commonly reported, but 90% and 99% confidence intervals are sometimes calculated as well. The CI is very important because it puts an upper and a lower boundary on the likely effect size of any real treatment. In doing so, it also provides an indication of the precision of the treatment effect estimate. A smaller confidence interval indicates greater precision. If a confidence interval is very wide, more data may need to be collected before any definite conclusions can be drawn about the estimate.⁵

Because relative risk and odds ratios are calculated as fractions comparing a treatment group to a nontreatment group, a CI which includes 1 indicates that no statistically significant difference between the groups has been found. Conversely, a CI for relative risk or an odds ratio that does not include 1 is an indication of a statistically significant treatment effect. Research studies often

report both p values and CIs, but if only one is reported, it should be the CI.⁵

Although explanation and application illustrations are beyond the scope of this chapter, other measures of effect size include, but are not limited to, Pearson's r and Cohen's d . The number needed to treat (NNT) and the number needed to harm are additional examples of metrics that provide clinically applicable “magnitude of effect” information. Some of these metrics are discussed in [Table 4.8](#).

TABLE 4.8
Examples of Effect Size Measures Used in a Meta-analysis

Measure	Attributes
Cohen d	Difference between 2 means divided by the standard deviation (SD) of either group; works when the variances of the 2 groups are homogeneous. In a meta-analysis, the mean differences are subtracted such that the resultant difference is positive in the direction of improvement. Measurements must be on a continuous scale. Variations exist for data using similar or different measures. Generally, effect size is as follows: $d = 0.2$, small; $d = 0.5$, medium; $d = 0.8$, large.
Correlation measures	Many types, such as phi (Φ), r , point biserial, and Kendall tau (τ), depending on the nature of the variables; portray the strength of association between factors under consideration and the outcome.
Number needed to treat (NNT)	Useful measure of an intervention's effectiveness. Describes the active treatment and control/comparison in achieving the desired outcome. NNT = 1 implies a favorable outcome in every patient given the treatment and no patient in the comparison group. An NNT of 50 implies that 50 patients must receive the treatment for one of them to experience the desired effect.
Number needed to harm	Similar to NNT; used to examine adverse effects of an intervention.
Odds ratio (OR)	The probability of an event in one group compared with the probability of that event in another. If the OR = 1.0, the likelihood is the same; if the OR > 1.0, the event is more likely in the first group. The calculation puts the odds in the experimental group in the numerator and the odds in the comparison group in the denominator.
Relative risk	The risk of an event happening in a group exposed to a treatment compared with the risk in a non-exposed group. A number > 1.0 implies greater risk.
Confidence interval (CI)	Defines a range of values likely to include a measure, generally reported as a 95% CI; implies that 19 times out of 20, the “true” value will be in the specified range of values. Many outcome measures are often reported with their associated 95% CI.

Selecting the Appropriate Statistical Procedure

There are two major categories of inferential procedures: parametric analyses and nonparametric analyses. The major factors that dictate which category should be selected involve the assumptions the investigator makes regarding the data. Parametric procedures are

best performed on normally distributed, large interval- or ratio-level data sets in which values are independent and exhibit similar variance. For data that does not fall under these parameters, nonparametric statistical procedures are used. Tables 4.9 and 4.10 provide some guidelines for selecting a statistical procedure.

TABLE 4.9
Choice of Statistical Test Based on Assumptions

	Parametric Procedures	Nonparametric Procedures
Nature of the assumptions	Data are interval or ratio level	Data are nominal or ordinal level
	Each value is independent of the other values	Not necessarily distributed "normally" (i.e., data do not "fit" a bell-shaped curve)
	Value is normally distributed	
	Groups have similar variance	
	Usually works best with large population	
Examples of tests	<i>t</i> -test for independent groups*	Chi-squared test
	<i>t</i> -test for dependent samples†	Mann-Whitney test
	Analysis of variance	Kruskal-Wallis test

*For example, two totally unrelated groups are compared.

†For example, a pretest and posttest comparison on one group of people.

TABLE 4.10
Choice of Statistical Test Based on Purpose

Test	Goal
<i>t</i> -test, independent groups	To test the difference between the means of two independent groups
<i>t</i> -test, dependent samples	To test for the difference between dependent, paired samples (e.g., pretreatment and post treatment) outcome
Analysis of variance	To test the difference among the means of more than two independent groups or more than one independent variable
Chi-squared	To evaluate the difference between observed and expected frequencies
Correlation coefficient	To test whether a relationship exists between two variables (e.g., product-moment)
Simple linear regression	Used when one independent variable (x) is used to predict a dependent variable (y)
Multiple linear regression	To understand the effects of two or more independent variables on a dependent measure
Analysis of covariance	To test for differences between group means after adjustment of the scores on the dependent variable to eliminate the effects of the covariate
Factor analysis	To reduce a large set of variables into a smaller, more manageable set of measures
Canonical	To analyze the relationship between two or more independent variables and two or

correlation	more dependent variables
Discriminant analysis	To make predictions regarding membership in categories or groups, in contrast to using interval- or ratio-level measures

Power

The sensitivity of the planned experiment and analysis is known as its *power*. The concept of power is important to anyone planning a research project or evaluating a published paper. The estimate of an experiment's ability to accurately test the hypothesis under question should be computed before the research is begun. A researcher should ask two critical questions:

1. What is the chance I will incorrectly determine that my treatment had an effect when it really did not (type I error)?
2. What is the chance I will miss an effect that is actually present (type II error)?

Power estimates obtained during a study's design stage encourage investigators to thoughtfully enhance the study's sensitivity. Making such estimates forces the posing of questions regarding effect size (e.g., how potent is the effect of the independent variable on the dependent variable?) and sample size, both of which are essential in a study. Many adverse outcomes that occur as a result of anesthetic management are rare (e.g., death, postspinal hematoma, blindness, stroke), and studies proposing to measure such outcomes as a function of a particular interventional approach must be "powered" by a large sample size and other methodologic controls.

Common Parametric Tests

Statistical tests are designed to accept or reject the assumed null hypothesis (i.e., there are no differences between groups). Each type of statistical test computes a unique statistical test that reflects the difference between the groups of interest. This test statistic is then reported in terms of significance as a *p* value, allowing the researcher to conclude whether there is any significant difference

between the groups. Any elementary statistics textbook contains tables which list significant values for each type of test statistic.

The t-test is probably the most common parametric test encountered in clinical research studies. Three types of Student t-tests are used to test the null hypothesis that there is no difference between two group means. A one-sample t-test is used to determine whether the mean of a sample is different from the mean of a known, at-large population. To evaluate whether a study sample in which weight loss interventions were used had a lower BMI than the general population, a one-sample t-test can be conducted to compare the mean BMI of the sample with that of the general population. The resulting test statistic, reported as a p value that falls below 0.05, indicates a 95% probability that the mean sample BMI does not differ from the mean population BMI by chance. That is, the difference between the sample BMI and the population BMI is likely due to the weight loss intervention. An unpaired t-test is used when two independent samples are compared, such as comparing the effect on blood pressure of two different manipulations performed during laryngoscopy. A paired t-test is used on two dependent samples, such as might occur when preintervention and postintervention group scores are compared in the same group of subjects.

The analysis of variance (ANOVA) is another commonly used parametric test that incorporates group means and variances to determine the test statistic. The test statistic is then used to determine whether three or more groups of data vary from one another in a meaningful way. As with other statistical procedures, the ANOVA assumes that the null hypothesis is stated such that all group means are the same. The ANOVA then accepts or rejects the null hypothesis. The test statistic for ANOVA is called the F ratio. As with other statistical tests, statistical tables provide the F ratio values required to achieve statistical significance. The multiple ANOVA (sometimes called *MANOVA*) is used when the effect of multiple grouping factors (e.g., exercise routine, diet, and food journaling) is analyzed. The ANOVA with repeated-measures test is commonly used when all members of a random sample's dependent variable are measured under a number of different conditions or repeatedly measured over time.

Should the ANOVA indicate that a significant difference exists when more than two groups are compared, it cannot localize where the groups differ, only that there is a difference somewhere. In this case, a post hoc test must be used to isolate the between-group or among-group difference. There are many of these tests, and different computer programs and statisticians have their preference; examples include the Fisher, Scheffé, Tukey, Newman-Keuls, and Dunnett tests.

Propensity Score

An increasingly common analysis that is used is called the *propensity score* (PS). This is particularly important in observational studies where bias may be a powerful confounder. The PS determines the conditional probability, based on a set of baseline metrics such as gender, ASA classification, age, some comorbidity, etc., that a patient would or would not have received a certain intervention. If there is no hidden bias and treatment assignment is thus random, the PS should be indicative. There is considerable movement, using the PS methodology, to elevate the “power” of observational studies to near that of the randomized trial. However, this is a very contentious issue.

Recursive Partitioning

A commonly used tool that has both statistical and methodologic attributes and implications is recursive partitioning. Its roots are in the word recursive, meaning to use a rule or procedure that can be applied repeatedly, and partitioning, indicating a division into or distribution into portions or shares. This type of approach creates a rule such as “if a patient has finding a, b, or c, then he or she likely has condition x or should be treated with z.” Examples of where this kind of rule application has been used include the Goldman Cardiac Risk Stratification, obstructive sleep apnea scales such as STOP-BANG, and the ASA Difficult Airway Algorithm.

Common Mistakes

At this step in the research process, mistakes include selecting an

inappropriate statistical procedure, using only one statistical procedure when several should be used, overstating the importance of small differences that are statistically significant but of little clinical importance, interpreting correlational research as evidence of cause-and-effect relationships, and overgeneralizing the findings of the investigation. Some common errors in statistical usage are

Box 4.4 Box 4.4.

Top 10 Common Errors in Statistical Usage

1. No justification for reporting statistical results

- No control group (when one is possible)
- Random sampling or random group assignment not performed (or reported)
- Statistical test not specified
- Obvious biases or threats to validity
- No documentation of consent or institutional review board approval

2. Errors in use of the *t*-test

- Multiple application without correction
- Use of independent groups form for paired data and vice versa
- Use for ordinal data

3. Negative conclusions when statistical test results are not significant

4. Use of a test for independent samples for paired data or repeated measures
 5. Inappropriate or no follow-up to analysis of variance
 6. Hypotheses generated by the data
 7. Use of one-sided tests without justification (or disclosure)
 8. Inadequate number for chi-squared analysis
 9. Standard error of the mean used for specifying variability
- . Misinterpretation or misrepresentation of p value
- Small p value called “highly significant”
 - No confidence intervals stated
 - Different interpretation of $p = 0.04$ and $p = 0.06$

Stage 7: Dissemination of the Findings to Interested Colleagues

The research process is not complete until the results, conclusions, and implications have been adequately communicated to those likely to be interested in the study. Clearly, a study that has been completed but whose results have not been disseminated is of little value. Communication of the research findings can be done through a variety of routes, including publication in journals or newsletters, oral and poster presentations at formal symposia, or even simply discussion with others interested in the phenomenon.

Researchers fail to publish the results of their work for many reasons. These include such claims as “my findings were not significant,” “my results were negative,” and “the sample size was small.” Negative or insignificant results can be as valuable as positive ones. For example, it has been found that in most circumstances, the byproduct of atracurium breakdown,

laudanosine, is unlikely to have significant clinical effects.⁶ This is an important negative finding that has contributed substantively to clinical understanding.

Similarly, small sample sizes may provide an element of control over variables not present in larger studies or may indicate some preliminary direction as to how to approach a problem. An example is the finding that epidural anesthesia or analgesia in conjunction with light general anesthesia may be preferable to a purely general anesthesia technique and may be associated with lower mortality rates in critically ill patients.⁷ Although the sample size in this particular investigation is relatively small, the overall design is acceptable and contributes to our understanding of the issue by stimulating other investigators to pursue answers to the questions raised.

The goal of nurse anesthesia research is the improvement of practice and the dissemination of research findings to clinicians. In a report directed at a highly research-oriented audience, the introduction is usually somewhat detailed, emphasizing the theoretic basis for the research. The introduction is followed by an extensive methodologic section that focuses on establishing the reliability and validity of the instruments used. The findings of the study are presented next, with emphasis on the statistical procedures employed. Finally, the conclusion focuses on the limitations and implications of the study's results.

Writing for a Clinically Oriented Audience

Generally, clinicians find research literature difficult to understand and its clinical application cumbersome. Both authors and journal editors can do much to make research more palatable to the clinical reader, thereby improving the chance that the research findings will be broadly disseminated and integrated into clinical situations. A recipe for successful clinical writing follows.

Clinical readers of research want to extract information applicable to clinical practice as quickly as possible. Therefore the introduction of the research report should be brief, should establish the practical importance of the study, and should present a clear statement of the study's purpose. A deliberate effort should be made to connect the study with the realities of clinical practice.

With respect to the methods section, writing that “a quasi-experimental, Solomon three-group crossover design yielded data that were subjected to canonical and discriminant analysis” does little to satisfy the needs of the average clinical reader. Instead, stating how the subjects were obtained, what manipulations were made, how the measurements were taken, and how the statistical analysis was performed provides the reader with clear straightforward information, allowing him or her to put the study into a clinical context. The methods section should completely describe both the research design and the statistical procedures used, and it should indicate why this approach was selected.

The results of the study should focus on the relevant findings and describe them clearly and fully. Tables or figures, explicitly labeled and simple in design, should be used for representing the findings visually. Admittedly, the more complex the findings, the more difficult it is to avoid a statistical or technical focus.

In the discussion section, the implications of the investigation for theory and future research are somewhat less important to the clinical reader than are the implications for practice. For example, assume that a study demonstrates that the proposed intervention is not ready to be implemented in practice. In this situation, the discussion section should emphasize why this is so and what can be done about it. Encyclopedic comparisons of the results with those of other investigators at this point probably will not contribute materially to the report and may, paradoxically, deter the reader. Alternatively, if a researcher finds that a particular intervention, strategy, or assessment is ready to be introduced into clinical practice, the discussion section should emphasize how and for whom it should be used. It should include considerations such as efficiency and cost, as well as suggestions for clinical implementation.

This recipe for making research reports more palatable to primarily clinically oriented readers is not meant to diminish the importance of highly theoretic research-oriented writing. Many nurse anesthetists continue to generate and publish valuable theoretical manuscripts that contribute to a scientific basis for practice. Researchers and writers must keep the nurse anesthetist audience in mind as they develop and disseminate their findings.

All researchers must understand that the results of their studies, once published, become part of the general knowledge of the scientific community at large. However, the use of this knowledge requires acknowledgment of the original researchers; additionally, published results may be subject to copyright protection laws (i.e., their use may require permission from the publisher). It is not until the information becomes common knowledge that others may use it freely without acknowledgment.

Common Mistakes

At this stage of the research process, common mistakes include not keeping the study focused on the original problem, overwriting, generalizing the findings too broadly, and failing to address the clinical significance of the study.

Stage 8: Evaluation of the Research Report

Both clinicians (in their reading for application) and researchers (in their writing and analysis) are called on to evaluate research reports, despite the fact that many may not have received formal training in reading and interpreting professional literature.

Evaluation is the process of appraising the quality of a phenomenon; in this case, the findings of research as they bear on the art and science of nurse anesthesia. Outside of the practice settings, humans evaluate hundreds of things every day: Are the apples on the grocery shelves to our liking? Does the description of the program in the television guide entice us to tune in? Is the weather too warm to wear a jacket? Have we cooked the eggs sufficiently? These seem trivial and informal compared with the clinical evaluations the nurse anesthetist must perform daily: Is the patient's anesthesia too deep, too light, or about right? Should I administer more opioid? Is the patient dehydrated, or is the hematocrit level misleading me? Should I perform a rapid-sequence induction? What dose of hypnotic do I use in this 80-year-old patient with a fractured hip? How does the patient's coagulation status affect the choice to place a neuraxial block? Both sets of questions, nonprofessional and professional, are highly evaluative and parallel the evaluative decision making that occurs when

anesthesia research literature is read.

Systematic evaluation of the research, which influences the practice of nurse anesthesia, consists of a formal appraisal of the quality and value of the research. This essential step in the research process is multidimensional and can be approached in many ways. The approach outlined in the following subsections involves asking carefully orchestrated, critical questions. The answers to the suggested questions are not necessarily a dichotomous yes or no, but rather are qualitative in nature. An overview of this approach is

Box 4.5 in [Box 4.5](#).

Research Scenario: A Guide for Researchers* and Clinicians† in Evaluating Research for Completeness and Clinical Application

Problem

- Is it lucid, researchable, justified, and practical?

Hypothesis

- Is it clear, with the appropriate variables under consideration correctly identified?

Definitions

- Are terms adequately defined and put into context?

Literature

- Is it relevant, current, and organized?

Review

- Is it logical, and does it justify the study?

Methods

- Is the sample representative of the population being considered?
- Is the sample large enough?
- If human subjects were used, was institutional approval granted?
- Is the instrumentation described and valid?
- Is the design compatible with the problem and the hypothesis or research question?
- Is there any evidence of drift from established procedure?
- Are the data-gathering procedures defined?
- Is there enough information for replication of the study, if desired?
- Are the statistical procedures described, and are they appropriate?

Results

- Are results presented clearly, concisely, and without bias?
- Are they organized and displayed logically in tables or figures?
- Are they relevant to the problem or hypothesis?

Discussion

- Is the discussion logically based on the results?
- Is it intimately grounded in the original problem or hypothesis?
- Is there overgeneralization of the findings?
- Is the writing impartial and scientific?
- How can this study be used in the practice setting?

- How similar is the study's environment to the real world?
- What are the risks associated with implementation of the recommendations?

*Researchers should benefit from this by critically asking themselves whether they have included answers to these questions in their report.

†Clinicians should benefit from this by judging the report on the basis of completeness and utility and by finding out whether it contains answers to these questions.

Evaluating a Study: The Bottom Line

Ultimately, the nurse anesthetist evaluating a study is faced with three questions:

1. Do I disregard the study and its findings entirely, not applying them to either clinical practice or future analysis in any fashion?
2. Do I apply the study only in the sense of expanding my cognitive approach to anesthetic management? (In this scenario, although one may not materially or directly apply the study or its findings to practice, some intellectual growth or understanding is gained from the study, which subsequently is incorporated into one's repertoire.)
3. Do I make a direct application of the study to my practice?

Some questions to ask when one reads a study are listed in [Box 4.6](#)

Questions to Ask in the Reading of a Study

Object or Hypothesis

- What are the objectives of the study or the questions to be answered?
- What is the population to which the investigators intend to refer

their findings?

Design of the Investigation

- Was the study an experiment, planned observations, or an analysis of records?
- How was the sample selected? Do possible sources of selection exist that would make the sample atypical or nonrepresentative? If so, what provision was made for dealing with this bias?
- What is the nature of the control group or standard of comparison?

Observations

- Are there clear definitions of the terms used, including *diagnostic criteria*, *measurements made*, and *criteria of outcome*?
- Was the method of classification or of measurement consistent for all the subjects and relevant to the objectives of the investigation? Do possible biases in measurement exist, and, if so, what provisions were made to deal with them?
- Are the observations reliable and reproducible?

Presentation of Findings

- Are the findings presented clearly, objectively, and in sufficient detail to enable the reader to judge them for herself or himself?
- Are the findings internally consistent? That is, do the numbers add up properly, can different tables be reconciled, and so on?

Analysis

- Are the data worthy of statistical analysis? If so, are the methods of statistical analysis appropriate to the source and nature of the data, and is the analysis correctly performed and interpreted?

- Is analysis sufficient for determining whether “significant difference” may be the result of lack of comparability of the group in gender or age distribution, in clinical characteristics, or in other relevant variables?

Conclusions

- Which conclusions are justified by the findings? Which are not?
- Are the conclusions relevant to the questions posed by the investigators?

Constructive Suggestions

- Assume you are planning an investigation to answer the questions put forth in this study. If they have not been clearly asked by the authors, frame them in an appropriate manner. Suggest a practical design, criteria for observations, and type of analysis that would provide reliable and valid information relevant to the questions under study.

Adapted from Colton T. *Statistics in Medicine*. Boston: Little, Brown; 1974.

Common Mistakes

At this stage of the research process, mistakes include failing to adequately evaluate a study's methods and findings, and, in the process, uncritically accepting into practice information that may be misleading or incorrect. Although articles in professional journals should undergo critical review by peers who can detect mistakes, omissions, and alternative explanations, the ultimate responsibility for evaluating a study and determining the pros and cons of the implementation of its recommendations rests with the clinical reader.

Evidence-Based Practice: Empowering Decision Making Through Research

Understanding these concepts of clinical research provides the tools necessary to implement EBP in nurse anesthesia. EBP involves the conscientious and critical use of quality published evidence in making decisions related to the care of a particular patient, considering the caregiver's unique expertise and the setting in which the patient presents. From EBP's very conception, the application of sound empirical evidence to clinical practice has had a dramatic impact on patient outcomes. In 1972, Scottish epidemiologist Dr. Archie Cochrane realized that thousands of low-birth-weight premature infants were dying unnecessarily because the results of randomized controlled trials documenting the therapeutic effect of corticosteroid therapy in high risk mothers had not been systematically reviewed and made available to the public. When a rigorous review of existing studies was published, it revealed that corticosteroid therapy reduced the odds of premature infant death from 50% to 30%. Dr. Cochrane's efforts to bring empirical evidence to bear on clinical practice significantly improved premature infant mortality and formed the foundation for modern EBP. The Cochrane Center and the Cochrane Collaboration were established shortly thereafter and continue to assist health care providers in bringing EBP to the clinical environment today.⁸

One only needs to examine former “best practices” in the field of anesthesia to understand the importance of informing clinical practice with current, quality research. Many former practices that lacked a foundation in clinical research have since been found to be unsafe or ineffective. Some of these practices include:

- Innovar (a fixed combination of fentanyl and droperidol)
- Chymopapain
- Rapacuronium
- Methoxyflurane (Penthrane)

- Insufflated halothane for tonsillectomy
- “Twilight sleep” for obstetrical delivery
- CO₂ gas to increase cerebral blood flow during carotid surgery
- Doxapram (Dopram) to speed anesthetic emergence

The nurse anesthetist can avoid the use of unsafe or ineffective interventions by using EBP. EBP ensures that the safety and efficacy of clinical practices are firmly grounded in systematically reviewed research studies. In the quest to protect patients from harmful or ineffectual practices, EBP is the most powerful weapon in the nurse anesthetist's arsenal.

Clinicians, academics, and the health care environment have much to gain from a structured method to bring scientific advances and the rigor of the clinical research environment to patient care. For the nurse anesthetist, EBP provides a systematic approach to incorporate current research into daily practice. Studies such as those conducted by Shin et al. and Sackett et al. highlight the drastic need to improve the clinical application of recent research findings. These and other studies demonstrate a negative correlation between knowledge of current best practices and length of time in clinical practice.⁹⁻¹¹

Ely et al.¹² found that clinicians failed to look to current clinical research studies to inform their patient care decisions. The study revealed that clinicians endeavored to seek current best evidence for less than half of the patient management questions they encountered. EBP provides a framework to allow the nurse anesthetist to remain up to date on current best practices throughout a lifetime of clinical practice and to incorporate empirical evidence in everyday patient care decisions.

Evidence-based practice not only requires knowledge and interventions based on quality research but also facilitates decision-making among interventions of apparent equal empirical soundness based on the needs and values of the patient. It is this combination of empirical evidence with patient-centered decision-making that renders EBP its greatest value to clinicians and patients alike. With EBP, practitioners are not simply making decisions based on the highest quality evidence, they are making decisions based on the highest quality evidence that are best for the patient.

Finally, just as EBP brings the clinician back to the evidence, so too does EBP bring the academic back to clinical practice. Facilitating interaction between the academic and clinical settings provides the optimal environment for accurate and informed patient care.

When solid evidence evolves into sound clinical decision making, patients receive the best possible care; EBP helps the nurse anesthetist choose scientific evidence over confusing (or even unsound) opinion. In addition, EBP complements other foundational approaches to patient care and teaching. Some researchers argue that there is a crucial final step in the EBP model; namely, that clinicians self-evaluate their own EBP. In doing so, clinicians provide an ongoing process of evaluation and sensitivity testing for practice-based decisions.

Clinical research seeks to resolve, refine, and clarify issues involved in the care and management of patients. Each day, the nurse anesthetist is faced with a host of common and uncommon patient scenarios that demand thoughtful, efficient decision making and resultant interventions. How the practitioner comes to decide what course of action to take is in many cases as important as the action itself. Decisions involving the care of patients should be evidence based, a process of considerable complexity involving judging sources of information, evaluating the quality and relevance of information, recognizing the contextual elements that may alter the application of that information in a particular setting, and assessing its impact on the patient.

The Process of Evidence-Based Clinical Practice

What we do in a given circumstance is often more a matter of entrenched belief than a course of action firmly grounded in high quality research. The published series *Clinical Evidence*, the international source of best available evidence related to common clinical interventions in various disease states, reveals that of 2500 treatments reviewed, 325 (13%) were rated “beneficial,” 575 (23%) “likely to be beneficial,” 200 (8%) as “a tradeoff between benefit and harm,” 150 (6%) “unlikely to be beneficial,” 100 (4%) “likely to be ineffective or harmful,” and 1150 (46%) as having “unknown

effectiveness.” One might interpret this in many ways, but it indicates that many treatment decisions are inadequately grounded in firm scientific rationale.¹³

The fundamentals of medicine and nursing have evolved from a time when the teaching and practice of authoritative figures (sages) were simply passed down and uncritically applied to patients. Advances came with clinical evolution, but primarily in the form of case reports, case series, editorials, and other publications that were too often based on preconceived notions, and deliberate or unintentional bias. The advent of the RCT some six decades ago set the stage for a new era in patient care. Despite advances, practitioners, and nurses in particular, are often resistant in regard to bringing research advances to the bedside. EBP involves a series of consecutive, somewhat overlapping steps that are described in the following sections.

Step 1: Asking a Question That Deserves an Answer

Should we anesthetize and perform elective surgery on a child who presents with an upper respiratory infection on the day of the scheduled procedure? What fluid and glucose management strategy should be used in the diabetic patient recovering from a major peripheral vascular procedure? Is it safe to use ketorolac in the patient just now recovering from a tonsillectomy? What can be done to minimize the risk of ventilator-acquired pneumonia in the postoperative patient receiving mechanical ventilation? Should all patients recovering from general anesthesia receive supplemental oxygen in the postanesthesia care unit? Should obstructive sleep apnea patients recovering from general anesthesia receive continuous positive airway pressure throughout their hospital stay if significant pulmonary hypertension is present? What is the lowest acceptable platelet concentration that permits use of neuraxial anesthesia in the obstetrical patient? Such questions are common in practice and merit careful consideration of intervention-related outcomes, but relevant questions can also apply to diagnosis, prognosis, and the potential for harm. It may seem like word play, but the answers to patient care questions are more likely

to be important and valid if the questions posed are good. Questions should be focused to the extent that they are both applicable to the patients who are cared for and can be researched.

The “PICO” Approach.

A common model used in developing an appropriate clinical question is the PICO approach. PICO is a mnemonic device that describes key components of good question construction, that is, Patient, Intervention (or cause), Comparison (if appropriate), and Outcome. Because clinical circumstances, and their associated questions, vary considerably, not all questions will have a “comparison” group, although many will. Examples of PICO-derived questions follow:

Patient	Intervention	Comparison	Outcome
61-year-old male, infarction	Streptokinase	Plasminogen activator	Death
31-year-old female, laparoscopy	Ondansetron 4 mg	Droperidol 1.25 mg	Nausea
17-year-old male, arthroscopy	Spinal anesthesia	—	Time in PACU

Using the PICO approach, a clinically focused, relevant question emerges from each of the scenarios established earlier. For example, with respect to the second, a comparison scenario, the following question might emerge:

- In young women undergoing diagnostic laparoscopy for nonspecific pelvic pain and receiving anesthesia with sevoflurane, atracurium, and fentanyl, is there a difference in the rate of postoperative nausea when either ondansetron 4 mg or droperidol 1.25 mg is given 30 minutes prior to emergence?

With respect to the third, noncomparison question, the following question might emerge:

- In adolescents undergoing knee arthroscopy under spinal anesthesia with lidocaine 75 mg and sufentanil 10 mcg, what is the anticipated length of stay in the postanesthesia care unit (PACU) before they are street fit?

Step Two: Searching for Relevant Evidence

Once a question is at hand, the search for information begins; this is a process that can be both time consuming and challenging. Seeking evidence to address the question “What is the best antiemetic for

the postoperative patient?” is much different than asking “Is isopropyl alcohol inhalation more effective than ondansetron in managing post-general anesthesia nausea in the postpartum tubal ligation patient?” Although providers usually have an opinion about care-related questions, EBP demands that we critically evaluate researchable and meaningful information sources to best address a particular patient's care. Choosing a database is an important first step that can have a significant impact on the studies available to answer patient care questions. *Index Medicus* and *MEDLINE* are familiar, excellent sources but are not applicable in all circumstances, especially if time is of the essence. A particularly valuable database specifically related to EBP is the *Cochrane Collaboration*, a collection of well-conducted clinical trials organized into specific topics. Other sources, such as established websites, well-regarded (peer reviewed, authoritative) textbooks, or even colleagues with a more robust knowledge base may suffice. The crucial aspect of these sources is confidence that the colleague, database, or book chapter is evidence based. The phrase “garbage in, garbage out” has particular application here.

An especially powerful and underused search tool that readers should investigate is CINAHL, the Cumulative Index of Nursing and Allied Health Literature. This tool has exceptional utility in the anesthesia domain and should be a part of any broad or focused research that is performed. Here, CINAHL is used to demonstrate efficient search strategies to answer the question about adolescents undergoing knee arthroscopy.

Step 3: What Is It Worth?

Evidence-based practice is an approach to patient care founded on the belief that clinical decisions must be based on results obtained from rigorously controlled investigations. It is important to recognize that not all evidence that is retrieved or brought to bear on a question has the same value. The pyramid of evidence, [Fig. 4.4](#), demonstrates that the randomized, double-blind, controlled clinical trial has greater worth than the editorial or case report. This hierarchy of value is case and issue sensitive, because not all questions have relevant or applicable RCTs. On the other hand, when a number of RCTs are directed toward a similar issue, these

can sometimes be combined using rigorous methodology and a common set of statistical procedural processes to produce a meta-analysis (or quantitative systematic review).

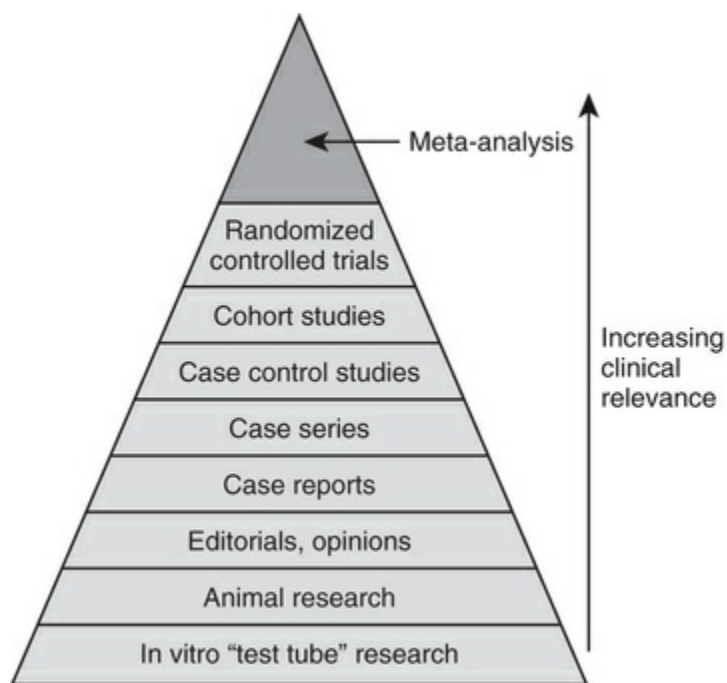

FIGURE 4.4 The pyramid of evidence.

The dizzying array of studies in the field of anesthesiology coupled with the complexities and vagaries of this patient population produce an informational tidal wave both frustrating and daunting to clinicians who endeavor to remain on the cutting edge with respect to patient care decisions. EBP cautions against using studies with low external validity (e.g., animal studies) or those based on uncontrolled observations (e.g., case reports, retrospective studies) in rendering decisions that influence or dictate patient care interventions. Here, we will focus on the appraisal of the three study designs which produce the most valuable empirical evidence: the randomized controlled trial, the systematic review, and the meta-analysis.

Randomized Controlled Trials.

Among single studies, the RCT is widely considered the gold standard for measuring the effectiveness of clinical interventions. In an RCT, patients are randomly assigned, or "randomized," to one

of two or more groups. The aim of randomization is to decrease bias, in part, by equally distributing both known and unknown confounders in the study arms. Any differences in the measured outcomes of each group can thus be attributed to the study's intervention. In an RCT, a control group is used as a baseline for comparison with the intervention groups. The control group may receive a placebo or sham treatment, or it may receive the standard treatment for a particular condition. Among the intervention groups, multiple interventions may be tested or the same intervention may be tested in different magnitudes. The latter is typical of trials involving drugs, in which different dosages are applied to gauge efficacy, the side-effect profile, and safety.

Fig. 4.5 illustrates a fictional trial comparing 3 antifibrinolytic agents used in cardiac surgery to reduce the need for transfusion. Antifibrinolytic B is currently the standard treatment. The starting group of 21 open-heart surgical patients is randomized to receive antifibrinolytic A, B, or C. The patients undergo anesthesia, surgery, and the antifibrinolytic intervention. They are followed for 90 days to assess survival, as well as the number of units of blood transfused postoperatively. Group differences in mortality would be assessed with a nonparametric procedure such as the χ^2 test, and group differences in the amount of blood transfused would be assessed with a parametric tool such as the analysis of variance. Using relative risk or odds ratio would allow quantification of the magnitude of the effect of interventions A, B, and C on the outcomes of interest.

FIGURE 4.5 A fictional example of a randomized controlled trial comparing the effects of antifibrinolytics **A**, **B**, and **C** on the need for blood products following cardiac surgery. The total number of units of blood required by the patients in each treatment group who survived 90 days after surgery is then analyzed to determine the treatment effect of the drugs.

There is an important distinction to be made between the terms *efficacy* and *effectiveness* when considering an RCT. Although these terms are elsewhere used interchangeably, they have markedly different associations in the realm of clinical research. *Efficacy* is an evaluation of the treatment effect under the highly artificially controlled conditions of the RCT and refers to whether an intervention produces the expected result under ideal circumstances. *Effectiveness* evaluates the treatment effect under the conditions of normal practice and represents a more practical consideration of the magnitude of treatment effect under real-world conditions. Such trials are often termed *pragmatic trials*. Thus the concept of effectiveness is more reflective of what is likely to be observed in patients encountered on an everyday basis.

The means of randomization is also an important aspect to consider when evaluating an RCT. Alternating assignment or assignment by birth date or hospital admission number are not considered random and are prone to bias. In large clinical trials,

simple randomization may be sufficient to eliminate differences in patient characteristics between intervention groups, but other techniques are required for smaller sample sizes. Block randomization and stratification are two strategies used to evenly distribute patient characteristics among small intervention groups. Block randomization groups patients in blocks of two or more. The number of intervention groups determines the number of different patient assignment sequences which are randomly applied to each block of patients. For example, a study using blocks of three patients with intervention groups A and B would have possible patient assignment sequences of AAA, ABA, AAB, ABB, BBB, BAA, BBA, and BAB. A patient block randomly assigned the ABA sequence would assign the first and third patients to intervention group A and the second patient to intervention group B. Stratification takes the process a step further by first grouping together patients with similar clinical features.⁵ Block randomization is then conducted separately on each group to ensure that patients with similar clinical features are randomly distributed into the intervention and control groups.

Additional strategies to reduce bias in the RCT involve the concealment of intervention group assignment and details of the intervention itself. Allocation concealment prevents researchers from consciously or unconsciously assigning a patient to a particular treatment group based on their own personal biases.⁵ Blinding (masking) prevents the introduction of bias by participants who know whether or not they are receiving treatment.

Bias may be introduced into the RCT when a study fails to account for patients who do not complete the study. In clinical trials, patients may discontinue treatment for a number of reasons, including unpleasant side effects. When these patients are left out of the data analysis process, individual variation is no longer equally distributed between patient groups. Without equivalent treatment and non-treatment groups, the intervention can no longer be said to be the sole determinant of treatment effect. Intention-to-treat analysis incorporates data from all patients regardless of study completion and minimizes bias introduced by patient noncompliance. Published articles should always specify which participants are included in data analysis and use intention-to-treat

analysis to evaluate the primary outcome.⁵

It is important to keep in mind that bias inherently exists even in the most rigorously controlled clinical trial, due to the simple fact that no two people (let alone groups of people) are exactly alike. Any small difference between groups has the potential to bias the study results. It is important that the nurse anesthetist critically evaluate the quality of an RCT to determine whether a treatment effect can be reliably determined. A checklist is noted in [Box 4.7](#) to [help judge](#) the value of a particular RCT.

Checklist for Evaluation of the Randomized Controlled Trial

- Is a clear objective for the study stated?
- Is the sample size adequate?
- Is the study population well described?
- Are the interventions clearly described?
- Are randomization and blinding procedures adequate?
- Are valid and reliable outcome measures used?
- Is attrition (dropouts) considered in the analysis?
- Are the statistical methods appropriate?
- Are both clinical and statistical significance reported?
- Are the results generalizable to clinical practice?

Systematic Reviews.

We all rely to one extent or another on reviews of primary research to assist us in coming to understand and apply clinical research findings. However, reviews differ substantially in the quality of primary studies included and the methodological rigor used to assess them. In a traditional narrative review, authors use informal, subjective methods to select and analyze primary studies, often

only including those studies which support their hypothesis.¹⁴ By contrast, the authors of a systematic review conduct an exhaustive search of primary studies based on a focused clinical question and use explicit and reproducible methods to select, critically appraise, and synthesize the results of high quality reports.^{14,15} [Box 4.8](#)

[Box 4.8](#) provides an overview of the methodology of a systematic review.

The Methodology for a Systematic Review

- State the objectives of the review and define eligibility criteria
- Search for trials that meet criteria
- Describe characteristics of each trial; assess methodological quality
- Apply eligibility criteria; explain any exclusions
- Assemble/compile the most comprehensive dataset possible
- Analyze results of eligible RCTs using a common statistical metric
- Compare alternative analyses if appropriate and possible
- Prepare a critical summary based on the analysis, stating goals, describing nuances of studies employed, and reporting results

RCTs, Randomized controlled trials.

The meta-analysis represents a comprehensive, exhaustive survey of high quality trials on a focused clinical question/objective. There must be clearly articulated and reproducible predetermined criteria for inclusion, and a highly critical appraisal of the studies for quality and synthesis.

The title of “systematic review,” however, is not in and of itself an indication of quality. It is vital that the nurse anesthetist critically evaluate systematic reviews to determine the validity of the stated results. [Box 4.9](#) provides a list of questions to consider when appraising a systematic review. The validity of the trial methodology, the magnitude and precision of the treatment effect,

and the applicability of results to the patient or population of interest should all be considered.¹⁶

Questions to Ask When Evaluating a Systematic Review

- Did the review address a clearly focused question?
- Was a thorough search done of the appropriate databases?
- Were other potentially important sources explored?
- Did the review include the right type or types of study?
- Did the reviewers try to identify all relevant studies?
- Did the reviewers assess the quality of all the studies included? If so, how?
- If the results of the study have been combined, was it reasonable to do so?
- How are the results presented and what are the main results?
- How precise are the results?
- How sensitive are the results?
- Can the results be applied to your local population?
- Were all important outcomes considered?
- Should practice or policy change as a result of the evidence contained in this review?

Adapted from CASP UK. Critical Appraisal Skills Programme (CASP). *Systematic Review Checklist*. 31 May 2013. Accessed 2016 at http://media.wix.com/ugd/dded87_a02ff2e3445f4952992d5a96ca562576.pdf.

As with any research study, a quality systematic review demands a precisely defined research question. The clinical question should

incorporate patients or populations of interest, the intervention, comparisons (if any), and the outcomes of interest. The research question is especially important in a systematic review as it determines the relevance, and therefore inclusion, of associated studies. The search strategy is also critical to the validity of a systematic review. In most cases, searching one database isn't sufficient to yield all the important articles on a topic.¹⁷ Moreover, searching only published sources fails to eliminate publication bias, or the underrepresentation of negative results in published reports. A comprehensive search that is not limited to the English language and includes both published and unpublished sources is essential to minimize selection bias. Many authors of systematic reviews also seek out alternative data sources, including "gray literature" (theses, internal reports, pharmaceutical industry files, etc.) and raw unpublished data from primary studies.¹⁵

A systematic review is only as valid as the poorest quality study it includes. The validity of the incorporated studies is therefore paramount in determining the quality of a systematic review. The authors should specify the quality criteria used to evaluate each study and the quality rating ultimately given to each included study. At least two reviewers should independently assess study quality to reduce the risk of excluding relevant publications and to limit selection bias.¹⁶ The study design should also be appropriate for the clinical question to be answered.

Finally, the results of a systematic review should be an accurate reflection of the aggregated results of each primary publication. Conducting a sensitivity analysis is a useful means of assessing the accuracy of the review's results. A sensitivity analysis involves slightly modifying the parameters of the systematic review to account for possible bias. Changing the inclusion criteria, assigning quality ratings differently, incorporating unpublished studies, and including (or excluding) publications of lower quality should not significantly alter the review's overall results. If the key findings disappear when any of these parameters are modified, the review's conclusions should be interpreted with caution.¹⁵

Whenever possible, the nurse anesthetist should endeavor to use systematic reviews. Systematic reviews are those that incorporate (1) a comprehensive study retrieval process that minimizes

publication bias, (2) selection criteria that identify only relevant studies, (3) a critical appraisal of the emergent literature accomplished by knowledgeable and sophisticated clinicians and researchers, and (4) reproducible decisions regarding the relevance and methodologic rigor of the selected primary research. When the results of a systematic review are analyzed quantitatively, it is called a *meta-analysis*. The meta-analysis is explored next.

Meta-analyses.

The meta-analysis has gained an appropriate foot-hold in the anesthesia literature as the pinnacle of high quality empirical evidence. A meta-analysis is a systematic review that includes a quantitative statistical analysis of the findings that have emerged from several (or many) discrete studies examining a similar phenomenon. Its purpose is to provide an estimate of the overall benefit or risk of an intervention that has been gleaned from carefully selected RCTs (Fig. 4.6). Rather than simply pooling data from smaller studies, the meta-analysis accounts for differences in sample size, and variability in both study design and determination of the treatment effect.¹⁸ The meta-analysis draws on a heterogeneous group of patients studied in a range of trials and therefore achieves increased power to detect any clinically significant effects. The meta-analysis also provides a precise estimate of the size of any treatment effect that is revealed. A high-quality meta-analysis provides many benefits, including:

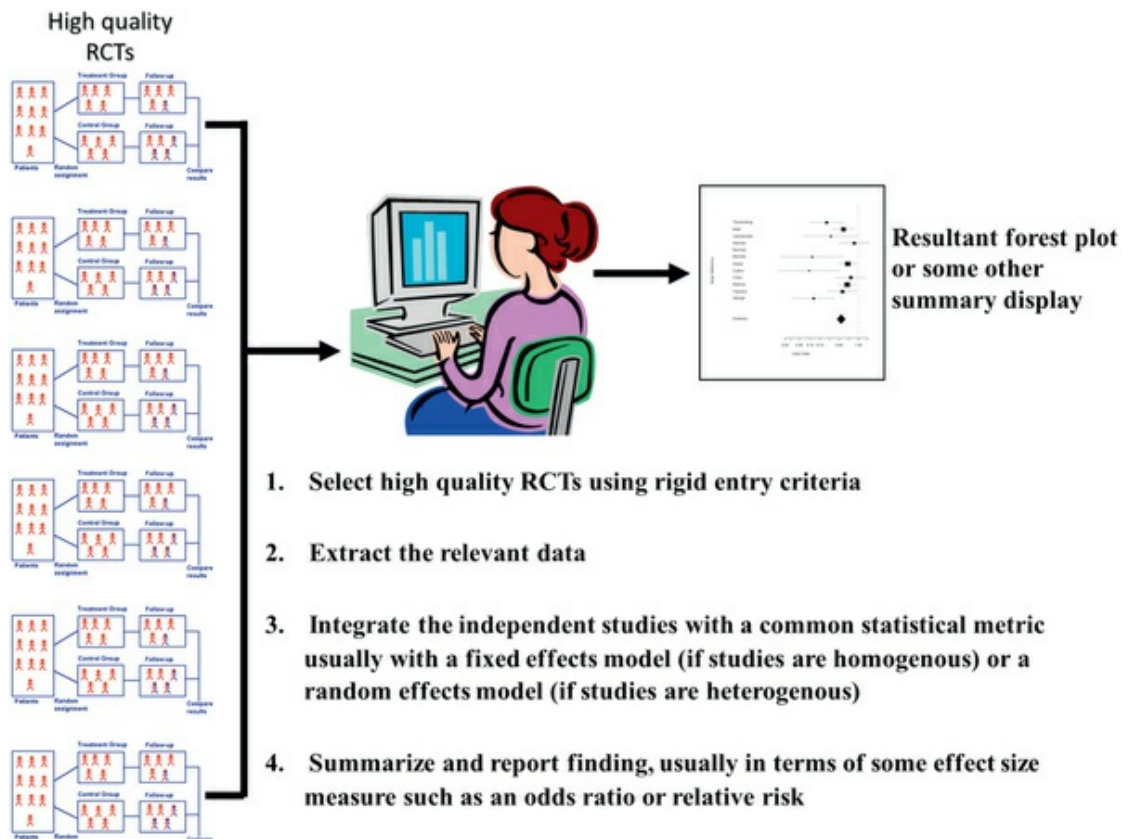

FIGURE 4.6 A meta-analysis is a systematic review that includes a quantitative statistical analysis of an intervention studied in carefully selected RCTs.

- A valid and weighted course of action based on aggregated studies
- Reduced overall risk of bias
- Estimation precision and determination of the effect size of an intervention in a defined patient group
- Transparency in the overall process, improving risk-benefit in a unique patient

Examples of anesthesia-based meta-analyses include those by Tramer, who examined ondansetron as an antiemetic; Ballantyne et al., who studied pulmonary outcomes in patients who had epidural analgesia; Lee et al., who looked at acupuncture and acupressure as alternative approaches in the management of postoperative emetic symptoms; and Biddle, who evaluated the use of nonsteroidal antiinflammatory drugs in the treatment of acute postoperative pain, and later compared the use of ephedrine and phenylephrine on newborn APGAR scores.¹⁹⁻²²

The steps involved in developing a meta-analysis are described in [Box 4.10](#). The need for rigor in a meta-analysis demands that there be a formal process for conducting it, allowing the researcher to account for the range of relevant findings from high quality, published research. The primary risk inherent in unsystematic, narrative reviews is that there is a great opportunity for bias in the retrieval, analysis, and critique of selected articles and reports. The meta-analysis overcomes these risks and distinguishes itself from the narrative review through methodological rigor, producing an [evidence-based synthesis](#) of the extant literature.

Steps Involved in a Meta-Analysis

1. List the objectives of the planned review of the randomized control trials.
2. Carefully describe the eligibility criteria for inclusion in the systematic review.
3. Seek research that meets the stated eligibility criteria.
4. Assess each trial or published source individually for its methodologic worth.
5. Assemble the best evidence with oversight (ensuring agreement for inclusion).
6. Analyze the assembled evidence using standard statistical procedures.
7. Compare other analyses, if available.
8. Write up the critical appraisal, carefully describing the previous elements, defining conclusions, and indicating potential applications to the care of patients.

As the distinguishing characteristic of both systematic reviews and meta-analyses is the rigor with which relevant evidence is retrieved, filtered, analyzed, and synthesized, it is especially important that the nurse anesthetist conduct a critical appraisal of

these studies before applying the results to clinical practice. Questions that should be asked when evaluating a meta-analysis are similar to those asked in the appraisal of a systematic review:

- Is there a focused, clearly written hypothesis?
- Are there stringent criteria for inclusion of studies in the analysis?
- Are exclusionary criteria justified?
- Are the included studies of high quality?
- Is there a systematic approach to evidence retrieval and filtering?
- Are the inclusion criteria strictly adhered to and meticulously described?
- How are the data analyzed and presented?
- Does the effect size measure provide insight into the direction and magnitude of the intervention being studied?
- Are alternative explanations or analyses considered?
- Is bias considered?
- Does the report include a critical examination of the review process?

An important attribute of the meta-analysis is that it is inclusive of all research that meets the established criteria. Unpublished dissertations, theses, and reports may prove to be important sources of information yet can be difficult to track and access. Discussions with acknowledged experts in the domain are often an efficient means by which to access these materials.

A meta-analysis commonly analyzes and reports results using one of several effect size measurements. [Table 4.10](#) presents a list of effect size measures frequently used in a meta-analysis. A common means of displaying data is the use of a pictorial representation, such as a forest plot, and a summary effect size measure such as an odds ratio. The forest plot displays the results of individual studies in comparison with the overall result of the meta-analysis. Squares represent an estimate of the mean result of each study. A horizontal line running through each square indicates the 95% confidence interval boundaries. The overall estimate of the treatment effect revealed by the meta-analysis and its confidence interval are found at the bottom of the plot, usually depicted as a diamond with a horizontal line running through it. In the middle of the plot, a

central line represents the threshold of statistical significance. The intervention has achieved a statistically significant treatment effect if the diamond is clear of this line. Generally, at the bottom of the forest plot is a line indicative of the odds ratio that reveals the overall magnitude of the effect (positive or negative), grounding it in clinically practical perspective (Fig. 4.7).

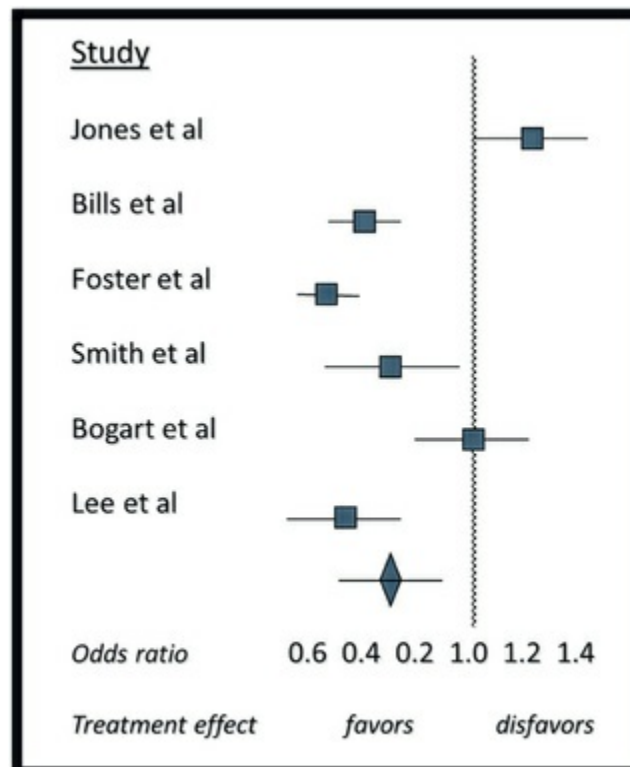

FIGURE 4.7 A typical forest plot. A meta-analysis was conducted on the effect of a drug preventing tachycardia. Of the six studies that met the criteria, four found tachycardia less likely to occur in the group receiving the drug compared to the control group. Another way of expressing these results is with an odds ratio, which gives the probability of a given person experiencing an outcome of interest (tachycardia) in a specific circumstance (taking a drug). Because the experimental group (in the numerator) was less likely to experience tachycardia than the control group (in the denominator), the odds ratio is less than 1.0. One of the studies found that people taking the drug were more likely to experience tachycardia, expressed as an odds ratio greater than 1.0. In this example, an odds ratio of less than 1.0 favors a treatment effect of the drug (less tachycardia), whereas an odds ratio of greater than 1.0 disfavors a treatment effect. A square

represents the mean effect seen in each study and horizontal lines show the 95% confidence intervals. A diamond indicates the combined odds ratio of all the studies and its confidence interval. A vertical line represents an odds ratio of 1.0, which indicates neither a greater nor lesser likelihood of tachycardia when the drug is taken, and thus neither a favorable nor unfavorable treatment effect.

Systematic reviews and meta-analyses are not perfect. Major objections to the meta-analysis and systematic review include:

1. The potential to combine studies of great variance in overall quality.
2. A possible failure on the researcher's behalf to fully consider variations in subjects, methods, interventions, or outcomes measurement.
3. A nonlinear effect of the intervention—a limit (above or below) in which one factor has little or no effect on the other.

Careful reading and thoughtful analysis of any published article, whether a case report, a retrospective review, an RCT, or a systematic review, is a responsibility the nurse anesthetist must assume before making direct application of findings to a patient. EBP does not and cannot rely on any one published source. The burden is on the nurse anesthetist to navigate the best possible course of action for the patient's unique circumstance.

Step 4: Applying Evidence to Your Patient

Translating knowledge into practice is the next critical step. If it has been determined that the evidence is valid and important, you must now decide whether you should apply it to the care of your patient. EBP then becomes an ongoing process of inquiry, asking, “Why am I doing it this way?” and “Are there compelling reasons for me to do it differently to achieve a better outcome?” [Box 4.11](#) provides a list of questions that must be asked when preparing to apply an intervention to a patient. The factors influencing these decisions are complex. Ultimately, the decision to implement an intervention is a

blend of experience and science as the value of the evidence is carefully assessed in the context and setting of a particular patient. What is meant by context? [Box 4.12](#) illustrates just a few of the [contextual](#) factors that must be considered in the process of EBP.

Applying an Intervention to a Patient

- Is the patient well represented by the studies selected?
- Is the planned intervention one with which we are familiar and experienced?
- What are the risks of the intervention: do the benefits outweigh the drawbacks?
- When possible, has the patient been adequately informed and drawn into the decision-making process?

Box 4.12

Some Contextual Considerations in the Process of Evidence-Based Clinical Practice*

Considerations in Weighing the Application of a Therapy in a Particular Patient

- Age and gender
- Hydration status
- Smoking history
- Current drug therapy
- Duration of illness
- Severity of symptoms
- Cost of therapy

- Side effects
- Inpatient or outpatient
- Coexisting conditions
- Physician and staff familiarity and experience with intervention
- The degree of technical mastery necessary to perform the intervention
- Staff makeup (specialists, generalists)
- Type of hospital (community, medical center, urban, rural)
- Support personnel
- Is reasonable follow-up available to assess the intervention's outcome?

*The list is partial and meant only to stimulate thinking regarding how factors may influence the application and outcome of a particular intervention.

Often underemphasized in a discussion of EBP is the essential value of clinical experience and clinical judgment, as well as an understanding of individual patients in the context of their personality, culture, and unique experiences. Even with a substantial amount of meaningful evidence to apply, a lack of experience and judgment may result in enormous faltering in its application to individual patients. Experience and judgment are indispensable when considering and ranking interventional options. Certainly, part of the process of EBP is based on consideration of the skill of the clinicians in the studies selected to evaluate and whether all important outcomes have been measured. Similarly, sensitivity to a patient's desires and beliefs is vitally important in taking full advantage of an EBP approach to care.

Most EBP related to anesthesia occurs under circumstances in which the patient's input is likely to be minimal to nonexistent (e.g.,

choice of neuromuscular blocking drug, intraoperative fluid management, selection of antifibrinolytic, approach to managing body temperature and its measurement, and type and settings of ventilator management). However, many decisions should actively involve patients, especially risk-benefit comparisons (e.g., regional vs general anesthesia, perioperative blood transfusions, postoperative nausea and pain control, and management of the risks of vision disturbances and peripheral nerve injury).

Although one goal of EBP is to provide the best care possible in the unique contextual situation of a given patient, another is for nurse anesthetists to act as patient advocates. Basing interventions on the triad of the latest research evidence, clinical expertise and experience, and the needs and wishes of the patient (Fig. 4.8) requires nurse anesthetists to act as patient advocates throughout the process. EBP is, by definition, the marriage of excellent clinical science with humanitarianism. Extracting the contextually essential, highest-quality information from the vast, representative research literature and merging it with the art of applying that information to a patient is EBP at its finest. Next, it is time to evaluate the outcome of the intervention.

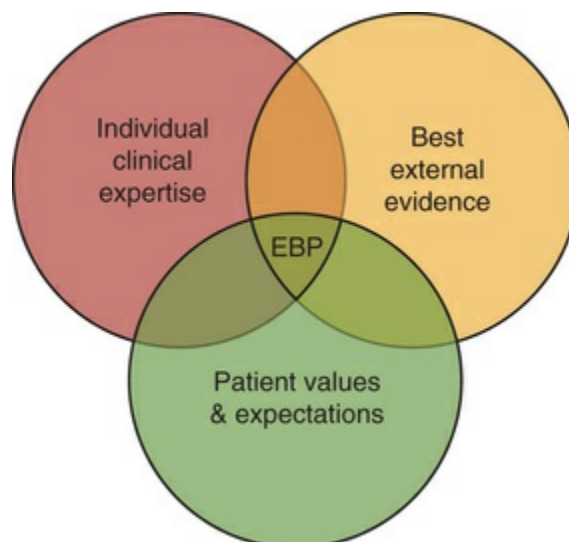

FIGURE 4.8 Evidence-based practice (EBP) combines a practitioner's individual experience with the highest quality empirical evidence and the needs of the patient.

Step 5: Evaluating the Effect (Outcome) of the Evidence-Based Intervention

A vital component of the process of EBP is evaluation. Here one determines whether the evidence has altered the “usual” practice pattern. If so, has it been associated with improved efficiency and health outcomes, and has it maintained the quality of care?

Evaluation allows not only for deciding whether the intervention “works” but also for determining whether variations arise (e.g., dosing, timing, duration, complications, and unexpected occurrences). In doing so, a kind of living, evolving document arises that can be used for purposes of assessing efficacy, quality assurance, and risk.

Evidence-Based Practice in Nurse Anesthesia

Evidence-based practice is the hallmark of quality anesthetic care. Whereas nurse anesthetists are increasingly likely to assume the role of primary researcher, all nurse anesthetists regardless of research experience are in a position to read about the latest advances in nurse anesthesia practice and incorporate validated interventions into their clinical practice. Nurse anesthesia research is grounded in solving patient-care problems during the preoperative, intraoperative, and postoperative periods. Although much behavioral, educational, and product evaluation-oriented research has been conducted by nurse anesthesia researchers, all nurse anesthesia research is wedded inextricably to patient care. EBP is essential to the professional evolution of nurse anesthesia as nurse anesthetists become increasingly accountable for their own independent basis for practice.

A number of antiscience movements are operative in the world today. At the heart of all these movements is the sophisticated use of the concept of proof by proclamation rather than proof by experimentation. As active consumers and producers of scientific knowledge, nurse anesthetists can do their part by resisting the integration of aberrant and ill-founded thinking into their discipline. This can be achieved if each nurse anesthetist understands the need to maintain a critical dialogue regarding what can be incorporated into nurse anesthesia practice.

All nurse anesthetists are mandated to practice evidence-based care. The American Nurses Association strongly urges even undergraduate nursing students to learn how to read, interpret, and evaluate published research for applicability to nursing practice. Although the evolution of nursing research—and that of nurse anesthesia research in particular—has lagged behind that of many other disciplines, tremendous strides are being made as greater numbers of nurse anesthetists are prepared at both the master's and doctoral levels. It is essential that nurse anesthetists recognize the need to promote nurse anesthesia as a science-based profession.

There is no better way to achieve this end than to continue emphasizing the importance of EBP.²³

Summary

Basic fluency in research methods is essential to today's anesthesia practice. The ability to evaluate the literature allows the clinician to stay up to date with the rapid advances in medical knowledge. It also gives the anesthetist an avenue to answer questions that arise in daily practice with appropriate evidence to ensure the best patient care and outcomes.

General Principles, Pharmacodynamics, and Drug Receptor Concepts

John J. Nagelhout

The practice of anesthesia requires a full spectrum of drugs from which an anesthetic plan can be implemented to achieve the desired level of surgical anesthesia, analgesia, amnesia, and muscle relaxation. In addition to surgical anesthesia, pain medicine has evolved as a significant clinical practice component.^{1,2} Now that the human genome has been mapped and the field of molecular and cellular proteomics is exploring new concepts; specific receptor-targeted drugs are envisioned, as is a revolution in the way health care is delivered. Likewise, the methods used to provide anesthesia care will undergo a profound change based on this new knowledge. Studies are already challenging long-held concepts of pharmacodynamics and pharmacokinetics that guide the clinical use of anesthetic agents. Target-controlled drug administration that factors in clinical pharmacodynamic and pharmacokinetic information is already being applied.^{3,4}

Although the mechanism of action of the general anesthetics remains unknown, the primary site of anesthetic action is now considered to be membrane receptors and not the lipid bilayer surrounding the nerve cells.⁵⁻⁷ It remains unclear how the inhalation anesthetic drugs affect the brain to suppress consciousness and movement. The picture that is emerging includes multiple cellular and molecular targets in distinct brain regions that are involved in both the desired and adverse effects of general anesthetics. Consciousness is inhibited in the brain of course, but movement may be obtunded at the spinal cord level.^{8,9}

Spinal cord receptors are being differentiated from receptors in the brain and targeted with specific drugs. A more in-depth

knowledge of the concept of minimum alveolar concentration, which is used to define inhalation anesthetic dosing, is now coming to light.^{10,11} Receptor super families with definable amino acid subunits are the targets of new classes of anesthetic drugs such as α_2 -agonists and analgesics.¹² The potentiation of the inhibitory γ -aminobutyric acid (GABA) receptors is considered a primary mechanism of action of inhalation and intravenous anesthetics.¹³ The recovery from intravenous anesthesia is described in terms of context-sensitive halftime, which in addition to the usual concept of drug half-life takes into consideration the duration of anesthetic administration rather than just drug redistribution and elimination profiles.¹⁴⁻¹⁶

The importance of the individual, with his or her unique genetic profile, is surfacing as a major determinant of anesthesia outcome.^{17,18} The number of patients who now make up the portion of the population classified as elderly—those age 60 years and above—is ever increasing. Clinical experience has shown that the response to anesthetic drugs in elderly patients differs from that in younger patients. Age-related changes in drug pharmacokinetics do not totally explain the differences in drug dosing necessary to achieve anesthetic end-points in elderly patients. Studies to date in elderly patients demonstrate an age-related decline in most receptor populations and an overall decrease in pharmacodynamic responses.¹⁹⁻²² Preoperative assessment may soon take on an entirely different meaning as patient information becomes more genetically oriented. The choice of anesthetic agents will be based on age-related receptor profiles and the patient's genetic ability to rapidly clear and recover from anesthetic drugs once their administration has been terminated.²³⁻²⁶ Until that time, anesthesiologists will continue to administer anesthesia based on age-indexed population drug profiles adjusted for individual pathologies (i.e., general principles of pharmacology).

The current medical economic climate necessitates the optimum selection and use of anesthetic drugs based on their pharmacologic profiles. The term *pharmacology* refers to the study of processes by which a drug produces one or more measured physiologic responses. The concept of a drug-induced tissue response has changed little since Ehrlich first proposed it (circa 1905). What has

changed, and continues to change, is our understanding of the processes involved in drug-receptor interactions.²⁷⁻²⁹ Attention is now being focused on the biosphere or the protein receptor site, as not only the locus of drug binding, but also a primary regulator of the measured pharmacologic response. Secondary processes, including drug absorption, distribution, biotransformation, and excretion, also influence the pharmacologic response.³⁰

Receptor Structure

A *receptor* is a protein or other substance that binds to an endogenous chemical or a drug. This coupling causes a chain of events leading to an effect. Receptors have three common properties: sensitivity, selectivity, and specificity. These properties are characterized by the fact that a **drug response occurs from a low concentration (sensitivity) produced by structurally similar chemicals (selectivity), and the response from a given set of receptors is always the same because the cells themselves determine the response (specificity)**. The bonds that form between drugs and receptors typically fall into these categories from weakest to strongest: van der Waals, hydrophobic, hydrogen, ionic, and covalent.

Drug Receptors

The historic concept of a drug receptor complex, considered the receptor to be a single protein to which the drug aligned and attached itself. We have now identified multiple mechanisms by which an endogenous substance or drug may complex with a receptor and transmit a signal. There are seven classes of drug receptor proteins based on genetic characterization and similarity of structure and functions.³¹ Some examples of different types of **Box 5.1** receptors are given in **Box 5.1**.

Receptor Classification

- G protein-coupled receptors
- Ligand-gated ion channels
- Ion channels
- Catalytic receptors
- Nuclear receptors
- Transporters

- Enzymes
- Other protein targets

Data from SPH Alexander et al. The Concise Guide to Pharmacology 2013/14: Overview. *Br J Pharmacol.*2013;170:1449-1458.

Drug receptor proteins may be located within the luminal membrane and at the surface of the ionic channel. They also occupy intracellular sites. The drug lidocaine and other amide and ester local anesthetics, for example, act at intracellular receptor sites near the sodium channel. Studies of acetylcholine and its receptor at the neuromuscular junction indicate that less than 1% of the cell surface binds drug to receptor protein to achieve the tissue response.³² Complete saturation of available receptors with drug molecules is not necessary for a desired tissue response to be elicited. With recent advances in molecular biology, many receptors have been extensively characterized, with amino acids sequenced and cloned. This is leading to new and better understanding of receptor pharmacology and new approaches to drug discovery.³³⁻³⁶

For intravenously administered drugs sufficient drug for a maximal tissue response is delivered to the receptor site within the time required for a single complete circulation (approximately 1 minute) provided an adequate drug dose was administered initially. Current understanding of molecular pharmacology suggests that the delay recorded from initial drug administration to the onset of the tissue response reflects the time required for molecular orientation and attachment to the receptor—that is, the time course of the receptor protein conformational change and the tissue response time.³⁷ As long as both the drug and the receptor are hydrophobic, bonding occurs.³⁸ Intravenous anesthetics act by binding to membrane receptor channel proteins. The GABA_A (ionotropic receptor family A) inhibitory receptor has been implicated and suggested as a primary site of intravenous anesthetic action, except in the case of ketamine.³⁹⁻⁴¹ Inhalation anesthetics have long been thought to produce their anesthetic action by dissolving in the lipid bilayer surrounding membrane ion channels and interfering with their ability to open and close. Electrophysiologic evidence gathered since 2011, however,

indicates that inhalation anesthetics, like intravenous anesthetics, bind to GABA_A receptor proteins and cause inhibition of signal transduction by increasing the influx of chloride ions through membrane channels.^{13,39-41}

Individual agonist drugs have at least three configuration points for attachment to their receptors. With more points of attachment a more perfect drug-receptor fit occurs. Agonist drugs can induce receptor proteins to alter their topography to achieve a more exacting fit with the drug. The alignment of a drug with its receptor is aided by various bonding forces, of which van der Waals forces and ionic bonding are prominent. Volatile anesthetics (e.g., desflurane, sevoflurane, isoflurane, and nitrous oxide) bond to cell receptors by means of a nonspecific hydrophobic bonding mechanism.

Some endogenous proteins provide alternative drug-binding sites. These sites are more correctly termed *acceptors*; the acceptor reduces the amount of unbound drug available for receptor complexing. Albumin contains numerous acceptor sites and generally binds to acidic drugs. α_1 -Acid glycoprotein and β -globulin favor basic drugs. Drugs bound to these proteins are unavailable to interact with receptors, therefore reducing the available active drug concentration.

Types of Receptors

As previously noted, a variety of receptor types have been isolated and investigated, including GABA, opioid, alpha, beta, acetylcholine, histamine subtypes, and the pain-related capsaicin receptor, in addition to numerous others.⁴¹⁻⁴⁵ The nicotinic and muscarinic cholinergic receptors that bind acetylcholine have been studied extensively.⁴⁶⁻⁴⁸ The acetylcholine receptor protein is a pentamer of five peptide subunits conceptually forming a five-sided ring with the central portion serving as the transduction ion channel. Only two of the five subunits are involved in acetylcholine binding. The remaining three peptide subunits participate in the signal transduction process that involves a protein conformational shift allowing inward movement of sodium ions through the opened ion channel. It is interesting to note that the GABA_A

receptor has also been shown to be composed of five peptide subunits arranged to form a pentameric ring.^{45,49–51}

Signal Transduction

In biology, *signal transduction* refers to processes by which a cell converts one kind of signal or stimulus into another. Most often these involve ordered sequences or cascades of biochemical reactions inside the cell. They are commonly referred to as *second messenger pathways*. An example of a G protein–coupled receptor (GPCR) and its second messenger system is shown in Fig. 5.1.

FIGURE 5.1 Major modes of signal transduction and intracellular signaling. Binding of an agonist to a receptor

ion channel (e.g., GABA_A receptor or nicotinic acetylcholine receptor) leads to opening of a transmembrane pore that permits movement of ions across the plasma membrane. This leads to a change in membrane potential that results in the physiologic response (e.g., change in the firing characteristics of a neuron or muscle contraction). Binding of a ligand to a receptor tyrosine kinase results in receptor dimerization and phosphorylation of the intracellular kinase domain. The activated (phosphorylated) kinase domain is then specifically recognized by proteins such as Src and phospholipase C that in turn activate a network of downstream effectors. These signal transduction pathways ultimately lead to changes in physiologic functioning of the cell such as glucose utilization and cell growth. Binding of a ligand to a seven-transmembrane domain G protein-coupled receptor (GPCR) results in the dissociation of the G protein into the membrane α subunit and the soluble $\beta\gamma$ dimer. The α subunit then interacts with downstream effectors such as adenylyl cyclase, which converts ATP into cAMP (a second messenger) that then modifies a number of effector proteins. The $\beta\gamma$ dimer can also exert direct cellular effects by modulating activity of a number of ion channels, for example. Effects of steroid hormones are mediated by intracellular receptors, which upon binding their ligand dissociate from a heat shock protein and translocate into the nucleus where they serve to modify gene expression by binding to hormone response elements in the promoter regions. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate; *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate; *Tyr*, tyrosine. (From Hemmings HC Jr, Egan TD. *Pharmacology and Physiology for Anesthesia*. Philadelphia: Elsevier; 2013.)

Many of the actions of the common anesthetic drugs are transduced through cell-surface receptors that are linked to GPCRs. Receptor signaling translates changes to G proteins that are then linked to a second messenger such as cyclic AMP (adenosine monophosphate) or cyclic GMP (guanosine monophosphate). These second messengers regulate enzymes such as protein kinases and phosphatases, which drive their ultimate intracellular actions. Some common second messengers and their physiologic and pharmacology targets are shown in [Table 5.1](#).

TABLE 5.1**Select Second Messengers**

Second Messenger	Target Responses	Common Drug Effectors
Cyclic adenosine monophosphate (cAMP)	Release protein kinases, beta receptor stimulation of energy release, inotropic and chronotropic cardiac effects, production of adrenal and sex steroids, many other endocrine and neural processes	Catecholamines, caffeine, milrinone
Phosphoinositides and calcium	Activate calmodulin	Lithium
Cyclic guanosine monophosphate (cGMP)	Activate protein kinases	Nitroglycerin and sodium nitroprusside

Signal transduction for the GABA_A receptor, for example, involves inward chloride ion movement through the opened central channel. The protein compositions of acetylcholine and GABA receptors are remarkably similar, despite their functional differences—specifically, acetylcholine and sodium ions transduce an excitatory signal, and GABA and chloride ions transduce an inhibitory signal.^{52,53}

For many drugs the composition of the receptor protein and the signal transduction process may be identical even though the drug-induced tissue response is not. The primary difference among drug receptor proteins may be only the selective binding subunits and the ion species moving through the channel.^{39,41,43,54,55} The specific peptide subunits are ultimately responsible for the pharmacologic properties of specificity, affinity, and potency.

In addition, specific isomers that have fewer side effects than the racemic mixture have been marketed. Drugs such as dexmedetomidine, ropivacaine, and cisatracurium are selective in their receptor binding and thus achieve a better clinical side effect profile.^{56,57}

Drug Response Equation

The drug response equation is fundamental to pharmacologic principles.³⁷ It is derived from the law of mass action and is shown in the following equation, where drug (D) combines with receptor (R) to form a drug receptor complex (DRC) that elicits a tissue response (TR).

What remains unique about this equation is that in most cases the drug receptor complex represents a highly selective process. Yet the resultant tissue response tends to vary from individual to individual, reflecting each individual's receptor and genetic profile and physiologic state. The basic drug response relationship conceptually depends on a common pharmacologic theory of drug action. This is the *occupancy theory*. Simply stated, the magnitude of a drug's effect is proportional to the number of receptors occupied. Although it is understood that drug receptor interactions have more complexity than this theory accounts for, it serves as a useful background for many pharmacologic concepts.

Pharmacogenetics

Pharmacogenetics is the study of genetically determined variations in response to drugs. This can include variations in how a drug is metabolized and also how drugs interact with intended and unintended targets in the body. Pharmacogenetic testing can be useful in ensuring accurate drug dosing, avoiding adverse side effects, and selecting drugs. A variety of pharmacogenetic tests are routinely used to guide treatment of oncology and infectious disease patients based on evidence of clinical benefit. Testing for mutations in patients' tumors is now a part of routine oncologic care for a growing variety of cancers, including breast, colon, lung, stomach, leukemia and lymphoma, and metastatic melanoma. The availability of low-cost sequencing of patient normal and tumor DNA is driving innovation in cancer care at a very rapid pace, and many more clinical applications of pharmacogenetic testing relevant to cancer care are in the pipeline for clinical release.

Genomic approaches are being used to discover new pathways in common cardiovascular diseases and thus potential new targets for drug development. In the case of clopidogrel, warfarin, and statins, the literature has become sufficiently strong that guidelines are now available describing the use of genetic information to tailor treatment with these therapies, and some health centers are using this information in the care of their patients. Further testing is ongoing to maximize clinical benefit.⁵⁸⁻⁶¹

Population Variability

Because the objective of pharmacologic intervention is to achieve a desired therapeutic response, anesthetists recognize that a range of responses to a given drug and dosage is possible within a patient population. Therapeutic drug doses reflect average doses of a “normal” population of individuals. Specific therapeutic doses for population subsets (e.g., pediatric, neonatal, geriatric, patients with cardiac or other chronic diseases) are available, thereby narrowing the degree of response variability for a given drug and clinical population. The age, sex, body weight, body surface area, basal metabolic rate, pathologic state, and genetic profile of an individual directly influence the pharmacologic response.

Given the increasing median age of the population in the United States studies of the influence of age on the responses to anesthetic drugs have increased. Steady-state plasma concentrations of hypnotic drugs such as midazolam and propofol and minimum alveolar concentrations (MAC) for inhaled anesthetics (e.g., desflurane, isoflurane, or sevoflurane) required to achieve desired anesthetic end-points decrease as age increases, independent of any age effect on drug pharmacokinetics.⁶²⁻⁶⁶ Unfortunately, the specifics responsible for the observed age-related decrease in an effective dose of anesthetic drugs is multifaceted. Receptor changes associated with aging and kinetic differences in the elderly are in part responsible for the variation in response. Dose reduction or the use of dosing algorithms for the elderly patient population is indicated.⁶⁷

Mean, Median, and Mode

A graphic description of the dose-response relationship is displayed in [Fig. 5.2](#). The theoretic normal distribution of quantal (desired) responses to increasing drug dose takes the shape of a gaussian curve. Theoretically the numbers of respondents on both sides of the mean (average dose) are equal, with the greatest percentage of individuals responding near the center of the curve. In a gaussian distribution curve, the mean, median, and mode are equidistant

from the two extremes.⁶⁸ Atypical responders fall at each end of the curve.

FIGURE 5.2 The theoretic normal frequency distribution of a drug response in a normal population.

On the curve, the mean dose is the arithmetic average of the range of doses that produce a given response. The median dose is that dose on either side of which half of the responses occur. The mode dose is the dose representing the greatest percentage of responses. The mean, median, and mode doses are often close but are rarely the same in actual dose-response curves.

Standard Deviation

The terms *standard deviation* (SD) and *standard error of the mean* (SEM) describe population response variability.⁶⁹ The SD provides information regarding the actual responses measured and their difference from the calculated mean. In Fig. 5.3, one SD makes up 68% of the responses (34% to the left and 34% to the right of the mean value); two and three SDs constitute 95% and 99.7% of the responses, respectively. The greater the SD, the less the mean reflects the central tendency of responses.

FIGURE 5.3 A normal distribution curve showing the standard deviation (SD) in relation to the mean (average) dose value.

Standard Error of the Mean

The SEM describes the variance of the mean. It is equivalent to the SD of the mean. By repeating the dose-response measurements on different, normally distributed populations, a slightly different mean dose value is obtained each time because the mean value is only an arithmetic average of the responses obtained. In Fig. 5.4, one SEM represents the range within which the mean value would occur on repeat testing 68% of the time, and two and three SEMs (not shown) represent the range within which the mean value would occur 95% and 99.7% of the time, respectively. Both the SD and the SEM are important statistical descriptors of observed drug responses in patient care and in research and reflect pharmacologic principles of population variance.⁶⁹

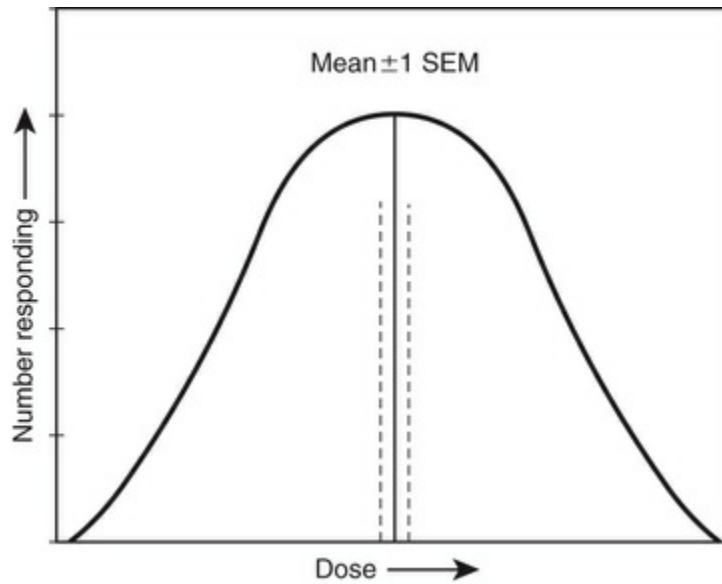

FIGURE 5.4 A normal distribution curve showing the relationship of the standard error of the mean (SEM) to the mean (average) value.

Drug Dose Response

The administration of drugs is largely determined by a mean therapeutic dose per kilogram of body weight or body surface area calculated from a previously determined average dose for the normal population. This approach may be responsible for underdosing and overdosing of patients because population variability is not considered in the calculation. The individual therapeutic response to a fixed mean dose is frequently less than optimal.

Studies that used sensitive quantitative measurement techniques identified a response variability to given drug doses in the normal population that was far greater than previously demonstrated.²⁷ Clearly, the optimal dosing approach for patients when drugs are administered by the intravenous route is by titration until the desired therapeutic response is attained. This is particularly true in critical care and anesthesia patients in whom drug onset and offset responses are relatively rapid.

Two types of dose-response curves—graded and quantal—describe average drug response and subject variability within a given population.

Graded Dose Response

The graded dose-response curve, which is plotted in linear fashion, characterizes the change in measured response as an administered dose is increased (Fig. 5.5). The response curve has a hyperbolic shape, with the greatest change in response occurring to the left on a small portion of the x-axis. When plotted on a logarithmic scale, the graded dose-response curve takes an S-shape; at the lowest dose, the measured response (e.g., vascular response to norepinephrine) is small or even nonexistent. At the highest doses, the response is maximal and approaches a plateau (Fig. 5.6). Typically, at some point between 20% and 80% of the maximal response, the curve approaches a straight line because changes in dose and response reflect a proportional relationship.

FIGURE 5.5 A linear arithmetic-graded response curve showing blood vessel constriction to increasing norepinephrine concentrations.

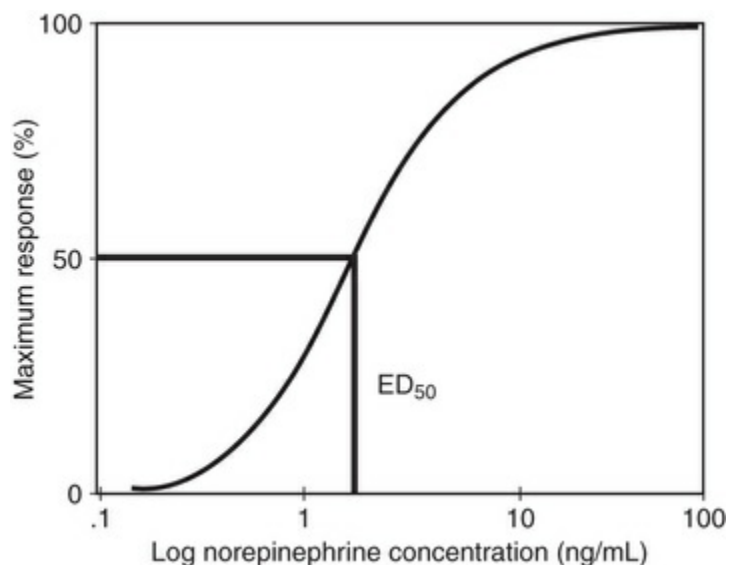

FIGURE 5.6 A logarithmic plot of the data from Fig. 5.5 showing blood vessel constriction to increasing concentrations of norepinephrine. The median effective dose (ED_{50}) is identified.

Plotting on a semilogarithmic scale, with the dose in log units, provides a more detailed representation of the entire graded dose-response curve especially at the two extremes.²⁷ From a semilogarithmic plot of graded dose responses, the potency of different agonist drugs with similar mechanisms of action (i.e.,

action through the same receptor) can be compared, or the ability of an antagonist drug to reduce the response to an agonist (e.g., in the alpha receptor blocker, phenoxybenzamine antagonism of norepinephrine-induced vasoconstriction) can be observed. It should be noted that “antagonist” drugs that do not bind to the agonist receptor are actually not antagonists. For example, neostigmine is not an antagonist of rocuronium because it does not compete with rocuronium for the muscle end-plate receptor site. Neostigmine inhibits acetylcholinesterase, which allows acetylcholine to compete effectively with rocuronium and other nondepolarizing muscle relaxants for the receptor, leading to a recovery of muscle tone. Therefore its effect is at least a partial form of indirect antagonism. Sugammadex is the first and, so far, only drug in a new class of muscle relaxant reversal drugs. Known as a *selective relaxant binding agent* (SRBA), sugammadex offers a unique mechanism in that it encapsulates the muscle-relaxant molecule rendering it inactive. The complex formed is eliminated. This is a form of chemical antagonism because no direct receptor action is evident.⁷⁰

Quantal Dose Response

Clinically, a quantal dose-response curve provides information on the frequency with which a given drug dose produces a desired therapeutic response in a patient population. The response is measured in an all-or-nothing fashion. The quantal response curve describes the variation in response to the threshold dose within a population of seemingly similar individuals (Fig. 5.7). For example, with propofol induction of anesthesia a small number of patients become unconscious after administration of 0.5 mg/kg, more after administration of 1 mg/kg, and virtually all after administration of 2 to 3 mg/kg. Plotting the cumulative number of patients with all-or-nothing responses over a range of doses produces an S-shaped response curve. However, the quantal dose S-shaped curve differs from the graded dose-response S-shaped curve because it reflects population variation for the threshold dose needed to produce a given all-or-nothing desired response.

FIGURE 5.7 A quantal dose-response curve indicating the frequency of all-or-nothing dose responses. The *dashed line* represents a histogram of the number of responses measured at each dose. The *solid line* represents the cumulative response curve of the total number of responses up to and including each dose.

Descriptive information about population dose-response characteristics can be obtained from quantal dose-response curves.²⁷ Descriptors such as effective dose, toxic dose, and lethal dose can be identified. The effective dose 99% (ED₉₉) and lethal dose 1% (LD₁) identify the therapeutic safety margin of a drug, as shown in the following equation.

$$\text{Safety margin} = \text{LD}_1 - \text{ED}_{99} / \text{ED}_{99} \times 100$$

When the therapeutic safety margin is great the risk of drug-induced death is small, and the margin of therapeutic safety is wide. The opposite is true when the therapeutic safety margin is small.

The term *therapeutic index* (LD₅₀/ED₅₀) describes a drug's median therapeutic safety margin for a particular therapeutic effect.²⁷ For example, chemotherapeutic drugs have a very narrow margin of safety. Drugs that produce surgical depths of anesthesia, such as sevoflurane and other halogenated anesthetics, also have a relatively narrow margin of safety. Sevoflurane is administered clinically in an amount that is 1.3- to 1.4-fold the MAC, or the dose

at which 50% of the patients do not move on surgical stimulation. The MAC can be lethal if the volume percentage delivered is increased to 1.7- to 2.0-fold and maintained for a prolonged period of time.

Another descriptor obtained from the quantal dose-response curve is the median effective dose (ED_{50})—the dose at which 50% of a population responds as desired. The ED_{50} is often used for comparing the potency of drugs within a class. Because the ED_{50} is derived from the linear portion of the quantal dose-response curve (20% to 80% of the responders), relatively accurate comparisons of drugs that cause similar responses can be made (see Fig. 5.6). Important in each of these descriptions is the word *median*. Median ED_{50} dose values are derived average response doses from a population of patients.²⁷ Each individual within the population responds, more or less, to a median dose on the basis of his or her biologic variation, or specifically, genetic variations in drug-receptor protein. Confidence limits for a given median dose and its therapeutic response can be calculated. Typically, the proportion of subjects responding to an ED_{50} dose ranges from 45% to 55%. Derived median population dose values provide a point of reference for achieving an individual's optimum therapeutic dose.

For intravenously administered drugs used in anesthesia, the trend is toward drugs that have brief onset-offset times and can be administered by infusion, often with the use of a computer-controlled pump.^{71,72} For example, the desired anesthetic response to propofol and remifentanyl can be effectively titrated after an initial loading dose.

Future developments related to drugs will include the availability of indwelling drug-analyzing probes similar to the continuous mass spectrometers currently used for analysis of end-tidal anesthetic gas concentrations. Real-time analysis of drug concentration can incorporate feedback control to drug-infusion devices. These target-controlled infusions allow the dose to be set to patient response and automatically maintained with minimal fluctuations in blood and effect site drug concentrations and the tissue response.^{73,74} Currently computer-controlled infusion pumps use programs based on pharmacokinetic modeling studies in an attempt to approximate the required effect site drug concentration to achieve and maintain a

desired level of anesthesia in patients. The continuing development of ultrafast onset-offset anesthetic drugs such as remifentanyl and propofol will simplify titration of the anesthetic end-point by the anesthetist and minimize undesired effects.

Drug Receptor Interactions

Advances in molecular receptor pharmacology have provided a new understanding of patient drug responses.²⁸ The *drug receptor interaction* describes the formation of a single drug receptor complex, which leads to a fractional tissue response (FTR):

The desired tissue response is observed when sufficient receptors have been occupied and activated by free drug. This process obeys the law of mass action: At steady state, equilibrium exists between bound and unbound drug receptors and the concentration of free unbound drug at the site.⁷⁵ Specific characteristics of the drug and the receptor determine the association and dissociation of a drug with regard to its receptor and the kinetic, k , rates, which are constants.³⁷

Drug Affinity and Efficacy

The terms *affinity* and *efficacy* (intrinsic activity) describe the degree of drug receptor interaction for a given drug and receptor protein population (e.g., GABA_A and propofol). The observed tissue response reflects the quantity of drug receptor complexes intact at any given moment. Each drug receptor interaction elicits a quantum of excitation, and the summation of many individual quanta produces the tissue response.⁶² The four concepts derived from a dose response relationship are potency, efficacy, variability, and slope. [Fig. 5.8](#) shows the overall clinical information derived from determining the dose response relationships.

FIGURE 5.8 Pattern produced in a dose-response population study in which both effect and toxicity are measured. The therapeutic window is shown as the range of therapeutically effective concentrations, which includes most of the efficacy curve and less than 10% of the toxicity curve. The therapeutic index is calculated by dividing the 50% value on the toxicity curve by the 50% value on the efficacy curve. (From Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 25th ed. Philadelphia: Elsevier; 2016:172.)

The time constant that describes the fractional tissue response after the drug receptor complex formation typically has been considered to be near zero or instantaneous. It was believed that the primary time constant thought to influence the onset of tissue response was the duration of the delay in the delivery of drug to the receptor sites. The phrase *pharmacokinetic analysis* of drug absorption and distribution describes onset time and magnitude of drug response. *Drug elimination kinetic analysis* describes the duration of the tissue response.

Drug-Receptor-Response Triad

Current understanding of receptor dynamics has added an additional and possibly the most descriptive component of the drug-receptor-response triad. When a drug combines with its receptor a conformational change occurs in the receptor protein itself. No tissue response can occur without the structural shift. Evidence does suggest that events within the biosphere after drug association with the receptor are the principal regulatory variables

of the response onset-offset time course.⁶⁹ An additional theory of drug action is referred to as the *two-state model*. In this model, the receptor is thought to exist in equilibrium between either an activated or inactivated state. Constitutively active receptors can exist and are shifted toward the activated state even though no agonist or ligand is present. Receptors for benzodiazepines, cannabinoids, and serotonin are examples. Agonists shift the equilibrium toward activation. Antagonists freeze the equilibrium, and inverse agonists shift the equilibrium toward inactivation.^{76,77} The two-state model is shown in Fig. 5.9.

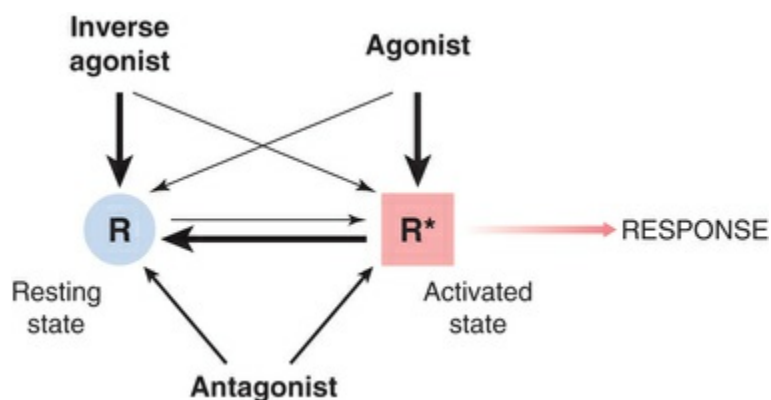

FIGURE 5.9 The two-state model. The receptor is shown in two conformational states, “resting” (R) and “activated” (R^*), which exist in equilibrium. Normally, when no ligand is present, the equilibrium lies far to the left, and few receptors are found in the R^* state. For constitutively active receptors, an appreciable proportion of receptors adopt the R^* conformation in the absence of any ligand. Agonists have higher affinity for R^* than for R , and so shift the equilibrium toward R^* . The greater the relative affinity for R^* with respect to R , the greater the efficacy of the agonist. An inverse agonist has higher affinity for R than for R^* , and so shifts the equilibrium to the left. A “neutral” antagonist has equal affinity for R and R^* , and so does not by itself affect the conformational equilibrium but reduces by competition the binding of other ligands. (From Rang HP, et al. *Rang and Dale's Pharmacology*, 8th ed. Edinburgh: Elsevier; 2016:14.)

Until recently, the terms *drug absorption*, *distribution*, and *elimination* were used solely to describe the tissue-response time course.⁷⁸ However, the response may be more complex than was

originally thought. It is now known that drug delivery sufficient to occupy 1% of the receptors is in many instances all that is required for a maximum tissue response to occur. Furthermore, the synthesis and destruction of receptor proteins occur at a much more rapid rate than was previously believed—within minutes rather than days. Receptor up-regulation and down-regulation can occur during drug infusion, with new receptor protein being synthesized in response to availability of free unbound drug.^{27,28,79,80}

Drug Antagonism

Pure Antagonists

Pure pharmacologic antagonist drugs are similar in molecular structure to their corresponding agonist drugs. However, owing to the addition or subtraction of one or more chemical moieties, they are unable to initiate the receptor protein conformational shift necessary for eliciting a tissue response. Such antagonist drugs have receptor affinity but lack intrinsic activity or efficacy.

Antagonists that possess the property of weak affinity for the same receptor protein (e.g., atropine, esmolol) are competitive and may be displaced by an agonist. Noncompetitive antagonists, such as phenoxybenzamine and aspirin, have a strong affinity for the receptor protein, usually via covalent bonds, and cannot be displaced by the agonist.⁸¹ New receptor protein must be synthesized if agonist receptor complexing is to occur.^{80,81} As with agonist drugs, not all receptors are bound by antagonists. Antagonists cause a rightward shift in the drug dose-response curve. The extent of rightward shift reflects the number of available receptors occupied by the antagonist drug (Fig. 5.10). Comparison of the ED_{50} in Fig. 5.10 shows a reduced affinity of the agonist for its receptor when the antagonist is present.

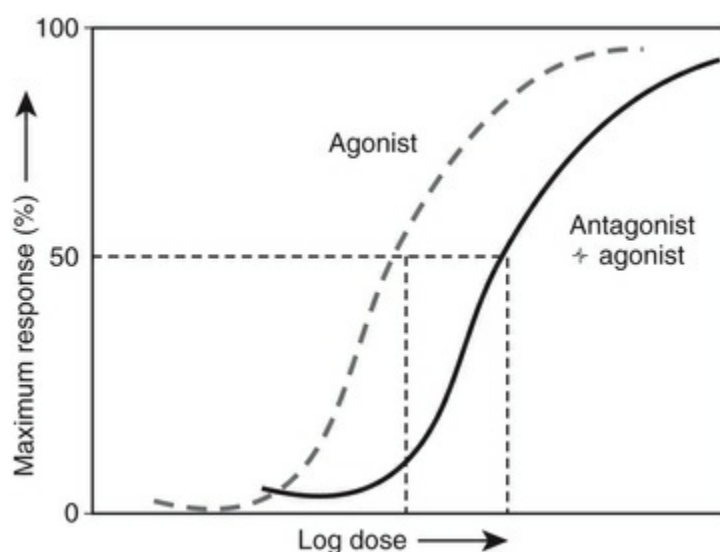

FIGURE 5.10 A logarithmic dose-response curve that

shows an agonist drug response alone (*dashed line*) and in the presence of an antagonist drug (*solid line*).

Agonist-Antagonists

Agonist-antagonists are the second major type of antagonist drugs.²⁵ As the name implies, agonist-antagonist drugs have receptor protein affinity and intrinsic activity, but often only a fraction of the potency of the pure agonist. Narcotic antagonists are often of the mixed agonist-antagonist type, such as nalbuphine. The mechanism by which agonist-antagonist drugs elicit less of a tissue response is not fully understood. An incomplete receptor protein conformational shift has been suggested.

Physiologic Antagonism

Physiologic antagonism, another form of antagonism, involves two agonist drugs that bind to different receptors.²⁷ For competitive antagonism, the agonist and antagonist have affinity for the same receptor protein; in contrast, in physiologic antagonism, both drugs bind to specific unrelated receptor proteins, initiate a protein conformational shift, and elicit individual tissue responses. The responses, however, generate opposing forces such as are observed with isoproterenol-induced vasodilation and norepinephrine-induced vasoconstriction. The net effect on blood pressure is less than it would be if either drug were used by itself. The drug response that predominates depends on the intrinsic activity of each and on the extent of the tissue response that can be elicited.

Chemical Antagonism

Chemical antagonism occurs when a drug's action is blocked and no receptor activity is involved. For example, protamine is a positively charged protein that forms an ionic bond with heparin, thus rendering it inactive. Sugammadex, mentioned previously, is another example.

Receptor Regulation and Adaptation

Receptors not only initiate regulation of physiologic and biochemical functions but also are themselves subject to many regulatory and homeostatic controls. These controls include regulation of the synthesis and degradation of the receptor by multiple mechanisms, covalent modification, association with other regulatory proteins, and/or relocation within the cell. Modulating inputs may come from other receptors, directly or indirectly, and receptors are almost always subject to feedback regulation by their own signaling outputs.

Continued stimulation of cells with agonists generally results in a state of desensitization, also referred to as *refractoriness* or *down-regulation*, such that the effect that follows continued or subsequent exposure to the same concentration of drug is diminished. This phenomenon is very important in therapeutic situations; an example is attenuated response to the repeated use of β -adrenergic agonists as bronchodilators for the treatment of asthma. Clinically the patient experiences tolerance; increasing doses are required to achieve the same effect.

Chronic administration of an antagonist results in up-regulation as the number and sensitivity of the receptors increase as a response to chronic blockade. Again the patient develops tolerance, requiring higher doses of the antagonist to counteract the increasing receptor number.

Drug Interaction Terminology

A drug interaction is an alteration in the therapeutic action of a drug by concurrent administration of other drugs or exogenous substances. The common classification is given in [Table 5.2](#).

TABLE 5.2

Drug Interaction Terminology

Drug Interaction	Explanation	Viewed as an Equation
Addition	The combined effect of two drugs acting via the same mechanism is equal to that expected by simple addition of their individual actions. EXAMPLE: midazolam plus diazepam	$1 + 1 = 2$
Synergism	The combined effect of two drugs is greater than the algebraic sum of their individual effects. EXAMPLE: Midazolam plus propofol	$1 + 1 = 3$

Potentiation	The enhancement of the action of one drug by a second drug that has no detectable action of its own. EXAMPLE: penicillin plus probenacid	$1 + 0 = 3$
Antagonism	The action of one drug opposes the action of another. EXAMPLE: fentanyl plus naloxone	$1 + 1 = 0$

Summary

The pharmacologic principles described in this chapter are essential to understanding drug responses in patients. The drug receptor subunit site is the primary regulator of onset-offset drug response. More and more evidence suggests that individual genetic variation in receptor proteins accounts for drug-response variation within seemingly normal populations. In clinical anesthesia, the range of patient responses to a given drug dose reflects this variation. The trend toward dosing by titration with rapid onset and offset anesthetic drugs minimizes the response variability factor by optimizing the use of available receptor proteins.⁸² The age-related decline in anesthetic drug dose needed to achieve a desired anesthetic end-point is related to a change in both pharmacodynamics and pharmacokinetics.

The anesthetist uses pharmacologic intervention to elicit a desired patient response. The site of the intervention is the biosphere, or the protein drug receptor, which is the primary regulator of the therapeutic response. Observed variation in patient drug response reflects the functionality of the biosphere and genetics, in addition to physiologic variability.

The mean, median, and mode typically describe the dose-response relationship of a “normally distributed” population. In anesthesia, the patient population is rarely “normal.” The drug response of population subsets can be expected to vary around the mean dosage. The trend toward dose titration by infusion allows individualization of the desired drug response, with fewer resultant overresponses and underresponses. The SD, SEM, and median effective dose provide a description of a population's response to a drug. Such descriptors provide only an approximate dosage; the clinician must adjust this dosage for each patient to achieve the desired physiologic response. Viewed at the molecular level, the observed response to a drug represents countless individual drug responses at the biosphere. Each drug-receptor interaction at the protein receptor elicits a fractional tissue response, and the sum of the fractional responses provides the observed response. In accordance with the law of mass action, when free drug binds to a

receptor, a conformational shift occurs in the receptor protein. This shift causes a central space or channel to open, allowing specific ions to enter or leave the cell or a G protein to be activated, resulting in a biochemical cascade yielding pharmacologic effects. The resultant tissue response continues until the drug dissociates from the receptor. Antagonist drugs also bind to the receptor but lack the ability to initiate the required protein conformational shift. The sum of fractional tissue responses elicited when an antagonist is present is inadequate for maintaining the desired tissue response.

Box 5.2 Common pharmacodynamic concepts are given in **Box 5.2**.

Pharmacodynamic Concepts

- **Agonist:** An agonist is a substance that binds to a specific receptor and triggers a response in the cell. It mimics the action of an endogenous ligand (such as hormone or neurotransmitter) that binds to the same receptor. In adequate concentrations, it can cause maximal activation of all receptors (a full agonist).
- **Antagonists:** An antagonist is a drug that has affinity for the receptor but no efficacy. It does not activate the receptor to produce a physiologic action. By occupying the receptor, it may block an endogenous chemical response, thereby producing a physiologic consequence. Antagonists commonly have a higher affinity for a given receptor than do agonists. Types of antagonism include pharmacologic, in which competitive is reversible and noncompetitive is irreversible, requiring syntheses of new receptors to reestablish homeostasis. Pharmacokinetic, chemical, and physiologic antagonism may also occur.
- **Affinity or potency:** When considering agonists, the term *potency* is used to differentiate between different agonists that activate the same receptor and can all produce the same maximal response (efficacy) but at differing concentrations. The most potent drug of a series requires the lowest dose.
- **Efficacy or intrinsic activity:** The efficacy of a drug is its ability to produce the desired response expected by stimulation of a given receptor population. It refers to the maximum possible effect that

can be achieved with the drug. The term *intrinsic activity* is often used instead of efficacy, although this more accurately describes the relative maximum effect obtained when comparing compounds in a series.

- **Partial agonist:** A partial agonist activates a receptor but cannot produce a maximum response. It may also be able to partially block the effects of full agonists. It is postulated that partial agonists possess both agonist and antagonist properties, thus the term *agonist-antagonist* has been used. A partial agonist has a lower efficacy than a full agonist.
- **Inverse agonist:** A drug or endogenous chemical that binds to a receptor, resulting in the opposite action of an agonist. Using the two-state model they appear to bind preferentially to the inactivated receptor. They may have a theoretic advantage over antagonists in situations in which a disease state is partly due to an up-regulation of receptor activity.
- **Spare receptor concept:** The relationship between the number of receptors stimulated and the response is usually nonlinear. A maximal or almost maximal response can often be produced by activation of only a fraction of the receptors present. A good example can be found in the neuromuscular junction. Occupation of more than 70% of the nicotinic cholinergic muscle receptors by an antagonist is necessary before there is a reduction in response, implying that a maximal response is obtained by activation of only 30% of the total number of receptors.
- **Tolerance:** Individual variation can result in a situation in which an increasing concentration of drug is required to produce a given response. This usually results from its chronic exposure to the agonist. Very rapid development of tolerance, frequently with acute drug administration, is referred to as *tachyphylaxis*. The underlying mechanism may not be clear. Common causes include up- or down-regulation, enzyme induction, depleted neurotransmitter, protein conformational changes, and changes in gene expression.

- **Ligand:** In biochemistry, a ligand is a molecule that is able to bind and form a complex with a receptor to produce a biologic response. Ligands are endogenous chemicals such as neurotransmitters and hormones that are exogenously administered drugs.
- **Quantal drug response:** Using dose response curves, the actions of a drug can be quantified and expressed as the effective dose ED_{50} , toxic dose TD_{50} , and lethal dose LD_{50} . The therapeutic index is the LD_{50}/ED_{50} .
- **Receptor adaptation or homeostasis:** The number and activity of a receptor population may increase or decrease in response to (usually) chronic drug administration. *Up-regulation* is the process by which a cell increases the number of receptors to a given drug. *Down-regulation* is the process by which a cell decreases the number of receptors for a given drug in response to chronic stimulation. β -Adrenergic receptors, for example, up-regulate in the presence of antagonists and down-regulate in the presence of agonists.
- **Tachyphylaxis:** Acute tolerance; the rapid appearance of a progressive decrease in response to a given dose of a drug after continuous or repetitive administration.
- **Efficacy:** The ability of a drug to produce a desired effect or the maximum response. Efficacy is the magnitude of response with respect to the given dose.
- **Ceiling Effect:** The ceiling effect of a drug refers to the dose beyond which there is no increase in effect. Additional dosing often leads to adverse effects.
- **Therapeutic Window:** the dosage range of a drug that provides safe effective therapy with minimal adverse effects

Molecular pharmacology is identifying site-specific and age-related causes for the observed variation in patient drug response. The fact that we can now sequence and clone many of the receptors

and other proteins responsible for a drug's action is rapidly increasing our understanding of pharmacologic events.

Pharmacokinetics

John J. Nagelhout

Pharmacokinetics is a term used to describe the study of the changes in the concentration of a drug during the processes of absorption, distribution, metabolism or biotransformation, and elimination from the body. Essentially, it is the study of what the body does to a drug once the agent has been introduced into the system. The knowledge of this discipline is important to understanding the time course and disposition of the anesthetic drugs and the variability of responses from patient to patient. Knowledge of pharmacokinetic concepts is vital for the delivery of serum concentrations that will result in desired effects while minimizing side effects.

Regardless of the route of administration, the vascular system delivers the drug to various tissues. Therefore, most kinetic concepts revolve around assessment of blood level over time, even if the correlation with the amount of drug at the effector site is poor. Once in the blood, the drug can either remain within the vascular system and body water, bound to proteins, or cross membranes to enter tissues. The unbound drug enters organs, muscles, fat, and of greatest importance, the site of activity—the receptors. This transfer of drug to various sites depends on several intrinsic properties of the agent, such as molecular size, degree of ionization, lipid solubility, and protein binding. In addition to these drug properties, uptake also depends on the amount of blood flow to the tissue and the concentration gradient of the drug across membranes.

Properties That Influence Pharmacokinetic Activity

Molecular Size

The smaller the molecular size of an agent, the better it crosses the lipid barriers and membranes of tissues. When a drug is administered, it must be absorbed across biologic membranes that have very small openings or pores. Generally, molecules with molecular weights greater than 100 to 200 do not cross the cell membranes. Transport across the membranes can occur passively or actively. Passive transport does not require energy and involves transfer of a drug from an area of high concentration to an area of lower concentration. Active transport mechanisms are generally faster and require energy. This transport system uses carriers that form complexes with drug molecules on the membrane surface and can involve movement of the drug molecule against a concentration gradient from an area of low concentration to an area of high concentration.¹ Fig. 6.1 depicts the movement of a drug across cell membranes.

FIGURE 6.1 Routes by which solutes can traverse cell membranes. (From Rang HP, Ritter JM, Flower RJ, et al. *Rang & Dale's Pharmacology*. 8th ed. Edinburgh: Elsevier; 2016:102.)

Drug Transporters

Many cell membranes possess specialized transport mechanisms that control entry and exit molecules, such as sugars, amino acids, neurotransmitters, and metal ions. They can be grouped as efflux or uptake transporters depending on the direction in which they flux their drug substrates through membranes. Efflux transporters drive their substrates out of cells, whereas uptake transporters transfer them into cells. Transporters may belong to the ABC (adenosine triphosphate [ATP]-binding cassette), the SLC (solute carrier) transporter, or the OST (organic solute transporter) families.^{2,3}

The SLCs control passive movement of solutes down their electrochemical gradient. The ABCs are active pumps requiring energy derived from ATP. Over 300 human genes are believed to code these transporters, most of which act on endogenous substrates; however, some drugs are also transported. Other SLCs are coupled to ATP-dependent ion pumps and transport can occur against an electrochemical gradient. It may involve exchange of one molecule for another, which is called *antiport* or transport of two molecules together in the same direction, referred to as *symport*. The main sites where SLCs, including organic cation transporters (OCTs) and organic anion transporters (OATs), are important are the blood-brain barrier, gastrointestinal (GI) tract, renal tubule, biliary tract, and placenta. Drug transporters are recognized as key players in the pharmacokinetic processes. Transporter proteins have a unique gatekeeper function in controlling drug access to metabolizing enzymes and excretory pathways. This can affect bioavailability, clearance, volume of distribution, and half-life for orally dosed drugs. A classification model referred to as the *Biopharmaceutics Drug Disposition Classification System (BDDCS)* categorizes drug transporter effects.^{4,5}

Degree of Ionization and Lipid Solubility

Most drugs are salts of either weak acids or weak bases. When introduced into the body, they behave as a chemical in solution. As acids or bases they exist in solutions in both ionized and nonionized forms. The charged (ionized) form is water soluble, and the uncharged (nonionized) form is lipophilic. Because the nonionized

molecules are lipid soluble, they can diffuse across cell membranes such as the blood-brain, gastric, and placental barriers to reach the effect site. On the other hand, the ionized molecules are usually unable to penetrate lipid cell membranes easily because of their low lipid solubility. This results from the electric charges exerted by the ionized drug molecules. These charged drugs are repelled by those sections of the cell membranes with similar charges, preventing their diffusion across the membrane.¹ The higher the degree of ionization, the less access the drug has across tissues such as the GI tract, the blood-brain and placental barriers, liver hepatocytes and renal reabsorptive membranes. This is important in that ionized drugs are not absorbed well when taken orally and may not be metabolized by the liver to a significant extent. Instead, they are commonly excreted via the renal system.⁶

Whether acidic or basic, the degree of ionization of an agent at a particular site is determined by the dissociation constant (pK_a) of the agent and its pH gradient across the membrane. The pK_a is the negative log of the equilibrium constant for the dissociation of the acid or base. The relationship between the pK_a of the drug and the pH of the solution may be expressed by two equations. The first equation applies to drugs that are **basic** in nature:

$$pK_a = pH = \log \frac{(HA^+)}{(A^-)}$$

The second equation applies to **acidic** drugs:

$$pK_a = pH = \log \frac{(A^-)}{(HA^+)}$$

From these equations, an estimate of the degree of drug absorption can be developed.^{6,7} **Acids** are usually defined as **proton donors**, whereas **bases** are made up of molecules that can **accept a proton**. When the pH is equal to the pK_a , the two species exist in equal amounts; for example, because phenobarbital has a pK_a of 7.4 and blood has a pH of 7.4, in the bloodstream the drug is present in

equal proportions of charged and uncharged forms.

It is of importance to note that relatively modest changes in the pH of the environment, when it is close to the pK_a , are more significant in changing the ratio of charged to uncharged forms than the same change in pH at some value far removed from the pK_a . For example, phenobarbital, with a pK_a of 7.4, is for the most part nondissociated and therefore is nonionized at a pH of 1.4. This results from the fact that the pH is well below the pK_a , and when phenobarbital is in a relatively strongly acidic environment with an abundance of protons, it does not give up its protons readily. If a drug is a **weak acid** and if the **pH** of the fluid environment is **below** the **pK_a** , most of the drug's protons are associated with the drug molecule, and the predominant species is **uncharged** and therefore **lipid soluble** (Fig. 6.2). Conversely, if the **pH is below the pK_a** for a drug that is a **weak base**, an abundance of protons exists, and most of the drug tends to **ionize** as the proton is donated by the drug molecule, which results in a species that is **highly charged** and therefore **lipid insoluble**⁶ (Fig. 6.3). The effects of pK_a and pH on ionization are summarized in Box 6.1.⁸ The pH ranges in various body compartments are noted in Box 6.2.

FIGURE 6.2 When acidic drugs are placed in physiologic

solutions, the degree of nonionization is greater if the pH of the solution minus the pK_a of the drug ($pH - pK_a$) is less than zero. Conversely, when the $pH - pK_a$ is greater than zero, more of the drug exists in an ionized, less absorbable form.

FIGURE 6.3 $pK_a - pH$ versus the percent ionized. The degree to which a basic drug remains in its nonionized state depends on the medium in which it is placed. pK_a is the dissociation constant (see text for further explanation).

Box 6.1

Relationship Between pH, pK_a , and Ionization for Weak Acids and Weak Bases*

Weak Acids

- If the $pK_a - pH$ is 1 or higher and the pH is lower than the pK_a , then the drug is essentially 100% nonionized and in a lipid-soluble form. It will **easily cross** biologic membranes.

- If the $\text{pH} - \text{pK}_a$ is 1 or higher and the pH is higher than the pK_a , then the drug is essentially 100% ionized and in a water-soluble form. It will **not cross** biologic membranes.

Weak Bases

- If the $\text{pK}_a - \text{pH}$ is 1 or higher and the pH is lower than the pK_a , then the drug is essentially 100% ionized and in a water-soluble form. It will not cross biologic membranes.
- If the $\text{pH} - \text{pK}_a$ is 1 or higher and the pH is higher than the pK_a , then the drug is essentially 100% nonionized and in a lipid-soluble form. It will easily cross biologic membranes.

For Both Weak Acids and Weak Bases

- If the $\text{pK}_a - \text{pH}$ is less than 1, regardless of whether the pH is lower or higher than the pK_a , the drug will be partially ionized (water soluble) and partially nonionized (lipid soluble), and if the dose is adequate, the nonionized fraction can cross biologic membranes.

*Rule of thumb for determining ionization: use absolute values for all calculations.

Box 6.2

pH of Select Body Fluids

Fluids	pH
Gastric juice	1.0–3.0
Small intestine: duodenum	5.0–6.0
Small intestine: ileum	7–8
Large intestine	7–8
Plasma	7.4
Cerebrospinal fluid	7.3
Urine	4.0–8.0

Ion Trapping

Ion trapping has several anesthesia-related applications. Influences on oral absorption of drugs, maternal-fetal transfer, and central nervous system toxicity of local anesthetics are commonly cited. The degree of ionization for a specific agent can vary across a membrane that separates fluids with different pH values. For example, morphine sulfate, a base with a pK_a of 7.9 when present in the blood (pH 7.4), exists in appreciable amounts in both ionized and nonionized forms. The uncharged drug fraction moves freely across tissue membranes, and the charged fraction does not. As the drug enters the stomach, a very acidic environment with a pH of 1.9, morphine accepts protons and becomes ionized, and ion trapping occurs.⁶ (Fig. 6.4 illustrates this phenomenon using diazepam as an example.) The drug, however, will be absorbed later, as stomach contents move farther down the GI tract to the more basic and favorable environment of the small intestine.

FIGURE 6.4 For both weak acids and weak bases, the total concentration of a drug is greater on the side of the membrane where it is more highly ionized. Diazepam, a basic drug with a pK_a of 3.3, is more ionized at gastric pH than it is in plasma. Consequently, it has a greater total concentration in the gastrointestinal (GI) compartment than it does in the plasma.

A similar scenario occurs when agents are transferred between a mother and a fetus, where the placenta is the membrane separating fluids with varying pH values—that of the fetus is more acidic than

that of the mother. Again, the lipid-soluble fraction of basic agents such as lidocaine (pK_a 7.9) crosses to the placenta easily. However, once there, because of the lower pH of the fetus, the drug becomes more ionized and cannot easily cross the lipid bilayer of placenta, resulting in accumulation of drug in the fetus. Finally, ion trapping may occur in a local anesthetic overdose situation in which high concentrations of a basic local anesthetic agent have entered the central nervous system and caused toxicity. If the patient experiences respiratory arrest and hypoxia, the resulting acidosis may trap the drug in the brain, resulting in prolonged and possibly more intense toxicity. Ion trapping also plays a role in the use of bicarbonate solutions and carbonated local anesthetics. A discussion of the effects of ion trapping on local anesthetics can be found in [Chapter 10, Box 10.3](#).^{9,10}

Protein Binding

Changes in protein binding have long been theorized to influence a drug's clinical effect. Two situations are commonly cited. The first involves a patient with a reduction in proteins, such as that which occurs with severe liver or kidney disease, with protein deficiencies caused by poor nutrition, and during the last trimester of pregnancy, when fluid shifts alter distribution volume. The second situation involves a drug interaction between two or more highly protein-bound drugs.

Potential clinical changes are conceptualized by the following phenomena. Some drugs are bound extensively to proteins in the plasma because of their innate affinity for circulating and tissue proteins. The drug-protein molecule is too large to diffuse through blood vessel membranes and is therefore trapped within the circulatory system. **Albumin** is quantitatively the **most abundant plasma protein**, and although it is capable of binding basic, neutral, or acidic drugs, it **favors acidic** compounds. Two other proteins, α_1 -acid glycoprotein (AAG) and β -globulin, favor binding to basic drugs.¹¹ Lipoproteins bind cyclosporine, and transcortin binds corticosteroids. Protein binding influences how a drug is distributed, because a protein-bound drug is not free to act on receptors. High protein binding prevents the drug from leaving the

blood to enter into tissue, which results in high plasma concentrations. The degree of protein binding for a drug is proportional to its lipid solubility such that the more lipid soluble **Box 6.3** agent, the more highly protein bound it tends to be (**Box 6.3**).¹²

Binding of Drugs to Plasma Proteins

- Plasma albumin is most important and is a source of species variation; β -globulin and α_1 -acid glycoprotein also bind some drugs that are bases.
- Plasma albumin binds mainly acidic drugs (approximately two molecules per albumin molecule). Saturable binding sometimes leads to a nonlinear relationship between dose and free (active) drug concentration.
- Extensive protein binding slows drug elimination (metabolism and excretion by glomerular filtration).
- Competition between drugs for protein binding can lead to clinically important drug interactions, but this is uncommon

Modified from Rang HP et al. *Rang and Dale's Pharmacology*. 8th ed. Edinburgh: Elsevier; 2016:108.

The number of potential binding sites on plasma proteins for drugs is finite; therefore, the kinetics for binding behaves like any saturable process in that protein binding can be overcome by adding more agents.⁴ The bond between drug and protein is usually weak, and they can dissociate when the plasma concentration of the drug declines or a second drug that binds to the same protein is introduced. For example, when a drug has been in chronic use and is at a steady state, an equilibrium will be reached between free and protein-bound drugs. If a new drug with a high affinity for the same protein sites is introduced, the new drug competes with the chronic drug for binding sites. This leads to displacement of the first drug with an increase in free fraction of that agent. It is important to note that the displaced free drug does become available for biotransformation and elimination, so unless these clearance mechanisms are at capacity, a rise in free fraction

will lead to a small change in free plasma concentrations.

Protein binding is expressed in terms of the percentage of total drug bound. Drugs with protein binding greater than 90%, such as warfarin, phenytoin, propranolol, propofol, fentanyl and its analogs, and diazepam, are conceptualized to have an unexpected intensification of their effect if they are displaced from plasma proteins.¹³ Drugs that exhibit less than 90% binding have so little change in free active fractions that they are not a concern. The anticoagulant warfarin is commonly used as an example. Because warfarin is approximately 98% bound to plasma proteins, a reduction in bound fraction to 96% causes an increase in the free active fraction of the drug. Furthermore, when hypoalbuminemia exists, decreased albumin levels result in the availability of a greater amount of free drug. These theoretic concerns are rarely clinically relevant, as explained subsequently.

No clinically relevant examples of changes in drug disposition or effects can be clearly ascribed to changes in plasma protein binding. The idea that a drug displaced from plasma proteins increases the unbound drug concentration, increases the drug effect, and perhaps produces toxicity seems a simple and obvious mechanism. Unfortunately, this simple theory, which is appropriate for a test tube, does not work in the body, which is an open system capable of eliminating unbound drugs.¹⁴

First, a seemingly dramatic change in the unbound fraction from 1% to 10% releases less than 5% of the total amount of drug in the body into the unbound pool, because less than one-third of the drug in the body is bound to plasma proteins, even in the most extreme cases (e.g., when warfarin is used). Drug displaced from plasma protein, of course, distributes throughout the volume of distribution, so a 5% increase in the amount of unbound drug in the body produces at most a 5% increase in the pharmacologically active unbound drug at the site of action.

Second, when the amount of unbound drug in plasma increases, the rate of elimination increases (if unbound clearance is unchanged), and, after four half-lives, the unbound concentration returns to its previous steady-state value. When drug interactions associated with protein binding displacement and clinically important effects have been studied, it has been found that the

displacing drug is also an inhibitor of clearance, and it is the change in *clearance* of the unbound drug that is the relevant mechanism explaining the interaction.

The clinical application of plasma protein binding is only to help interpretation of measured drug concentrations. When plasma proteins are lower than normal, total drug concentrations are lowered, but unbound concentrations are not affected.¹

Absorption

Routes of Drug Administration

An important variable in the bioavailability of a drug at its effect site is the route by which the agent is administered. The route of administration determines how much of the drug is delivered to the systemic circulation. When the entire amount of drug given is delivered, the drug is said to have *100% bioavailability*. Many routes of drug administration are used; each has advantages and disadvantages (Table 6.1). The routes of drug administration are enteral (involving the GI tract); parenteral (injected subcutaneously, intramuscularly, intravenously, intrathecally, or epidurally); pulmonary; and topical.¹⁵ Absorption mechanisms of relevance to anesthesia are discussed in the following sections.

TABLE 6.1
Routes of Administration

Route	Bioavailability (%)	Comments
Intravenous	100 (by definition)	Most rapid onset; allows for titration of doses; suitable for large volumes
Intramuscular	75 to 100	Moderate volumes feasible; may be painful
Subcutaneous	75 to 100	Smaller volumes than intramuscular; may be painful; suitable for implantation of pellets
Oral	5 to 100	Most convenient and economical; first-pass effect may be significant; requires patient cooperation
Rectal	30 to 100	Less first-pass effect than oral; useful in pediatric patients
Inhalation	5 to 100	Common anesthetic use for inhalation drugs, steroids, bronchodilators, and occasionally resuscitative drugs; very rapid onset (parallels intravenous administration)
Sublingual	60 to 100	Lack of first-pass effect; absorbed directly into systemic circulation
Intrathecal	Low (intentionally)	Specialized application, as with local anesthetics and analgesics, chemotherapy, and antibiotic administration; circumvents blood-brain barrier
Topical	80 to 100	Includes skin, cornea, buccal, vaginal, and nasal mucosa; dermal

		application results in slow absorption; used for lack of first-pass effect; prolonged duration of action
Intranasal	Up to 95%	Rich vascular plexus provides a direct route into the blood; best for lipid soluble agents; mist or atomized formulation is most effective; 0.25–0.3 mL ideal or up to < 1 mL of highly concentrated preparation; avoids gastrointestinal (GI) destruction and first pass metabolism; may rapidly achieve therapeutic brain and spinal cord (CNS) drug concentrations.
Intraosseous	Up to 100 depending on site	Recommended for emergency access when an intravenous line cannot be established such as during resuscitation or in pediatrics

Enteral Administration.

The oral route is the most common and convenient method for administration of drugs. It is relatively inexpensive, does not require a sterile technique, and can be carried out with little skill. However, several disadvantages exist because many conditions, such as emotions, physical activity, and food intake, change the GI environment. Thus orally administered drugs tend to have a lower bioavailability. The stomach has a large surface area, and the length of time a drug remains there is a significant factor in absorption. Because of the low pH in the stomach (1.5 to 2.5), drugs that are highly acidic, such as barbiturates, tend to remain nonionized and are highly absorbed. Basic drugs that remain intact in the stomach acids can pass through and are more readily absorbed in the intestine. The small intestine is highly vascular and has an alkaline environment (pH 7 to 8).¹⁵

The enteral route often results in failure of the drug to be absorbed into the systemic circulation. Alternatively, chemical alteration may occur before entry into the intestines. *Presystemic elimination* refers to the elimination of drug by the GI system before the drug reaches the systemic circulation. This occurs by means of three mechanisms: the stomach acids hydrolyze the drug (e.g., penicillin); enzymes in the GI wall deactivate the drug; or the **liver biotransforms the ingested drug before it reaches the effect site.**⁶ This liver activity is called *first-pass* hepatic effect. Drugs absorbed from the GI tract after oral ingestion enter the portal venous blood and pass through the liver first, with subsequent delivery to the tissue receptors. In the liver, they may undergo extensive hepatic extraction and metabolism before they have a chance to enter the systemic circulation (Box 6.4). Agents such as these exhibit large differences between oral and intravenous dosages. To have the

desired effect, oral dosages must be exaggerated to compensate for the initial metabolism that occurs before the drug reaches the effect

Box 6.4

Drugs That Undergo Substantial First-Pass Elimination

- Aspirin
- Glyceryl trinitrate
- Hydralazine
- Levodopa
- Lidocaine
- Metoprolol
- Morphine
- Cimetidine
- Felodipine
- Verapamil
- Neostigmine
- Midazolam

The role transporters play in drug absorption and distribution should be further clarified. The P-glycoprotein transporter is part of a larger family of efflux transporters found in the intestine, liver cells, renal proximal tubular cells, and capillary endothelial cells comprising the blood-brain barrier. Using ATP as an energy source, they transport substances against their concentration gradients. They appear to have developed as a mechanism to protect the body from harmful substances and can influence the ability of a drug to traverse barriers.

The sublingual and buccal routes of administration of drugs bypass the presystemic, portal system first-pass effect and are delivered rapidly to the superior vena cava for transport to the effect site.¹ Nitroglycerin is an example of a sublingual drug that is put under the tongue and absorbed by the rich blood supply there. If ingested, the drug would be hydrolyzed by the stomach; therefore sublingual administration is the ideal route for this agent. Protein hormones that would also be digested by the stomach are instead placed between the gum and cheek (buccal administration) and enter venous drainage without undergoing hepatic, presystemic elimination.^{16,17}

Occasionally, the rectal route of drug administration is the ideal route for prevention of emesis caused by irritation of the GI mucosa by the drug. It is also a preferred method of drug delivery for patients in whom oral ingestion poses difficulty. For example, rectal acetaminophen is administered to infants and young children undergoing general anesthesia for postoperative pain control. Drugs placed in the proximal rectum are absorbed into the portal system via the superior hemorrhoidal vein. They will therefore undergo significant first-pass effect in the liver before entering the systemic circulation, leading to unpredictable responses.¹ Conversely, agents placed in the distal rectum do not undergo presystemic elimination and therefore have more predictable circulatory levels. The disadvantage historically associated with this route was the unpredictability of drug retention and absorption because of rectal contents. However, studies carried out in 2010 have demonstrated that regardless of enema volume, agents are absorbed with consistent plasma concentrations within subjects.¹⁸

Parenteral Administration.

Parenteral administration refers to administration by injection. The most rapid and predictable route to the systemic circulation is the parenteral route. With intramuscular injections, the drug is instilled deep into the muscle among the muscle fascicles.⁶ Subcutaneous agents are placed under the skin. With both intramuscular and subcutaneous injections, the systemic absorption of the drug is dependent on the capillary blood flow to the area and the lipid solubility of the agent.¹ Conversely, intravenous injections allow for

rapid and accurate delivery of a drug into the systemic circulation. Parenteral administration is the route of choice for anesthetists, because it is an exact method of achieving the desired effect from agents delivered.

Pulmonary Administration.

The lungs provide a large surface area for drugs administered by inhalation. Bronchodilators and antibiotics are administered via devices such as nebulizers, used to propel aerosols into the alveolar sacs.¹⁸ Anesthetic gases are also effectively administered through the lungs, as described in detail in [Chapter 7](#).

Transdermal (Topical) Administration.

The transdermal route is usually chosen for administration of a sustained release agent, providing the patient with a steady therapeutic plasma concentration. Drugs that are administered via this route must possess several characteristics. They usually exist in a combined form; they are both water soluble and lipid soluble. The water solubility is necessary so the drug can penetrate the hair follicles and sweat ducts. Once in the system, the drug must be lipid soluble to traverse the skin and exert effect at the receptors. These agents must have a molecular weight of less than 1000, dose requirements less than 10 mg in a 24-hour period, and a pH of 5 to 9.¹ The area to which the drug is applied must have a relatively thin epidermis with a sufficient blood supply ([Fig. 6.5](#)).

FIGURE 6.5 The main routes of drug administration and elimination. CSF, Cerebrospinal fluid. (From Rang HP, Ritter JM, Flower RJ, et al: *Rang and Dale's Pharmacology*. 8th ed. Edinburgh: Elsevier; 2016:108.)

Bioavailability

Bioavailability is the extent to which a drug reaches its effect site after its introduction into the body. The rate at which systemic absorption occurs establishes a drug's duration of action and intensity. Many factors play a role in the bioavailability of agents, including lipid solubility, solubility in aqueous and organic solvents, molecular weight, pH, pK_a , and blood flow. For example, drugs given in aqueous solution are more rapidly absorbed than those given in oily solution or solid form because they mix more readily with the aqueous phase at the absorptive site.^{19,20}

The environment into which the drug is introduced also has an impact on its bioavailability. The patient's age, sex, pathology, pH, blood flow, and temperature are all factors to consider. For example, pH plays a role when local anesthetic (a weak base) is

injected into an infected wound (an acidic environment). In this instance, the local anesthetic is highly ionized (basic agent in acidic environment) and therefore cannot enter the lipid nerve membrane to reach the site of action.

The first-pass effect, which is also referred to as *first-pass hepatic metabolism* or *presystemic metabolism*, may occur when a drug is administered orally or, to a lesser extent, rectally. Metabolism occurs in the intestinal wall or the liver prior to the drug entering the systemic circulation. Venous drainage from most portions of the GI tract enters the portal circulation to the liver which may metabolize a drug, thus reducing the amount available for systemic release.

Therefore the first pass through the liver greatly reduces the bioavailability of the drug. Drugs with a high first-pass effect require a much larger oral dose than sublingual or intravenous doses. Four enzyme systems that are associated with the first pass effect are located in the GI lumen, gut wall, intestinal bacteria, and liver.²¹ Bioavailability ranges with different administration routes are shown in [Table 6.1](#).

Some drugs require metabolism to the active form before a clinical effect is seen. These drugs are administered as prodrugs and are converted from inactive to active form in the liver. This is usually done to improve some selected property of the molecule, such as water solubility or lipid solubility, in order to improve either absorption or distribution. Common prodrugs include dolasetron, amlodipine, levodopa, and quinapril.^{22,23} Some important concepts influencing absorption are listed in [Box 6.5](#).

Movement of Drugs Across Cellular Barriers

- To traverse cellular barriers (e.g., gastrointestinal mucosa, renal tubule, blood-brain barrier, placenta), drugs must cross lipid membranes.
- Drugs cross lipid membranes mainly by passive diffusional transfer or by carrier-mediated transfer.
- The main factors that determine the rate of passive diffusional

transfer across membranes are a drug's lipid solubility and the concentration gradient.

- Most drugs are weak acids or weak bases; their state of ionization varies with pH according to the Henderson-Hasselbach equation.
- With weak acids or bases, only the uncharged species (the protonated form for a weak acid; the unprotonated form for a weak base) can diffuse across lipid membranes; this gives rise to pH partition or ion trapping.
- The term *pH partition* means that weak acids tend to accumulate in compartments of relatively high pH, whereas weak bases do the reverse.
- Carrier-mediated transport involves solute carriers (SLCs), including organic cation transporters (OCTs) and organic anion transporters (OATs), and P-glycoproteins or P-gps (P for permeability, also referred to as ABC [ATP-binding cassette] transporters) in the renal tubule, blood-brain barrier, and gastrointestinal epithelium. These are important for determining the distribution of some drugs, are prone to genetic variation and are targets for drug interactions. Many are chemically related to endogenous substances.
- Drugs of very low lipid solubility, including those that are strong acids or bases, are generally poorly absorbed from the gut.
- A few drugs (e.g., levodopa) are absorbed by carrier-mediated transfer.
- Absorption from the gut depends on many factors, including the following:
 - Gastrointestinal motility
 - Gastrointestinal pH
 - Particle size

- Physicochemical interaction with gut contents (e.g., chemical interaction between calcium and tetracycline antibiotics)
- Bioavailability is the fraction of an ingested dose of a drug that gains access to the systemic circulation. It may be low because absorption is incomplete or because the drug is metabolized in the gut wall or liver before reaching the systemic circulation.
- Bioequivalence implies that if one formulation of a drug is substituted for another, no clinically untoward consequences will ensue.

Distribution

Compartment Models

Compartment models depict the body as composed of distinct sections that represent theoretic spaces with calculated volumes and are used to describe the pharmacokinetics of agents. These models are useful for prediction of serum concentrations and changes in drug concentrations in other tissues. A single-compartment model represents the entire body, through which homogeneous distribution occurs (Fig. 6.6A). Although a one-compartment model is sufficient to describe the action of many drugs, it is generally insufficient to explain the kinetics of lipid-soluble anesthetic drugs. A two-compartment model is typically used to simplify and explain pharmacokinetic concepts that can be extrapolated to more complex models.²⁴

FIGURE 6.6 **A**, In the one-compartment model, a drug instantaneously and homogeneously is distributed throughout the fluids and tissues that constitute the compartment. When changes in drug concentration occur in any of these tissues, a corresponding quantitative change occurs in drug concentration in all the other tissues. **B**, In the two-compartment model, the body is assumed to be made up of two compartments: a central compartment (C_1) made up of a small apparent volume (V_1) and a peripheral compartment (C_2) made up of a larger apparent volume (V_2). **C**, The three-compartment model is depicted as having a central compartment into which the drug is administered and two peripheral compartments to which reversible drug distribution occurs.

k_{12} , Rate of distribution of drugs to the peripheral compartment; k_{21} , rate of redistribution of drugs back to the

central compartment; k_{el} , rate of drug removal or elimination from the body; k_{13} , rate of distribution of drugs from the central compartment to a shallow peripheral compartment; k_{31} , rate of distribution of drugs from the shallow peripheral compartment back to the central compartment (see text for further explanation).

In the two-compartment model, the first compartment is termed the *central compartment* and is composed of intravascular fluid and the highly perfused tissues such as the heart, lungs, brain, liver, and kidneys (see Fig. 6.6B). The **central compartment** represents only approximately **10% of body mass** in an adult; however, it receives approximately 75% of the cardiac output and is also referred to as the *vessel-rich group*. The **peripheral compartment** (vessel-poor group) is composed of muscle, fat, and, bone and represents **90% of body mass**. This second compartment receives approximately **25% of the cardiac output**.²⁴ The terms *central* and *peripheral compartments* refer to differences in the size of the compartments and the rate at which a drug is distributed to them. In reality, the compartments are not true anatomic areas, but instead are conceptual representations of two separate volumes in which a quantitative change in drug concentration occurs.²⁵

Drugs leave the central compartment in two phases. Drugs leave by distribution into the tissues or via metabolism and excretion. In the initial phase, after an intravenous bolus dose, those organs with the highest blood flow have the largest amount of drug delivered to them. These highly perfused tissues equilibrate with the initial high serum concentration and attain a high concentration of drug (Table 6.2). As blood flows through the less perfused organs, the drug begins to be deposited in those tissues as well.¹⁹ However, the tissue levels rise more slowly and do not reach as high a concentration as in the vessel-rich group or central compartment, with extraction occurring to a lesser degree. As blood flows through the tissues, serum concentrations drop because of this distribution, and the fall in plasma concentration is described mathematically via the alpha half-life.²⁶ When the plasma concentration falls below the tissue concentration, the drug reemerges from the highly perfused tissue, enters the plasma serum, and is again redistributed. The drug enters the central compartment for clearance from the body. The

degree to which drugs distribute and redistribute from the central compartment to the peripheral compartment, and the resultant concentration of the drug established before elimination occurs, allow for the calculation of the volume of distribution.

TABLE 6.2
Tissue Groups Based on Perfusion*

Characteristic	Vessel Rich	Muscle	Fat	Vessel Poor
Percentage of body weight	10	50	20	20
Percentage of cardiac output	75	19	6	0
Perfusion (mL/min per 100 g)	75	3	3	0

*The vessel-rich group represents the central compartment, and the muscle, fat, and vessel-poor groups are peripheral compartments.

Volume of Distribution

The volume of distribution (V_d) is a proportional expression that relates the amount of drug in the body to the serum concentration. It is the apparent volume in which the drug is distributed after it has been introduced into the system.¹ Essentially it is calculated by dividing the dose of the drug administered intravenously by the plasma concentration before elimination occurs. The V_d is used to calculate the loading dose of a drug that will achieve a steady-state concentration.²⁴ In practice, a patient's V_d is unknown, and an average V_d is assumed and used to calculate a loading dose that will attain a therapeutic concentration rather than a steady-state concentration.

$$\text{Volume of distribution} = \frac{\text{Dose of drug}}{\text{Plasma concentration of drug}}$$

The theoretical compartments and volumes are envisioned as follows. The plasma compartment contains 4 liters (L). The interstitial fluid (IF) volume contains 10 L. The extracellular fluid (ECF) volume combines the plasma and IF and therefore contains (4+10) or 14 L. The intracellular fluid (ICF) volume is 28 L. Total

body water is equal to plasma (4L) + IF (10L) + ICF (28L) = 42 L. The typical V_d , normalized for the body weight of a 70 kg adult, would be 42L/70 kg or 0.6L/kg. The V_d gives one the sense of how extensively a drug distributes throughout the body. A drug with a large V_d (> 0.6L/kg) implies that it is widely distributed in the body and likely lipid soluble. A drug with a small V_d (< 0.4 L/kg) is largely contained in the plasma and likely water soluble. Other factors such as size, carrier molecules, disease states, and fluid shifts associated with burn injuries or pregnancy may also alter expected distribution volumes.

The V_d of a drug is affected by the physiochemical properties of that drug, such as lipid solubility, plasma protein binding, and molecular size.⁶ Drugs that are free, unbound to plasma proteins, and lipid soluble easily cross membranes to tissues and therefore have large calculated volumes of distribution with low plasma concentrations. An example of a drug with a large V_d is propofol.¹ On injection of an induction dose, this highly lipid-soluble drug is distributed quickly to peripheral tissue, thereby ending its action much more rapidly than its elimination half-life would predict. The patient wakes up in just a few minutes because of redistribution from the brain (central compartment) to the peripheral compartment; however, the patient may feel sleepy for hours because of the long elimination half-life of the drug from the whole body (11.6 hours).⁶

The V_d of a drug administered by bolus is also calculated by dividing the total dose administered by the area under the plasma concentration curve. The greater the area under the curve, the longer the drug acts and the drug intensity increases.⁶ However, if the drug is infused or given in multiple doses and the amount given equals the amount eliminated, the central and peripheral compartments are in equilibrium. Therefore, the V_d at this steady state would differ if the agent were given as a bolus injection.⁷

Structure-Activity Relationship

The affinity of a drug for a specific macromolecular component of the cell and its intrinsic activity are intimately related to its chemical structure.²⁷ The relationship is frequently quite a rigid one, in that

relatively minor modifications in the drug structure may result in major changes in pharmacologic properties. In fact, manipulation of structure-activity relationships often leads to the synthesis of therapeutic agents quite varied in their therapeutic effects, as well as their side effects. Changes in molecular configuration must occur in a manner that leads to alterations of all actions and effects of a drug equally. Therefore, it is sometimes possible to develop a congener with a more favorable ratio of therapeutic to toxic effects, enhanced selectivity among different cells or tissues, or more acceptable secondary characteristics than those of the parent drug.²⁷ Additionally, effective therapeutic agents have been developed by cultivating structurally related competitive antagonists of other drugs or of endogenous substances known to be important in biochemical or physiologic function. Minor modifications of structure can also have profound effects on the pharmacokinetic properties of drugs. The structure of a drug can therefore occasionally supersede all of the previously discussed properties, and this structure is of great importance in how a drug behaves in vivo. Important considerations in structure-activity relationships are enantiomerism and isomerism.

Stereochemistry

A carbon-containing compound usually exists as stereoisomers—molecules with the same chemical bonds but different configurations in their fixed spatial arrangements. A specific configuration is achieved by either the presence of double bonds, where there is no freedom of rotation, or by chiral centers, around which varying groups are arranged in a specific sequence.²⁸ Chiral centers are therefore formed by a carbon atom with four different asymmetric substituents. A molecule with one chiral carbon can have two stereoisomers; however, as the number of carbons in a molecule increases, so does the number of its potential stereoisomers. Some stereoisomers are nonsuperimposable mirror images of each other called *enantiomers*. Free rotation about a chiral carbon is not possible, resulting in the existence of two stable forms of the molecule. These concepts become important in that interactions between biomolecules are stereospecific, and interfaces with biologic receptors can differ greatly between two enantiomers,

even to the point of no binding. There are numerous examples among drug molecules in which only one isomer exhibits the desired pharmacology. Some isomers may even cause side effects or entirely different effects than their mirror image.²⁷ For instance, D(-) ephedrine, with a relative potency of 36, is used to a large extent as an antiasthmatic and, by an anesthesia professional, as a pressor amine to restore low blood pressure in the operating arena, whereas L(+) pseudoephedrine, with a relative potency of 7, is used primarily as a nasal decongestant (Fig. 6.7). These drugs therefore have varying activities and potencies, rendering them ideal for varying situations. Cisatracurium, levobupivacaine, ropivacaine and dexmedetomidine are additional examples of select isomers with improved clinical properties.

FIGURE 6.7 Ephedrine has two chiral centers and four isomers with varying potencies.

Plasma Concentration Curve

A schematic depiction of the decline in plasma concentration of a drug with time after rapid intravenous injection into the central compartment is plotted on a logarithmic graph in Fig. 6.8. The y-axis of the graph represents the plasma concentration, and the x-axis reflects the time after the dose is injected. The first phase of the curve is the α phase, or the distribution phase, which represents the initial dispersal of drug into the tissue compartments from the central compartment. This slope is usually steep with drugs that are highly lipid soluble, which demonstrates the ability of these agents to cross membrane lipid bilayers and be distributed to the peripheral compartment rapidly, leading to a rapid fall in plasma

levels.¹

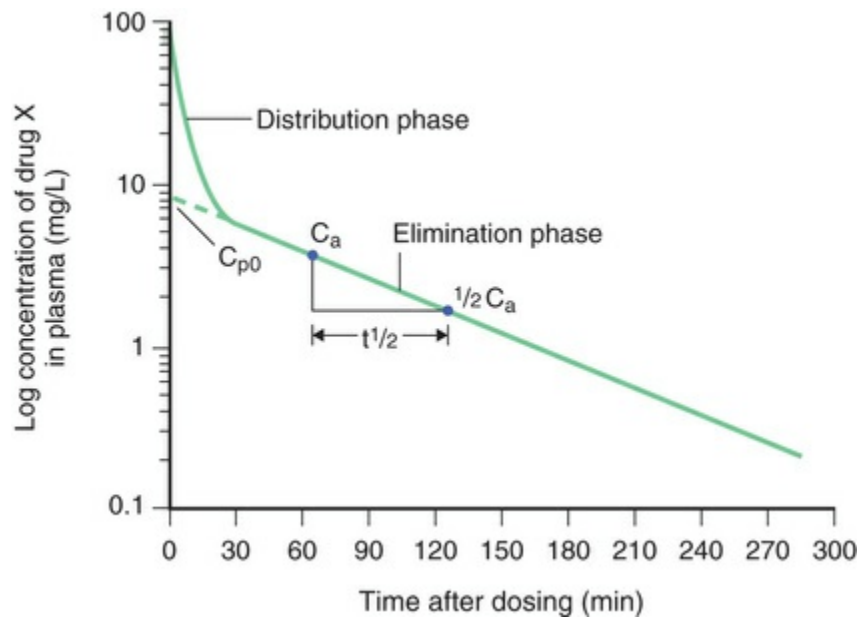

FIGURE 6.8 Representative drug concentration versus time plot used in pharmacokinetic studies. Concentration of drug is plotted with a logarithmic scale on the ordinate, and time is plotted with a linear scale on the abscissa. The resultant curve has two phases: the distribution phase, which is the initial portion of the plotted line when the concentration of drug decreases rapidly; and the later elimination phase, during which there is an exponential disappearance of drug from the plasma over time. The *dotted line* extrapolated from the elimination phase back to time zero is used to calculate plasma concentration at a time zero (C_{p0}). During the elimination phase, the half-life ($t_{1/2}$) can be calculated as the time it takes to decrease the concentration by half (shown here as the time needed to decrease from concentration C_a to $\frac{1}{2} C_a$). (From Goldman L, Schafer AI. *Goldman-Cecil Medicine*. 25th ed. Philadelphia: Elsevier; 2016.)

The second phase of the curve is a logarithmic plot of the slower elimination, or β phase of the plasma concentration curve. Once equilibrium has been reached, the concentration falls exponentially because of elimination. This portion of the graph is much less steep and has a plateau shape, illustrating the more gradual decline in the drug's plasma concentration. The slope is flatter because it reflects the elimination of the drug from the circulation by the hepatic,

renal, and other systems, which is a more gradual process. The plasma concentration curve is an example of a biexponential decay curve, because two distinct components of decay exist—a steep slope that describes distribution and a second, less steep slope that depicts the elimination phase.⁶

The elimination phase of the plot is used to determine the elimination half-life of drugs, which becomes important with regard to dosing intervals.

Steady State

Theoretically, a steady state occurs when a stable plasma concentration of a drug is achieved. In this instance, all body compartments will have had ample opportunity to equilibrate with the circulating agent, and although tissue concentrations of the drug vary from organ to organ, they are not changing. At this point, drug elimination is equal to the rate at which the drug is made available, so the amount being eliminated in a given time equals the amount being added to the system at the same time.²⁹ This state is typically reached with chronic administration of a drug or by continuous intravenous administration. Some important

Box 6.6 Distribution concepts are listed in [Box 6.6](#).

Drug Distribution

The major compartments are as follows:

- Plasma (5% of body weight)
- Interstitial fluid (16%)
- Intracellular fluid (35%)
- Transcellular fluid (2%)
- Fat (20%)
- Volume of distribution (V_d) is defined as the volume of plasma that would contain the total body content of the drug at a concentration equal to that in the plasma.

- Water-soluble drugs are mainly confined to plasma and interstitial fluids; most do not enter the brain after acute dosing.
- Lipid-soluble drugs reach all compartments and may accumulate in fat.
- For drugs that accumulate outside the plasma compartment (e.g., in fat, or by being bound to tissues), V_d may exceed total body volume.
- For many drugs, disappearance from the plasma follows an exponential time course characterized by the plasma half-life.
- Plasma half-life, in the simple case, is directly proportional to the volume of distribution and inversely proportional to the overall rate of clearance.
- With repeated dosage or sustained delivery of a drug, the plasma concentration approaches a steady value within 4 or 5 plasma half-lives. Elimination of a drug also takes 4 or 5 half-lives.
- A two-compartment model is often needed. In this case the kinetics are biexponential. The two components roughly represent the processes of transfer between plasma and tissues or distribution (α phase) and elimination from the plasma (β phase).
- Some drugs show nonexponential “saturation” kinetics, with important clinical consequences, especially a disproportionate increase in steady-state plasma concentration when the dose is increased.

Modified from Rang HP et al. *Rang and Dale's Pharmacology*. 8th ed. Edinburgh: Elsevier; 2016:116–132.

Metabolism

Drug metabolism is synonymous with drug **biotransformation**. Metabolism is an enzyme-catalyzed change in the chemical structure of agents, and it usually involves more than one pathway. The main organ for drug metabolism is the liver, although

metabolism can occur in the plasma, lungs, GI tract, kidneys, heart, brain, and skin. The goal of metabolism is to **change lipid-soluble agents into more water-soluble forms** so the kidneys can then eliminate them from the body. Metabolism usually leads to transformation of active drugs into inactive metabolites; however, numerous consequences can occur. For example, a drug can be metabolized to an active drug with the same or new activity, or an agent can be converted from an inactive prodrug to its active form, as previously noted with dolasetron.^{22,23}

For most drugs administered in therapeutic doses, metabolism occurs as a **first-order process**, in that the **drug is cleared at a rate proportional to the amount of drug present in the plasma**. Thus a constant fraction of total drug is metabolized in a set time period. The greatest amount of drug eliminated per unit time occurs when the concentration is highest.³⁰

Drugs such as alcohol undergo **zero-order** kinetics at therapeutic doses. This means that even at therapeutic levels, **they exceed the body's ability to excrete or metabolize them**. In zero-order kinetics, the available enzyme systems for elimination of drugs are saturated. For these agents, **a constant amount of drug is cleared regardless of the plasma concentration**, as opposed to a constant percentage as occurs with first-order kinetics. The amount of agent cleared per unit time during zero-order kinetics is the same amount, independent of its plasma concentration.

Drug metabolism occurs in two phases. Phase I reactions are oxidation, reduction, and hydrolysis reactions and generally result in increased polarity of the molecule, transforming a lipid-soluble compound to a water-soluble one. Phase II reactions involve conjugation reactions, in which a drug or metabolite is conjugated with an endogenous substrate such as glucuronic, sulfonic, or acetic acid.³¹

Phase I Reactions

Oxidation reactions generally are reactions in which oxygen is introduced into the molecule or the oxidative state of a molecule is changed so that its relative oxygen content is increased. The molecule of oxygen is split; one atom oxidizes each molecule of drug, and the other is incorporated into a molecule of water. The

loss of electrons results in oxidation. Oxidative metabolism reactions are catalyzed by the enzymes of the **cytochrome P-450** system.³¹ Reduction pathways of metabolism also use the cytochrome P-450 system. When insufficient amounts of oxygen are present to compete for electrons, these enzymes transfer electrons directly to a substrate rather than to oxygen. Reduction involves the gain of electrons.^{32,33}

Hydrolysis is the addition of water to an ester or amide to break the bond and form two smaller molecules. Adding water to these compounds leads to an acid and alcohol, in the case of esters, and to an acid and an amine, in the case of amides. Amide drugs rarely undergo hydrolysis, even though they are formed by removing water. Steric hindrance limits the ability to add water to a drug (hydrolyze it) once the water has been removed. Examples of drugs **Box 6.7** are hydrolyzed are listed in **Box 6.7**.

Common Anesthesia-Related Drugs That Undergo Phase 1 Hydrolysis

Pseudocholinesterase Catalyzed

- Succinylcholine
- Mivacurium
- Cocaine
- Procaine
- Chlorprocaine
- Tetracaine
- Neostigmine (partial pathway)
- Edrophonium (partial pathway)

Nonspecific Esterase Dependent

- Remifentanyl

- Atracurium (partial pathway)
- Cisatracurium (partial pathway)
- Esmolol (RBC esterase)
- Aspirin
- Clevidipine

RBC, Red blood cell.

The end result of phase I reactions is typically a more polar compound that is easily excreted by the kidneys. It is also important to note that phase I reactions, by placing hydroxy or carboxy groups on drug molecules, enable phase II reactions to occur.¹

Phase II Reactions

Phase II reactions are also referred to as *synthetic reactions* because the body actually synthesizes a new compound by donating a functional group usually derived from an endogenous acid. The new compound is the conjugate of the drug or the drug product of the phase I reaction with either glucuronic acid, sulfuric acid, glycine, acetic acid, or a methyl group.²⁹

The products of phase II reactions almost always have little or no biologic activity. Conjugation always leads to a more polar compound that is more highly ionized at physiologic pH and therefore more easily extractable by the kidney via glomerular filtration. The conjugation proceeds by joining the body's donated group (during phase I reactions) with an OH, COOH, or NH group to form an ester or amide bond. However, many drugs already possess an appropriate functional group for conjugation and therefore do not need to be modified by a prior phase I reaction in order to be conjugated.

Many intracellular sites exist for drug metabolizing enzymes, such as the endoplasmic reticulum, mitochondria, cytosol, lysosomes, and plasma membrane. Hepatic microsomal enzymes,

responsible for biotransformation of numerous agents, reside mainly in the smooth hepatic endoplasmic reticulum. They are termed *microsomal enzymes* because microsomes are fragments of the endoplasmic reticulum that are obtained in vitro by physical disruption of the tissue and differential centrifugation. This microsomal fraction includes proteins called *cytochrome* (iron-containing hemoprotein) *P-450*, indicating its peak absorption at 450 nm, when it reacts with carbon monoxide. The cytochrome P-450 is also called the *mixed-function oxidase system* because it includes both oxidation and reduction steps and has low substrate specificity.⁶ Some extrahepatic sites of the P-450 system exist, such as the kidneys, lungs, skin, and intestinal mucosa.

Six well-characterized forms, or isozymes, of the cytochrome P-450 system are involved in drug metabolism in humans: CYP1A2, CYP2D6, CYP2C19, CYP2E1, CYP2C9, and CYP3A.³⁴ The letters CYP stand for cytochrome P-450; the first number denotes genetic family, the next letter describes the genetic subfamily, and the second number stands for the specific gene or isozyme.

It is important to note some characteristics of these isozymes. It should be appreciated that small differences in amino acid sequences of the different isozymes lead to differences in drug metabolism and account for genetic variability among individuals' abilities to metabolize agents.³⁴ Therefore hepatic enzyme activity varies among individuals and is determined genetically. Genetic variability exists in the expression of CYP2C19, CYP2C9, and CYP2D6 and other cytochromes. Genetic variation in the CYP2D6 enzyme, for example, leads to changes in metabolism of β -blockers, which may produce toxicity or their ultrarapid degradation, decreasing efficacy. These polymorphisms in the adrenergic signaling pathway and CYP2D6 gene may influence efficacy, safety, and toxicity of β -blocker therapy in prevention and treatment of perioperative myocardial infarction and the treatment of heart failure and other cardiac diseases.³⁵⁻³⁷

It is possible to increase enzyme activity by stimulating the enzymes over a period of time. This is called *enzyme induction* and is usually produced by exposure to certain drug or chemical compounds. Alcohol is one such compound; when ingested chronically it induces enzymatic activity. The system can more

quickly break down agents that use the same enzymatic system for biotransformation. Other drugs capable of enzyme induction include phenobarbital, phenytoin, rifampin, and carbamazepine. This increased capacity to clear drugs leads to reduction in half-lives of agents and is important with regard to dosing intervals.^{38,39}

Microsomal enzymes can also be inhibited. This usually occurs through exposure to certain drugs and chemicals, leading to accumulation of the substrate agent, and can cause elevated plasma levels and potentially greater activity and toxicity. For example, erythromycin inhibits the metabolism of theophylline, and cimetidine inhibits the metabolism of many drugs.³⁴ **Box 6.8** contains a summary of important metabolic concepts. A list of cytochrome enzymes, metabolites, inducers, and inhibitors is given in **Table 6.3**. Some common cytochrome enzyme inducing and **Box 6.8** inhibiting drugs are listed in **Tables 6.4** and **6.5** respectively.

Drug Metabolism

- Phase I reactions involve oxidation, reduction, and hydrolysis—usually form more chemically reactive products; sometimes pharmacologically active, toxic, or carcinogenic. Phase I reactions often involve a monooxygenase system in which cytochrome enzymes play a role.
- Phase II reactions are conjugation (e.g., glucuronidation) of a reactive group (often inserted during phase I reaction) and usually form inactive and polar products that are readily excretable in urine.
- Some conjugated products are excreted via bile, are reactivated in the intestine, and then reabsorbed (e.g., enterohepatic circulation).
- Induction of enzymes by other drugs and chemicals can greatly accelerate hepatic drug metabolism. It can also increase the toxicity of drugs with toxic metabolites and is an important cause of drug interactions as in enzyme inhibition.
- Some drugs show rapid “first-pass” hepatic metabolism and

therefore poor oral bioavailability due to presystemic metabolism in the liver or intestinal wall when they are given by mouth.

Drug Elimination

Elimination Half-Life

The elimination half-life ($t_{1/2}$) is the time necessary for the plasma content of a drug to drop to half of its prevailing concentration after a rapid bolus injection. It takes the same amount of time to reduce a drug's concentration from 100 to 50 mg/L as it does to decrease the concentration from 10 to 5 mg/L. The amount of drug remaining in the body is related to the number of elimination half-lives that have elapsed (Table 6.6). For practical purposes, a drug is regarded as being fully eliminated when approximately 95% has been eliminated from the body. This usually occurs when four or five half-lives have elapsed and is important with regard to dosing intervals because drug accumulation occurs if dosing intervals are shorter than this. The body has not been able to rid itself of the initial dose, and subsequent doses will lead to overdose and potential adverse effects. Instances can occur in which, although only 5% of the drug amount remains, it is still somewhat active; however, for the majority of agents, four half-lives is considered sufficient time for the drug's action to be terminated and the agent

eliminated from the body. As noted earlier, most drugs leave the body at a constant rate or percentage over time. This is referred to as *first-order kinetics or dosage independence* and is the reason half-life is constant. Other elimination rate kinetic models include zero-order (e.g., alcohol) elimination, in which a constant amount (not a percentage) is eliminated over time, and Michaelis-Menten models (e.g., phenytoin), which are dose dependent and follow zero-order at high doses and first-order once drug levels have fallen.⁴

TABLE 6.6

Relationship Between Half-Life and Drug Remaining in the Body

Half-Life	Drug Eliminated (%)	Drug Remaining (%)
0	0	100
1	50	50
2	75	25
3	87.5	12.5
4	93.75	6.25
5	96.875	3.125

Context-Sensitive Half-Time

Deficiencies in the use of standard pharmacokinetic parameters such as half-life when describing anesthetic drug administration have led to a proposal for the introduction of a new model that accounts for continuous infusion or repeated dosing-induced changes in drug behavior.⁴⁰ Context-sensitive half-time was developed through use of computer simulations of typical anesthetic dosing practices to provide a more clinically relevant measure of drug concentrations, taking into consideration the method and duration of administration.⁴¹ It is defined as the time to halving of the blood concentration after termination of drug administration by an infusion designed to maintain a constant concentration. It is believed that through incorporation of the effect compartment, the context-sensitive half-time of the pharmacodynamic effect can be modeled.⁴² A flaw in the concept is that it describes only the time to a 50% decrease in central compartment concentration, which may not be the decrement in drug level required to achieve recovery.⁴³ Determining whether

context-sensitive half-time is a useful secondary kinetic descriptor may need to await its more widespread application. Advantages and disadvantages of the various elimination models are summarized in [Table 6.7](#).

TABLE 6.7

Pharmacokinetic Metrics for Describing Drug Offset

Parameter	Definition	Advantages	Limitations
Terminal half-life	Time taken for drug concentration in the blood to fall by one half of the current value	Easily understood Simple to calculate Useful for describing drug disposition in a one-compartment model	One-compartment models rarely used for describing the kinetics of anesthetic drugs Not “context sensitive” with respect to infusion duration Not informative with respect to actual duration of action
Context-sensitive decrement times	Time required for drug concentration to decrease by a given percentage, after termination of an infusion of a given duration	Can be calculated for the central (plasma) or a peripheral effect compartment Context sensitivity allows rational drug selection based on anticipated infusion duration	Decrement curves are generated by kinetic-dynamic simulation using known models Impractical to attempt clinical validation due to vast numbers of patients required An arbitrary decrement time (particularly if relating to plasma concentration) may not relate to actual recovery time
Mean effect time	Calculation of the average recovery time, based on the probability of drug effect as a function of drug concentration and time	An extension of the context sensitive half-time. For example, estimates of C ₉₀ , the concentration at 90% recovery, which considers the probability of drug effect, in addition to pharmacokinetic parameters	Calculation requires knowledge of the concentration-effect relationship and the variance of drug concentration Useful for quantifying the duration of drug effect when dealing with “response or no response” binary data

Adapted from Rigby-Jones AE, Sneyd JR. Pharmacokinetics and pharmacodynamics—is there anything new? *Anaesth.* 2012; 67(1):5–11; Minto CF, Schnider TW. Contributions of PK/PD modeling to intravenous anesthesia. *Clin Pharmacol Ther.* 2008; 84(1):27–38; Bailey JM: Context-sensitive half-times: what are they and how valuable are they in anaesthesiology? *Clin*

Pharmacokinet. 2002;41(11):793–799.

Other parameters have been introduced, including the relative decrement times. This is the time needed for 80% or 90% decreases in inhalation anesthetic concentration. The major differences in the rates at which desflurane, sevoflurane, and isoflurane are eliminated occur in the final 20% of the elimination process.^{44,45}

Clearance

The clearance of a drug is an independent value and is governed by the properties of the drug and the body's capacity to eliminate it. It is defined as the volume of plasma completely cleared of drug by metabolism and excretion per unit of time. Clearance is directly proportional to the dose and inversely related to the agent's half-life, as well as its concentration in the central compartment. Clearance is a very important pharmacokinetic concept, because it influences the steady-state concentration for a given drug administered at repeated intervals or by infusion.

The two main organs for clearance are the liver and kidneys. The rate of clearance is determined by the blood flow to these organs, as well as by their ability to extract the drug from the bloodstream. Mathematically, clearance is equal to the product of the blood flow (Q) and extraction ratio (E):

$$\text{Clearance} = Q \times E$$

Total clearance is the sum of all organs' clearance values. The changes in clearance occur when blood flow to the liver or kidney is altered or when their extraction ratios are changed.

Hepatic Clearance.

Drugs typically go through perfusion-dependent elimination or capacity-dependent elimination in the liver. Drugs that have a high extraction ratio of 0.7 or greater rely heavily on the perfusion of the liver to be cleared. These drugs are referred to as *high-clearance drugs*. Examples of high-clearance drugs are verapamil, morphine, and lidocaine. Hepatic blood flow for these agents far outweighs enzymatic activity in clearing them from the body, so a decrease in

hepatic blood flow decreases the rate of clearance, and a high perfusion state leads to faster clearance. This is termed *perfusion-dependent* elimination.¹

Capacity-dependent elimination occurs with agents that possess a low extraction ratio of 0.3 or less. When a low extraction rate exists, only a small fraction of the agent is removed per unit of time, and changes in hepatic perfusion do not have significant effect on hepatic clearance. Clearance of these drugs depends on hepatic enzymes and the degree of protein binding. Therefore, alterations such as enzyme induction or suppression cause a change in the elimination of these drugs from the body. An increase in enzyme activity causes faster elimination from the body, and enzyme suppression has the opposite outcome. A decrease in protein binding (increase in availability of drug at hepatocytes) also leads to a greater rate of clearance. Examples of drugs with a low hepatic extraction ratio are diazepam and theophylline.¹

Renal Clearance.

The kidneys excrete water-soluble molecules with great ease. The excretion of drugs involves passive glomerular filtration, active tubular secretion, and some reabsorption. Substances that are actively secreted include morphine, meperidine, furosemide, penicillin, and many quaternary ammonium compounds. The amount of drug made available to the renal tubule for elimination depends on the amount of free, unbound drug and the glomerular filtration rate. Water-soluble metabolites are filtered by the glomeruli and eliminated. The kidneys do not excrete lipid-soluble agents as efficiently as water-soluble compounds. For these agents, elimination depends on the liver for metabolism into water-soluble molecules. Indeed, increased water solubility reduces the V_d of agents, leading to their excretion by the kidneys. Conversely, lipid-soluble molecules are reabsorbed from the renal tubules back into the systemic circulation. An example of a lipid-soluble drug that is almost completely reabsorbed (such that little or none of it is excreted unchanged) is propofol.

The pH of the urine can also affect the elimination of drugs. Weak acids are better excreted in alkaline urine; conversely, weak bases are readily excreted in acid urine. The kidneys can use

glomerular filtration for elimination of drugs that are highly polar (e.g., aminoglycoside antibiotics). Certain agents (e.g., penicillin) are eliminated via secretion. Some important clearance concepts are **Box 6.9** [Box 6.9](#).

Elimination of Drugs by the Kidney

- Most drugs, unless highly bound to plasma protein, cross the glomerular filter freely.
- Many drugs, especially weak acids and weak bases, are actively secreted into the renal tubule and therefore are more rapidly excreted.
- Lipid-soluble drugs are passively reabsorbed by diffusion across the tubule and are not efficiently excreted in the urine.
- Because of pH partition, weak acids are more rapidly excreted in alkaline urine, and vice versa.
- Several important drugs are removed predominantly by renal excretion and are liable to cause toxicity in elderly persons and patients with renal disease.
- There are instances of clinically important drug interaction due to one drug reducing the clearance of another. Examples include diuretics and lithium and indomethacin and methotrexate. These are less common than interactions due to altered drug metabolism.

Modified from Rang HP, et al. *Rang and Dale's Pharmacology*. 8th ed. Edinburgh: Elsevier; 2016:124.

Other Factors That Influence Pharmacokinetics

Age

Age plays an important role in the manner in which drug disposition occurs. Elderly patients have a decrease in renal function, resulting in impaired excretion of agents that are eliminated in the urine.⁸ Creatinine clearance, as an indicator of renal function, parallels the kidneys' ability to excrete drugs and is a useful test in predicting renal pharmacokinetics in the elderly.⁶ Liver blood flow decreases with age as well, decreasing the metabolism of agents with moderate to high extraction ratios. The elderly also have an increase in the fat compartment, leading to an increased volume of distribution, which can lead to accumulation of lipid-soluble agents.¹⁷ Liver and renal function are also important in neonates. Elimination of drugs via the kidneys is altered in neonates because of poor renal function in the first year of life. Neonates and premature infants lack the ability to metabolize certain agents because of immature liver enzyme systems.⁶ It is therefore important to consider extremes of age when administering any agent that may be highly lipid soluble with a high hepatic extraction ratio or that relies primarily on the kidneys for elimination.

Gender

Gender differences account for some variability in the pharmacokinetics of many agents. In a review of the literature, it was found that female patients had a 20% to 30% greater sensitivity to the muscle relaxant effects of vecuronium, pancuronium, and rocuronium.^{46,47} It was also found that male patients were more sensitive to propofol than female patients and that it may be necessary to reduce propofol doses as much as 30% in male patients.^{46,48} Gan et al.⁴⁹ studied emergence from general anesthesia with propofol, alfentanil, and nitrous oxide. Female patients emerged significantly more quickly than male patients. In fact,

female patients were three times more likely than male patients to experience recall under general anesthesia. Females are more sensitive than males to some of the effects of opioid receptor agonists while being more resistant to others.⁴⁶⁻⁴⁸ Females given opiates may experience respiratory depression and other adverse effects more easily if they are given the same doses as males. These gender differences seem to be more pronounced in premenopausal women, suggesting hormonal mechanisms are a major contributing factor.^{50,51}

Temperature

Because temperature affects tissue metabolism and blood flow, it follows that the pharmacokinetics of agents are also affected by varying temperatures. In general, metabolism and clearance are delayed for almost all drugs during hypothermia and increased with fever.⁵²

Knibbe et al.⁵³ examined the pharmacokinetics of long-term propofol sedation in critically ill patients. Temperature was a significant covariate for clearance of propofol. Warmer temperatures led to faster elimination of propofol, regardless of the concentration of the drug in solution.

Disease States

The incidence of chronic kidney disease (CKD) is growing due to the aging of the population and an increasing incidence of diabetes, hypertension and obesity, which are leading risk factors of renal failure. CKD is known to impair clearance and elimination of drugs and their metabolites. Uremic toxins, inflammatory cytokines and parathyroid hormone, which are common in CKD, may be implicated. Altered plasma protein binding of drugs and the activity of several drug-metabolizing enzymes and drug transporters has also been shown to be impaired in chronic renal failure^{54,55}

Hepatic disease may have a large influence on a drug's effect. To predict how hepatic disease will influence drugs in an individual patient may be difficult. Pharmacokinetic alterations vary among acute and chronic hepatic disorders, as well as with the degree to

which the liver is impaired. In cirrhosis, all pharmacokinetic phases may be affected, including absorption, distribution, metabolism and elimination of the drug. Some changes include high portosystemic pressure, which impedes GI absorption. Less first-pass effect in the diseased liver leads to a higher bioavailability of highly extracted drugs administered orally. The V_d for highly protein-bound drugs may be changed secondary to the lowered production of albumin and other plasma proteins. Water-soluble drugs may also exhibit an altered V_d due to volume overload and ascites in patients with cirrhosis. Drug metabolism and elimination is reduced due to impairment of drug metabolizing enzymes. Phase 1 mechanisms are affected to a greater extent than phase 2 processes.⁵⁶

Other disease states can cause variability, as illustrated by a 2003 study that found an increase in the volume distribution of ketamine disproportional to increases in clearance in spinal cord injury inpatients in the intensive care unit, leading to a longer than expected half-life for the drug, again placing the patients at risk for overdose.⁵⁷ See [Box 6.10](#) for a summary of some pharmacokinetic

Box 6.10

Summary of Pharmacokinetic Principles

- Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients who require drug therapy.
- Clearance is the most important pharmacokinetic parameter, because it determines the steady-state concentration for a given dosage rate. Physiologically, clearance is determined by blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug from the bloodstream.
- The dosage and clearance determine the steady-state concentration.
- The fraction of drug absorbed into the systemic circulation after extravascular administration is defined as its *bioavailability*.

- Pharmacokinetic models are useful for description of data sets, prediction of serum concentrations after several doses or different routes of administration, and calculation of pharmacokinetic constants such as clearance, volume of distribution, and half-life. The simplest case uses a single compartment to represent the entire body.
- The volume of distribution is a proportionality constant that relates the amount of drug in the body to the serum concentration. The volume of distribution is used to calculate the loading dose of a drug that will immediately achieve a desired steady-state concentration. The value of the volume of distribution is determined by the physiologic volume and how the drug binds in blood and tissues. The volume of distribution determines the loading dose.
- Half-life is the time required for serum concentration to decrease by one half after absorption and distribution are complete. Half-life is important because it determines the time required to reach steady state and the dosage interval. Half-life is a dependent kinetic variable because its value depends on the values of clearance and volume of distribution.
- The half-life determines the time to reach steady state and the time for “all” of the drug to be eliminated from the body.
- If a drug obeys first-order pharmacokinetics, a simple ratio of dosage to steady-state concentration can be used to estimate a new dosage, as long as the clearance has not changed.
- Phenytoin is an example of a drug that obeys the Michaelis-Menton model rather than first-order pharmacokinetics. In this case, as plasma concentration increases, the clearance decreases and the half-life becomes longer.
- *Cytochrome P-450* is a generic term for the group of enzymes responsible for most drug metabolism oxidation reactions. Several P-450 isozymes have been identified, including CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4.

- Factors to be taken into consideration when deciding on the best drug dose for a patient include age, gender, weight, ethnic background, other concurrent disease states, and other drug therapy.
- The importance of transport proteins in drug bioavailability and elimination is now better understood. The principal transport protein involved in the movement of drugs across biologic membranes is P-glycoprotein. P-glycoprotein is present in many organs, including the gastrointestinal tract, liver, and kidney.

Pharmacogenetics and Pharmacogenomics

Definition

Pharmacogenetics is the study of variations in human genes that are responsible for different responses to drug therapy. These differences are identified in the pharmacodynamic and pharmacokinetic processes.⁵⁸ Pharmacogenomics is an evolution of pharmacogenetics research and involves the identification of drug response markers at the level of disease, drug metabolism, or drug target.^{59,60}

Pharmacogenetics and pharmacogenomics take into account the genetic basis for the variability in an individual's drug response. Pharmacogenetics studies variations in genes suspected of affecting drug response, whereas pharmacogenomics encompasses the genome (all genes). The discipline of pharmacogenetics integrates biochemical and pharmacologic concepts and seeks to correlate phenotypic biomarkers with responses. Pharmacogenomics involves DNA sequencing and gene mapping to identify the genetic basis for variations in drug efficacy, metabolism, and transport.⁶¹

Any clinician can describe the wide variation in patient responses to anesthetic drugs. Much of the variation has been attributed to differences in patient size, age, disease profile, and sex. Advances in pharmacogenetics and pharmacogenomics reveal that genetic differences in drug response also play an important role. We are quickly getting to the point of personalized medicine where genetic testing allows for individualized prevention and therapy. Inherited variations have been identified in approximately 20 genes that affect approximately 80 medications and are clinically actionable. For example, genetic variants now direct the choice of “targeted” anticancer drugs for individual patients. Prevailing efforts are focusing on implementation of an evidenced-based strategy for improving the use of drugs providing a cornerstone for precision medicine.^{62,63}

History

The history of pharmacogenetics goes back to the days of Pythagoras (510 BC) when he recognized that only some people had fatal responses to ingestion of fava beans, but not all.⁶⁴

Archibald Garrod's 1902 study of alkaptonuria constituted the first genetic link to disease in humans. He later advanced the hypothesis that genetically determined differences in biochemical processes may be the reason for adverse drug reactions.⁶⁵

Familial clustering of toxic drug responses led to suspicion of a biochemical genetic basis for the toxicities.⁶¹ In a seminal article published in 1957, Motulsky⁶⁶ outlined many genetic conditions associated with toxic reaction to a specific drug or chemical and proposed that inheritance of certain traits may explain individual variations in drug efficacy and toxic reactions.

Early advances in the field of pharmacogenetics came from research into the biochemical and genetic basis for idiosyncratic drug responses. Several independent observations were made. For example, in the 1950s, after reports of prolonged muscle relaxation following administration of succinylcholine during anesthesia, the variation in serum cholinesterase levels was found to be an inherited trait.^{67,68} Similarly, hemolytic anemia found in African-American male soldiers after administration of the antimalarial drug primaquine during World War II led to the discovery of a defect in the gene encoding glucose-6-phosphate dehydrogenase (G6PD).⁶¹

The term *pharmacogenetics* was coined by Vogel in 1959 and is defined as a “clinically important hereditary variation in response to drugs.”⁵⁸ In 1962, Kalow wrote a text, *Pharmacogenetics: Heredity and the Response to Drugs*.⁶⁹

In the 1960s, twin studies established the role of genetic factors in individual variations in rates of drug metabolism; however, they did not identify the specific genes involved. Gene identification emerged in the 1980s.⁵⁸ Now that the human and many animal genomes have been sequenced, huge strides in genomics and drug therapies are occurring. The development of genomics has led to the hope of individualized drug therapy with increased and targeted efficacy and fewer side effects. The characterization of single nucleotide polymorphisms (SNPs) and the effect on drug

action has opened new areas of drug research. The emergence of pharmacometabolomics assesses the influence of the metabolic factors and the environment on gene expression. The combination of these disciplines permits factors involving the genetic background of individual and exterior interventions to tailor individual therapies.^{70,71}

Polymorphisms

Polymorphic genes relevant to pharmacokinetics (absorption, distribution, metabolism, and excretion) and pharmacodynamics (drug targets: receptors and enzymes) can have a significant impact on pharmacotherapy.⁷² Pharmacotherapy may be affected by three types of genetic variation. These include variations in target proteins, enzyme metabolism, or idiosyncratic effects.⁷³

Polymorphisms are defined as variations in the DNA sequences that occur in at least 1% of the population.⁷⁴⁻⁷⁷ There are a number of different types of polymorphisms, but most attention has been focused on SNPs, (pronounced “snips”) in which one nucleotide is exchanged for another in a given position.⁶⁴ Approximately 10 million SNPs exist, and they can occur anywhere on the genome, but only a fraction are likely to prove relevant to drug response. To matter from a pharmacologic standpoint, the differences generally affect either the function or amount of target proteins involved in the biochemical pathways of the disease processes the drugs are used to treat.⁷³

The genomes of any two individuals are nearly 99.9% identical regardless of race.⁷³ Most variations in the human genome (polymorphisms) occur in drug-metabolizing enzyme genes. Others occur in the enzyme receptor genes and drug transporter genes.⁵⁷ Much of the observed variability in drug response has a basis in pharmacogenetic polymorphisms arising in genetically determined differences in drug absorption, disposition, metabolism, and excretion. The best-characterized pharmacogenetic polymorphisms are those in the cytochrome P-450 family of drug-metabolizing enzymes.⁷⁶

Most drugs are lipophilic and must be metabolized to polar products for excretion. This involves hepatic enzymes and a sequence of steps dependent on the cytochrome P-450 system.

Drugs are first metabolized by phase I enzymes (oxidation) and then phase II enzymes (conjugation that involves sulphation, glucuronidation, or acetylation). Although the effects of polymorphism in phase II enzymes are often less pronounced, the effects of inherited variations in both phase I and II metabolism can be synergistic.

Genetic polymorphisms occur in most, if not all, of the human cytochrome P-450 (CYP) isoenzymes, but functional polymorphisms reside in only four, which account for 40% of all drug metabolism (CYP2A6, CYP2C9, CYP2C19, and CYP2D6). Thus genetically controlled variations are common.⁵⁸ As previously noted, cytochrome P-450 (CYP450) is a superfamily of liver enzymes that catalyze phase 1 drug metabolism. The D6 isozyme of the CYP2 family is particularly affected by genetic variability and currently has 80 identified CYP2D6 alleles, resulting in a variable enzymatic activity ranging from 1% to 200%. Individuals can be classified as having an ultra-rapid metabolism, an extensive metabolism, an intermediate metabolism or a poor metabolism. The distribution of CYP2D6 phenotypes varies according to ethnicity (Table 6.8).

TABLE 6.8
Ethnic Distribution of CYP2D6 Activity

Ethnic Group	CYP2D6 PM	CYP2D6 IM	CYP2D6 UM
Caucasian	7–10%		
Asian	1–2%	30%	
African-American	2–4%	30%	
Ethiopian			29%
Southern European			10%
Northern European			1–2%

Codeine is a prodrug and requires metabolism by CYP2D6 to be converted into morphine and become analgesic. Morphine is further metabolized into morphine-6-glucuronide and morphine-3-

glucuronide; both morphine and morphine-6-glucuronide display opioid activity. Codeine was commonly prescribed because of the belief that, being a weak opioid, it was safe and would not result in adverse outcomes. However, serious morbidity and mortality have occurred in two separate patient populations^{63,78} (Fig. 6.9). They include postoperative pediatric tonsillectomy patients and neonates of breast feeding mothers receiving codeine analgesia. Mothers, neonates and children who are CYP2D6 ultra-rapid or extensive metabolizers may produce toxic levels of active drug from the codeine prodrug. A Food and Drug Administration (FDA) warning and contraindication involving both groups has been added to the package literature. An FDA-approved genetic test (AmpliChip CYP450; Roche Diagnostics, Palo Alto, CA, USA) is commercially available to test genetic variants of CYP2D6.

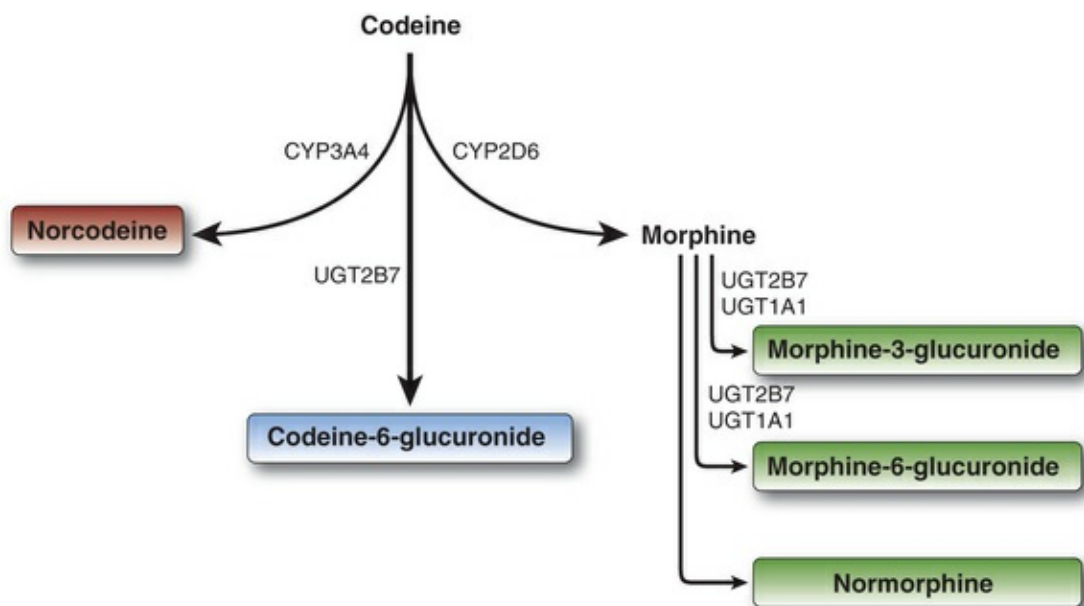

FIGURE 6.9 Codeine metabolic pathway.

Individual Drug Response/Genetics

Many variations of pharmacogenetic interest have been elucidated, and with the deciphering of the human genome, many innovative opportunities exist. Genetic variations can modify responses to drugs. Variations in target pathways and metabolic enzymes may

render a drug ineffective for some, yet effective for others.⁷⁴⁻⁷⁷

Recognition of genetic differences among patients has the potential to allow for individualized drug therapy. Furthermore, with the recognition that certain genetic differences are associated with risk of disease, opportunities to identify these individuals and treat them early may improve efficacy and specificity of their treatment.⁵⁸

Clopidogrel, warfarin, β -blockers, statins, angiotensin converting enzyme inhibitors, and other cardiovascular medications can now be prescribed by algorithms which are based on genetic profiles. Rapid advances in characterizing genetic relationships is helping to bring these advances in pharmacokinetics into the clinic.⁷⁹ The pharmacogenetics influences on many psychiatric drugs, electroconvulsive therapy, and serotonin syndrome are also being reported.⁸⁰⁻⁸³

Summary

Pharmacokinetics is an integral part of modern anesthesia clinical practice. Anesthesia providers balance the administration of a number of drugs simultaneously to achieve the necessary drug actions that constitute anesthesia. A thorough understanding of the processes that govern drug kinetics allows for safe and effective practice and facilitates operating room efficiency. This knowledge also allows the clinician to anticipate and avoid potential problems and tailor each anesthetic to particular patient characteristics. Advances in pharmacokinetics and pharmacogenomics will further impact anesthesia care in years to come. Pharmacogenomics has made a significant impact on the direction of drug research and drug therapy. Diseases and drug therapies are complex processes that may challenge the predictive powers of pharmacogenetics. A systems approach may be needed to integrate overall pharmacotherapeutic effects with polymorphisms in multiple genes.^{74,75,77}

Pharmacokinetics of Inhalation Anesthetics

John J. Nagelhout

The basic action of an anesthetic in the body is largely a function of the drug's chemical structure and the resulting interaction with a cellular receptor complex (Fig. 7.1). A number of heterogeneous compounds exhibit anesthetic properties. The inorganic molecule nitrous oxide and halogenated ethers (e.g., isoflurane, desflurane, and sevoflurane) are all capable of binding to central nervous system and spinal cord neuronal membranes to produce reversible depression. A single specific anesthetic receptor has yet to be found. In fact, multiple sites of action and protein targets probably exist; however, once a critical concentration of drug has entered the brain and spinal cord, loss of consciousness ensues.¹⁻³

FIGURE 7.1 Chemical structure of anesthetic agents. Nitrous oxide is inorganic, and the rest are halogenated ethers.

The administration of inhalation anesthetic gases plays a primary role in modern clinical anesthesia. In anesthesia's early years,

administration of a gas such as diethyl ether constituted the entire anesthetic regimen. Now one or two gas anesthetics are combined with a variety of intravenous drugs to produce an anesthetic state. These intravenous drugs include sedative induction agents such as propofol or etomidate, analgesics, neuromuscular blocking drugs, and local anesthetics. This combination allows the use of smaller and more easily manipulated doses of specific receptor agonists and antagonists. Used in the proper combination the desired amount of anesthesia, analgesia, amnesia, and muscle relaxation can be achieved. Current practice dictates that the anesthetic technique allow for a quick and pleasant induction and recovery with maximum patient safety and efficient caseload management. A sound understanding of inhalation anesthetic pharmacokinetics is essential to safe practice.

Primary Factors Controlling Uptake, Distribution, and Elimination of Anesthetics

The basic task of anesthetic administration involves taking a drug supplied as a liquid, vaporizing it in an anesthesia machine, and delivering it to the patient's brain and other tissues via the lungs. Therefore, the main factors that influence the ability to anesthetize a patient are technical or machine specific, drug related, respiratory, circulatory, and tissue related. The primary factors that influence absorption of the inhalation anesthetics are ventilation, uptake into the blood, cardiac output, the solubility of the anesthetic drug in the blood, and alveolar-to-venous blood partial-pressure difference. Other factors such as the concentration, and second gas effects, also play a role (Fig. 7.2).⁴

FIGURE 7.2 Transfer of an anesthetic gas from the machine through the lungs into the blood and tissues.

A few assumptions are usually made. The level of anesthesia is related to the alveolar concentrations of anesthetic agents, which can be readily and continuously measured or inferred. The concentration or partial pressure of anesthetic in the lungs is assumed to be the same as in the brain, because the drugs are highly lipid soluble and diffusible, and they quickly and easily reach equilibrium among the highly perfused body compartments. For this reason the dose of an individual drug is expressed in terms of the minimum alveolar concentration (MAC) necessary to

produce anesthesia (lack of movement) upon surgical stimulation.⁵⁻⁸ The definition of MAC is the *minimum alveolar concentration* required to produce anesthesia (lack of movement) in 50% of the population upon surgical stimulation. It is age dependent in that the required dose peaks at approximately 6 months of age and then decreases with increasing age.⁹ The faster the lung (and therefore brain) concentration rises, the faster anesthesia is achieved. Conversely, the faster the lung (brain) concentration falls after discontinuation of the drug, the more quickly the patient emerges.¹⁰ Some factors that can influence MAC are given in [Box 7.1](#).

Factors That Influence MAC

Impact of Physiologic and Pharmacologic Factors on Minimum Alveolar Concentration

Increases in MAC

- Hyperthermia
- Drug-induced increases in central nervous system activity
- Hypernatremia
- Chronic alcohol abuse

Decreases in MAC

- Hypothermia
- Increasing age
- Preoperative sedatives
- Drug-induced decreases in central nervous system activities
- α_2 -agonists
- Acute alcohol ingestion

- Pregnancy
- Postpartum (returns to normal in 24–72 hours)
- Lithium
- Lidocaine
- Hypoxia
- Hypotension
- Cardiopulmonary bypass
- Hyponatremia

MAC, Minimum alveolar concentration.

Machine-Related Factors

Concepts regarding the anesthesia machine and its function are described in detail in [Chapter 16](#). Two factors that may affect uptake early in anesthetic administration are drug solubility in the rubber and plastic machine parts and total machine liter flow of the gases chosen.

The rubber and plastic components of the machine, in addition to the ventilator and absorbent, can retain small quantities of anesthetic gases. Theoretically this could slow administration to the patient at the start of anesthetic delivery. The effect on uptake is minimal in actual clinical practice and essentially ceases after approximately 15 minutes of administration.¹¹ Nonetheless, sequestration of small amounts of gas in the apparatus has other implications, such as when anesthetizing patients with malignant hyperthermia. All gases except nitrous oxide are potent triggering agents for a hyperthermic episode. To avoid exposure resulting from residual trace amounts of gases, a thorough flush of the anesthesia machine with 100% oxygen at 10 L/min for at least 20 minutes, replacement of breathing circuits and the carbon dioxide canister, and inactivation or removal of vaporizers are advised when preparing for a patient who is susceptible to malignant

hyperthermia. Newer anesthesia workstations may require flowing 10 L/min of fresh gas for up to 104 minutes. For both new and older machines, adding commercially available activated charcoal filters to the circuit will remove anesthetic gases and obviate the need for purging the system as described. However, the anesthesia machine will still need to be flushed with high fresh gas flows (≥ 10 L/min) for 90 seconds prior to placing the activated charcoal filters on *both* the inspiratory and expiratory ports. These filters are effective in keeping gas concentration below 5 ppm for up to 12 hours with fresh gas flows of at least 3 L/min.¹² Proper preparation may vary with different machines and consultation with the machine manufacturer is advised.^{13,14}

Low liter flows of oxygen and nitrous oxide carrier gas, although economical, deliver the anesthetic more slowly at the start of induction. Increasing liter flows for the first few minutes of the anesthetic minimizes this effect without unduly adding to cost.¹⁵

Drug-Related Factors

Blood/Gas Solubility

The blood/gas solubility coefficient of an anesthetic is an indicator of the speed of uptake and elimination.^{16,17} It reflects the proportion of the anesthetic that will be soluble in the blood, “bind” to blood components, and not readily enter the tissues (blood phase) versus the fraction of the drug that will leave the blood and quickly diffuse into tissues (gas phase). The more soluble the drug (high blood/gas coefficient), the slower the brain and spinal cord uptake and therefore the slower that anesthesia is achieved in the patient. Soluble drugs stay in the blood in greater proportion than less soluble agents; therefore, less of the drug is released to the tissues during the early, rapid-uptake phase of induction. For example, isoflurane has a blood/gas solubility coefficient of 1.4, or expressed as a ratio, 1.4:1. Therefore 1.4 times as much stays in the blood as a nonreleasable fraction for every 1 molecule that enters the tissues and produces anesthesia. Conversely, agents with low solubility properties (low blood/gas coefficient) leave the blood quickly and enter the tissues, producing a rapid anesthetic state. Desflurane, for example, has a low blood/gas coefficient of 0.42, or expressed as a

ratio, 0.42:1. Only 0.42 of a molecule stays in the blood for every 1 molecule (greater than twice as much) that enters the brain. Anesthesia is achieved quickly. Blood/gas solubility coefficients for the inhalation anesthetic agents are listed in [Table 7.1](#).^{1,18,19} The rate of rise of an anesthetic in the alveoli relative to the concentration administered is graphically depicted by plotting the fraction in the alveoli over the fraction inspired ([Fig. 7.3](#)).

TABLE 7.1
General Anesthetic Properties of Inhalation Agents

Anesthetic	MAC (%)	Blood/Gas Partition Coefficient (at 37°C)	Oil/Gas Partition Coefficient (at 37°C)
Sevoflurane (Ultane)	2	0.6	50
Isoflurane (Forane)	1.15	1.4	99
Nitrous oxide	105	0.47	1.4
Desflurane (Suprane)	5.8	0.42	18.7

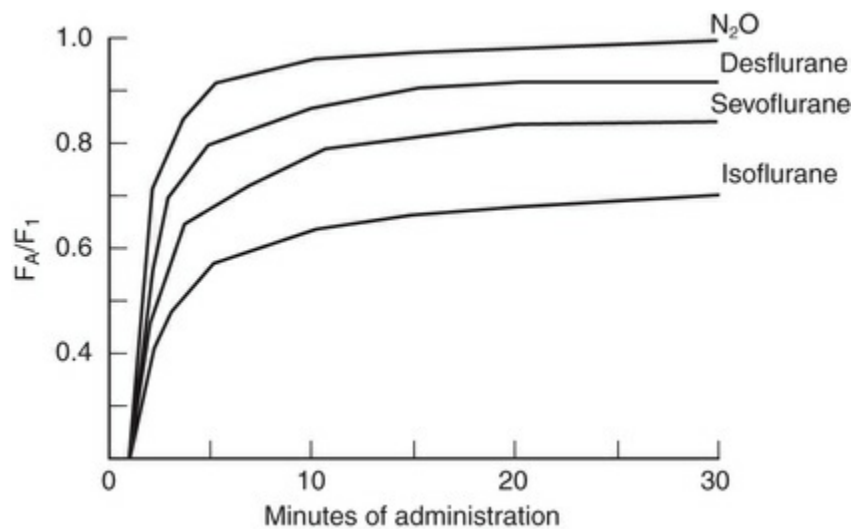

FIGURE 7.3 Rate of rise (F_A/F_I) of alveolar concentration of inhalation anesthetics over time. Low blood/gas anesthetics such as nitrous oxide and desflurane achieve a lung concentration much faster than moderate-solubility gases such as isoflurane. Note that nitrous oxide rises in the lungs more quickly than desflurane, in spite of a slightly higher blood/gas solubility. This is the result of the concentration effect.

As noted previously, the lower the blood/gas solubility, the faster the rise in lung and brain concentrations. The rate of rise of low-solubility agents such as nitrous oxide and desflurane is greater than moderately soluble drugs such as isoflurane. Note in Fig. 7.3 that nitrous oxide exhibits a slightly faster rate of rise compared with desflurane, despite a higher blood/gas coefficient. This variation in the usual trend is a result of the concentration effect—that is, nitrous oxide is given at much higher concentrations (50% to 70%) than desflurane (3% to 9%). Fig. 7.4 depicts the effect of anesthetic blood solubility on uptake.

FIGURE 7.4 Effect of anesthetic blood/gas solubility on uptake. *Left*, an anesthetic gas with a low blood/gas solubility is not taken into the blood (*lightly shaded circles*); therefore, the alveolar (thus brain) concentration rises rapidly (*darkly shaded circles*), and the patient achieves anesthesia quickly. *Right*, an anesthetic gas with a high blood/gas solubility is taken up and held in the blood (*lightly shaded circles*), resulting in a slower rise in alveolar (thus brain) concentration (*darkly shaded circles*) and a slower onset of anesthesia.

Ventilation Factors

As with all diffusible drugs anesthetics move down a concentration gradient. Continuous inhalation administration of the agent into the lungs promotes subsequent diffusion into the blood and tissues as the anesthetic progresses. Anesthetic uptake slows throughout the surgical procedure as the tissue compartments become more saturated.²⁰ The anesthetic is delivered along with the necessary amount of oxygen or an oxygen mix appropriate for the patient's condition. Supplemental nitrous oxide may also be used. Basically the faster and more deeply a patient breathes or is ventilated, the faster the patient loses consciousness at the start of anesthesia and emerges at the end.^{17,21,22} This is often referred to as the *ventilation effect*.

Ventilation-perfusion deficits or poor lung function hinders inhalation drug administration.^{23,24} Rapid-acting (low blood/gas solubility) agents are affected by these deficits to a greater extent than are slower-acting (high blood/gas solubility) drugs.²⁵ These decreases in speed can be partially compensated for by increasing the concentration of insoluble (fast) agents or increasing ventilation with soluble (slow) drugs.

Concentration or Dose

During the first minutes of gas administration, a higher concentration of the drug than necessary for maintenance, or a loading dose, is delivered to speed initial uptake. This is commonly referred to as *overpressuring* or the *concentration effect*.²⁶

Overpressuring during initial administration is a common clinical practice and is more effective the more soluble the anesthetic. Overpressuring can speed the effect of slow agents, but has less of an effect on relatively fast agents. This practice follows the kinetic standard of using a loading dose to speed onset. After the first few minutes the dose is decreased to normal maintenance levels.²⁷

As noted previously, the dose of an anesthetic is expressed in terms of MAC—the relative concentration when the anesthetic is combined with all the other gases in the lungs. Induction and maintenance doses are given as vaporizer settings of partial pressure in [Table 7.2](#).

TABLE 7.2**Inhalation Anesthetic Doses***

Anesthetic	Induction (%)	Maintenance (%)
Nitrous oxide	50–70	Same
Isoflurane (Forane)	1–4	0.5–2
Desflurane (Suprane)	3–9	2–6
Sevoflurane (Ultane)	4–8	1–4

*Doses vary according to patient status, procedure, and types of medications coadministered. Doses are given as vaporizer setting or partial pressures.

Second-Gas Effect

Simultaneous administration of a relatively slow agent such as isoflurane and a faster drug such as nitrous oxide (in high concentrations) can speed the onset of the slower agent. This is known as the *second-gas effect*.²⁸ The uptake of the slower agent in the alveoli, and to an even greater proportion in the arterial blood, is increased by administering it with a high concentration of the faster anesthetic nitrous oxide.²⁹ The faster the inherent speed of the second gas on its own, however, the less prominent the augmentation when given with nitrous oxide. For example, sevoflurane, which has low blood solubility (blood/gas solubility coefficient 0.6) is rapidly taken up into tissues. Coadministration of sevoflurane with the slightly faster nitrous oxide produces a small but significant increase in uptake as compared with sevoflurane administration alone.^{27,30–32} The mechanism for the second-gas effect is not definitive, but it has traditionally been explained as the large volume uptake of nitrous oxide concentrating the other alveolar gases. Data from 2008 suggests an added effect of ventilation perfusion scatter on the distribution of blood flow and gas uptake in the lung.²⁹ The second-gas effect also occurs during emergence where the rapid elimination of nitrous oxide produces a clinically significant acceleration in the removal of the accompanying volatile agent.³³

Tissue-Related Factors

Oil/Gas Solubility

The oil/gas solubility coefficient is an indicator of potency. The higher the solubility, the more potent the drug (see [Table 7.1](#)).^{34,35} A high solubility coefficient reflects high lipid solubility. Because the anesthetic must traverse the blood-brain barrier and penetrate other lipid membranes to produce its action, highly lipid-soluble drugs tend to be the most potent. Of the current agents, isoflurane (oil/gas partition coefficient 99) is the most potent, and nitrous oxide (oil/gas partition coefficient 1.4) is the least potent. Remember that two factors are at play: how fast the drug is delivered to the tissues (blood/gas solubility), and how efficiently it can access and affect the sites of action (oil/gas solubility). Investigations suggest that polarity along with lipophilicity plays an important yet not fully understood role in the mechanism of inhalation anesthetics.³⁶⁻³⁸

Circulatory Factors

The cardiovascular system exerts two major influences on anesthetic uptake and distribution.³⁹ First, the majority of the blood leaving the lungs with anesthetic is normally distributed to the vital organs or high-blood-flow areas, commonly referred to as the *vessel-rich group* or *central compartment*. Organs such as the heart, liver, kidneys, and brain receive proportionately more anesthetic sooner than the muscle and fat areas ([Table 7.3](#)). The longer the anesthetic is given, the greater the saturation of all body compartments.

TABLE 7.3

Tissue Compartments and Perfusion Comparisons

Characteristic	Vessel Rich	Muscle	Fat	Vessel Poor
Body weight	10%	50%	20%	20%
Cardiac output	75%	19%	6%	0%
Perfusion	75 mL/min per 100 g	3 mL/min per 100 g	3 mL/min per 100 g	0 mL/min per 100 g

Second, during induction, increases in cardiac output slow onset. All anesthetics are affected; however, the more soluble the agent (higher blood/gas coefficient, and therefore slower), the greater the effect. An increased cardiac output removes more anesthetic from the lungs, which slows the rise in lung and brain concentration.⁴⁰⁻⁴² This effect dissipates as the anesthetic proceeds.

Metabolism

The modern anesthetics are minimally metabolized (Table 7.4).⁴³ Possible toxic metabolite formation is not currently a clinical issue.⁴⁴ Drug metabolism has historically been associated with various anesthetic-related toxicities. These include hepatotoxicity from halothane⁴⁵ and other agents, and nephrotoxicity from methoxyflurane. Nitrous oxide, desflurane, and isoflurane are the least metabolized and do not result in metabolism-related toxicity. Although sevoflurane is metabolized approximately 5% to 8% releasing free fluoride ions, no related clinically significant toxicity has been noted.⁴⁶⁻⁴⁹

TABLE 7.4
Anesthetic Metabolism

Agent	Average Metabolism (%)
Sevoflurane	5-8
Nitrous oxide	< 1
Isoflurane	< 1
Desflurane	< 0.1

Temperature

Inhaled anesthetics are often administered to patients during hyperthermic or hypothermic conditions. The rate of induction of anesthesia depends on a balance among alveolar ventilation, cardiac output, tissue perfusion, anesthetic solubility in blood and tissues, anesthetic requirement, and potency. As temperature falls both solubility and potency increase, thereby tending to cancel each other as factors affecting the rate of induction. Decreases in alveolar ventilation and perfusion of brain and other tissues tend to retard induction. Under hypothermia tissue/blood partition coefficients are maintained relatively constant; however, there is an enlargement of tissue anesthetic capacity. The decrease in the perfusion of tissues tends to slow drug delivery to the brain and retard induction. However, these effects are balanced by a decrease in anesthetic requirement and an increase in potency of the anesthetics during hypothermia. Overall induction tends to be slower during hypothermia. This can be somewhat overcome by

increasing concentrations. During recovery from anesthesia the increased tissue capacity of anesthetics and slower perfusion during hypothermia appears to slow recovery. Hyperthermia increases anesthetic requirement and cardiac output, which also leads to a slower induction.⁵⁰⁻⁵³ Some factors that can affect induction rate are

Box 7.2 Box 7.2.

Factors That Can Affect Induction Rate

Faster Induction

- Low blood gas solubility
- Low cardiac output
- High minute ventilation
- High fresh gas flows
- High concentration (overpressuring)
- Second gas effect

Slower Induction

- High blood gas solubility
- High cardiac output
- Low minute ventilation
- Low fresh gas flow rates
- Low concentrations
- Ventilation perfusion deficits
- Hypothermia

Emergence

After surgery, when the anesthetic is discontinued, the same principles that influence onset apply. The anesthetic leaves the tissues via the blood and exits the lungs with ventilation. Routine practice is to administer 100% oxygen to assist recovery. If nitrous oxide was given, 100% oxygen prevents diffusion hypoxia. Anesthetics redistribute out of the tissues in a more uniform manner compared with the way they distribute during onset. An equilibrium is approached among tissues during the anesthetic period, so recovery tends to be smoother than induction with respect to the excitatory stage responses. In general, the longer an anesthetic is administered, the slower the patient emerges. This effect is greatest with the most soluble isoflurane and less with sevoflurane and desflurane, respectively. Differences among anesthetics are small but significant and are seen primarily during the final 10% of the elimination process.⁵⁴ As expected, the least soluble desflurane exhibits the fastest clinical recovery, with sevoflurane and isoflurane following in that order. Residual anesthetic has been shown to remain in the body for several days following a routine anesthetic.⁵⁵ Research from 2015 indicates that emergence may also be influenced by the release of neuropeptides such as orexins A and B, which are important factors regulating sleep wake cycles and a current target for pharmacologic manipulation.^{56,57} **Box 7.3** shows several signs and phases of **Emergence**.

Emergence From General Anesthesia

General Anesthesia

- Stable administration of anesthetic drugs
- Arousal not possible, unresponsive; eyes closed, with reactive pupils
- Analgesia, akinesia
- Drug-controlled blood pressure and heart rate
- Mechanically controlled ventilation

- EEG patterns ranging from delta and alpha activity to burst suppression

Emergence, Phase 1

- Cessation of anesthetic drugs
- Reversal of peripheral-muscle relaxation (akinesia)
- Transition from apnea to irregular breathing to regular breathing
- Increased alpha and beta activity on EEG

Emergence, Phase 2

- Increased heart rate and blood pressure
- Return of autonomic responsiveness
- Responsiveness to painful stimulation
- Salivation (7th and 9th cranial nerve nuclei)
- Tearing (7th cranial nerve nuclei)
- Grimacing (5th and 7th cranial nerve nuclei)
- Swallowing, gagging, coughing (9th and 10th cranial nerve nuclei)
- Return of muscle tone (spinal cord, reticulospinal tract, basal ganglia, and primary motor tracts)
- Defensive posturing
- Further increase in alpha and beta activity on EEG
- Extubation possible

Emergence, Phase 3

- Eye opening
- Responses to some oral commands
- Awake patterns on EEG
- Extubation possible

Diffusion Hypoxia

During emergence, when high concentrations of a rapid (insoluble) anesthetic such as nitrous oxide have been given, the drug exits the body quickly through the lungs and is replaced by less soluble nitrogen in air. This may result in a transient dilution of normal respiratory gases such as oxygen and carbon dioxide. This phenomenon is referred to as *diffusion hypoxia*. Administration of 100% oxygen for several minutes when anesthesia is terminated entirely avoids this potential problem.

Diffusion of Nitrous Oxide Into Closed Spaces

Nitrous oxide diffuses into air-containing cavities in the body during an anesthetic procedure. These air-containing spaces are normally rich in nitrogen, which is 34 times less soluble than nitrous oxide. If the space is expandable, it increases in volume. Examples of expandable air cavities include air embolism, pneumothorax, acute intestinal obstruction, intraocular air bubbles produced by sulfur hexafluoride gas injection, and pneumoperitoneum. Rigid air-containing spaces will undergo an increase in pressure. This includes tympanic membrane grafting after tympanomastoid procedures, and intracranial air during diagnostic or surgical intracranial procedures. Nitrous oxide should be avoided in these situations. The endotracheal tube cuff, laryngeal mask airway, and balloon-tipped pulmonary artery catheters may expand during nitrous oxide anesthesia, and appropriate precautions and adjustments should be considered.⁵⁸⁻⁶⁰

Some characteristics and time courses for air expansion are noted

in Table 7.5.⁶¹

TABLE 7.5

Nitrous Oxide–Induced Space or Compartment Change*

Air Space	Nitrous Oxide–Induced Change
Pneumoencephalogram	CSF pressure increases to three times baseline in 5 minutes
Intraocular hexafluoride gas	2–18 mm Hg increase in pressure in 20 minutes
Middle ear pressure	Increased 1–7 mm Hg in 1 hour
Pneumothorax	2–3 times the volume in 5–20 minutes
Intestinal gas	Double in 150 minutes
Air bubble	Immediate increases in size occur

*The rate at which the pressure changes depends on the perfusion of surrounding tissue, compliance of the space, and the concentration of nitrous oxide.

CSF, Cerebrospinal fluid.

Data adapted from Evers AS, et al, eds. *Anesthetic Pharmacology*. 2nd ed. Cambridge: Cambridge University Press; 2011:393.

Pediatrics

The uptake of anesthetic drugs is faster in children than in adults.⁶² In other words, a child goes to sleep faster than an adult patient.⁶³ The child's higher alveolar ventilation per weight accounts for this effect.

Infants and children have a higher cardiac output per weight than adults. As noted previously, the higher the cardiac output, the slower the onset. This effect is minimized, however, by the increased cardiac output distributed to the vessel-rich group in children. The infant's lower muscle mass allows more of the agent to concentrate in the vital organs. This overall effect is to promote uptake to the brain.

Finally, anesthetics appear to be less blood soluble (i.e., they work faster) in children than in adults. This effect varies with age and the agent.⁶⁴⁻⁶⁶ The MAC or required dose of anesthetics is higher in infants and children and decreases with increasing age. Infants aged 6 months have a MAC 1.5 to 1.8 times higher than a 40-year-old adult.⁶⁷

Occasionally, during recovery from anesthesia with some inhalation agents, especially sevoflurane and to a lesser extent desflurane, emergence reactions and agitation may occur in infants, children, and young adults.⁶⁸⁻⁷⁰ Evidence suggests that this phenomenon is not pharmacokinetic or related to rapidity of emergence.⁷¹ Risk factors include preschool age 2 to 5 years, difficult parental separation behavior, anxiety, and postoperative pain.^{70,72} Administration of fentanyl, dexmedetomidine, propofol, or ketamine reduce the incidence of emergence agitation.^{73,74} Midazolam, serotonin antagonists, or parental presence upon emergence have no reducing effect.⁷⁰ A glossary of pharmacokinetic concepts is given in [Table 7.6](#).

TABLE 7.6

Inhalational Anesthetic Pharmacokinetic Concepts

Concept	Comments
Minimum alveolar	The MAC required to achieve surgical anesthesia (immobility) in 50% of patients exposed to a noxious stimulus.

concentration (MAC)	
Minimum alveolar concentration awake (MAC awake)	The MAC suppressing appropriate response to commands in 50% of patients; memory is usually lost at MAC-awake; approximately 0.3–0.5 MAC.
Minimum alveolar concentration –block adrenergic responses (MAC-BAR)	The alveolar concentration of anesthetic that blunts the autonomic response to noxious stimuli; approximately 1.6–2.0 MAC.
Ventilation effect	The greater the alveolar ventilation, the faster the patient achieves anesthesia.
Concentration effect	The higher the concentration of anesthetic delivered, the faster anesthesia is achieved; this is also referred to as <i>overpressuring</i> ; as with any drug, the larger the initial dose administered, the faster the onset of action.
Blood/gas solubility coefficient	The blood/gas solubility coefficient is the indicator of an anesthetic's speed of onset and emergence: the higher the coefficient, the slower the anesthetic; conversely, the lower the coefficient, the faster the anesthetic.
Oil/gas solubility coefficient	The oil/gas solubility coefficient is the indicator of an anesthetic's potency: the higher the coefficient, the more potent the agent.
Second-gas effect	The second-gas effect is a phenomenon in which two anesthetics of varying onset speeds are administered together: a high concentration of a fast anesthetic such as nitrous oxide is administered with a slower second anesthetic gas; the slower gas achieves anesthetic levels more quickly than if it had been given alone.
Diffusion hypoxia	Diffusion hypoxia occurs when high concentrations of nitrous oxide are administered; at the end of the procedure, when nitrous oxide is discontinued, it leaves the body very rapidly, causing a transient dilution of the oxygen and carbon dioxide in the lungs; hypocarbia and hypoxia may occur; administration of 100% oxygen for approximately 3–5 min when nitrous oxide is discontinued alleviates this problem.
Cardiac output effect	Increases in cardiac output decrease the speed of onset of all anesthetics; the more soluble anesthetics are affected to a much greater extent than the insoluble anesthetics.
Ventilation-perfusion abnormalities	Ventilation-perfusion abnormalities reduce the speed of onset of all anesthetics and affect the insoluble agents to a much greater degree than the soluble agents
Pediatrics	Children achieve anesthesia more rapidly than adults because of a higher ventilatory rate and vessel-rich-group blood flow; this occurs despite the fact that the required dose and cardiac output are higher in children.
Obesity	Obesity has minimal clinical effects on anesthetic induction; however, emergence may be slower because of deposition of anesthetics in fat.
Pregnancy	The kinetics of the inhalation anesthetics are similar in pregnant women and nonpregnant women; placental transfer is time dependent as expected.

Other Factors

Obesity

Obesity has a minimal clinically significant effect on the uptake of the inhalation anesthetics. Some clinicians prefer desflurane because of its low solubility and lipophilicity, which appears to promote a slightly faster recovery. Long procedures and morbid obesity allow for an increase in deposition of anesthetics into fat and may prolong recovery.⁷⁵⁻⁷⁷

Pregnancy

Pregnant women have a higher minute ventilation than nonpregnant women, which would predict a faster uptake. Conversely, they also have a higher cardiac output, which tends to slow uptake. Overall, these actions oppose each other so that the uptake of anesthetics in pregnant women will be similar to nonpregnant women.⁷⁸ Maternal to fetal transfer of the nitrous oxide has been studied and data suggests that placental transfer during cesarean section is slower than maternal uptake and time dependent.⁷⁹

Shunts

Right-to-Left Shunt

A right-to-left shunt may be pathophysiologic or produced as part of the anesthetic technique such as one lung ventilation. With a right-to-left shunt, the shunted blood mixes with and dilutes the blood coming from the ventilated alveoli resulting in a reduction of alveolar partial pressure of the anesthetic. The decrease in the rise in alveolar concentration slows induction of anesthesia. The extent of slowing a right-to-left shunt will produce in the rate of increase in the alveolar concentration, varies with the solubility of the anesthetic. The rate of rise of the alveolar concentration of an insoluble agent (low blood/gas coefficient) will be affected more than that of a soluble anesthetic (high blood/gas coefficient). This

occurs because uptake of a soluble anesthetic offsets dilutional effects of shunted blood on the alveolar concentration. Uptake of an insoluble drug is minimal so dilutional effects on the alveolar concentration are unopposed. The impact of a right-to-left shunt is opposite to that observed with changes in cardiac output and alveolar ventilation. When considering these opposing forces there is no clinically significant effect on the speed of induction.^{80,81}

Left-to-Right Shunts

Left-to-right tissue shunts result in the blood delivered to the lungs containing a higher partial pressure of anesthetic than that present in blood that has passed through tissues. Systemic left to right shunting causes the anesthetic partial pressure in mixed venous blood to increase more rapidly than it would in the absence of such shunts. When blood flow to other tissues remains normal and the left-to-right shunt simply represents excess cardiac output, the resulting increase in anesthetic uptake is offset by the increase in anesthetic partial pressure in mixed venous blood. The result is a slight increase in the rate of anesthetic delivery or uptake into the brain, muscle, and other tissues. In cases where large left-to-right shunts result in reduced blood flow to other tissues, anesthetic equilibration in those tissues will be relatively slow.

Left-to-right shunts offset the dilutional effects of a right-to-left shunt on the alveolar concentration. The effect of a left-to-right shunt on the rate of increase in the alveolar anesthetic concentration is detectable only if there is a concomitant right-to-left shunt. Likewise, the effect of a right-to-left shunt on the rate of increase in the arterial anesthetic concentration is maximal in the absence of a left-to-right shunt.^{80,81}

Cardiopulmonary Bypass

The transfer characteristics of modern membrane oxygenators are more limited than the lungs. During bypass it is necessary to administer a relative higher concentration of the volatile agent compared to that which is required when administered by normal lung inhalation. This will ensure the adequate transfer across the membrane of the oxygenator and an adequate depth of anesthesia.

The uptake of volatile agents administered by the oxygenator is dependent on three factors: blood/gas solubility, which increases as temperature falls; tissue/gas solubility, which increases as temperature falls; and oxygenator uptake.

Like the intact circulation, the uptake and elimination of volatile anesthetic agents during cardiopulmonary bypass (CPB) is inversely proportional to blood/gas solubility. Whereas increasing gas flow to the oxygenator increases uptake of volatile agents, changes in pump flow rate have no impact. This is likely because of a relatively small blood volume and large pump flow at the oxygenator. This is quite different from the intact circulation where cardiac output has a major impact on the pulmonary uptake of volatile anesthetic agents.^{82,83}

Summary

A thorough understanding of the basic pharmacokinetic principles involved in administering anesthetic gases and the development of clinical skills in their use are the cornerstones of modern anesthesia practice. Adults are generally induced with one of the several available intravenous agents and maintained with a combination of inhalation and intravenous drugs. Better anesthesia machines and more sophisticated monitoring have greatly facilitated the quantification of clinical anesthetic levels and depth, contributing to the remarkable safety of modern anesthesia practice.

Inhalation Anesthetics

John J. Nagelhout

The author would like to thank Mark Kossick for his contribution to this chapter in previous editions.

In the span of almost two centuries, major advances have been made in the development and clinical use of inhalation anesthetics (Table 8.1); this continuum includes the investigation of nitrous oxide (N_2O) in 1800 by Humphry Davy¹ following its preliminary discovery by Dr. Priestly in 1786² with what was termed *dephlogisticated air*. Then, 195 years later, in 1995, the most current inhaled anesthetic (sevoflurane) was approved by the United States Food and Drug Administration (FDA).

TABLE 8.1

History of the Introduction of Inhalation Anesthetics

Anesthetic	Year Anesthetic Properties Demonstrated/Introduced
Ether (Crawford Long)	1842
N_2O (Horace Wells)	1845
Chloroform (James Simpson)	1847
Cyclopropane (George Lucas, Velyien Henderson)	1934
Fluroxene	1951
Halothane	1956
Methoxyflurane	1960
Enflurane	1973
Isoflurane	1981
Desflurane	1993
Sevoflurane	1995

The present-day use of N_2O can be credited to Edmund Andrews, a professor of surgery in Chicago. In 1868, he declared that a safer anesthetic could result from combining oxygen (O_2) with N_2O .³ Before that time, N_2O was administered through a mouthpiece with a nose clamp to prevent the rebreathing of air.

One of the earliest “complete” anesthetic agents used was diethyl

ether ($C_2H_5-O-C_2H_5$). The first ether anesthetic was administered in Georgia on March 30, 1842, when Crawford Long anesthetized a patient for a minor operation (excising a tumor).⁴ However, the recognition of numerous unfavorable characteristics (excessive secretions with inhalation induction, laryngospasm, excessive depths of anesthesia) prompted its disappearance from clinical practice as newer agents were subsequently developed.

In the 1930s, research into potential anesthetic agents was based on the principle of a structure-activity relationship.⁵ One of the earliest inhalation anesthetics developed in this manner was divinyl ether. Halothane was introduced into clinical practice in 1956 by Bryce-Smith and O'Brien in Oxford⁶ and Johnstone in Manchester,⁷ and represented a significant advancement in inhalation anesthesia. Its sweet odor, nonflammability, and high potency offered clinical characteristics that were absent from the previously available inhaled anesthetics. The search for newer and improved inhalation anesthetics persisted, as concerns with the hepatotoxicity and arrhythmogenicity of this alkane derivative began to be documented.

The two most recently released inhalation agents, sevoflurane (synthesized by Regan in the late 1960s) and desflurane (the 653rd compound of more than 700 synthesized by Terrell and colleagues between 1959 and 1966), are commonly used today for a diverse surgical population, based on their pharmacokinetic and pharmacodynamic profiles. Although desflurane and sevoflurane do not possess all of the properties of an ideal inhalation agent, anesthesia providers routinely select one or the other for most surgical procedures due to the sufficient number of clinical benefits attributed to these agents.

Only four new anesthetics have been approved by the USA FDA over the past 30 years (1985–2014), compared to ten during the preceding 30 years (1955–1984). Investigational anesthetics are almost exclusively intravenous anesthetics (nine compounds), and only one has been approved. None demonstrate a truly novel mechanism of action. The lack of new anesthetics may be due to multiple reasons, including the dramatic improvement in anesthesia safety (which decreases the pressure to develop new drugs with better safety margins), lack of pharmaceutical industry

profit, lack of academic interest, and the fact that the mechanism of action of general anesthetics is poorly understood.⁸

Relationship Between Chemical Structure and Agent Characteristics

An understanding of the chemical structure of inhalation agents provides insight into their physical properties (e.g., flammability). However, the relationship between the pharmacologic characteristics (e.g., arrhythmogenic properties) and chemical structure of agents is not as predictable. This section reviews the structure-activity relationship of anesthetic vapors and their clinical relevance. Some selected physical and chemical properties of the anesthetics are listed in [Table 8.2](#).

TABLE 8.2
Select Characteristics of Inhalation Anesthetics

Characteristics	Nitrous Oxide	Isoflurane	Desflurane	Sevoflurane
Molecular formula	N ₂ O	C ₃ H ₂ ClF ₅ O	C ₃ H ₂ F ₆ O	C ₄ H ₃ F ₇ O
Ostwald blood/gas partition coefficient (37°C)	0.47	1.43	0.42	0.68
Oil/gas partition coefficient	1.4	99	18.7	50
Saturated vapor pressure (mm Hg, at 20°C)	gas	238	669	157
Molecular weight (g/mol)	44.01	184.49	168.04	200.05
Preservative	none	none	none	none

All commonly used inhalation agents are ethers (R–O–R) or aliphatic hydrocarbons (straight-chain or branched nonaromatic hydrocarbons) with no more than four carbon atoms ([Fig. 8.1](#)). The length of the anesthetic molecule is significant in that immobility (anesthetic effect) is attenuated or lost if the chain length exceeds four or five carbon atoms (5 angstroms [Å]).⁹ The molecular shape of the agents is spherical or cylindrical with a length less than 1.5 times the diameter.¹⁰

Exceptions to this principle exist and demonstrate that the correlation between potency and lipid solubility is not perfect.

With regard to arrhythmogenic properties, increasing the number of halogen atoms within a volatile agent favors the genesis of cardiac dysrhythmias.¹⁴ Nevertheless, alkanes that contain five halogens (e.g., halothane) are more prone to induce arrhythmias than ethers with six halogen atoms (e.g., isoflurane). This may be due to the lack of an oxygen molecule in halothane versus the ethers.¹⁵

Volatile anesthetics interact with the main repolarizing cardiac potassium channels (hERG) and IKs channels, as well as with calcium and sodium channels at slightly higher concentrations. Inhibition of these ion channels alters both action potential shape (triangulation) and electrical impulse conduction, which may facilitate arrhythmogenesis by volatile anesthetics per se and is potentiated by catecholamines. Action potential triangulation by regionally heterogeneous inhibition of calcium (Ca^{2+}) and potassium (K^+) channels will facilitate catecholamine-induced afterdepolarizations, triggered activity, and enhanced automaticity. Inhibition of cardiac sodium channels will reduce conduction velocity and alter the refractory period; this is potentiated by catecholamines and promotes reentry arrhythmias.¹⁶

Flammability is reduced and chemical stability enhanced by substituting hydrogen atoms with halogens. The epitome of this relationship is demonstrated with desflurane, a compound that contains fluorine as its only halogen and thus strongly resists biodegradation; desflurane is metabolized one tenth as much as isoflurane.^{17,18}

Pharmacodynamics

Mechanisms of Action

The exact mechanism of action of inhalation anesthetics remains elusive. A favored hypothesis proposes that general anesthesia results from direct multisite interactions with multiple and diverse ion channels in the brain. Neurotransmitter-gated ion channels and two-pore K⁺ channels are key players in the mechanism of anesthesia; however, new studies have also implicated voltage-gated ion channels. A variety of ligand-gated ion channels, receptors, and signal transduction proteins are modulated by anesthetics at myriad levels of the central nervous system (CNS). Recent biophysical and structural studies of Na⁺ and K⁺ channels strongly suggest that halogenated inhalational general anesthetics interact with the gates and pore regions of these ion channels to modulate function. A combination of many different mechanisms could be responsible for general anesthetic action. Evidence indicates that no single universal receptor explains the actions of general anesthetics. The multiple components of the anesthetic state, amnesia, sedation/unconsciousness, analgesia, and immobility are mediated by separate effects on different receptors and neuronal pathways.¹⁹⁻²²

The following properties of anesthetics must be taken into account when developing a theory that attempts to explain their mechanism of action:²³

- Lipid solubility is directly proportional to potency (Meyer-Overton rule).
- Reversal of anesthetic effect can be achieved with the application of pressure, with some exceptions (animal species variation).
- No common chemical structure for the variety of compounds is capable of producing anesthesia.
- The molecular and structural changes responsible for producing anesthesia must occur within seconds and be reversible.
- A reduction in body temperature lowers anesthetic requirements.

The unitary hypothesis was previously offered as an attempt to

meet these prerequisites. This theory proposed that all inhalation anesthetics work via a similar (undefined) mechanism of action, but not necessarily at the same site of action. One factor that supported this hypothesis was the Meyer-Overton correlation, which recognized that the more lipid soluble the agent, the greater its potency (the lower its MAC value). The Meyer-Overton theory postulated that even though the anesthetic agents have a wide variety of structures, they share the ability to alter the lipid environment of proteins, thus changing their function. Though elegant, this theory has not been supported by research, which instead points to anesthetics binding to specific pockets in proteins and altering their function.^{24,25}

In vitro, in vivo, animal, and human subject research has permitted the description of the mechanism of action of inhaled anesthetics relative to distinct anatomic regions of the body (including the cellular level) and molecular changes. The spinal cord is known to mediate immobility to a painful stimulus via several mechanisms, including: (1) enhancing background K^+ currents in tandem-pore-domain, weak inward-rectifying K^+ channels (TWIK, TASK [TWIK-related acid-sensitive K^+ channel])²⁶⁻²⁸ and (2) reducing spontaneous action potential firing of spinal neurons via glycine receptors and γ -aminobutyric acid type A ($GABA_A$) receptors.²⁹ Investigators have also demonstrated that nonimmobilizers with lipophilic characteristics (e.g., perfluoropentane) are able to produce amnesia but not immobility to noxious stimuli, which suggests two separate sites and mechanisms of anesthetic action for some drugs.³⁰ In contrast with other research, spinal and cerebral $GABA_A$ receptors (which have the same receptor-clinical effect) were shown to contribute to the ability of volatile anesthetics to produce immobility; therefore, the anesthetic effect of immobility is modulated at the spinal cord and supraspinal level.^{31,32}

The CNS effects of amnesia and loss of consciousness are likely produced separately from immobility, as conceptualized in the theory of MAC. The concept of MAC refers to the concentration required to prevent movement in response to a surgical situation. This is probably the result of an effect at the spinal cord level via glycine, sodium, and *N*-methyl-D-aspartate (NMDA) receptor

action. K^+ , $GABA_{A}$, opioid, α_2 -, $5HT_3$, and acetylcholine receptors are likely not involved in producing immobility.³³ They may be involved in varying degrees in the amnestic and anesthetic effects in the CNS.^{34,35} The CNS effects are dose-related, with amnesia requiring the lowest dose, followed by sedation, unconsciousness, and immobility. These effects are produced at varying anatomic sites, as shown in Fig. 8.2. A summary of the mechanisms of action of inhalation anesthetics reviewed in this chapter is provided in Box 8.1.

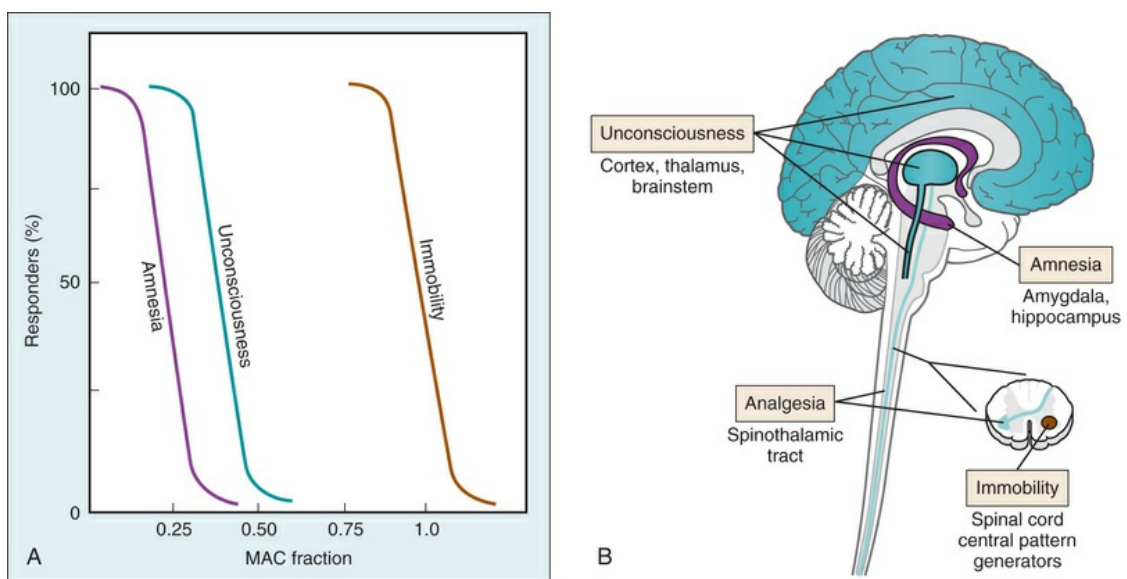

FIGURE 8.2 Multiple sites of volatile anesthetic action. **A**, Volatile anesthetics lead to multiple dose-dependent behavioral endpoints. Cardiovascular responses occur at even greater doses (not shown). **B**, Amnesia, the most sensitive anesthetic endpoint, probably involves the hippocampus, amygdala, mediotemporal lobe, and possibly other cortical structures involved in learning and memory. Unconsciousness likely involves the cerebral cortex, thalamus, and brain stem reticular formation essential to consciousness and arousal. Immobility occurs by anesthetic action on the spinal cord central pattern generators. Anesthetic effects on the spinal cord blunts ascending impulses arising from noxious stimulation, leading to analgesia, and might indirectly contribute to anesthetic-induced unconsciousness. (From Hemmings Jr. HC, Egan TD. *Pharmacology and Physiology for Anesthesia*. Philadelphia: Elsevier; 2013:164.)

Box 8.1

Mechanisms of Action of Inhalation Anesthetics

No single comprehensive or unitary theory of anesthesia exists. The effects of the inhalation anesthetics cannot be explained by a single mechanism. Multiple targets contribute to the sedation, unconsciousness, amnesia, immobility, and analgesic actions of anesthetics.

The most likely targets include tandem pore potassium channels, voltage-gated sodium channels, NMDA receptors, and the pentameric ligand-gated ion channels (pLGICs), including glycine receptors (GlyRs) and GABA_ARs.

The potency of general anesthetics correlates with their solubility in oil, which is expressed as the oil/gas solubility coefficient of the anesthetic (Meyer-Overton rule). The more lipid-soluble the anesthetic, the higher the potency.

Mutational analysis using transgenic and knock-in/knock-out mice is being used to identify the role of specific types of proteins, ion channels, and other actions of general anesthetics.

Important actions of inhaled anesthetics are associated with altered activity of neuronal ion channels, particularly the fast synaptic neurotransmitter receptors such as nicotinic acetylcholine, GABA, and glutamate receptors. Anesthetics affect neuronal ion channels by binding directly to protein sites.

The immobilizing effect of inhaled anesthetics involves actions in the spinal cord. These involve modulation of ion channels, reduced spontaneous action potential firing of spinal neurons via glycine, effects on GABA_A receptors and NMDA receptors, and depression of motor neurons (perhaps via hyperpolarization).

GABA_A, γ -amino butyric acid A; NMDA, *N*-methyl-D-aspartate.

Minimum Alveolar Concentration

A useful means of comparing the potencies of inhalation agents is to use the concept of MAC, defined as the MAC at equilibrium (expressed as a percentage of 1 atmosphere), where 50% of subjects will not respond to a painful stimulus (i.e., initial surgical skin incision).³⁶ A response is defined as gross, purposeful movement of the head or extremities. The MAC represents the required dose of the anesthetic. The MAC values for the modern inhalation agents are listed in [Table 8.3](#).³⁷⁻⁴⁰

TABLE 8.3

Potencies of Volatile Anesthetics in Humans With and Without N₂O, Expressed as MAC Values

Anesthetic	MAC* (Expressed as a % of 1 Atmosphere)	MAC in 60–70% N ₂ O
Nitrous oxide	104	—
Isoflurane	1.17	0.56
Desflurane	6	2.38
Sevoflurane	2	0.66

*For patients aged 30 to 60 years.

MAC, Minimum alveolar concentration; N₂O, nitrous oxide.

MAC-awake is the minimum alveolar concentration of anesthetic that inhibits responses to command in half of patients. It is approximately one-third of MAC.

MAC-BAR is the minimum alveolar concentration of anesthetic that blunts the autonomic response to noxious stimuli. It is approximately 1.6 times higher than MAC.

The MAC of volatile agents can be affected by numerous factors, surprisingly even hair color.⁴¹ With increasing age, the MAC of all inhaled anesthetics is reduced; in humans with a mean age of 18 to 30 years, the MAC of desflurane is 7.25%, in contrast to 6% in humans 30 to 55 years of age.³⁹ Infants represent an exception to the MAC age concept, in that their anesthetic requirements exceed those of neonates. In general, the duration of anesthesia is believed not to affect MAC; however, one group of investigators found that the MAC of isoflurane was reduced over time during surgery.⁴² **Box**

Box 8.2 variables shown to reduce and increase MAC.

Relationship of Physiologic and Pharmacologic Factors to the MAC of Inhaled Anesthetics

Factors That Reduce MAC

- Increased age
- Hypothermia
- Administration of sedative hypnotics
- Coadministration of other anesthetics
- α_2 -Agonists
- Opioids
- Acute ethanol consumption
- Hypoxemia
- Hyponatremia
- Anemia (less than 4.3 mL O₂/dL blood)
- Hypotension (MAP less than 50 mm Hg)
- Pregnancy
- Lithium

Factors That Increase MAC

- Young age
- Hyperthermia
- Hyperthyroidism

- Hyponatremia
- Acute administration of CNS stimulant drugs
- Red hair in females
- Chronic alcohol abuse

Factors with No Effect on MAC

- Duration of anesthesia
- Gender
- Hypocapnia and hypercapnia
- Metabolic alkalosis
- Hypertension
- Hyperkalemia or hypokalemia

CNS, Central nervous system; *MAC*, minimum alveolar concentration; *MAP*, mean arterial pressure; O_2 , oxygen.

Two other areas related to MAC are MAC-awake and MAC-BAR (block adrenergic response). MAC-awake is defined as the MAC at which 50% of subjects will respond to the command “open your eyes.” It has also been described as the anesthetic concentration that falls between the end-tidal values that allow and prevent response to a command.⁴³ This end-tidal concentration is usually associated with a loss of recall, and encompasses approximately one-third of MAC values. MAC-awake can also be used in combination with MAC values to evaluate the potency of each agent with regard to amnestic properties. This is done by dividing MAC-awake by MAC (to calculate the MAC-awake/MAC ratio). Agents with MAC-awake/MAC ratios between 0.3 and 0.4 (e.g., desflurane, sevoflurane, and isoflurane) are considered potent anesthetics. In contrast, N_2O , which has a ratio of 0.64, is considered a weak

amnestic agent.

The MAC-BAR parameter represents the MAC necessary to block the adrenergic response (e.g., changes in plasma norepinephrine concentration, heart rate [HR], rate-pressure product, and mean arterial pressure [MAP]) to skin incision. It can be expressed as a MAC-BAR₅₀ or MAC-BAR₉₅. The former value is similar to AD₉₅ values, which represent the anesthetic dose that inhibits somatic evidence of light anesthesia in 95% of subjects in response to skin incision. Established MAC-BAR₅₀ values for volatile agents (in 60% N₂O) include 1.85 MAC for both isoflurane and desflurane. The MAC-BAR₅₀ value of desflurane can be reduced by 85% by administering 1.5 mcg/kg of fentanyl intravenously (IV) 5 minutes before skin incision.⁴⁴ When investigating desflurane in 60% N₂O combined with remifentanyl at a target plasma concentration of 1 ng/mL (via a computer-driven infusion device), the MAC-BAR₅₀ is reduced by 60%, and with a target concentration of 3 ng/mL can be reduced by a further 30%.⁴⁵

The MAC-BAR₅₀ for sevoflurane in 66% N₂O is 2.2.⁴⁶ It should be emphasized that MAC-BAR values exceed the requirements for ablation of skeletal muscle movement with surgical stimulation; therefore, blocking an adrenergic response requires a greater depth of anesthesia than preventing skeletal muscle movement. From a clinical standpoint, patients usually require anesthetic concentrations that exceed the MAC by 20% to 30% (1.2 to 1.3 times MAC). At this alveolar concentration, somatic evidence of light anesthesia will typically be abated, and fewer patients will have an adrenergic response to the stresses of surgery.⁴⁷

The concept of MAC has limitations when applied clinically to determine adequacy of anesthesia.⁴⁸ It should be viewed as a general guide to the overall depth of anesthesia. Anesthetic requirements vary throughout surgery and from patient to patient. Recent efforts have attempted to correlate MAC with the bispectral index monitor (BIS) to aid in anesthesia administration. The data show that equipotent doses of the volatile anesthetics yield different BIS values, and the clinical correlation is directly related to a specific value.⁴⁹ A 2012 outcome study noted that a triple low state, defined as an intraoperative MAP of 75 mm Hg, MAC less than 0.8,

and a BIS value less than 45, was associated with an increased length of stay and increased 30-day mortality.⁵⁰ Subsequent studies have not replicated these findings.^{51,52}

Influence of Inhalation Agents on Organs and Systems

Central Nervous System

The CNS is the primary site of action of the volatile agents, which exhibit important dose-dependent effects with significant clinical considerations. Such effects include intracranial compliance, autoregulation of cerebral blood flow (CBF; e.g., cerebrovascular reactivity to carbon dioxide [CO₂]), cerebral metabolic rate, cerebrospinal fluid pressure (CSFP), and neurologic assessment. Their typical actions, as well as their effects in patients with CNS pathology, are considered in the following sections.

Cerebral Metabolic Rate and Cerebral Blood Flow

In general, volatile agents, including isoflurane, sevoflurane, and desflurane, decrease cerebral metabolic rate of O₂ consumption (CMRO₂) in a dose-dependent manner, whereas their effect on CBF varies with dose.⁵³⁻⁵⁵ Volatile anesthetics also produce a dose-dependent increase in CBF. This effect depends on the balance between vasoconstrictive properties, due to flow-metabolism coupling, and the direct cerebral vasodilatory action of the anesthetics. When vascular resistance is decreased, CBF, cerebral blood volume, and CSFP increase. The order of potency for increasing CBF varies; it is affected by the dose of volatile anesthetic, the administration of other drugs (e.g., propofol, N₂O), and the rate of change in end-tidal concentration of agent.⁵⁶⁻⁵⁸

Uncoupling of Cerebral Blood Flow and Metabolism

When decreases in CMRO₂ are accompanied by increases in CBF, *uncoupling* is said to occur. As noted earlier, volatile anesthetics are capable of producing this effect. This paradoxical response

(decreased CMRO₂ occurring in conjunction with increased CBF) seems not to occur with 1.0 MAC or less of desflurane or isoflurane.⁵⁹ The magnitude of change is variable and dose-dependent, meaning some flow-metabolism coupling mechanism is preserved.⁶⁰

N₂O reduces cerebrovascular tone significantly. This effect is unmasked and enhanced when N₂O is combined with a volatile anesthetic (decreased autoregulation).⁶¹ The mechanism for increased CBF may be related to a sympathoadrenal-stimulating effect of N₂O. The changes produced by N₂O in the CMRO₂ are the reverse of what takes place with volatile agents (i.e., increased CMRO₂). Thus, N₂O increases CMRO₂ and CBF. Nevertheless, the combination of elevated CBF and CMRO₂ still results in an uncoupling between flow and metabolism, because the increase in CMRO₂ exceeds, albeit slightly, the elevation in CBF. In summary, N₂O use in neurosurgical procedures is acceptable, as long as the anesthesia provider recognizes that its vasodilatory effects might adversely affect surgical outcome in patients with reduced intracranial compliance. Mild hyperventilation to low normal ranges of carbon dioxide helps attenuate the increase in CBF that accompanies the use of N₂O.⁶²

Cerebral Vasculature Responsiveness to CO₂

The normal physiologic response of the cerebral vasculature to CO₂ is to vasoconstrict in the presence of hypocapnia and vasodilate with hypercarbia. This reflex is effective in the acute setting when used during neurosurgical procedures to counteract drug-induced vasodilation and to reduce brain bulk within a closed compartment (cranial vault). The usual goal for patients in whom a reduction in intracranial volume is desired is a partial pressure of arterial carbon dioxide (PaCO₂) of approximately 30 to 35 mm Hg, with a duration of effectiveness being perhaps no more than 4 to 6 hours.⁶³

Differences exist among the volatile agents in their ability to interfere with the cerebral vasculature's responsiveness to CO₂. Variables that affect the reported differences include the type of surgical procedure the patient is undergoing, associated

pathophysiology, and the presence of any coexisting disease(s). In general however, the concentrations of isoflurane, sevoflurane, and desflurane that are used clinically preserve the reactivity to changes in carbon dioxide and flow-metabolism coupling.^{64,65} One study showed that neither isoflurane nor desflurane increases intracranial pressure in normocapnic patients undergoing removal of supratentorial brain tumors. The cerebral perfusion pressure declined in parallel with MAP, as did the cerebral arteriovenous oxygen content difference. The investigators concluded that flow-metabolism coupling may be preserved during anesthesia with isoflurane and desflurane.⁶⁶ These findings suggest that the increase in CBF produced by isoflurane, desflurane, and sevoflurane can be effectively prevented by very mild hyperventilation and using concentrations less than 1.5 MAC.

Electroencephalogram and Evoked Potentials

The volatile agents produce a dose-related suppression of electroencephalography (EEG) activity (an initial increase [and a later decline] in amplitude and decreased frequency), and at high concentrations produce electrical quiescence. At deeper levels of anesthesia, the EEG may temporarily stop recording; at such time, burst suppression is said to have occurred. This is usually achieved at 1.5 to 2 MAC desflurane, and 2 MAC isoflurane or sevoflurane.^{58,67}

For those procedures requiring monitoring of the integrity of the spinal cord or mapping of cortical regions of the brain, the anesthetist should be aware that inhalation agents can skew cortical somatosensory-, motor-, brainstem-, auditory-, and visual-evoked potentials. Isoflurane, desflurane, sevoflurane, and N₂O produce a dose-dependent reduction in these evoked potentials, with visual-evoked potentials being most sensitive and brainstem-evoked potentials most resistant. Two evoked-potential variables commonly assessed are latency and amplitude. An increase in latency or decrease in amplitude of evoked potentials can reflect ischemia, or may be secondary to the volatile agent. Latency is the time between the initiation of a peripheral stimulus (e.g., electrical stimulation of the median nerve at the wrist) and onset of the

evoked potential (e.g., cortical) recorded by scalp electrodes.^{58,67-70} Sevoflurane can augment epileptic activity. Sevoflurane is the preferred anesthetic for pediatric anesthesia; however, precautions may be advisable in children with a history of epileptic activity.^{71,72} The effects of the commonly used anesthetic drugs on sensory- and motor-evoked potentials and some advantages and disadvantages for their use are listed in [Table 8.4](#). The effects of the volatile anesthetics on EEG are listed in [Chapter 19, Table 19.3](#).

TABLE 8.4

The Effect of Various Anesthetic Agents on Neurophysiologic Monitoring of Evoked Potentials

Drug Name	Drug Class	Effect on SSEPs	Effect on MEPs	Length of Emergence	Approximate CST1/2 (min) at 2/4/6 h and B:GC for volatile agents	Clinical Advantages Relating to Intraoperative Neurophysiologic Monitoring	Disadvantages

Emergence and Neurologic Assessment in Adults

Although a smooth and rapid emergence from a general anesthetic is desirable for all surgical patients, it is especially meaningful for neurosurgical patients. Delayed emergence in this specialty of anesthesia can have devastating consequences. A slow return of consciousness makes it difficult to perform the initial postoperative neurologic examination. It can also lead to unnecessary therapeutic or diagnostic intervention and predispose the patient to respiratory complications.⁷³

Because of this, research has focused on recovery profiles following anesthesia techniques with or without an inhalation agent. Some investigators report a more rapid awakening (after

approximately 2 hours of anesthesia) from total intravenous anesthesia (TIVA) in nonneurosurgical patients compared with patients who have received sevoflurane and desflurane combined with N₂O.⁷⁴ In side-by-side comparisons of desflurane and sevoflurane, desflurane permits for a more rapid awakening than sevoflurane in volunteers after 8 hours of exposure.⁷⁵ One study also found no difference in early postoperative recovery and cognitive function between a balanced sevoflurane-fentanyl technique versus propofol-remifentanyl (TIVA) management in patients undergoing supratentorial intracranial surgery.⁷⁶ Similarly, a multicenter randomized controlled trial of patients scheduled for elective supratentorial craniotomy surgery found no significant difference between sevoflurane-remifentanyl and propofol-remifentanyl techniques.⁷⁷ The inhalation agents continue to be widely used in most neurosurgical procedures.

Cerebral Neuroprotection

An area of ongoing research has been the application of volatile anesthetics via preconditioning and postconditioning techniques for neuroprotection following global and/or focal ischemia/hypoxia. Although a growing body of preclinical data suggests that anesthetic agents such as volatile anesthetics and propofol might have neuroprotective properties, clinical evidence is lacking. There are differences in baseline conditions, comorbidities, the severity of ischemia, and affected brain regions among patients that may interfere with evaluating the neuroprotective effect of volatile anesthetics. The goal of neuroprotective treatments is to reduce the clinical effects of cerebral damage through two major mechanisms: increased tolerance of neurological tissue to ischemia and changes in intracellular responses to energy supply deprivation. Of the various preconditioning strategies, remote ischemic preconditioning (RIPC) and pharmacologic preconditioning appear to be the most clinically promising. Anesthetic preconditioning is a phenomenon of transient organ exposure to anesthetics, within clinical concentrations, that triggers endogenous cellular protection. Anesthetic postconditioning is a concept based on modulation of reperfusion after ischemia that includes the introduction of

anesthetics immediately at the onset of reperfusion. RIPC shows potential and is noninvasive, inexpensive, and reasonably well-tolerated. Brief episodes of ischemia are induced in an arm or leg by inflation of a blood pressure or tourniquet cuff to more than 20 or 30 mm Hg above systolic blood pressure for 5 to 10 minutes in two to five cycles prior to the potentially injurious cerebral insult.

Magnesium also shows promise, although timing and dosing require clarification. Given the complex pathophysiology of cerebral ischemia and hypoxia, a multimodal approach to neuroprotective strategies may prove the best approach.^{78–80}

Proposed mechanisms for the neuroprotective effects of the anesthetics are shown in [Box 8.3](#).

Mechanisms Underlying the Neuroprotective Effects of IV and Inhaled Anesthetics in the Brain Mechanism

- Inhibition of glutamate release and postsynaptic glutamate receptor-mediated responses
- Stimulation of GABA_A receptors
- Inhibition of the peripheral sympathetic response to ischemia
- Prevention of apoptosis
- Antioxidative effect
- Direct scavenging of free radicals and decrease in lipid peroxidation
- Preconditioning (activation of sarcolemmal and mitochondrial K_{ATP} channels, activation of adenosine receptors and the activation of signaling cascades, such as Akt and PKC signaling pathways)
- Anti-inflammatory activity

Akt, serine/threonine kinase; GABA_A, γ -aminobutyric acid A; *IV*,

intravenous; *PKC*, protein kinase C.

Developmental Neurotoxicity

A great deal of concern has arisen regarding the safety of anesthesia in infants and children. There is a growing body of evidence in rodents and nonhuman primates that anesthetics in common clinical use are toxic to the developing brain. Proposed mechanisms of anesthetic-induced neurodegeneration in the newborn involve activation of the intrinsic and extrinsic apoptotic cell death pathways. An estimated 6 million children (including 1.5 million infants) undergo surgery and anesthesia each year in the United States alone, so the clinical relevance of anesthetic neurotoxicity is an urgent public health matter.^{81–84}

Three large-scale clinical studies further address this issue. The Pediatric Anesthesia and NeuroDevelopment Assessment (PANDA) study is a multisite, ambidirectional sibling-matched cohort study conducted at four sites in the United States. Researchers enrolled a total of 105 sibling pairs. Anesthesia consisted of a single exposure to general anesthesia during inguinal hernia surgery in the exposed sibling and no anesthesia exposure in the unexposed sibling, before age 36 months. Among healthy children with a single anesthesia exposure before age 36 months, compared with healthy siblings with no anesthesia exposure, there were no statistically significant differences in IQ scores in later childhood.⁸⁴

Another large-scale study is the General Anaesthesia Compared to Spinal Anesthesia (GAS) Trial, which compares the neurodevelopmental outcome between two anesthetic techniques. It is an international randomized trial comparing general sevoflurane anesthesia with regional anesthesia. A total of 363 infants were randomly assigned to receive awake-regional anesthesia and 359 to receive sevoflurane-based general anesthesia. Outcome data were available for 238 children in the awake-regional group and 294 in the general anesthesia group. Researchers found no evidence that less than 1 hour of sevoflurane anesthesia in

infancy increases the risk of adverse neurodevelopmental outcome at 2 years of age compared with awake-regional anesthesia.⁸⁵

Finally, a recent population-based cohort study assessing developmental outcomes at primary school entry (age 5–6) in more than 28,000 children exposed to general anesthesia was reported. The anesthesia group was compared with more than 55,000 matched controls. They found no evidence of adverse developmental outcomes in children exposed to anesthesia before age 2 or in those with multiple exposures to anesthesia. While there was a very small risk of adverse developmental outcomes in children exposed after age 2, the significance and cause of this finding was unclear. The authors noted that it was reassuring that no adverse effects were seen in such a large group of children exposed to anesthesia under age 2, which is a vulnerable period of human neurodevelopment.⁸¹

The U.S. Food and Drug Administration (FDA) is warning that repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years or in pregnant women during their third trimester may affect the development of children's brains.⁸² This is based on animal studies. They note that recent human studies suggest that a single, relatively short exposure to general anesthetic and sedation drugs in infants or toddlers is unlikely to have negative effects on behavior or learning.⁸² In the United States clinicians can recommend that parents visit the SmartTots website (www.smarttots.org), which is a collaboration between the International Anesthesia Research Society and the FDA to coordinate and fund research on the topic of anesthesia and neurodevelopment. This website contains useful resources and a consensus statement created by experts in the field on this topic for both parents and professionals.

Until proven otherwise, it can be recommended to keep anesthesia and surgery as short as possible and to use short-acting drugs and/or a combination of general anesthesia and multimodal pain therapy, including systemic analgesics and local or regional anesthesia to reduce the overall drug dosage.

Postoperative Cognitive Dysfunction

Postoperative cognitive dysfunction (POCD) as a result of surgery

and anesthesia is a concern, especially in the elderly. In a recent study of 8503 twins, a negligible but statistically significant decrease in a sensitive composite cognitive score was present in twins where only one the twins underwent at least one major surgery, but there was no difference by intrapair analysis. There was no clinically significant association of major surgery and anesthesia with long-term cognitive dysfunction, suggesting that factors other than surgery and anesthesia are more important. A discussion of POCD can be found in [Chapter 54](#).⁸⁶

Emergence Phenomenon in Children

Emergence delirium (ED) occurs after the use of sevoflurane and desflurane in preschool-aged children in the postanesthesia care unit. Symptoms usually last approximately 15 minutes and resolve spontaneously once the child eliminates more of the anesthetic. A variety of factors have been suggested to play a potential role in ED. Restless behavior upon emergence causes discomfort to the child, postanesthesia recovery nurses, and parents. Some suggested factors related to transient emergence delirium are noted in [Box 8.4](#). A dose-dependent effect of sevoflurane, which increases seizure-like EEG activity, has also been proposed.^{87,88} These children may require analgesics or sedatives, which can delay discharge. It also places patients at increased risk of falls, disruption of surgical repairs, and removal of lines and tubes. ED is self-limiting and devoid of apparent sequelae, as long as the child is protected from self-injury. Preventive measures include reducing preoperative anxiety and postoperative pain and providing a quiet, stress-free environment for postanesthesia recovery. Treatment may include small doses of midazolam, ketamine, fentanyl, clonidine, or dexmedetomidine, as well as dexamethasone and nonsteroidal anti-inflammatory drugs (NSAIDs). Reuniting the child with the parents is helpful.⁸⁹⁻⁹¹ ED is discussed further in [Chapter 55](#).

Possible Etiologic Factors of Pediatric Emergence Agitation/Delirium

- Intrinsic characteristics of the anesthetics desflurane and sevoflurane

- Postoperative pain
- Surgery type (ear, nose, and throat surgery)
- Age
- Preoperative anxiety
- Previous hospital experience
- Type of induction
- Child temperament and personality
- Adjunct medication
- Behaviors including nonpurposefulness; eyes averted, staring, or closed; and unresponsiveness during early emergence

Cardiovascular System

All inhalation agents are capable of altering hemodynamics, and the extent is related to various preoperative and intraoperative factors (e.g., ASA physical status classification; coadministration of vasoactive drugs, opioids, benzodiazepines, and propofol). This section reviews the influence of volatile agents on the cardiovascular system.

Systemic Hemodynamics

Isoflurane, desflurane, and sevoflurane all reduce MAP (Fig. 8.3), cardiac output (CO), and cardiac index (CI) in a dose-dependent fashion.^{92,93} For example, desflurane, sevoflurane, and isoflurane predominantly reduce MAP via a reduction in systemic vascular resistance (SVR); sevoflurane has the lowest dose-response relationship (Fig. 8.4).⁹⁴ N₂O activates the sympathetic nervous system and increases SVR,⁹⁵ which can also lead to an increase in central venous pressure and arterial pressure. This sympathetic nervous system response appears to be intact during coadministration of volatile agents.⁹⁶

FIGURE 8.3 Mean arterial pressure response to the administration of isoflurane, sevoflurane, and desflurane in healthy volunteers. With increasing minimum alveolar anesthetic concentration, progressive decreases in blood pressure occurred with each of the volatile anesthetics. (Adapted from Ebert TJ, Muzi M. Sympathetic hyperactivity during desflurane anesthesia in healthy volunteers: a comparison with isoflurane.

Anesthesiology. 1993; 79(3):444–453; Ebert TJ, et al. Neurocirculatory responses to sevoflurane anesthesia in humans: a comparison to desflurane. *Anesthesiology*. 1995; 83(1):88–95.)

FIGURE 8.4 Forearm vascular resistance response to the administration of isoflurane, sevoflurane, and desflurane in healthy volunteers. In general, forearm vascular resistance was progressively decreased with increasing minimum alveolar anesthetic concentrations of each of the volatile anesthetics; however, this decline was less in the group receiving sevoflurane. (Adapted from Ebert TJ, Muzi M. Sympathetic

hyperactivity during desflurane anesthesia in healthy volunteers: a comparison with isoflurane. *Anesthesiology*. 1993; 79(3):444–453; Ebert TJ, et al. Neurocirculatory responses to sevoflurane anesthesia in humans: a comparison to desflurane. *Anesthesiology*. 1995; 83(1):88–95.)

In general, N₂O used in combination with inhalation agents increases SVR and helps support arterial blood pressure. Desflurane supports CI better than sevoflurane and isoflurane at both low and high MAC levels (i.e., 0.5 - 1.66 MAC) (Fig. 8.5).⁹⁷ With light levels of anesthesia, desflurane maintains the CI without an accompanying elevation in HR. For deeper levels of anesthesia, the CI is probably supported by the associated rise in HR. Some investigators believe the favorable circulatory profile of desflurane, isoflurane, and sevoflurane results from their ability to attenuate the body's circulatory compensatory mechanisms in a dose-related manner.^{98,99} In summary, there is no appreciable difference in the ether anesthetics' ability to produce dose-dependent depression in arterial pressure and CO.^{92,93}

FIGURE 8.5 The effects of increasing concentrations (MAC) of halothane, isoflurane, desflurane, and sevoflurane on cardiac index (L/min) when administered to healthy volunteers. MAC, Minimum alveolar concentration.

Regarding the impact of the duration of anesthesia on hemodynamics, isoflurane, sevoflurane, and desflurane produce a similar response; specifically, as MAC-hours of anesthesia increase, CI and HR increase slightly.⁹⁷ The CI effect may be secondary to a continued reduction in SVR and increase in HR following prolonged exposure to each of the agents. Protracted anesthesia (8 hours) in healthy volunteers anesthetized with desflurane and sevoflurane led to an increase in pupil size and HR independent of surgery.¹⁰⁰ These changes are not associated with increases in plasma catecholamines, blood pressure, or CO₂ production; therefore, mydriasis and tachycardia as signs of anesthetic depth could be misleading at times.

Although anesthetic changes produced at the cellular level have already been discussed, it is sensible to briefly review the cellular effects of inhaled anesthetics on the aforementioned areas of the cardiovascular system. In vitro and in vivo studies have revealed that isoflurane, sevoflurane, and desflurane reduce intracellular free Ca²⁺ concentrations in cardiac and vascular smooth muscle. The mechanism for this is believed to be a reduction in Ca²⁺ influx through the sarcolemma and a depression of depolarization-activated Ca²⁺ release from the sarcoplasmic reticulum.^{92,93,101} The end result is a depression in the contractile state of the myocardium, along with dilation of the peripheral vasculature. Other reported cellular effects of volatile agents include augmentation and attenuation of endothelium-derived relaxation factor, inhibition of acetylcholine-induced vascular relaxation,¹⁰² and attenuation of sodium (Na⁺)/Ca²⁺ exchange that leads to a reduction in the quantity of intracellular Ca²⁺.¹⁰³

Heart Rate

Volatile agents and N₂O induce changes in HR relative to the concentration of the anesthetic being used. Alterations in HR are a result of several variables: antagonism of sinoatrial (SA) node automaticity,¹⁰⁴ modulation of baroreceptor reflex activity,¹⁰⁵ and

sympathetic nervous system activation via activation of tracheopulmonary and systemic receptors.¹⁰⁶

Rapid increases in inhaled concentrations of isoflurane, and especially desflurane, can lead to increases in HR and blood pressure secondary to sympathetic activation, due to an irritant effect (Fig. 8.6). Sevoflurane has minimal HR effects. HR increases are accelerated when the concentration is increased rapidly.

FIGURE 8.6 The effects of sevoflurane (solid line with squares) and desflurane (dashed line with circles) on heart rate in healthy young volunteers when the inspiratory concentration is rapidly increased from a steady-state value of 0.83 MAC to 1.25 MAC. *Bpm*, Beats per minute; *ET*, end-tidal; *MAC*, minimum alveolar concentration.

Coronary Blood Flow

The term *coronary steal* is defined as a reduction in the perfusion of ischemic myocardium with simultaneous improvement of blood flow to nonischemic tissue. Simply stated, blood has been taken from the “poor” and given to the “rich” (a “reverse–Robin Hood” syndrome). In addition, this phenomenon has been demonstrated to

occur more easily with “coronary steal-prone anatomy” (i.e., in multivessel disease models).¹⁰⁷ Reduced SVR is most prominent with isoflurane, leading to suggestions that it could promote a steal phenomenon in patients with coronary artery disease and should be avoided. However, there is no convincing clinical evidence that isoflurane is riskier than other inhaled anesthetics in patients with coronary artery disease, as long as perfusion pressure is maintained.¹⁰⁸

An important qualifier to isoflurane's ability to maldistribute coronary blood flow is the presence of hypotension; when normotension is maintained, a steal phenomenon is abated.¹⁰⁹

To summarize the effects of isoflurane, desflurane, and sevoflurane on the coronary circulation, each produces vasodilation, with sevoflurane doing so the least. In the presence of hypotension, a steal phenomenon can occur, as it can with inappropriate use of many coronary dilators, and this effect is reversible if normotension is reestablished. Any of these three volatile anesthetics can be used in patients with a history of ischemic heart disease.

As mentioned previously, volatile agents may produce a neuroprotective effect; similarly, the heart appears to benefit from the isoflurane, sevoflurane, and desflurane inhaled anesthetics via the initiation of the phenomenon of preconditioning.¹¹⁰ Anesthetic preconditioning (APC) results in a cascade of intracellular events that help protect the myocardium from ischemic and reperfusion insult, potentially limiting infarct size. The mechanism for this effect is multifactorial, and includes such elements as improving contractile function, which prevents the down-regulation of major sarcoplasmic reticulum Ca^{2+} cycling proteins, thereby reducing Ca^{2+} overload in the myocardial cells. The latter effect has been shown to be independent of K^+ -sensitive adenosine triphosphate (K_{ATP}) channels, and confers 30% to 40% of the cardioprotective effect produced by inhalational anesthetics.^{111,112} On the molecular level, sevoflurane has been found to produce late preconditioning in healthy male volunteers (24 to 48 hours after sevoflurane administration), as evidenced by altered gene expression in white blood cells (e.g., reduced proinflammatory L-selectin [CD62L] expression on granulocytes).¹¹³ A theoretic application of APC along

with other cardioprotective substances such as insulin and adenosine would include administering preconditioning drugs during early coronary artery reperfusion, as is currently done with antiplatelet and antithrombotic therapies. Research has shown that the administration of volatile agents during myocardial reperfusion activates a group of prosurvival kinases called the *Reperfusion Injury Salvage Kinase (RISK)* pathway. These prosurvival kinases produce potent cardioprotective effects. The RISK pathway has also been found to be activated during ischemic preconditioning (a brief stimulus of myocardial ischemia/occlusion leading to cardioprotection).¹¹⁴

Other factors that have been identified with preconditioning include protein kinase C activation of K_{ATP} channel opening, adenosine receptors (α_1 and α_2 subtypes), and inhibitory G proteins.^{115–117} The American College of Cardiology/American Heart Association Guidelines on Perioperative Cardiac Evaluation and Care note that it can be beneficial to use volatile anesthetic agents during noncardiac surgery for the maintenance of general anesthesia in hemodynamically stable patients at risk for myocardial ischemia.¹¹⁸ This is due to a protective effect on the myocardium associated with preconditioning.

It has been advocated that sulfonylurea oral hyperglycemic drugs be discontinued 24 to 48 hours prior to elective surgery, due to their ability to close K_{ATP} channels. The glitazones and the NSAIDs also exhibit an anticonditioning effect. Insulin is recommended as replacement therapy during this time period to abate the negative impact of hyperglycemia on preconditioning.^{119,120} A recent multicenter trial of upper limb RIPC performed while patients were under propofol-induced anesthesia did not show a relevant benefit among patients undergoing elective cardiac surgery.¹²¹

Arrhythmias

The inhalation anesthetics have complex effects on cardiac conduction, including both proarrhythmic and antiarrhythmic actions. Isoflurane, desflurane, and sevoflurane all prolong the electrocardiographic QT interval, potentially increasing the risk of torsades de pointes. Prolongation of the QT interval is likely due to

inhibition of the delayed rectifier K^+ current through hERG channels that normally contribute to cardiomyocyte repolarization.^{122,123} The arrhythmogenic potential of inhalation agents has long been recognized. All of the agents, with the exception of isoflurane and probably desflurane, are conducive to the development of bradycardia and disturbances in atrioventricular (AV) nodal conduction (excluding second- or third-degree AV block). The mechanism for this is their ability to depress slow-response (SA and AV nodal tissue) and fast-response (atrial or ventricular musculature, Purkinje fibers) action potentials. When fibers become ischemic or injured, the volatile agents are prone to producing reentrant excitation.¹²⁴ In addition, desflurane and sevoflurane⁹⁴ have been shown to prolong action potential duration. This effect is consistent with the clinical finding of a prolonged QTc interval in healthy adults and in children receiving desflurane.^{125,126}

The ability of the volatile agents to reduce the quantity of catecholamines necessary to evoke arrhythmias is commonly, but inaccurately, called *sensitization*. It is more accurate to describe this phenomenon as an adverse drug interaction. Researchers have determined the nasal and oral submucosal ED₅₀ dosage (median effective dose) of epinephrine for volatile agents to be 2.11 ± 0.15 mcg/kg for halothane and 6.72 ± 0.66 mcg/kg for isoflurane.¹²⁷ With these dosages, 50% of subjects experienced three or more premature ventricular contractions or developed ventricular tachycardia during or immediately after a single injection of epinephrine (which required 3.5 to 11 minutes to complete). Variables that may influence epinephrine ED₅₀ values are differences in systemic absorption, route of administration, genetic polymorphisms and mutations, and preexisting atrial or ventricular arrhythmias.¹²⁸ When these variables are taken into consideration, it is not surprising that data regarding volatile agent sensitization are conflicting. Desflurane and sevoflurane both appear to be similar to isoflurane in their epinephrine-arrhythmogenic potential, meaning they also do not promote epinephrine-induced arrhythmias.^{129,130}

In general, it is reasonable to anticipate the fewest difficulties with arrhythmias in ASA physical status I and II patients if the subcutaneous epinephrine dose remains 10.0 mcg/kg or less with desflurane, sevoflurane, or isoflurane.^{129,130} Additional protection

may be achieved by combining a local anesthetic with epinephrine, the net effect being an increase in the minimum threshold dose of epinephrine.¹²⁷ Another commonly used method for calculating the “safe” concentration of epinephrine to inject during general anesthesia with a volatile anesthetic is as follows:

Maximum 10 mL of 1:100,000 epinephrine in a 10-minute period; or
a

Maximum of 30 mL per hour

Isoflurane and sevoflurane have been shown to be associated with an attenuation of arrhythmias associated with digitalis toxicity occlusion/reperfusion ischemia and a decreased risk of postmyocardial infarction. Isoflurane has also been demonstrated to increase the effective refractory period of the accessory pathway with preexcitement syndrome. These inhaled anesthetics may be preferred agents if a significant concern exists for the appearance of intraoperative arrhythmias related to these pathologic states.¹³¹⁻¹³³ A summary of the cardiovascular effects of the anesthetics is shown in [Table 8.5](#).

TABLE 8.5
Cardiovascular Effects of Inhalation Anesthetics

	Cardiac Output	System Vascular Resistance	Mean Arterial Pressure	Heart Rate
Isoflurane	↓ slight	↓	↓	↑
Desflurane	↔	↓	↓	↑
Sevoflurane	↔	↓	↓	↔
Nitrous Oxide	↓	↑	↔	↑

Arrows indicate an increase, decrease, or no change in the parameter. All effects are dose-dependent.

Pulmonary Circulation

Pulmonary vascular resistance (PVR) is also affected by the volatile agents and N₂O. The effects of N₂O on PVR vary with age and preexisting levels of PVR. In adults with normal PVR, the addition

of N₂O results in a small increase in PVR, presumably due to an increase in sympathetic nervous system tone. If a subject has preexisting pulmonary hypertension, the addition of N₂O results in larger increases in PVR, which may become clinically significant.¹³⁴ Volatile agents decrease pulmonary artery pressure.^{96,97}

The pulmonary vasculature also minimizes changes in alveolar-arterial oxygen tension gradient via hypoxic pulmonary vasoconstriction (HPV). HPV helps to match regional ventilation and perfusion, although it has little effect in normal lungs. In patients with lung pathology and any patient having one-lung ventilation, HPV contributes to maintaining oxygenation. It is mildly depressed by inhaled anesthetics, with isoflurane showing the greatest effect.¹³⁵ Consistent with this finding, one group of researchers noted only minimal impairment in oxygenation (an approximately 20% reduction in HPV at 1 MAC) in patients having one-lung ventilation performed during thoracotomy procedures. Desflurane and sevoflurane delivered at 1 MAC without N₂O have also been shown to only slightly affect arterial oxygenation in patients placed in a lateral position while undergoing esophagogastrectomy.^{136,137}

Respiratory System

As seen with other systems of the body, the volatile agents exert a dose-response effect on the respiratory system, primarily tidal volume (TV), followed by the depression of respiratory rate (RR). Responsiveness to CO₂ is depressed, and the TV reduces as concentrations of the agents are increased. The compensatory mechanism for the diminished TV with isoflurane, sevoflurane, desflurane, and N₂O is an increase in RR.¹³⁸⁻¹⁴⁰ However, the increase in RR is not sufficient to prevent elevations in arterial CO₂ tension. Nevertheless, surgical stimulation is a variable that helps to overcome the respiratory-depressant effects of volatile agents.¹⁴¹

Emergence from an anesthetic can be associated with hypercarbia if the minute volume (MV) is not adequately supported, owing to a volatile agent's capacity to depress the ventilatory response to PaCO₂ and partial pressure arterial oxygen (PaO₂).^{140,142,143} Hypercarbia also represents an increase in the apneic threshold

(higher PaCO₂ values are required for spontaneous ventilation to occur). Patients should be closely monitored during emergence from an anesthetic and following adequate reversal of muscle relaxants to avoid acidosis or hypercarbia. During this phase of the anesthetic, significant end-tidal values of residual volatile anesthetic may persist, particularly if there was recent administration of an opioid (synergistic effect). It is important to recognize that impairment of the hypoxic ventilatory response by volatile agents is not abated with CNS arousal or acute pain¹⁴⁴; even as little as 0.1 MAC of a volatile agent (excluding desflurane) can suppress ventilatory drive to hypoxia.¹⁴⁵ These findings have implications for patients whose MVs are maintained via a hypoxic drive (e.g., emphysematous patients with depressed central chemoreceptors).

The smoothness of an inhalation induction is directly related to the ability of an inhalation agent to avoid provoking an irritant response. N₂O and sevoflurane are considered the standards by which other agents are measured, because of the low incidence of breath withholding, coughing, secretions, and laryngospasm encountered during inhalational induction.¹⁴⁶ In contrast, desflurane is considered a respiratory irritant when used for mask induction in concentrations greater than 6%^{146,147}; therefore, it is generally not used to induce anesthesia in pediatric¹⁴⁸ and adult patients. Lastly, the volatile agents have been shown to relax airway smooth muscle and produce bronchodilation. They have also been used in the treatment of refractory status asthmaticus.¹⁴⁹

Kidneys

In general, autoregulation of renal circulation remains intact during the administration of inhalation agents. Reductions in systolic blood pressure are accompanied by decreases in renal vascular resistance.¹⁵⁰ Nevertheless, compensatory reductions in renal vascular resistance can still lead to a decline in the glomerular filtration rate. This may contribute to the commonly observed intraoperative reduction in urinary output.

The potential for a volatile agent to produce renal damage is commonly assessed by the extent to which it elevates creatinine,

blood urea nitrogen, and serum inorganic fluoride concentrations.¹⁵¹ With the older volatile agent methoxyflurane, a “toxic threshold” for peak serum concentration of was established (50 μmol/L)¹⁵²; at this value, vasopressin-resistant polyuric renal insufficiency occurs.¹⁵³

Of the inhalation agents currently in use, desflurane has been shown in both healthy and chronic renal disease patients¹⁵⁴ to alter indices of renal integrity the least, including no change in the renal function tests of urinary retinol-binding protein and *N*-acetyl-β-glucosaminidase (NAG).¹⁵⁵ In contrast to studies involving desflurane¹⁵⁶ and isoflurane,¹⁵⁷ early research with sevoflurane generated concerns about compromised renal function. Most researchers now accept that levels associated with sevoflurane administration do not represent a significant risk to patients, including those with compromised renal function.^{158–160} Millions of sevoflurane anesthetics worldwide have failed to demonstrate any significant untoward renal outcomes in the general surgical population, including patients having coronary artery surgery.¹⁶¹ Nevertheless, FDA guidelines recommend that sevoflurane be used with caution in patients with renal insufficiency (creatinine greater than 1.5 mg/dL). Researchers have found no appreciable difference in sevoflurane's biotransformation and subsequent fluoride levels in morbidly obese patients compared to nonobese patients.¹⁶²

There was a past concern regarding sevoflurane's degradation within anesthesia circuits by older carbon dioxide absorbents, producing potential toxins referred to as compound A and others. The development of newer formulations of carbon dioxide absorbents that do not contain strong bases (NaOH or KOH), which are substituted instead with Ca²⁺ or lithium hydroxide, has removed that concern. In the absence of the newer carbon dioxide granules, current FDA dosing guidelines recommend that sevoflurane exposure not exceed 2 MAC-hours at flow rates of 1 to less than 2 L/min.¹⁶³ Fresh gas flow rates less than 1 L/min are not recommended.

Liver

It has long been known that volatile anesthetics have the potential to impair liver function. Halothane in particular is associated with

significant risk of postoperative liver failure, termed *halothane hepatitis*. Due to the fatal outcome, liver toxicity of volatile anesthetics has been a longstanding issue over the years. For halothane, immunologic mechanisms and metabolism via reductive pathways may be involved in the underlying pathology; halothane hepatitis occurs several hours or days after anesthesia. Fever, jaundice, and elevation of transaminases (alanine transaminase [ALT], aspartate transaminase [AST]) in the postoperative setting should bring anesthetic-associated hepatitis into discussion.¹⁵⁹ A better understanding of the pathophysiology of this phenomenon has improved diagnostic capabilities for volatile-agent induced liver damage.^{164,165} It is extremely rare for isoflurane, sevoflurane, and desflurane to produce clinically significant liver damage.¹⁶¹ Their molecular structure (increased fluorination) resists hepatic degradation, and their pharmacodynamic profile is associated with no changes or slight reductions in hepatic blood flow.¹⁶⁶⁻¹⁶⁹ In summary, the current volatile agents have an extremely low risk for evoking hepatic injury.

As stated previously, the chemical structure of each inhalation agent determines the extent to which it is metabolized. The agents currently in use undergo metabolism at the following rates: sevoflurane at 5% to 8%, and isoflurane, desflurane, and N₂O in trace amounts.

All currently used volatile anesthetics are predominantly biodegraded by way of hepatic metabolism through cytochrome P-450 oxidation (phase I).

Nitrous Oxide

N₂O currently has a niche role as a supplement to the more potent anesthetics and as a component of most IV anesthesia techniques. Its use has declined in recent years in the United States. It was used in 33% of all general anesthetics given in 2009, but only 21% of those given in 2011, as safety questions have arisen.^{170,171} In vitro research suggests that N₂O is metabolized minimally (0.004%) by intestinal microflora, yielding molecular nitrogen (N₂).¹⁷² The limited metabolism does not necessarily mean that N₂O is an inert substance within the body. On the contrary, studies have

demonstrated that chronic exposure to N₂O can lead to inactivation of the vitamin B₁₂ cofactor for the enzyme methionine synthetase.¹⁷³ This may disrupt deoxyribonucleic acid (DNA) synthesis and is thought to be related to the teratogenic and immune suppression effects (Fig. 8.7).^{174,175} For routine surgical cases, this is generally not an issue, but caution should be exercised with patients who are at a risk for cobalamin deficiency (Box 8.5).¹⁷⁶ The contraindications to the use of N₂O are listed in Box 8.6. The safety of N₂O was assessed in several large scale studies, including the Nitrous oxide and perioperative cardiac morbidity (ENIGMA-11) and Perioperative Ischemic Evaluation (POISE) trials. These studies noted that N₂O in major noncardiac surgery did not increase mortality, cardiovascular complications, surgical site infections, or adverse outcomes. There was an increased risk of postoperative nausea and vomiting.^{171,177,178} N₂O is an antagonist of the NMDA receptor, and may produce a significantly lower risk of chronic pain after surgery.¹⁷⁹

FIGURE 8.7 Nitrous oxide (N₂O) oxidizes the cobalt atom on vitamin B₁₂, inhibiting methionine synthetase and causing accumulation of homocysteine and disruption of deoxythymidine synthesis. *THF*, Tetrahydrofolate. Box 8.6

Recommended Contraindications to the Use of Nitrous Oxide

Indications	Inhalational analgesia/sedation
Absolute contraindications	Known deficiency of enzyme or substrate in methionine synthase pathway
	Potential toxicity from expansion of gas-filled space, e.g., emphysema, pneumothorax, middle ear surgery, pneumocephalus, air embolus, bowel obstruction (see Chapter 7)
	Increased intracranial pressure
Relative contraindications	Pulmonary hypertension
	Prolonged anesthesia (> 6 h)
	First trimester of pregnancy*
	High risk of postoperative nausea and vomiting

*Based on the theoretical (but unproven) detrimental effects.

From Sanders RD, et al. Biologic effects of nitrous oxide: a mechanistic and toxicologic review. *Anesthesiology*. 2008;109(4):707–722.

Neuromuscular System

All volatile agents produce a dose-dependent relaxation of skeletal muscle, as well as an additive effect with the depolarizing and nondepolarizing muscle relaxants.¹⁸⁰ The mechanism by which this occurs is multifactorial, involving reduced neural activity within the CNS and a presynaptic and more prominent postsynaptic effect at the neuromuscular junction.¹⁸¹ In general, nondepolarizing muscle relaxant dosages are decreased by approximately 25% to 50% of that required with TIVA when they are used in combination with a volatile agent.¹⁸²

The volatile agents have also been shown to delay recovery from the nondepolarizing muscle relaxants. For example, after 30 minutes of exposure to sevoflurane, recovery from vecuronium to 25% of baseline neuromuscular function is prolonged by 89%, and

after 60 minutes, prolongation exceeds 100%.¹⁸³ The inhalation agents have also been implicated in impairing reversal of nondepolarizing neuromuscular block.^{184,185}

Malignant Hyperthermia

All of the potent volatile agents are capable of triggering malignant hyperthermia. These agents should not be used in malignant hyperthermia–susceptible patients. N₂O may be used in malignant hyperthermia–susceptible patients. Overall, the clinical use of N₂O, in combination with many other agents (e.g., propofol, ketamine, etomidate, opiates, and local anesthetics), is considered acceptable in patients susceptible to malignant hyperthermia.^{186,187}

Modern anesthetic techniques have resulted in a change in the clinical presentation of malignant hyperthermia: in some cases, it may present as less fulminant and develop more slowly. The shift in typical clinical presentation is possibly due to the lower triggering potency of modern volatile anesthetics, the mitigating effects of several IV drugs (neuromuscular blocking agents, α_2 -adrenergic receptor agonists, β -adrenergic blockade) or techniques (neuraxial anesthesia), and the routine use of end-tidal CO₂ monitoring, leading to the early withdrawal of triggering drugs.¹⁸⁸

The FDA has approved a new IV formulation of dantrolene (Ryanodex) for prevention and treatment of malignant hyperthermia in adults and children. The new formulation requires fewer vials, less fluid volume, and less time for preparation and administration than the older IV dantrolene products. Ryanodex is easier and faster to reconstitute and requires less fluid volume for administration, but it is more expensive, has a shorter shelf-life, and requires supplementary doses of mannitol.¹⁸⁹ A complete discussion of malignant hyperthermia can be found in [Chapter 36](#).

Inhalation Anesthetics and Pregnancy

Pregnant patients have a 0.2% to 0.75% chance of developing a medical condition that requires a general surgical intervention during pregnancy. The most common procedures are appendectomy, cholecystectomy, ovarian surgery, and trauma surgery.¹⁹⁰ In general, no anesthetic agents or drugs commonly used in anesthesia are listed as human teratogens. Non-drug-related maternal conditions, such as severe hypoglycemia, prolonged hypoxia and hypercarbia, and hyperthermia, may be teratogenic in humans.¹⁹¹ N₂O inhibits methionine synthetase, an enzyme necessary for DNA synthesis, and teratogenic effects have been shown in animals after administering high concentrations for prolonged periods. The conditions required for N₂O teratogenicity are not encountered in clinical practice; however, some clinicians still avoid N₂O in pregnant women. In current practice, it is never necessary to use N₂O in a pregnant patient, as there are many alternatives.¹⁷⁶ Exposure to N₂O has been of greatest concern in dental workers, due to the lack of effective scavenging. Most of the epidemiologic evidence points to a significant relationship between exposure to N₂O and both spontaneous abortion and reduced fertility in these workers.¹⁹² As discussed previously, there is also emerging evidence that inhaled anesthetics may have neurodevelopmental effects in animals, but the effect on a developing human fetus is not clear. The American Congress of Obstetricians and Gynecologists (ACOG) has issued a Committee Opinion on Nonobstetric Surgery during Pregnancy. They note that a pregnant woman should not be denied indicated surgery, but elective surgery should be delayed until after delivery, and nonurgent surgery should be performed in the second trimester.¹⁹³

Summary

Inhalation agents remain the most common class of drugs used to maintain a general anesthetic. The pharmacokinetic and pharmacodynamic profile of desflurane and sevoflurane facilitate meeting the anesthetic goals of an ever-increasing same-day surgery population. The ease of administration of all ether-based volatile anesthetics, with or without N₂O, lends itself to common use among a diverse surgical population. Continued research will help guide anesthetists in the selection and application of a variety of inhalation anesthetic techniques. A summary of the systemic effects of the major inhalation anesthetics is given in [Table 8.6](#). Some advantages and disadvantages of selected inhalation anesthetics are given in [Table 8.7](#).

TABLE 8.6

Select Effects of the Inhalation Anesthetics

Variable	Isoflurane	Desflurane	Sevoflurane
Kinetics			
Alveolar equilibration	Moderate	Fast	Fast
Recovery	Moderate	Very fast	Fast
Liver			
Hepatotoxicity	No	No	No
Metabolism (%)	0.2	0.02	5–8
Musculoskeletal relaxation	Moderate	Moderate	Moderate
Respiratory System			
Respiratory irritation	Significant	Significant	No
Central Nervous System			
Seizure activity on EEG	No	No	Yes
Renal System			
Renal toxic metabolites	No	No	No

EEG, Electroencephalogram.

TABLE 8.7

Clinical Advantages and Disadvantages of Selected Inhalation Anesthetics

Anesthetic	Advantages	Disadvantages
Nitrous oxide	Analgesia Rapid uptake and elimination Little cardiac or respiratory depression Nonpungent Reduces MAC of the more potent agents Minimal biotransformation	Expansion of closed air spaces Requires high concentrations Amount of oxygen delivered is reduced Diffusion hypoxia, increase in teratogenicity, PONV Supports combustion Immune suppression
Isoflurane	Moderate muscle relaxation Decreases cerebral metabolic rate Minimal biotransformation No significant systemic toxicity Inexpensive Possible neuro- and cardiac protection	Pungent odor Airway irritant Trigger for malignant hyperthermia Slower induction and emergence Trigger for malignant hyperthermia
Desflurane	Rapid uptake and elimination Stable molecular structure, Minimal biotransformation No significant systemic toxicity Possible neuro- and cardiac protection	Airway irritant Expensive compared to the other agents Needs special electrically-heated vaporizer Rapid increases in inspired concentration can lead to reflex tachycardia and hypertension Trigger for malignant hyperthermia
Sevoflurane	Rapid uptake and elimination Nonpungent Excellent for inhalation induction Cardiovascular effects broadly comparable to those of isoflurane Possible neuro- and cardiac protection	Reacts with soda lime Trigger for malignant hyperthermia Some biotransformation

MAC, Minimum alveolar concentration; PONV, postoperative nausea and vomiting.

Intravenous Induction Agents

John J. Nagelhout

A complete discussion of the pharmacology of the barbiturates is available in the fourth edition of this textbook.

A historic milestone in anesthesia was reached in 2011 with the decision to cease marketing sodium pentothal, a thiobarbiturate, in the United States and many other countries. Thiobarbiturates, when they were introduced in the 1930s, changed the way anesthesia was delivered. Although their use has declined dramatically in recent decades with the introduction of propofol, the practice of using intravenous push boluses of sedatives to initiate anesthesia remains the standard. Induction refers to the start of anesthesia when the patient is rendered unconscious. The intravenous induction agents allow the patient to experience a pleasant loss of consciousness while also rapidly achieving surgical levels of anesthesia.

Desirable properties for an induction agent include rapid and smooth onset and recovery, analgesia, minimal cardiac and respiratory depression, antiemetic actions, bronchodilation, lack of toxicity or histamine release, and advantageous pharmacokinetics and pharmaceuticals. A single ideal intravenous anesthesia induction drug has yet to be developed; however, the agents currently available can be exploited to select an appropriate drug for all surgical and anesthetic requirements. Propofol is the current standard agent and is widely used for induction of general anesthesia and intravenous sedation. Etomidate and ketamine are valuable agents for select anesthetics when propofol use is undesirable. Dexmedetomidine is gaining popularity for niche uses as well. This chapter discusses the advantages and limitations of the currently used intravenous anesthesia induction agents.

Nonbarbiturate Intravenous Anesthetics

Propofol

Chemical Structure and Pharmaceutics

Propofol is a 2, 6-diisopropyl phenol (Fig. 9.1). It is prepared as a 1% solution in a lipid emulsion of 10% soybean oil, 2.25% glycerol, and 1.2% purified egg lecithin. The pH of propofol (Diprivan) is 7 to 8.5, and the pK_a (negative logarithm of the acid ionization constant) is 11. The pH of the generic form of propofol is 4.5 to 6.4, and the pK_a is 11.¹ This unique vehicle is especially favorable to bacterial contamination. The original trade product, Diprivan, contains 0.005% disodium edetate (EDTA [ethylenediaminetetraacetic acid]) as a preservative to inhibit bacterial and fungal growth. Generic forms of propofol contain 0.025% sodium metabisulfite or benzyl alcohol depending on the manufacturer.² Clusters of infections reported after mishandling of earlier preservative-free preparations prompted the addition of these preservatives.³⁻⁵ Careful handling is still important. It is recommended that aseptic conditions be maintained and the drug be used immediately upon withdrawal from a vial for a single patient. Any remaining drug should be discarded. Syringes or vials should never be used for more than one patient. Opened vials or syringes should be discarded within 6 hours if propofol was transferred from the original container.

FIGURE 9.1 Agents used for the induction of general anesthesia, sedation, and benzodiazepine reversal.

The pharmaceutical preparations are shown in [Table 9.1](#).

TABLE 9.1

Pharmaceutic Preparation of Intravenous Anesthetic Agents

Class	Drug Name	Available Solution	Pain on Injection*
Benzodiazepines	Diazepam (Valium)	0.5% in 40% propylene glycol and 10% alcohol	+++
	Lorazepam (Ativan)	0.4% in propylene glycol	+
	Midazolam (Versed)	0.5% buffered aqueous solution (pH 3.5)	0
Imidazoles	Etomidate (Amidate)	Water soluble at acidic pH, lipophilic at physiologic pH (pK_a 4.24); 0.2% solution in 30% propylene glycol (pH 5)	+++
	Dexmedetomidine (Precedex)	Dexmedetomidine HCl is freely soluble in water and has a pK_a of 7.1 with a pH of 4.5–7.0. The solution is preservative free. Prepare by adding 2 mL of dexmedetomidine (100 mcg/mL) to 48 mL of 0.9% sodium chloride injection for a total of 50 mL. The final concentration is 4 mcg/mL.	0
Alkylphenol	Propofol (Diprivan)	1% solution in an aqueous emulsion containing 10% soybean oil, 2.25% glycerol, and 1.2% egg phosphatide, EDTA (pK_a 11)	++
	Generic propofol	Generic formulations vary; may contain metabisulfite (use with caution in patients with allergies and asthma); formulations that contain benzyl alcohol pH 7–8.5 (benzyl alcohol should be avoided in infants)	++
Arylcyclohexylamines	Ketamine (Ketalar)	White crystalline salt 1% or 10% aqueous solution (pH 3.3–5.5; pK_a 7.5)	0

* 0, None; +, mild; ++, moderate; +++, marked.

EDTA, Disodium ethylenediamine tetraacetic acid.

Reformulations of Propofol

Newer formulations of propofol that will have a more favorable vehicle than the lipid emulsion are being investigated. These include other soybean and albumin emulsions, micelles and nanoemulsion cyclodextrins, among others.^{1,2,6}

Although propofol has many advantages, such as rapid onset and offset when given for minor procedures such as colonoscopy or bronchoscopy, it can also present some challenges. It has a narrow therapeutic index, and hemodynamic and respiratory depression are troublesome in compromised patients. General anesthesia can easily result from minor dose adjustments. There are propofol supply shortages partly related to difficulties with manufacture of the lipid emulsion formulation. Propofol causes pain on injection, and its use for long-term sedation in the intensive care unit is compromised by propofol infusion syndrome, which may be lethal. It accumulates with longer infusions.⁷ Unlike the benzodiazepines, there is no pharmacologic antagonist.

Pharmacokinetics

Propofol exhibits a generally favorable kinetic profile, which is one of its main clinical benefits in comparison with other induction drugs (Table 9.2).⁸⁻¹⁰ Rapid distribution following an intravenous (IV) bolus dose into the brain and other highly perfused areas results in a fast onset of generally one circulation time. Rapid redistribution from the central to the peripheral compartments as the drug more evenly distributes to the entire body produces a quick initial decline in blood levels. As distribution continues, the drug is circulated to less well perfused tissues such as muscle, and the brain concentration falls. This effect leads to a rapid reawakening after sedative and anesthetic doses. The time to awakening is dose and patient dependent, but is usually in the range of 5 to 15 minutes. The movement of propofol through various body compartments over time is depicted in Fig. 9.2. A

visual conceptualization of the redistribution of drugs given by rapid push bolus is shown in Fig. 9.3.

TABLE 9.2

Select Pharmacokinetic Values for Intravenous Anesthetic Agents

Drug Name	Distribution Half-Life (min)	Elimination Half-Life (hr)	Clearance (mL/kg per min)	Volume of Distribution (L/kg)	Protein Binding (%)
Diazepam	10–15	20–50	0.3	0.8–1.3	98
Lorazepam	4–5	10–16	0.8–1.8	0.8–1.3	90
Midazolam	7–15	2–4	7–11	1–1.7	94
Etomidate	2–4	2–5	22.5	2.5–4.5	75
Propofol	2–4	1–5	25	2–8	98
Ketamine	11–17	2–3	14.5	2.5–3.5	12
Dexmedetomidine	6–8	2–2.6	8.9	1.54	94

FIGURE 9.2 Propofol kinetics. Note that propofol rapidly enters the brain and other vital organs, with peak effects at 1 minute after bolus injection. The brain concentration then falls rapidly over the next 10 to 15 minutes as the drug redistributes more evenly throughout the body to muscle and fat.

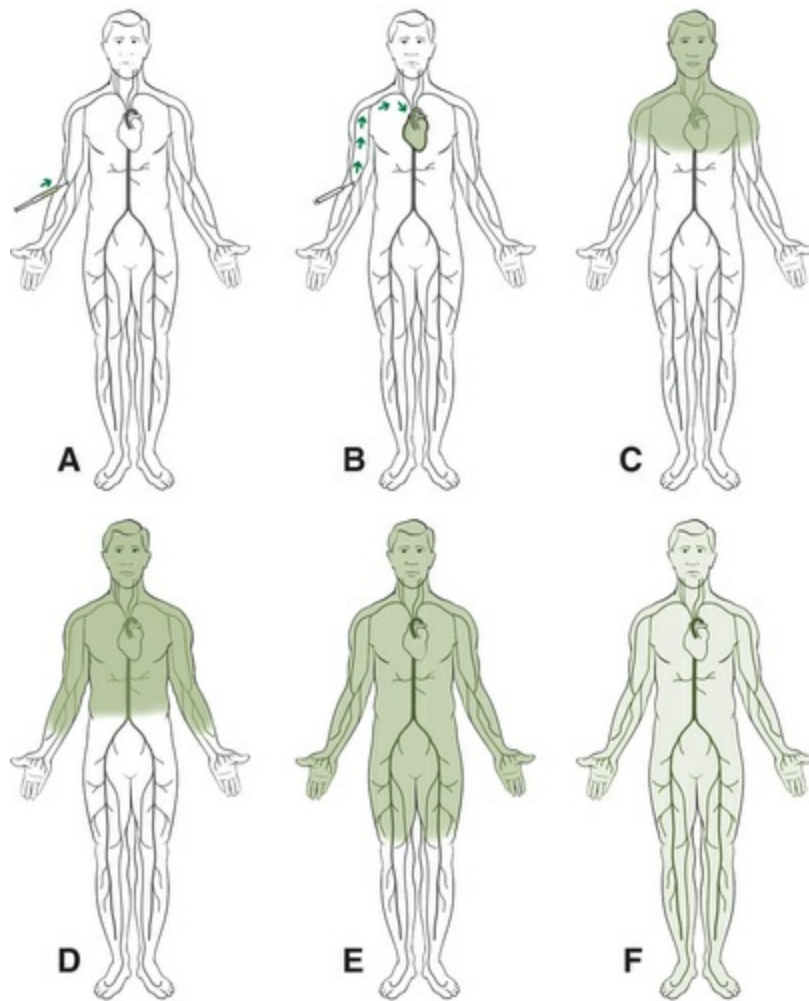

FIGURE 9.3 Redistribution of intravenous drugs is shown. **A** and **B**, A drug is administered in the arm and follows the venous circulation to the heart. **C**, The high cardiac output and circulatory flow initially distribute the drug to the brain and upper body, and rapid central nervous system effects begin. **D**, **E**, and **F**, As time passes, usually minutes, the drug more evenly distributes throughout the body, lowering the initial high brain concentration, and the patient awakens.

Metabolism plays little role in the initial awakening of the patient, but is important in the eventual clearance of the drug. Propofol is rapidly metabolized in the liver by CYP2B6, UGT1A4, and CYP2C6.¹¹ An interesting characteristic of propofol is its rapid metabolic clearance, which actually exceeds hepatic blood flow.¹² These extra hepatic sites of metabolism probably account for the lack of changes in elimination seen in patients with severe cirrhosis.¹³ Less than 1% of propofol is excreted unchanged. The

drug's kinetics are also influenced by age, with the elderly requiring lower doses.¹⁴ Children require a higher dose based on body weight because they have an increased volume of distribution compared to adults. Their rate of clearance is also higher.¹⁵ Some accumulation can occur with prolonged infusion secondary to tissue saturation.¹⁶ The elimination half-life is 1 to 2 hours.

Concerns that the traditional concept of half-life is misleading when drugs are given for prolonged periods by infusion led to the introduction of context-sensitive half time. The context is the duration of the infusion.¹⁷ It is the time required for a 50% decrease in plasma concentration after an infusion. Further refinements have described decrement times that include the 20% and 80% declines.¹⁸ The decrement time is from the end of the infusion to 50% recovery and includes pharmacokinetic data related to concentration decrease and pharmacodynamic data correlating with recovery. These concepts are discussed in [Chapter 6](#).

Propofol reversibly binds to erythrocytes (50%) and plasma proteins; it binds most commonly to plasma albumin (48%). The free concentration is less than 2%.¹⁹ Decreased plasma protein levels resulting from severe renal or hepatic disease and those patients in the third trimester of pregnancy may lower drug binding and increase the free active fraction. This may increase the effects of propofol. Clinically, this may be a factor when prolonged infusions are used.²⁰ Factors that can alter protein binding are noted in [Table 9.3](#). Drugs that are highly lipid soluble cross cell membranes rapidly, including the blood-brain and placental barriers. Propofol, being highly soluble, easily enters all body compartments.²¹

TABLE 9.3
Factors That Alter Protein Binding

Factors	Percent Bound
Decreased lipid solubility	Decreases binding
Increased pH (≤ 8.0)	Increases binding
Increased drug concentration	Decreases binding
Increased protein concentration	Increases binding
Increased competition for binding sites with other drugs	Decreases binding

Mechanism of Action

Like many other sedatives and anesthetics, propofol appears to exert its effect via an interaction with the inhibitory neurotransmitter γ -aminobutyric acid (GABA) and the GABA_A glycoprotein receptor complex.²² GABA is a major inhibitory transmitter in the central nervous system (CNS). The GABA_A receptor, which is a ligand-gated ion channel receptor, is activated by the binding of the neurotransmitter GABA. This binding of GABA to the GABA_A receptor initiates the movement of chloride (Cl⁻) through ion channels into the cell. This results in hyperpolarization of the postsynaptic cell membrane and the inhibition of neuronal cell excitation. A model has been developed that includes sites of action for GABA on the postsynaptic membrane, as well as sites for numerous other drugs. Propofol directly stimulates GABA_A receptors and potentiates the actions of endogenous GABA.^{23,24} The GABA receptor and its functions are described in [Fig. 9.4](#).

FIGURE 9.4 The GABA_A receptor. **A**, The generic GABA_A receptor subunit has four hydrophobic transmembrane segments that are thought to form amphipathic α -helices. The *N*-terminal domain contains *N*-glycosylation sites and a conserved cysteine bridge; it forms the agonist-binding site. The large intracellular loop undergoes phosphorylation in several isoforms. **B**, Plane view of the transmembrane hydrophobic segments showing interactions to form a central ion-conducting pore lined by the second transmembrane domains. The heterooligomeric structure consists of five subunits, with each subunit contributing to the ion channel pore. **C**, The GABA_A receptor gates an anion channel permeable to Cl⁻ and HCO₃⁻. The general anesthetics are distinguished from the benzodiazepines (which allosterically modulate GABA binding to potentiate GABA responses) by their

ability to activate/gate the GABA_A receptor channel directly. A separate site at the interface between the third and fourth transmembrane segments appears to interact with volatile anesthetics, alcohols, and etomidate, as demonstrated by site-directed mutagenesis studies. (From Hemmings HC, Hopkins PM, eds: *Foundations of Anesthesia Basic and Clinical Sciences*. 2nd ed. St Louis: Mosby; 2006.)

Pharmacodynamics

Central Nervous System Effects.

Propofol produces a rapid and pleasant loss of consciousness and emergence from anesthesia. Low-dose infusions for conscious sedation result in dose-dependent anxiolysis, sedation, and amnesia.²⁵ There are dose-dependent reductions in cerebral blood flow (CBF), cerebral metabolic rate of oxygen consumption (CMRO₂), intracranial pressure (ICP), and cerebral perfusion pressure (CPP).²⁶ These effects result in part from the decreased mean arterial pressure, depressed metabolic rate, and cerebral vasoconstriction produced by standard doses in a manner comparable to the effects of barbiturates and etomidate.^{27,28} Cerebral autoregulation and reactivity to changes in carbon dioxide (CO₂) are preserved with propofol.^{29,30}

Electroencephalogram (EEG) data produced a delta rhythm without evidence of epileptiform activity and burst suppression with higher doses.³¹ Propofol has been used successfully to manage status epilepticus.³² Even with these findings, controversy exists over the use of propofol in the patient with epilepsy.³³ Studies in patients with epilepsy showed no epileptogenic activity in any of the sites monitored. However, in another study, three epileptic patients were reported to experience increased epileptiform activity on EEG after the administration of propofol 2 mg/kg.³⁴ Studies in patients with epilepsy demonstrated a different response in that the EEG showed no increase in epileptogenic activity at any of the sites monitored.³⁵ It was also found that activation or extension of EEG activity was greater with thiopental than with propofol (although not statistically significant).³⁶ Myoclonia induced by propofol results in spontaneous excitatory movements secondary to selective

disinhibition of subcortical centers. Adequate dosage may prevent the occurrence of these movements. Myoclonia may occur on induction, but the incidence appears to be lower than that with etomidate. Intraocular pressure is decreased by propofol.^{37,38} Evidence for a neuroprotective effect is controversial because studies in both animals and humans have not been consistent. Propofol cannot be indicated as a clinical neuroprotectant alone, but it might play an important role in multimodal neuroprotection. Beneficial effects include preservation of cerebral perfusion, temperature control, prevention of infections, and tight glycemic control.^{39,40}

The use of propofol for electroconvulsive therapy (ECT) has been somewhat controversial as a result of the drug's effects on seizure duration. Several studies have shown that propofol reduces the duration of the ECT-induced seizure when compared with barbiturates. Evaluating the efficacy of ECT as an antidepressant was typically based on the duration of the seizure; a shortened seizure implied a less effective therapy. However, researchers have found that a reduction in seizure duration does not decrease the efficacy of the ECT. Propofol is associated with shorter seizures than other anesthetics, but that antidepressant efficacy does not seem to be compromised. It is commonly used due to the rapid recovery profile.⁴¹⁻⁴³

CNS effects of the intravenous induction drugs are shown in Table 9.4.

TABLE 9.4
Central Nervous System Effects of Intravenous Anesthetics

Agent	CBF	CPP	CMRO ₂	ICP	IOP
Etomidate	↓↓	↓↓	↓↓	↓↓	↓
Propofol	↓↓	↓↓	↓↓	↓↓	↓↓
Ketamine	↓↓	↑	↑	↑	↑
Midazolam	↑↓	↓	↓	↓	↓
Dexmedetomidine	↓	↑↓	0	↓	↓

↓, Decreases; ↑, increases; 0, no effect.

CBF, Cerebral blood flow; CPP, cerebral perfusion pressure; CMRO₂, cerebral metabolic rate of oxygen consumption; ICP, intracranial pressure; IOP, intraocular pressure.

Cardiovascular Effects.

Propofol usually results in a mild to moderate transient decrease in blood pressure in healthy adults and children during anesthesia induction. The decrease in blood pressure is not usually clinically significant. The effects are more pronounced than those seen with equivalent doses of etomidate or midazolam. It can, however, result in significant hypotension in usual induction doses in select patients. Predictors of hypotension during induction are age greater than 50 years, American Society of Anesthesiologists (ASA) class III to IV, baseline mean arterial pressure less than 70 mm Hg, and coadministration of high doses of fentanyl. Hypotension usually occurs within 10 minutes after induction and is more prevalent in the second half of the 0- to 10-minute interval.⁴⁴ As with most cardiovascular-depressing sedatives, these effects result from varying degrees of a combination of CNS, cardiac and baroreceptor depression, and decreases in sympathetic tone and systemic vasodilation. The primary reasons for propofol-induced hypotension are decreased sympathetic tone and vasodilation.⁴⁵ Central nervous system and direct cardiac depression play less of a role. A decrease in dose or alternative agents should be considered in the elderly or cardiac-compromised patients. Propofol has been used successfully for cardiac anesthesia when combined with fentanyl in low-dose or infusion regimens (Table 9.5).⁴⁶

TABLE 9.5

Cardiac and Respiratory Effects of Intravenous Anesthetic Agents

Drug Name	Mean Arterial Pressure	Heart Rate	Cardiac Output	Venous Dilatation	Systemic Vascular Resistance	Respiratory Depression	Bronchodilation
Etomidate	0	0	0	0	0	0/-	0
Propofol	--	-	-	++	--	--	0/+
Ketamine	++	++	+	0	+/-	0	+
Diazepam	0/-	-/+	0		-/0	0	0
Midazolam	0/-	-/+	0	+	-/0	0	0
Dexmedetomidine	-	--	0/-	0	0	0	0

-, Mild decrease; --, moderate decrease; +, mild increase; ++, moderate increase; 0, no effect.

Respiratory Effects.

Transient respiratory depression, more prominent than that seen with etomidate, is common with induction doses of propofol. Decreases in tidal volume are greater than decreases in respiratory rate, although apnea is common on initial administration of induction doses.⁴⁷ The frequency and duration of apnea are dependent on the dose, speed of injection, patient characteristics, and the presence of other respiratory depressant medications.⁴⁸ Dose-dependent respiratory depression is also common with maintenance infusions. This appears to result from a decreased sensitivity of the respiratory center to carbon dioxide.⁴⁹

Propofol has a minimal bronchodilating effect in patients with or without asthma and in patients who smoke. It does not cause histamine release and has been used successfully for anesthesia induction in asthmatic patients. After tracheal intubation, respiratory resistance is lower, and the incidence of wheezing is decreased, compared with the effects of etomidate.^{50,51} Propofol or ketamine are the preferred induction agents in patients with asthma.⁵²⁻⁵⁴

Other Pharmacologic Actions.

Propofol possesses mild antiemetic effects that are most prominent when given by continuous infusion.^{55,56} The mechanism for the antiemetic effects is unclear. It also exhibits antipruritic effects against opioid-induced pruritus.^{57,58}

Patients experience mild to moderate pain on injection with propofol. The incidence is approximately 60% and is most frequently related to the use of smaller veins for injection. The two most effective interventions to reduce pain on injection are the use of the antecubital vein or pretreatment with lidocaine 20 to 40 mg in conjunction with venous occlusion when the hand vein was chosen. Other effective pretreatments are using a lidocaine-propofol admixture, opioids, ketamine, and nonsteroidal antiinflammatory drugs.⁵⁹ Intraarterial injection of propofol does not cause vascular injury.

Obstetric Use.

As you would expect from a highly lipid soluble drug, propofol

easily passes the placental barrier when administered to a pregnant woman. Sedative effects occur in the neonate when propofol is used for cesarean delivery. Lower 1- and 5-minute Apgar scores have been noted.⁶⁰

The antiemetic effects of propofol may be an advantage in these patients. It is also used for sedation and hypnosis in postpartum tubal ligations and assistive reproductive techniques.

Contraindications and Precautions

Few absolute contraindications exist for propofol other than cases in which a known hypersensitivity exists to propofol or its components or the patient has a disorder of lipid metabolism.^{61,62} New generic formulations of propofol, which contain sodium metabisulfite, should not be used in sulfite sensitive patients. The sulfite may cause allergic-type reactions such as anaphylactic symptoms and life-threatening or less severe asthmatic episodes in certain susceptible people. Sulfite sensitivity is more common in patients with asthma than in patients without asthma.⁶³ As noted, caution is advised in elderly, debilitated, and cardiac-compromised patients.

Allergy

Propofol lipid emulsion formulations have been scrutinized because of their lecithin content. Lecithin (from the Greek *lekithos*, meaning “egg yolk”) is a phospholipid compound composed of a range of phosphatidyl esters such as phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine. These are combined with varying amounts of triglycerides and fatty acids. Lecithin was originally obtained from eggs, although soybeans and other vegetables with high lecithin content have also become useful sources. Apart from its use as an antioxidant synergist, lecithin has important surfactant properties and is used as an emulsifying agent.⁶⁴

Controversy exists regarding whether propofol should be avoided in patients who are allergic to eggs, soy, or peanuts. Egg allergy is most common in children and is usually outgrown by adulthood.^{65,66} The 2009 guidelines published by the Association of

Anesthetists of Great Britain and Ireland claim there is no evidence that propofol should be avoided in egg- or soy-allergic patients.⁶⁷⁻⁶⁹ The warning labels differ among countries for the same formulation of propofol supplied by the same company. The product information for Diprivan 1% warns of its use in egg- or soy-allergic individuals in Australia, soy/peanut (but not egg) in the United Kingdom, and lists no food allergy warnings in the United States. This is despite all three formulations being supplied by the same company.⁶⁷

A retrospective case review of 28 egg-allergic patients was reported in 2011. Two of the 28 patients had documented egg anaphylaxis. All but the two children with a history of egg anaphylaxis safely received propofol.⁷⁰ Data on the two children with documented egg anaphylaxis were not conclusive. The authors suggest propofol is likely to be safe in most egg-allergic children; however, propofol should not be administered to any child with a history of egg anaphylaxis until further evidence is available. Other authors note that there are no confirmed reports of propofol-induced anaphylaxis in egg-allergic patients. They generally demonstrate immediate hypersensitivity to proteins from egg whites. Lecithin is from egg yolks, so there is no reason to contraindicate propofol in egg-allergic patients.⁷¹⁻⁷³

Soy allergy is a common early onset food allergy in children. Many children outgrow the allergy by age 7.^{74,75} Refined soy oil of the types used in propofol have the allergenic proteins removed during refining; therefore, it is safe in patients with soy allergy. The suggestion that peanut-allergic patients may exhibit propofol allergy is due to cross reactivity between these leguminous plants; therefore, just as with soy allergy, there are also no data to support the avoidance of propofol in patients with peanut allergy.⁷¹

Propofol Infusion Syndrome

Propofol is frequently used in adult and pediatric intensive care units for prolonged sedation. Numerous case reports describe findings of various metabolic derangements and organ system failures known collectively as propofol infusion syndrome (PRIS) with long-term high-dose infusions of propofol.⁷⁶ This has not occurred in anesthesia, even with prolonged administration in

longer surgical procedures because it seems to require long-duration infusions of high doses, as only encountered in critical care units.⁷⁷ This syndrome is associated with significant morbidity and mortality. A precise mechanism of action of PRIS has yet to be demonstrated.⁷⁸ Risk factors include doses greater than 4 mg/kg per hour, duration greater than 48 hours, critical illness, high-fat low-carbohydrate intake, inborn errors of mitochondrial fatty acid oxidation, concomitant catecholamine infusion, and steroid administration. Many of the patients who developed this syndrome have been children, but cases in adults are more common.

The syndrome has occurred in patients with acute inflammatory disease with infection or sepsis or acute neurologic disease. One common denominator was the presence of impaired systemic microcirculation with tissue hypoperfusion and hypoxia. Propofol seemed to be a triggering agent when catecholamines and corticosteroids were also administered. Fatty acid metabolism and mitochondrial activity are impaired, creating an oxygen supply-and-demand mismatch that results in cardiac and peripheral muscle necrosis. The current theory proposes that propofol inhibits oxidative phosphorylation by (1) inhibition of the transportation of long-chain fatty acids into the cell, as well as (2) inhibitory effects on the mitochondrial respiratory chain and (3) blockage of β -adrenoreceptors and cardiac calcium channels. Symptoms include severe high anionic gap metabolic acidosis, refractory cardiac failure, persistent bradycardia refractory to treatment, fever, and severe hepatic and renal disturbances.⁷⁹ The clinical features are noted in [Box 9.1](#). In a 2015 analysis of 153 available case reports, several factors were evident.^{80,81} The typical patient who died with PRIS in the early 1990s was a child with respiratory infection who developed PRIS after having received a high dose of propofol. Nowadays, PRIS is more likely to be seen in an adult or elderly patient sedated with propofol in a critical care unit in whom mild unexplained acidosis and elevation of creatine kinase is noted, sometimes with worsening of acute kidney injury and arrhythmia, but other features of PRIS are often missing. Patients with a creatine kinase measurement of greater than 5,000 U/L represent a high-risk population for the development of PRIS. Independent predictors of death are the cumulative dose of propofol, being represented by

both mean infusion rate and the duration of infusion, the presence of traumatic brain injury and fever.

Box 9.1

Clinical Features of Propofol Infusion Syndrome

Cardiovascular

- Hypotension
- Widening of the QRS complex
- Bradycardia
- Ventricular tachycardia or fibrillation
- Asystole
- Ischemic EKG
- Arrhythmia
- Heart failure

Respiratory

- Hypoxia (preexisting)
- Pulmonary edema

Renal

- Acute kidney injury
- Hyperkalemia

Musculoskeletal

- Rhabdomyolysis

Metabolic

- Hyperthermia
- High anionic gap metabolic acidosis
- Fever
- Urine discoloration

Hepatic

- Hepatomegaly
- Abnormal liver function tests
- Steatosis
- Hypertriglyceridemia
- Lipidemia

EKG, Electrocardiogram

Treatment is supportive and includes discontinuing the propofol, improving gas exchange, cardiac pacing for bradycardia, phosphodiesterase inhibitors, glucagon, extracorporeal membrane oxygenation, and renal replacement therapy.⁷⁸ Recommended limits of propofol include administration for no more than 48 hours and no more than 4 mg/kg per hour or 67 mcg/kg per minute.^{80,81}

Key points regarding propofol are listed in [Box 9.2](#). Induction doses of the intravenous anesthetics are shown in [Table 9.6](#).

Key Points for Propofol Anesthesia

- Propofol is the most commonly used intravenous anesthetic as an induction drug and for sedation.
- Respiratory effects include transient respiratory depression or apnea, depending on dose. Although not a bronchodilator, safe

use in asthmatics has been well established.

- Propofol is unique among induction agents in that it exhibits mild antiemetic properties.
- Propofol has a rapid onset and emergence after bolus or continuous infusions of the drug.
- Patients emerge with a mild euphoria followed by rapid dissipation of the sedative effects.
- Propofol reduces cerebral blood flow, $CMRO_2$, and ICP.
- Propofol decreases blood pressure, cardiac output, and systemic vascular resistance to a greater extent than etomidate at equipotent doses.
- The induction dose is 1–2 mg/kg followed by a maintenance infusion of 100–200 mcg/kg per min. Conscious sedation doses are 25–75 mcg/kg per min.

$CMRO_2$, Cerebral metabolic rate of oxygen consumption; *ICP*, intracranial pressure.

TABLE 9.6

Induction Doses of the Intravenous Anesthetics

Agent	Dose (mg/kg)
Etomidate	0.2–0.3
Propofol	1–2
Ketamine	(see Box 9.4)
Dexmedetomidine	1 mcg/kg infused over 10 minutes followed by 0.2–0.7 mcg/kg per hr
Midazolam	0.1–0.2

Etomidate

Etomidate (1-[1-phenylethyl]-1*H*-imidazole-5-carboxylic acid ethyl ester) is an intravenous induction agent whose current clinical niche is as an alternative to propofol with little if any cardiorespiratory effects. No intrinsic analgesic properties are associated with the use

of this drug.⁸² Side effects such as pain on injection, myoclonia, nausea, vomiting, and adrenocortical suppression, however, have limited wider acceptance of the drug. Etomidate is a carboxylated imidazole derivative that was synthesized in 1965 and introduced to European anesthesia practice in 1972.⁸³ Etomidate has two isomers, but the (+) isomer is the only one with hypnotic properties (see Fig. 9.1 for the chemical structure of etomidate).⁸⁴

Etomidate is currently supplied as a 2 mg/mL preparation; each milliliter contains 35% propylene glycol as a solvent and has a pH of 8.1 and a pK_a of 4.2. This formulation has been changed over the years in an effort to decrease the incidence of pain on injection and spontaneous muscle movements or myoclonia. New formulations are being tested that are designed to maintain the favorable clinical features of etomidate while reducing the primary undesirable effect of prolonged inhibition of adrenal steroidogenesis.^{85,86}

Pharmacokinetics

Etomidate is rapidly metabolized in the liver by hepatic microsomal enzymes and plasma esterases. Ester hydrolysis is the primary mode of metabolism in the liver and plasma. Etomidate is hydrolyzed to form inactive carboxylic acid metabolites.

Approximately 10% of the administered dose can be recovered in bile, 13% can be recovered in feces, and the remainder of the metabolites are eliminated by the kidney.⁸⁷

The rapid redistribution of etomidate accounts for its extremely short duration of action (see Table 9.2). The drug is lipid soluble and has a volume of distribution that is several times greater than its body weight. Shortly after intravenous injection (within 1 minute), the brain concentration rises rapidly because of the drug's lipid solubility, and, over the next several minutes, extensive redistribution to other organs and tissues occurs and the patient regains consciousness.

The total body clearance of etomidate is rapid. The hepatic extraction ratio is 67%. Studies examining dose-response relationships have found a lack of accumulation with this compound.⁸² The terminal half-life is 2 to 5 hours.⁸⁵

Awakening occurs 5 to 15 minutes after bolus administration.

Like other intravenous induction drugs, this occurs secondary to rapid redistribution to nonnervous sites. Etomidate is 76% protein bound, mostly to albumin. Variations in the amount of available plasma protein alter the amount of free drug available to exert pharmacologic actions. Disease states that produce alterations in plasma protein content could theoretically effect the action, although this rarely happens clinically. Compensatory increases in metabolism and elimination can readily compensate for changes in protein binding.

The mechanism of action of etomidate, like many other CNS depressants, involves GABA modulation (see Fig. 9.4).^{88,89} In a clinical investigation of 2500 cases, Doenicke et al.⁹⁰ confirmed that no histamine is released by etomidate.

Pharmacodynamics

Central Nervous System Effects.

Etomidate produces a dose-dependent CNS depression within one arm-brain circulation. Its duration of action is also dose dependent,⁸² with awakening occurring 5 to 15 minutes after a 0.2 to 0.4 mg/kg dose. The drug is devoid of analgesic properties.

Cerebral blood flow and cerebral metabolic rate of oxygen consumption are both decreased by etomidate.^{91,92} In a study of fully alert patients without neurologic deficit or impaired consciousness, an etomidate induction was followed by an infusion of 2 to 3 mg/min. Cerebral blood flow decreased 34%, and cerebral metabolism was also reduced (mean decrease of 45%). Decreased oxygen consumption and the associated decrease in carbon dioxide production can cause cerebrovascular vasoconstriction, decreased cerebral blood flow, and decreased intracranial pressure. Also noted during this trial was the maintenance of cerebral blood vessel responsiveness to changes in carbon dioxide levels.⁹¹

In a study of patients with intracranial pathology, etomidate (0.2 mg/kg given intravenously) was shown to decrease intracranial pressure while maintaining cerebral perfusion pressure. Because of the cardiovascular stability of this drug, mean arterial pressure did not decrease below cerebral autoregulation values at which cerebral blood flow would become pressure dependent. Cerebral perfusion

pressure was maintained adequately in all study subjects.⁹²

The EEG changes that follow administration of etomidate are similar to those that follow administration of other intravenous induction anesthetics. When compared with thiopental, a lack of beta-wave activity was present during induction, along with a longer duration of stages III and IV.⁹³

One negative characteristic of etomidate is its excitatory phenomenon of muscle movements and tremors.^{93,94} Referred to as *myoclonia*, this phenomenon is defined as sudden, generalized, asynchronous muscle contractions.⁹⁵ Myoclonia can affect many muscle groups or a single muscle. The movements can be so severe that they resemble, and are often mistaken for, seizures. In EEG patterns monitored during etomidate anesthesia, no specific EEG disturbances occurred during or after myoclonic episodes.⁹³ The origin of these muscle movements is thought to be related to uneven drug distribution into the brainstem or deep cerebral structures and not to CNS stimulation.^{93,96} The incidence of myoclonia ranges between 10% and 60% and varies with the type and the amount of premedication given. Pretreatment with small doses of dexmedetomidine, midazolam, rocuronium, and lidocaine are all effective in reducing myoclonia.^{93,97-101} Etomidate is shown to decrease intraocular pressure.

EEG changes with etomidate are similar to those of other intravenous induction drugs. Bispectral index (BIS) monitor values decrease after a bolus of etomidate and correlate well with sedation scores. Etomidate decreases the amplitude and increases latency of auditory evoked potentials. The duration of epileptiform activity after ECT is longer after induction with etomidate versus propofol. Somatosensory-evoked potential amplitudes are enhanced by etomidate and motor-evoked potential amplitudes are suppressed less by etomidate than propofol.¹⁰²⁻¹⁰⁴

Cardiovascular Effects.

The primary clinical advantage of etomidate over propofol is the hemodynamic stability upon induction in healthy or modestly debilitated patients. In patients with compensated heart disease, changes in heart rate, pulmonary artery pressure, cardiac index, systemic vascular resistance, and systemic blood pressure were not

significant.¹⁰⁵ In one study of high-risk patients with significant cardiac disease, hemodynamic stability was maintained with induction doses of 0.3 mg/kg. Also, minimal changes in heart rate, blood pressure, central venous pressure, and intrapulmonary shunting have been demonstrated after etomidate administration.¹⁰⁶ Patients with aortic and mitral valve disease, however, are noted to have significant decreases in systemic blood pressure (17% to 19%), pulmonary artery pressure (11%), and pulmonary capillary wedge pressure (17%).¹⁰⁷ Slight decreases in blood pressure are thought to be caused by decreases in systemic vascular resistance. The hemodynamic stability seen with etomidate has been attributed to a unique lack of depression of sympathetic nervous system and baroreceptor function.¹⁰⁸ Etomidate acts as an agonist at α_2 -adrenoceptors, which mediates an increase in blood pressure. This effect contributes to the cardiovascular stability of patients with etomidate.¹⁰⁵

Myocardial oxygen supply and demand are kept constant by a balance of decreased myocardial blood flow and decreased oxygen consumption.¹⁰⁹ No significant cardiac dysrhythmias are associated with etomidate administration. Both renal and hepatic blood flows are maintained by the stability of cardiac output (see [Table 9.5](#)). In summary, at equivalent anesthetic doses, propofol depresses cardiorespiratory function to the greatest degree and etomidate depresses it the least.

Respiratory Effects.

Etomidate affects the respiratory system in a dose-dependent manner. Minute volume decreases, but respiratory rate increases. The respiratory depression seen with propofol use is significantly greater than that seen with etomidate.¹⁰⁹ The ventilatory response to carbon dioxide is decreased, and etomidate administration may cause brief periods of apnea following induction. Etomidate has little effect on bronchial tone and does not cause histamine release (see [Table 9.5](#)).^{110,111}

Adrenocortical Effects.

Adrenal cortical suppression by etomidate has been widely studied, and this effect significantly limits its clinical use. It is useful as a

single-dose anesthesia induction agent, but infusions are no longer used. The issue elicited widespread concern after 10 years of use in Europe. Researchers found an increased mortality rate in critically ill patients who received etomidate infusions. This phenomenon was attributed to adrenocortical hypofunction, demonstrated by decreased levels of plasma cortisol.¹¹² Multiple studies have shown adrenal hormone levels to be decreased for up to 8 to 24 hours after a single induction dose or more than 24 hours with infusion.¹¹³⁻¹¹⁹ These effects are caused by a reversible dose-dependent inhibition of adrenal steroidogenesis. The enzymes inhibited are the cytochrome P-450-dependent mitochondrial enzymes and 11 β -hydroxylase. To a lesser degree, 17 α - and 18-hydroxylases are also affected. This results in an increase in cortisol precursors but a decrease in cortisol, aldosterone, and corticosterone levels. This enzyme inhibition results in decreased ascorbic acid synthesis, which is necessary for steroid production.¹²⁰ In summary, these effects are primarily caused by a reversible dose-dependent inhibition of the adrenocortical enzyme 11 β -hydroxylase. The mechanism for the adrenocortical hypofunction following administration of etomidate is shown in [Fig. 9.5](#).

ADRENOCORTICOID SUPPRESSION BY ETOMIDATE

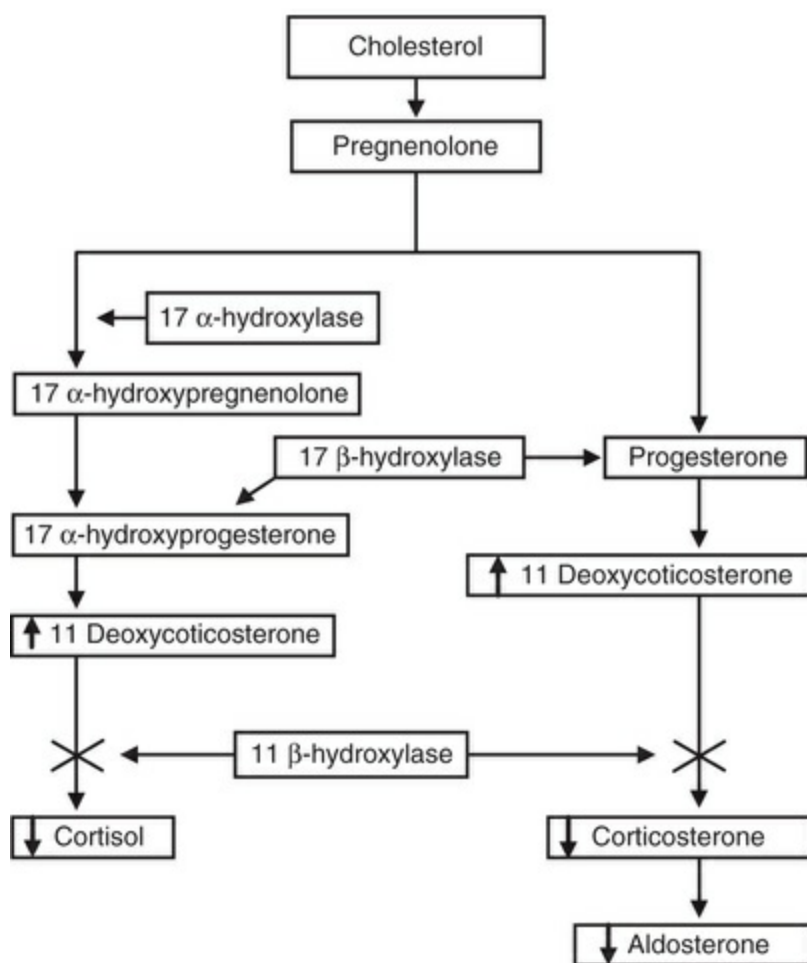

FIGURE 9.5 Adrenocorticoid suppression by etomidate. Etomidate produces prolonged inhibition of 11 β -hydroxylase, which leads to reductions in cortisol and aldosterone.

The clinical significance of this pharmacologic effect continues to be discussed. There have been several reports of single doses of etomidate resulting in patient morbidity. Critically ill patients given corticosteroid therapy for septic shock had poorer results when etomidate was also administered.¹²¹ A widespread controversy exists involving the likelihood of increases in morbidity and mortality from adrenal suppression when etomidate is used for intubation in septic patients.^{122,123} A large-scale study (CORTICUS) evaluating low-dose corticosteroid therapy in septic shock suggested that patients receiving etomidate before enrollment had a 28-day mortality, significantly higher than other patients in the trial, and that steroids provided no benefit to those who received

etomidate.^{124,125} A further analysis of the data led the authors to report that the use of a bolus dose of etomidate in the 72 hours before inclusion in the study was associated with an increased incidence of inadequate response to corticotrophins and an increase in mortality. They recommend that clinicians exercise caution in the use of etomidate in critically ill patients with septic shock.¹²⁵ The duration of adrenal insufficiency after single-dose etomidate and its effect on outcomes in this population is longer than 24 hours and may last up to 72 hours.¹²⁶ The administration of supplemental steroids to counter this effect is controversial. It did not appear effective in septic patients¹²⁵; however, others suggest that the empirical use of steroid supplementation for 48 hours after a single dose of etomidate in critical patients without septic shock should be considered.¹²⁶ Further research is needed to define the safe use of single boluses of etomidate in critical patients. It has been suggested that an alternative sedative induction agent should be considered for use in rapid sequence intubation in septic patients on multiple vasopressors or with abdominal source of infection.¹¹³

Adverse Effects

Other than the adrenal suppression and myoclonia that were discussed previously, the primary adverse effects of etomidate are pain on injection, thrombophlebitis, nausea, and vomiting. Etomidate has been formulated in various solvents in an effort to decrease pain on injection and also thrombophlebitis. The current formulation containing propylene glycol results in burning and pain on injection in up to 90% of patients.^{127,128} The incidence of subsequent venous sequelae up to 7 days postoperatively is 50%.¹²⁷ Some of the variables identified as contributing to pain on injection include site and speed of injection, size of vessel used, and type of premedication. The incidence of injection pain is significantly less with the lipid formulation.¹²⁹ As with other venous irritating drugs, injection pain can be decreased with lidocaine 20 to 40 mg pretreatment and use of larger veins. No vascular injury occurs after intraarterial injection of etomidate.

Nausea and vomiting is common with etomidate (30% to 40%).^{130,131} Nausea and vomiting are less common with the lipid emulsion of etomidate.¹³² Opioids also increase the susceptibility to

nausea and vomiting.

Contraindications

Etomidate is contraindicated in patients with a known sensitivity, adrenal suppression, and acute porphyrias.

The porphyrias are a group of rare metabolic conditions caused by deficiencies in the enzymes involved in the biosynthetic pathway of heme, a building block of hemoglobin. They can be inherited or acquired. The hereditary porphyrias comprise a group of eight metabolic disorders of the heme biosynthesis pathway. Each porphyria is caused by abnormal function at a separate enzymatic step resulting in a specific accumulation of heme precursors. Porphyrias are classified as hepatic or erythropoietic, based on the organ system in which heme precursors (δ -aminolevulinic acid [ALA], porphobilinogen and porphyrins) are overproduced.¹³³

Depending on deficient enzymatic steps, various porphyrins and their precursors accumulate in tissues and may lead to toxicity. They are considered either acute or nonacute and according to the specific biosynthetic step deficiency. The acute types of porphyria are inducible by various enzyme-inducing drugs that may precipitate an attack. The acute forms are acute intermittent porphyria; variegate porphyria; hereditary coproporphyria, and plumboporphyria. The nonacute forms are porphyria cutanea tarda; erythropoietic porphyrias; congenital erythropoietic porphyria, and erythropoietic protoporphyria.

The rate limiting enzyme in the biosynthetic pathway of porphyrins is ALA-synthetase. Drugs that induce this enzyme must be avoided. Symptoms of an attack may include skin lesions and neurovisceral symptoms such as abdominal and nonabdominal pain, vomiting, psychological symptoms, convulsions, muscle weakness, sensory loss, hypertension, tachycardia, and hyponatremia.

Etomidate and barbiturates are contraindicated. General anesthesia can be readily accomplished, however, with the current agents. Propofol is the induction agent of choice. Ketamine is safe as well. Most muscle relaxants appear to be reasonably safe, and all of the current inhalational agents may be used. Analgesia can be

provided with any of the currently used opiates. Local anesthetics may also be safely used.^{133–135}

Box 9.3 Key points of etomidate pharmacology are shown in **Box 9.3**.

Key Points for Etomidate

- Etomidate is used in compromised patients when the use of the other intravenous anesthetics may be problematic.
- The major advantage of etomidate is minimal cardiorespiratory depression.
- Etomidate reduces intracranial pressure, cerebral blood flow, and $CMRO_2$.
- The mechanism of action of etomidate appears to be GABA-mimetic.
- Involuntary movements or myoclonia during onset is common.
- Etomidate frequently causes burning on injection.
- Etomidate inhibits the enzyme 11β -hydroxylase, which is essential in the production of both corticosteroids and mineralocorticoids. Clinically significant reductions in steroid production may occur with single doses or prolonged infusions.
- Etomidate increases postoperative nausea and vomiting.
- The induction dose is 0.2–0.3 mg/kg.

$CMRO_2$, Cerebral metabolic rate of oxygen consumption; *GABA*, γ -aminobutyric acid.

Ketamine

Ketamine has a long history of anesthetic use, although its popularity has varied over the years. In modern practice, several specific situations exist in which it has unique advantages as an alternative to the more commonly used drugs. Research has led to

new uses, as well as a renewed interest in possible untoward effects. It can be very useful for anesthesia and sedation in high-risk, pediatric, and asthmatic patients. Ketamine also has excellent analgesic properties that can be exploited for treatment of perioperative pain.

Ketamine was introduced into clinical practice in 1970 and has a mechanism of action and pharmacologic effects that differ greatly from the classic anesthetic drugs. The anesthetic state is unique because it does not encompass the usual signs and stages of anesthesia with a typical CNS depressant. It produces a catatonic state in which the patient feels separated from the environment and has profound analgesia and amnesia yet retains most protective reflexes. This ketamine-induced anesthetic state was coined *dissociative anesthesia*, a concept described by Corssen and Domino.¹³⁶

Chemical Structure

The structural formula for ketamine is shown in Fig. 9.1. The chemical structure of ketamine is 2-(O-chlorophenyl)-2-(methylamino)cyclohexanone. It has a pK_a of 7.5, is partially water soluble, and is slightly acidic (pH 3.5 to 5.5). Ketamine is an optically active drug with a chiral center that exists as two optical isomers.¹³⁷ A racemic mixture is available in the United States and the S(+) isomer is available elsewhere. The S(+) isomer was believed to have a better safety profile, but the advantages of this pure enantiomer are minor.¹³⁸

Mechanisms of Action

Ketamine causes antagonism at *N*-methyl-D-aspartate amino acid (NMDA) receptors in the brain, resulting in a selective depressant effect on the medial thalamic nuclei that is responsible for blocking afferent signals of pain perception to the thalamus and cortex. The primary site of the analgesic action of ketamine is the thalamo-neocortical system. Ketamine has been shown to enhance opioid-induced analgesia and prevent hyperalgesia.¹³⁹ The NMDA receptor is a ligand-gated ion channel where anions Ca^{2+} and Na^+ are voltage dependent. L-glutamate, an amino acid, is probably the most

important excitatory neurotransmitter in the CNS. At the NMDA receptor, it causes the opening of the ion channel. A rapid influx of Na^+ , Ca^{2+} , and K^+ results in the depolarization of the normally negative postsynaptic membrane that initiates the action potential. Ketamine is a noncompetitive antagonist at this receptor.^{140,141} Afferent impulses are transmitted to cortical regions of the brain but are not interpreted, so responses to visual, auditory, and pain stimuli are inappropriate.¹⁴² Although cortical association areas are depressed, the limbic system, which is thought to cause excitatory behavior, is simultaneously activated. Ketamine also has effects on opiate, monoamine, cholinergic, purinergic, and adenosine receptors.^{143,144} It inhibits tumor necrosis factor-alpha ($\text{TNF-}\alpha$) and interleukin-6 (IL-6) gene expression, which may account for the antiinflammatory and antihyperanalgesic effects.^{145,146} The NMDA receptor is shown and described in [Fig. 9.6](#).

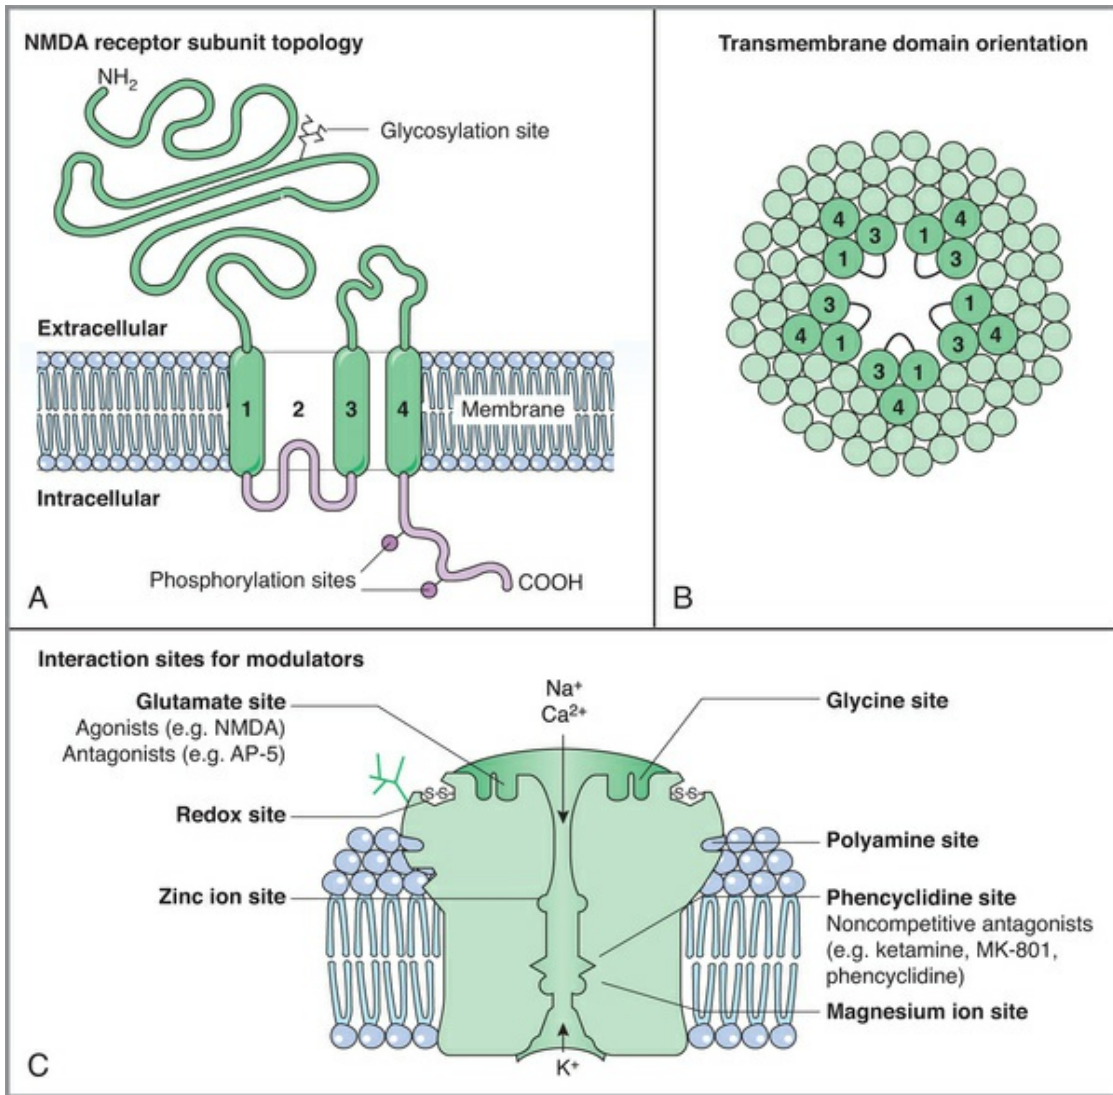

FIGURE 9.6 The *N*-methyl-D-aspartate amino acid (NMDA) receptor. **A**, The NMDA NRI receptor has three transmembrane segments and a fourth hydrophobic segment (*designated 2*) that loops into the membrane without traversing it. Mutation studies suggest that this loop is the putative channel-lining segment and that blockade by dizocilpine (MK-801), phencyclidine, and ketamine occurs through binding to a site that overlaps the Mg^{2+} site in the pore. The C-terminal domain undergoes phosphorylation, which regulates channel activity and mediates interactions with intracellular anchoring proteins. **B**, Transmembrane hydrophobic segments interact to form a central ion-conducting pore lined by the second hydrophobic segments. The stoichiometry of the heterooligomer is not known but may be four or five (as shown), by analogy with the homologous nicotinic cholinergic receptor. **(C)** The NMDA receptor gates a cation channel that is permeable to Na^+ , Ca^{2+} , and K^+ and is gated by

Mg²⁺ in a voltage-dependent fashion. Agonists (glutamate, NMDA) and the coagonist glycine, required for full activation, bind to the extracellular domain. (From Hemmings HC, Hopkins PM, (eds): *Foundations of Anesthesia Basic and Clinical Sciences*. 2nd ed. St. Louis: Mosby; 2006.)

The analgesia produced by ketamine has a spinal cord component. By injecting bradykinin intraarterially as a noxious stimulus, Nagasaka et al.¹⁴⁷ were able to demonstrate that ketamine blocked the stimulated excitatory activity of wide-dynamic-range neurons in the dorsal horn, thereby preventing transmission of noxious stimuli to the brain.

Metabolism

Hepatic microsomal enzyme systems are responsible for the biotransformation of ketamine. The primary pathway for ketamine metabolism by the cytochrome P-450 system is demethylation to form the metabolite I, norketamine. Hydroxylation of norketamine occurs at one of two positions in the cyclohexone ring to form hydronorketamine metabolites I, II, and III. These metabolites form a glucuronide derivation via conjugation to produce a more water-soluble compound that is eliminated primarily via renal excretion. Thermal dehydration forms dehydroxynorketamine, a cyclohexene derivative (metabolite II).^{68,148}

The pharmacologic activity of the metabolite norketamine is approximately 20% to 30% of the activity of ketamine. The activity of the other metabolites is unknown.¹⁴⁹

Pharmacokinetics

The distribution kinetics of ketamine follows a two-compartment model. Ketamine is able to cross the blood-brain barrier quickly to achieve rapid pharmacologic effect.¹⁵⁰ The onset of a standard 2 to 2.5 mg/kg dose is slower than propofol or etomidate, and it can take 3 to 5 minutes to achieve clinical anesthesia. Reawakening usually occurs within 15 minutes; however, there is wide patient variability. A much longer duration can be seen with high or repeat doses. Ketamine is approximately 12% protein bound. Like other induction drugs, brain concentrations decrease rapidly as ketamine

is redistributed from the central compartment to peripheral tissue compartments. Redistribution to low-blood-flow tissue compartments accounts for the termination of drug effect and return to consciousness. The slow elimination half-life of the drug is the result of hepatic metabolism and excretion. A large amount of ketamine remains in peripheral tissues as an active drug and may be responsible for prolonged or cumulative effects.⁸² The elimination half-life is 2 to 3 hours. Hepatic extraction of ketamine is high because the mean total body clearance is approximately the same as the hepatic blood flow.¹⁵¹ Ketamine elimination is therefore dependent on hepatic blood flow. Pharmacokinetic values remain consistent with analgesic and anesthetic doses of ketamine, which implies that distribution of ketamine is not dose dependent. Anesthetic levels are present with plasma levels of 640 to 1000 mcg/mL, and analgesic levels are present with plasma ketamine concentrations of 100 to 150 mcg/mL (see [Table 9.2](#)).¹⁴⁸

Intramuscular and Oral Route.

Given intramuscularly, ketamine reaches peak plasma concentrations within 22 minutes.¹⁵² Dosages range from 4 to 6 mg/kg.¹⁴⁰ The onset of anesthetic effects is seen within 5 to 15 minutes depending on dose. Analgesic doses of ketamine (0.44 mg/kg) can be used for painful procedures without causing loss of consciousness and psychic disturbances.⁶⁸ After intramuscular administration, approximately 93% of the drug is bioavailable.⁸² A consideration with the intramuscular route is the delayed onset of anesthesia. Ketamine can also be used orally in doses of 10 mg/kg. It is usually mixed in cherry syrup or soda to facilitate ingestion. Onset is 10 to 20 minutes. [Box 9.4](#) gives complete dosing

[Box 9.4](#) information.

Recommendation Doses of Ketamine

Premedication

- A benzodiazepine such as midazolam is administered if patient status allows. An antisialagogue may also be given to decrease secretions.

Induction of Anesthesia

- Ketamine 2–4 mg/kg IV, or 4–6 mg/kg IM (Oral dose is 10 mg/kg).

Maintenance of Anesthesia

- Ketamine 15–45 mcg/kg per min (1–3 mg/min) by continuous IV infusion or 0.5–1.0 mg/kg supplemental IV doses as needed.

Sedation and Analgesia

- Ketamine 0.2–0.8 mg/kg IV (over 2–3 min) followed by a continuous ketamine infusion (5–120 mcg/kg per min) 10–20 mg may produce preemptive analgesia.

IM, Intramuscular; *IV*, intravenous.

Pharmacodynamics

Central Nervous System Effects.

Ketamine produces a dissociative state of anesthesia, so called because the patient appears to be dissociated from the environment. The onset of anesthesia is slower than with propofol or etomidate and may make judgments regarding the onset of sleep and analgesia difficult. In the dissociative state, as originally described by Corssen,⁶⁸ the patient is cataleptic: the eyes remain open, the pupils are reactive to light, the corneal reflexes are intact, and horizontal nystagmus is present. Lacrimation and eye blinking continue, and salivary gland secretions are increased. Airway reflexes also remain intact (e.g., laryngeal reflex, pharyngeal reflex, coughing, sneezing, and swallowing). Skeletal muscle tone is increased, and occasional purposeless movements occur that are unrelated to painful stimuli.

Because the usual signs of anesthesia are not evident with ketamine, movement in response to painful stimuli is often required for judgments of adequate anesthesia. After administration of a single dose, full reorientation to person, place, and time takes place in 15 to 30 minutes, though as previously

noted, wide variability in durations have been noted.¹⁵³ Ketamine is a moderate analgesic that has a preference for skin, bone, and joint pain. Analgesia occurs with subanesthetic doses, and it is widely used for sedation in combination with low doses of benzodiazepines, propofol, and other analgesics.^{154,155}

CBF and regional and possibly global CMRO₂ and ICP are increased by ketamine. The effect on glucose utilization varies by brain region.¹⁵⁶⁻¹⁵⁸ The response of cerebral vessels to carbon dioxide is left intact. For these reasons ketamine has traditionally been thought to be contraindicated in patients with a head injury or an increased ICP. However, it has been noted that ketamine can be used safely in neurologically impaired patients under conditions of controlled ventilation, coadministration of a GABA receptor agonist such as midazolam or propofol, and avoidance of nitrous oxide.¹⁵⁷ Trauma patients with multiple injuries may still benefit from the favorable cardiovascular effects while avoiding untoward neurologic adverse actions.¹⁵⁵ Ketamine produces atypical anesthesia; thus EEG patterns also differ from standard anesthetics. On loss of consciousness and onset of analgesia, ketamine induces a transition from alpha to theta waves (slow waves with moderate to high amplitude) on the EEG. Alpha waves do not reappear until after consciousness returns and analgesia is lost.^{142,159} Ketamine alone does not decrease the BIS even when patients are unconscious. Several researchers have in fact noted an increase in BIS levels when ketamine is added to a propofol, fentanyl, or sevoflurane anesthetic.¹⁶⁰⁻¹⁶² Ketamine does not alter auditory evoked potentials (AEPs), mid-latency auditory evoked potential (MLAEP), or A-line autoregressive index monitors based on MLAEPs.¹⁵⁹ Ketamine appears advantageous for use in ECT.¹⁶³

Ketamine anesthesia emergence is associated with psychic disturbances immediately on return of consciousness.¹⁶⁴ These emergence reactions are the result of visual, auditory, proprioceptive, and confusional illusions. Descriptions of this phenomenon include vivid illusions, sensations of drunkenness, delirium, restlessness, altered states of consciousness, extracorporeal sensations, and combativeness.¹⁶⁵ The onset occurs with the first verbal contact and usually resolves in a few hours with full return of orientation to person, place, and time. The

incidence of emergence reactions is approximately 12%.¹⁶⁶ The incidence appears to be influenced by age, dose, gender, and psychological predisposition and concurrent medications. Recurrent dreams have been reported to occur weeks after a ketamine anesthetic.¹⁶⁷ The benzodiazepines diazepam, lorazepam, and midazolam were found to significantly decrease the incidence of these reactions. Subanesthetic doses of ketamine are being used for short-term treatment of acute and chronic pain. Low doses of ketamine are being used for sedation, postoperative pain relief, analgesia during regional or local anesthesia, and opioid-sparing effect.¹⁶⁶ Emergence reactions with low-dose ketamine are less frequent, but vivid dreaming may still occur. The use of positive mood elevating suggestion helps reduce the recall of unpleasant dreaming.^{167,168} Ketamine has little effect on postoperative nausea and vomiting (PONV). Subanesthetic doses used for analgesia may reduce opioid requirements.¹⁶⁹

Cardiovascular Effects.

Ketamine, unlike other intravenous anesthetics, acts as a circulatory stimulant, producing increases in systemic blood pressure, heart rate, cardiac contractility and output, and central venous pressure.¹⁶⁴ Systemic vascular resistance responded differently among patients undergoing cardiac catheterization and angiography ($\pm 25\%$), possibly because of patient variability in autonomic tone and disease states. Other studies have failed to show significant effects in systemic vascular resistance but have found evidence of an increase in pulmonary vascular resistance (42%), pulmonary artery pressure (47%), and right ventricular stroke work. These values persisted throughout the 12-minute measurement period, although they were somewhat decreased (pulmonary vascular resistance 42% at 3 to 5 minutes and 25% at 12 minutes; mean pulmonary arterial pressure 47% at 3 to 5 minutes and 23% at 12 minutes). In patients with congenital heart disease and increased pulmonary pressure and resistance, ketamine administration did not adversely affect myocardial function (ejection fractions remained constant).¹⁷⁰

Ketamine administration causes an increase in myocardial contractility, thereby affecting the myocardial oxygen balance. This

increase in myocardial oxygen consumption has not been shown to cause inadequate myocardial perfusion, because a concomitant rise in coronary artery perfusion occurs.¹⁷⁰

Ketamine-induced activation of the sympathetic nervous system that results in endogenous catecholamine release is believed to be one of the mechanisms for the cardiostimulatory properties experienced after administration of the drug.¹⁷¹ The positive inotropic effect of ketamine also results from an inhibition of neuronal and extraneuronal uptake of norepinephrine.¹⁷² The in vitro negative inotropic effects of ketamine are the result of a decrease in the available calcium ions (Ca^{2+}) intracellularly, caused by an interference with Ca^{2+} delivery mechanisms (net transsarcolemmal Ca^{2+} influx).¹⁷³ When the positive inotropic effects of ketamine are blocked, the negative inotropic effects predominate and may result in decreased blood pressure and cardiac output. This phenomenon may be seen clinically in the critically ill patient who, as a result of protracted illness, has decreased available catecholamine stores and limited ability to compensate. With an intact sympathetic nervous system, the positive inotropic effects dominate and counteract the negative inotropic effects. By decreasing sympathetic responses, some inhalation anesthetics are able to block the cardiovascular effects of ketamine to produce a decrease in systemic blood pressure and cardiac output.¹⁷⁴ The cardiovascular stimulation produced by ketamine may be deliberately decreased by the prior administration of benzodiazepines in patients in whom that response should be avoided.¹⁶⁴

Ketamine has been used successfully in patients who are hemodynamically compromised because of shock, trauma, debilitation, or hypovolemia.

Changes in systemic blood pressure are dose related; systolic and diastolic blood pressures increase when larger doses of ketamine are administered (0.5 to 2.0 mg/kg). However, the heart rate response to different dosages reaches a plateau, with no significant change in rate occurring between doses of 0.5 and 2 mg/kg.

Ketamine has been used successfully for both pediatric and adult cardiac surgery patients with congenital and acquired disease processes.^{170,175} The cardiac and respiratory actions of ketamine are

summarized in [Table 9.5](#).

Respiratory Effects.

The effects of ketamine on the respiratory system are minor and of short duration. Ventilation is generally preserved, as is normal respirations. Transient apnea upon initial administration may occur with rapid administration of larger doses although it is rare. Arterial blood gases remain within normal limits, and the central response to carbon dioxide is maintained.¹⁶⁴

Ketamine increases pulmonary compliance and decreases pulmonary resistance in patients with bronchospastic disease. It is the only active bronchodilating induction agent and the agent of choice in any patient with active asthma who requires surgery. Increased catecholamine levels stimulated by ketamine, along with bronchial smooth muscle relaxation and vagolytic actions, are thought to be the reason for the bronchodilating effects of the drug. Tracheal, bronchial, and salivary muscle gland secretions are increased with ketamine, which may require the use of an antisialagogue. Atropine is superior to glycopyrrolate for this application.¹⁷⁶ The muscle tone of the tongue and jaw is retained, and protective pharyngeal and laryngeal reflexes are left intact. Coughing, gagging, swallowing, and vomiting reflexes remain intact in response to airway stimulation, although some diminution may be present and silent pulmonary aspiration has occurred in some patients (see [Table 9.5](#)).

Intraocular Effects.

Research into the effects of ketamine administration on intraocular pressure (IOP) has yielded varied results.¹⁷⁷⁻¹⁸⁰ Measurement techniques and adjunctive anesthetics may play a role in the conflicting reports. Ketamine usually increases IOP, but the effect appears dose dependent.¹⁸¹ A 6 mg/kg dose raises IOP but a 3 mg/kg dose does not. Ketamine causes nystagmus, increased muscle tone, and muscle spasms, which may not be appropriate for some ophthalmic procedures.¹⁸² When used for procedural sedation in the emergency department at doses of 4 mg/kg or less, there are no clinically meaningful increases in IOP.¹⁸³ It blocks oculocardiac reflex-induced arrhythmias better than propofol during sevoflurane

anesthesia for strabismus surgery.¹⁸⁴ The common clinical effects of Ketamine are shown in Box 9.5.

Primary Clinical Characteristics and Effects of Ketamine

- Phencyclidine derivative
- Causes unconsciousness; amnesia referred to as *dissociative anesthesia*
- Increases cerebral metabolic rate, cerebral blood flow, and intracranial pressure
- Causes nystagmus; increased intraocular pressure
- Moderate analgesic
- Increases blood pressure and pulse
- Potent bronchodilator
- Maintains respirations and airway reflexes (NOTE: A period of initial apnea may occur, especially with high doses and rapid administration.)
- Increases salivation and respiratory secretions
- Increases muscle tone
- Associated with emergence delirium, nightmares, and hallucinations
- Requires caution in patients with hypertension, angina, congestive heart failure, increased intracranial pressure, increased intraocular pressure, psychiatric disease, and airway problems

Obstetric and Pediatric Use.

Ketamine can be used in obstetrics for analgesia or anesthesia. It is

highly lipid soluble and readily crosses the placenta into fetal tissue. As an induction agent, ketamine in doses of 0.5 to 1 mg/kg produces rapid anesthesia without compromising uterine tone, uterine blood flow, or neonatal status at delivery. For analgesia, 0.25 mg/kg of ketamine provides pain-related relief, airway stability, and a sustained maternal blood pressure and uninhibited uterine contractions. Use of doses reserved for surgical procedures (2 to 2.5 mg/kg) results, however, in a depressed neonate on delivery.^{185,186} Decreasing this dose to 0.2 to 1 mg/kg spared the newborn this CNS depression because of the rapid redistribution of the drug in the mother and less fetal transfer.

Ketamine is a very popular drug for neonates and children. Sedation, analgesia, amnesia, cardiac and respiratory stability, and a short duration offer advantages in many procedures in these patients.¹⁸⁷ Clinicians have noted it may be the agent of choice for children with a difficult airway or reactive airway diseases such as asthma. It can be used intramuscularly or orally for an uncooperative child requiring intravenous access.¹⁸⁸

A controversy exists with regard to anesthetic neurotoxicity caused by ketamine. Neuroapoptosis has been noted in several animal models when ketamine is used in the developing brain.¹⁸⁹ How this relates to the use of ketamine and other anesthetics in newborns and children is unclear. This is an area of intense research interest.¹⁹⁰⁻¹⁹³

Clinical uses of ketamine are given in [Box 9.6](#). Recommendations for using ketamine as a sedative, analgesic, or anesthetic during the postoperative period are listed in [Box 9.4](#). Key points of ketamine pharmacology are given in [Box 9.7](#).

Clinical Uses of Ketamine

Induction of Anesthesia in High-Risk Patients

- Shock or cardiovascular instability
- Hypovolemia
- Cardiomyopathy

- Trauma
- Bronchospasm

Obstetric Patients

Induction of General Anesthesia

- Severe hypovolemia/trauma
- Acute hemorrhage
- Acute bronchospasm

Low Dose for Analgesia

- To supplement regional anesthetic techniques
- As an additive to opioids in patient-controlled analgesia
- For use in therapy for chronic pain and depression

Adjunct to Local and Regional Anesthetic Techniques

- For sedation and analgesia during intravenous sedation or when a regional block is used
- To supplement an inadequate block

Outpatient Surgery

- For brief diagnostic and therapeutic procedures
- To supplement local and regional block techniques

Use Outside the Operating Room

- In burn units (e.g., débridement, dressing changes)

- In emergency rooms for minor procedures
- In intensive care units (e.g., sedation, painful procedures)
- During radiology procedures

Box 9.7

Key Points for Ketamine Anesthesia

- Site of action of ketamine appears to be the NMDA receptor, where it inhibits glutamate as a noncompetitive antagonist. Other actions are likely.
- Ketamine produces an anesthetic state referred to as *dissociative anesthesia*.
- Onset of effect is relatively slow compared to other induction drugs (2–5 min).
- Ketamine produces a rise in cerebral perfusion pressure.
- Ketamine is a bronchodilator, preserves airway reflexes, and increases secretions.
- Emergence phenomena—including vivid dreams, floating sensations, and delirium—can occur after ketamine administration. They are more common in adults than children and are reduced by benzodiazepine or other sedative administration.
- Ketamine is an indirect sympathomimetic, releasing catecholamines. This action accounts for the cardiac stimulation and bronchodilation
- Ketamine is a moderate analgesic and is used preoperatively as an analgesic

NMDA, N-methyl-D-aspartate.

Benzodiazepines

Benzodiazepines are used in many clinical situations due to their desirable pharmacologic properties, including sedation, hypnosis, muscle relaxation, anxiolysis, anticonvulsant effects, and amnesia. They also have a low incidence of side effects. Benzodiazepines used clinically in the United States are listed in [Table 9.7](#).

TABLE 9.7

Benzodiazepines Used Clinically in the United States

Generic Name	Trade Name	Half-Life (hr)	Clinical Application
Alprazolam	Xanax	12–15	Anxiolysis
Chlordiazepoxide	Librium	8–18	Treatment of alcohol withdrawal, etc.
Clonazepam	Klonopin	18.7–39	Treatment of epilepsy
Clorazepate	Tranxene	2.4	Treatment of epilepsy and alcohol withdrawal
Diazepam	Valium	36–50	Sedation; induction and maintenance of anesthesia
Estazolam	ProSom	14	Treatment of insomnia
Flurazepam	Dalmane	2–3	Treatment of insomnia
Lorazepam	Ativan	10–22	Anxiolysis and sedation
Midazolam	Versed	1.7–2.6	Sedation; induction and maintenance of anesthesia
Oxazepam	Serax	3–21	Anxiolysis
Quazepam	Doral	25–41	Treatment of insomnia
Temazepam	Restoril	10–21	Treatment of insomnia
Triazolam	Halcion	2–3	Treatment of insomnia
Flumazenil	Romazicon	0.7–1.3	Reversal of benzodiazepine agonists

Although similar compounds were first synthesized in 1933, the first benzodiazepine synthesized was chlordiazepoxide (Librium) in 1955. It was not introduced into clinical practice until 1960, when it was found to have antianxiety and hypnotic effects. Diazepam was synthesized in 1959, and its metabolite, oxazepam (Serax), was synthesized in 1961. Lorazepam (Ativan) was derived from oxazepam in 1971.¹⁹⁴ The last benzodiazepine to be developed was midazolam (in 1976, by Fryer and Walser), which was the first of the benzodiazepine group to be formulated with anesthesia as its target clinical use. The benzodiazepines available for clinical use have many similarities but there are differences in potencies, pharmacokinetics, and intensities of clinical properties. Midazolam is widely used in anesthesia and other areas as an anxiolytic, sedative, hypnotic, and amnestic drug. It is rarely used to induce anesthesia due to a prolonged effect at the high doses required.

Diazepam and lorazepam, which are also available as intravenous preparations, are occasionally used as well. They are usually reserved for inpatients requiring prolonged sedation.

Remimazolam is an ultra-short-acting benzodiazepine currently being developed for procedural sedation and induction and maintenance of anesthesia. It combines the properties of two unique drugs already established in anesthesia. It is a benzodiazepine like midazolam and has organ-independent metabolism like remifentanyl. The incorporation of a carboxylic ester moiety into the benzodiazepine core of remimazolam renders it susceptible to nonspecific tissue esterases and it is rapidly metabolized into its pharmacologically inactive metabolite.^{195,196}

Chemical Structure and Pharmaceutics

The chemical structures of the benzodiazepines share some common features: (1) the benzodiazepine ring system; (2) the presence at positions 1 and 4 of two nitrogen atoms; (3) a phenyl group at position 5; and (4) an electronegative group at position 7 (see Fig. 9.1).¹⁹⁴

Midazolam has a unique chemical structure in comparison with the other benzodiazepines. The imidazole ring is responsible for its basic formulation, which permits the preparation of salts that are water soluble at a pH of 4.0. In a chemical reaction that depends on the environmental pH, the diazepine ring opens reversibly between positions 4 and 5. Midazolam is water soluble and does not require a lipoidal vehicle (such as propylene glycol) for parenteral use. Minimal if any side effects of venous irritation or phlebitis occur. Once in physiologic solution with a pH greater than 4.0, the diazepine ring closes, and midazolam becomes lipophilic, an effect that accounts for its rapid onset of action.^{194,197}

Injectable midazolam is compounded with 0.8% sodium chloride and 0.01% disodium edetate and 1% benzyl alcohol as a preservative. A pH of 3 is adjusted with hydrochloric acid and, if necessary, sodium hydroxide. Each milliliter of preparation contains 1 or 5 mg of midazolam. An oral solution is also available for pediatric sedation.

In each milliliter of solution of diazepam, 0.4 mL of propylene glycol and 0.1 mL of ethyl alcohol are present as solvents, 0.015 mL

of benzyl alcohol is present as a preservative, and sodium benzoate or benzoic acid in water is present as a buffer. Each milliliter contains 5 mg of diazepam and the pH is 6.2 to 6.9.¹⁹⁴

Each milliliter of lorazepam solution contains 0.18 mL of polyethylene glycol and 2% benzyl alcohol, a preservative. Lorazepam is available in solutions of 2 or 4 mg/mL (see [Table 9.1](#) for the preparations of the benzodiazepines).¹⁹⁷

Mechanisms of Action

The clinical effects of benzodiazepines are a result of an agonist action at what are termed *benzodiazepine receptor binding sites* on the GABA_A receptor throughout the CNS. GABA is the major inhibitory neurotransmitter in the CNS. The receptor complex is composed of a pentameric array of protein subunits that contain binding sites for GABA itself, benzodiazepines, barbiturates, ethanol, propofol, and many other sedatives. The GABA_A receptor exerts its actions by modulating chloride channels. Many different families of the GABA_A receptors exist and these subtypes vary in location, function, and pharmacologic effects. When these binding sites are occupied by an agonist, GABA receptor modulation increases the frequency of chloride channel opening, which results in postsynaptic membrane hyperpolarization, and neuronal transmission is inhibited.^{198–200}

Three classes of ligands that bind to the benzodiazepine receptors have been identified: agonists, antagonists, and inverse agonists. Midazolam, diazepam, and lorazepam are receptor agonists that allosterically increase binding affinity for GABA, resulting in the opening of the chloride channels. Antagonists (e.g., flumazenil) form reversible bonds with the agonist receptor but produce no agonist activity. Inverse agonists cause CNS stimulation by interfering with GABA transmission, which is inhibitory.^{197,201} Because the benzodiazepines work allosterically to enhance endogenous GABA binding and not directly, there is a physiologic ceiling to their effect. Their safety and low toxicity is attributed to this built-in limit on their effect.²⁰² Peripheral benzodiazepine binding sites, not associated with the GABA_A receptor, exist in the mitochondrial membranes of many cells and may modulate

cardiovascular and immune function (see Fig. 9.4).²⁰³

Pharmacokinetics

The introduction of new generations of benzodiazepines since their initial release in the 1960s has largely focused on chemical alterations that improve the clinical pharmacokinetics. These changes have resulted in simplified metabolism with fewer active metabolites and thus more predictable time courses. The elimination pharmacokinetics of benzodiazepines can be examined in both two- and three-compartment models. Benzodiazepines have been classified according to their elimination half-lives. These classifications take into account the elimination half-lives of both the parent drug and the active metabolites. Diazepam is long acting ($T_{1/2}$ greater than 24 hours) lorazepam is intermediate ($T_{1/2}$ 6–24 hours) and midazolam is short acting ($T_{1/2}$ less than 6 hours).⁸² The pharmacologic effects of the benzodiazepines, as with the other anesthesia induction drugs, are terminated primarily by redistribution of the drug out of the CNS.

Their pharmacokinetics are influenced by age, gender, obesity, race, and hepatic and renal status to varying degrees. The pharmacokinetics of the three intravenous benzodiazepines are similar with a few important differences. Midazolam exhibits a higher clearance rate and therefore is shorter acting. Lorazepam is less dependent on hepatic cytochrome enzymes for metabolism because it undergoes phase 2 conjugation to a significant extent. Liver disease, as well as hepatic enzyme induction or inhibition, therefore, does not influence lorazepam as much as other drugs. Diazepam has a very slow distribution half-life, which limits its usefulness as an acceptable induction agent. Diazepam is extremely lipid soluble, a characteristic that promotes extensive distribution to the tissues. The volume of distribution is large, a characteristic of all benzodiazepines. Also characteristic is extensive protein binding, which theoretically may be affected by disease states that decrease plasma protein levels. All three drugs are primarily bound to albumin. Diazepam is 99% protein bound, lorazepam 85% to 90%, and midazolam 95%. The total body clearance of diazepam is 0.24 to 0.53 mL/min per kg and is totally dependent on hepatic

metabolism.

Diazepam exhibits a near-linear relationship between elimination half-life and patient age. Pharmacokinetics in the elderly are altered as a result of slowed drug absorption; increased percentage of adipose tissue in body mass; decreased plasma proteins, hepatic blood flow, and metabolism; and decreased cardiac output and circulation time. A prolonged circulation time allows for a slower onset and a higher plasma drug level that remains in the CNS longer before it redistributes; this phenomenon exaggerates the effects of the drug.⁸²

Hepatic microsomal enzymes are responsible for the metabolism of diazepam. Diazepam is demethylated to dimethyl diazepam (nordiazepam), which is an active metabolite that, although less potent, is responsible for prolonged drug effect as a result of its slower metabolism. Diazepam can also be hydroxylated to 3-hydroxydiazepam, which is then demethylated to oxazepam, which is also pharmacologically active and commercially marketed. The termination of action of diazepam is caused by redistribution and eventual metabolism. The terminal half-life is 20 to 50 hours, much longer than that of other benzodiazepines and induction agents.

Pharmacodynamics

Central Nervous System Effects.

All three intravenous drugs produce the characteristic dose-dependent CNS depressant effects of the benzodiazepines, from anxiolysis to sedation, sleep and with high enough doses of anesthesia. They all produce anticonvulsant effects, amnesia, and muscle-relaxing properties and are useful for inhibiting alcohol withdrawal symptoms. They are not antiemetic; however, lorazepam is used for its sedative, amnestic, and anxiolytic effects in reducing anticipatory chemotherapy-induced nausea and vomiting.

At higher doses they reduce $CMRO_2$ and CBF. They increase the threshold to local anesthetic-induced seizure activity, and midazolam is frequently used as a premedicant in patients having regional anesthesia requiring large volumes of local anesthetics.

All benzodiazepines produce dose-related anterograde amnesia.

They generally do not produce reliable retrograde amnesia. Intravenous administration of midazolam produces anterograde amnesia in low doses. Amnesia occurs within 2 to 5 minutes of administration and remains for 20 to 30 minutes.^{204–207} Deficits are seen in both short- and long-term memory. These include interfering with episodic, semantic, and iconic memory function.

Benzodiazepines also possess anticonvulsant activity and are effective in the treatment of status epilepticus and sedative-hypnotic withdrawal syndromes. EEG changes include disappearance of the alpha rhythm and the onset of higher-frequency beta-rhythm activity.²⁰⁸ Tolerance, dependence, and withdrawal symptoms occur and vary among the benzodiazepines. Midazolam produces synergistic CNS, cardiovascular, and respiratory effects with fentanyl (see [Table 9.4](#)).

Cardiovascular Effects.

In commonly used clinical doses, the benzodiazepines have minimal cardiovascular effects. A decrease in blood pressure is occasionally seen when midazolam is given with opioids in patients with heart disease or the elderly.

Respiratory Effects.

Benzodiazepines produce dose-dependent respiratory depression. Midazolam is the most respiratory depressing. Some respiratory depression occurs with diazepam, as evidenced by a decrease in minute ventilation and slope of the carbon dioxide response curve.²⁰⁹ Increased respiratory depression and apnea are possible when benzodiazepines are combined with other CNS depressants such as opioids.

Contraindications and Precautions

The most common adverse effects of the benzodiazepines are unexpected respiratory depression and oversedation. In the doses used currently, other adverse actions are rare. They should be avoided in patients with acute porphyrias.

Uses

Midazolam is the standard drug given for preoperative medication. Its rapid onset, short duration and half-life, and lack of adverse effects make it ideal for use as a preoperative anxiolytic, sedative, and amnestic.²¹⁰ Key points for the use of benzodiazepines are shown in Box 9.8.

Key Points for Benzodiazepines

- Benzodiazepines act by an agonist effect on the GABA_A receptor which enhances the inhibitory effect of GABA. Flumazenil is an antagonist at these receptors and reverses the clinical effect of the agonists. Inverse agonists (not used clinically) are anxiogenic.

- Benzodiazepines cause:

reduction of anxiety and aggression

sedation, leading to improvement of insomnia

muscle relaxation and loss of motor coordination

suppression of convulsions (antiepileptic effect)

anterograde amnesia.

- Differences in the pharmacological profile of different benzodiazepines are minor; clonazepam appears to have more anticonvulsant action in relation to its other effects.
- Benzodiazepines are active orally and differ mainly in respect of their duration of action and half-lives. Some long-acting agents (e.g. diazepam and chlordiazepoxide) are converted to a long-lasting active metabolite nordiazepam.
- Midazolam, diazepam and lorazepam are available intravenously.

- Zolpidem (Ambien) is a short-acting drug that is not a benzodiazepine but acts similarly and is used as a hypnotic.
- Remimazolam is an experimental benzodiazepine with an ester linkage that allows for rapid metabolism to inactive metabolites. It is administered by continuous infusion and may prove useful as a fast onset, short duration induction drug.

GABA, γ -Aminobutyric acid.

Flumazenil

Flumazenil is the sole benzodiazepine antagonist available in the United States (see Fig. 9.1). It is a competitive antagonist with a high affinity for the receptor site. It produces prompt and effective specific reversal of benzodiazepine agonist effects after anesthesia and overdose.^{211,212} As with any drug antagonist, its antidotal efficacy depends on the amount of free benzodiazepine at the receptor sites. Its relatively short duration and half-life make the possibility of re sedation clinically relevant, especially in overdose situations. A slow titration of 0.2-mg doses (2 mL) is given intravenously (up to 1 mg) until the desired level of consciousness is achieved. Doses rarely exceed 1 mg for the reversal of midazolam-induced sedation and 3 mg for suspected benzodiazepine overdose. Onset is 1 to 2 minutes and duration of action is 45 to 90 minutes depending on total flumazenil dose and the amount of agonist requiring reversal. Withdrawal reactions are possible in patients who are benzodiazepine dependent, and its use in these patients is contraindicated. Flumazenil does not reverse the actions of ethanol or barbiturates.²¹³ Side effects are rare, although mild anxiogenic effects have been reported.²¹⁴ Seizures have been reported in patients with suspected tricyclic and antidepressant overdose, and the use of flumazenil in these situations and in patients with a known history of seizures should be avoided.^{215,216}

Dexmedetomidine

The sedative and analgesic effects of alpha-2 (α_2) receptor agonists were long recognized from the use of clonidine and the veterinary

anesthetic xylazine. Dexmedetomidine was developed as a more selective α_2 agonist, which allows for greater sedation. There are three main chemical classes of α_2 receptor agonists: the phenylethylamines such as methyldopa and guanabenz; the imidazolines such as clonidine, dexmedetomidine, mivazerol, and azepexole; and the oxalozepines. The imidazolines are used in anesthesia. Stimulation of imidazoline receptors account for the hypotensive side effects. The primary effects of dexmedetomidine are sedation, analgesia, anxiolysis, reduced postoperative shivering and agitation, and cardiovascular sympatholytic actions.^{217,218}

Mechanism of Action

α_2 Adrenoreceptors are involved in various physiologic functions, particularly in the cardiovascular and central nervous systems. There are three subtypes of α_2 receptors. The subtypes and their putative functions are noted in [Box 9.9](#).^{219,220} Dexmedetomidine is highly specific for α_2 versus α_1 receptors at a ratio of 1600:1. α_2 Presynaptic receptors function as autoreceptors in the negative feedback loop controlling neurotransmitter release. When α_2 receptors are stimulated by an agonist such as dexmedetomidine, it results in a decreased catecholamine release. The main site of action for the sedative actions of dexmedetomidine is the pontine noradrenergic nucleus, the locus coeruleus. The α_2 receptors are G-protein–coupled receptors, which when activated, result in the inhibition of calcium channels, the activation of potassium channels, and the direct modulation of the exocytic release of proteins. This produces hyperpolarization of the cells and thus

Chemistry and Pharmaceuticals

Precedex (dexmedetomidine hydrochloride injection) is a sterile, nonpyrogenic solution for intravenous infusion following dilution. Dexmedetomidine hydrochloride is the S-enantiomer of medetomidine and is chemically described as (+)-4-(S)-[1-(2,3-dimethylphenyl)ethyl]-1H-imidazole monohydrochloride. Dexmedetomidine HCl is freely soluble in water and has a pK_a of 7.1. Its partition coefficient (n-octanol/water) at pH 7.4 is 2.89. Precedex is supplied as a clear, colorless, isotonic solution with a pH of 4.5 to 7.0. Each 1 mL of Precedex contains 118 mcg of dexmedetomidine HCl (equivalent to 100 mcg dexmedetomidine base) and 9 mg of sodium chloride in water. The solution is preservative free and contains no additives or chemical stabilizers. Prepare by adding 2 mL of dexmedetomidine (100 mcg/mL) to 48 mL of 0.9% sodium chloride injection for a total of 50 mL. The final concentration is 4 mcg/mL. The loading dose is 1 mcg/kg infused over 10 minutes followed by maintenance infusions of 0.2 to 0.7 mcg/kg per hour. It is approved for up to 24 hours use for sedation in critical care and for nonintubated patients requiring sedation for short-term surgical procedures. It is used for numerous off-label applications.

Pharmacokinetics

Dexmedetomidine exhibits a rapid distribution phase with a distribution half-life ($T_{1/2}$) of approximately 6 minutes; a terminal elimination half-life ($T_{1/2}$) of approximately 2 hours; and steady-state volume of distribution (V_{ss}) of approximately 118 L. Clearance is estimated to be approximately 39 L/hr. The mean body weight associated with this clearance estimate was 72 kg. Dexmedetomidine exhibits linear kinetics in the dosage range of 0.2 to 0.7 mcg/kg per hour when administered by IV infusion for up to

24 hours. Target concentrations are usually in the range of 0.3 to 0.6 mg/mL. Protein binding to both albumin and α_1 acid glycoprotein is 94%.²²² Dexmedetomidine undergoes almost complete biotransformation with very little unchanged in urine and feces. Biotransformation involves both direct glucuronidation as well as cytochrome P-450–mediated metabolism. There are no active metabolites. Similar kinetic data was noted in pediatric patients.^{223,224} Onset of action with loading infusion is 10 to 20 minutes, and the duration of action after the infusion is stopped is 10 to 30 minutes.

Central Nervous System Effects.

Dexmedetomidine produces a dose-dependent sedation that resembles natural sleep, unlike the classic GABA receptor agonists. Patients do not experience respiratory depression and are readily arousable.^{225,226} An advantage of this type of sedation is that procedures requiring “wake up” tests can be more readily accomplished compared to usual anesthetic regimens.^{227,228} Dexmedetomidine does not interfere with electrophysiologic monitoring, allowing brain mapping during awake craniotomy and microelectrode recording during implantation of deep-brain stimulators.²²⁹ Motor and somatosensory evoked potentials are maintained when added to a desflurane and remifentanyl technique.²³⁰ Decreases in the amplitude of motor evoked potentials may occur at high doses.²³¹ BIS values are decreased in a dose-dependent manner to a greater extent than with propofol.²³²

Dexmedetomidine does not change cerebral metabolism ($CMRO_2$). CBF is decreased due to cerebral vasoconstriction. This suggests uncoupling between cerebral metabolism and flow due to decreases in central catecholamine turnover. Effects on intracranial pressure are not clinically significant.²³³

The central sympatholytic effects also result in an antishivering action, hypothermia, and a reduction in the neuroendocrine stress response to surgery.²¹⁷ A reduction in postoperative agitation and emergence delirium in children and adults is an increasingly used clinical action.²²³ A neuroprotective effect has been proposed, but benefits in patients with head injuries remain to be clarified.²³⁴ Reductions in the withdrawal symptoms from sedatives, opioids,

and alcohol have been noted.²¹⁷ Analgesic- and anesthetic-sparing effects are well documented and are produced at both the brain and spinal cord level. Dexmedetomidine enhances the analgesic effects of nitrous oxide.²³⁵

Cardiovascular Effects.

The main cardiovascular effects of dexmedetomidine are hypotension and bradycardia. This results from CNS alpha receptor stimulation and systemic vasodilation. Occasionally, transient hypertension is seen with rapid initial loading doses or administration of high maintenance doses due to vasoconstriction; however, dose-dependent hypotension is the norm. There is no direct effect on myocardial contractility. There is a reduction in myocardial oxygen demand, an antianginal effect.²¹⁷ Transient profound hypertension was noted when using glycopyrrolate to treat dexmedetomidine-induced bradycardia in children and caution is advised when coadministering these drugs.²²³

Respiratory Effects.

A unique advantage of dexmedetomidine sedation is that respirations are maintained. Brain respiratory responsiveness to carbon dioxide is normal. Airway patency and reflexes are present or only slightly diminished. These properties allow for convenient use in out-of-operating room procedures and difficult airway situations. Dexmedetomidine completely blocked histamine-induced bronchoconstriction in dogs. It appears beneficial to decrease airway reactivity in patients with chronic obstructive pulmonary disease or asthma.²³⁶ It improves tolerance, agitation, and weaning and lessens the time required for sedation in mechanically ventilated patients.^{237,238}

Other Effects.

Dexmedetomidine has a mild diuretic effect mediated via α_2 receptor stimulation. Additional beneficial actions include renal, gastroprotective, and antiinflammatory effects. Dexmedetomidine is effective in reducing the incidence of emergence agitation in children.²³⁹ Dexmedetomidine is being widely used for many surgical and diagnostic procedures in both adults and children.

Which clinical situations become established as the best places to use this unique drug is still evolving. Some key points for the **Box 9.10** clinical use of dexmedetomidine are noted in **Box 9.10**.

Key Points for Clinical Use of Dexmedetomidine

- Dexmedetomidine is an α_2 receptor agonist that results in central sympatholysis.
- Dexmedetomidine sedation allows for an arousable patient to ascertain neurologic status.
- Dexmedetomidine does not interfere with neurologic monitoring.
- Hypotension and bradycardia are the most frequent cardiovascular adverse effects.
- It is useful for procedural sedation.
- Respirations are maintained.
- Reduces postoperative agitation and emergence reactions.

Anesthetic Neurotoxicity

General anesthetic and sedative drugs are administered to millions of infants and children each year. Data from animal and observational human studies have raised concerns that general anesthetics may cause neurotoxic changes in the developing brain that lead to adverse neurodevelopmental outcomes later in life. To address this concern, in 2009 the Food and Drug Administration (FDA) established a public–private partnership with the International Anesthesia Research Society (IARS) called *Strategies for Mitigating Anesthesia-Related Neurotoxicity in Tots*, or *Smart Tots*.²⁴⁰

Studies have confirmed that commonly used anesthetics and sedatives that either increase inhibitory GABA receptor activity (e.g., propofol, etomidate, sevoflurane, desflurane, and isoflurane) or block excitatory glutamate receptors (e.g., ketamine) produce profound neurotoxic effects in laboratory animals. Factors that influence the extent of injury include age at the time of drug exposure and cumulative anesthetic dose. Histologic changes include widespread apoptosis and cell death, a reduction in the number of synapses, changes in neuronal morphology, and impaired neurogenesis in the hippocampus.²⁴¹

In June 2014, Smart Tots convened a meeting to review the accumulated data. The participants concluded that the current data from animal studies are now sufficiently convincing that large-scale clinical studies are warranted. The group produced a new statement recommending that surgical procedures performed under anesthesia be avoided in children under 3 years of age unless the situation is urgent. The statement also emphasizes the need to determine whether anesthetic and sedative drugs cause brain damage in infants, toddlers, and children. In particular, randomized clinical trials are needed to determine whether general anesthetics impair neurocognitive development. In December 2015, Smart Tots released a supplemental consensus statement on a recent general anesthesia study (GAS). The GAS Study is the first prospective clinical trial to explore the effects of anesthetics on the developing brain in humans. The secondary outcome data, based

on 532 subjects, indicated that children who had undergone either general anesthesia or regional anesthesia in a surgical procedure lasting less than 1 hour showed no difference in cognitive development at the 2-year time point.²⁴²

Smart Tots has taken a first step by establishing an international working group of experts who will generate data on animal models that can inform the design and execution of appropriate clinical trials. In the meantime, parents and care providers should be made aware of the potential risks that anesthetics pose to the developing brain. Further clinical studies may clarify whether anesthetics cause injury in humans. Surgeons, anesthesiologists, and parents should consider carefully how urgently surgery is needed, particularly in children under 3 years of age.^{243,244} Anesthetic neurotoxicity is discussed further in [Chapter 8](#).

Summary

The availability of a variety of unique intravenous drugs that contain the necessary properties for use in induction has allowed the clinician to tailor the induction to fit the needs of the patient and surgeon. This characteristic has made it much easier to care for an increasingly diverse and complex patient population. Intravenous anesthetics can be chosen with consideration for the health status of the patient, the type of procedure to be performed, and the patient's susceptibility to possible adverse effects to produce the remarkably safe techniques and excellent outcomes achieved today.

Local Anesthetics

John J. Nagelhout

Local anesthetics are drugs that reversibly block the conduction of electrical impulses along nerve fibers. Their ability to perform this function depends on various factors, including the nerve or nerves being blocked, the chemical structure, and physicochemical properties of the local anesthetic. These drugs have always been used as a major component of clinical anesthesia and are increasingly being used to treat acute and chronic pain in new and innovative ways.

Anatomy of the Peripheral Nerve

To fully address the action of local anesthetics a brief review of the anatomy and physiology of nerve fibers is appropriate. The axon, an extension of a centrally located neuron, is the functional unit of peripheral nerves. A cell membrane, or axolemma, and intracellular contents, or axoplasm, are the major components of the axon. Schwann cells, whose functions are support and insulation, surround each axon. In unmyelinated nerves single Schwann cells cover several axons. Conversely, in larger nerves the Schwann cell sheath covers only one axon and has several concentric layers of *myelin*.

Between Schwann cells are periodic segments of nerve that do not contain myelin. These areas, known as *nodes of Ranvier*, are where conduction is propagated. Voltage-gated sodium channels (Na_v) are located in these nonmyelinated segments and are the primary site at which local anesthetics exert their action. Action potentials jump from node to node, and this phenomenon is known as *saltatory conduction*, which significantly facilitates conduction speed along the axon.^{1,2} Myelinated nerves are larger, conduct impulses faster, and are more difficult to block with local anesthetics than are unmyelinated nerves^{3,4} (Fig. 10.1).

FIGURE 10.1 Myelinated axon. **A**, The diagram shows a cross section of an axon and its coverings formed by a Schwann cell: the myelin sheath and neurilemma. **B**, Transmission electron micrograph showing how the densely wrapped layers of the Schwann cell's plasma membrane form the fatty myelin sheath. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 9th ed. St. Louis: Elsevier; 2016:401.)

Peripheral nerves have structures containing bundles of axons called *fasciculi*. Three layers of connective tissue—the endoneurium, perineurium, and epineurium—also are components of a peripheral nerve.^{4,5} The endoneurium, which is a delicate connective tissue composed of longitudinally arranged collagen, surrounds and embeds the axons in the fasciculi. The perineurium, which consists of layers of flattened, overlapping cells, binds a group of fascicles together. The epineurium, which surrounds the perineurium, is composed of areolar connective tissue that functionally holds the fascicles together to form a peripheral nerve.⁵ These layers of connective tissue are important because they serve as barriers through which local anesthetics must diffuse if they are to exert their pharmacologic action (Fig. 10.2).

FIGURE 10.2 Transverse sections of a peripheral nerve (A) showing the outermost epineurium; the inner perineurium, which collects nerve axons in fascicles; and the endoneurium, which surrounds each myelinated fiber (B), and is encased in the multiple membranous wrappings of myelin formed by one Schwann cell, each of which stretches longitudinally over approximately 100 times the diameter of the axon. The narrow span of axon between these myelinated segments, the node of Ranvier, contains the ion channels that support action potentials. Nonmyelinated fibers (C) are enclosed in bundles of 5 to 10 axons by a chain of Schwann cells that tightly embrace each axon with but one layer of membrane. (From Miller RD. *Miller's Anesthesia*. Vol 1, 8th ed. Philadelphia: Elsevier; 2015:1033.)

Neuron Electrophysiology and the Action Mechanism of Local Anesthetics

Electrophysiology

Measurement with an electrode placed in the axoplasm of a resting peripheral nerve demonstrates a negative membrane potential of -70 mV to -90 mV.^{3,5} This voltage difference across the neuronal membrane at steady state is called the *resting membrane potential* (Fig. 10.3). An ionic imbalance between the axoplasm and the extracellular fluid causes the electrical potential. Several physiologic mechanisms create the ionic gradient; the primary one is an active, energy-dependent process executed by a sodium-potassium pump (Na^+ - K^+ /ATPase) located in the axolemma.^{6,7}

FIGURE 10.3 Typical changes in conductance of sodium and potassium ion channels when the membrane potential is suddenly increased from the normal resting value of -90 millivolts to a positive value of $+10$ millivolts for 2 milliseconds. This figure shows that the sodium channels open (activate) and then close (inactivate) before the end of the 2 milliseconds, whereas the potassium channels only open (activate), and the rate of opening is much slower than that of the sodium channels. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. St. Louis: Elsevier; 2016:67.)

Although the membrane is relatively permeable to the outward diffusion of K^+ , an intracellular-to-extracellular K^+ ratio of 150 : 5 mmol, or 30:1, exists. An important contributor to this concentration difference is the impermeability of the membrane to other cotransported ions such as Na^+ .⁷ In addition, the movement of K^+ out of the neuron leaves an excess of intracellular negatively charged organic ions. The negative charge results in an electrostatic counterforce that limits K^+ movement out of the neuron.

Two opposing forces influence K^+ movement into and out of the neuron. First, a concentration gradient pushes K^+ outward. Second, an electrostatic gradient, created by the impermeability of the membrane to cations, tends to keep the K^+ in the cell. The net effect of these counterforces is modest movement of K^+ out of the cell, and this movement creates an intracellular negative charge. The Nernst equation expresses the charge created by the K^+ concentration gradient³:

$$\text{Membrane potential} = -58 \log \frac{(K^+ \text{ 30 inside})}{(K^+ \text{ outside})}$$

Determination of the resting membrane potential is not as simple as the Nernst equation for K^+ indicates, because Na^+ and chloride (Cl^-) ions have a minor role in establishing the intracellular resting potential.³

When an electrical impulse is applied to a resting nerve, the membrane potential is reversed because of the intracellular movement of Na^+ . This occurs because of the higher concentration of Na^+ outside the cell, and the stimulation-induced increase in membrane permeability to this ion. The sudden influx of Na^+ that occurs in response to stimulation overrides the efflux of K^+ directed at maintaining the resting membrane potential. Once the process has reversed the membrane potential to 20 mV, an outward electrochemical gradient develops; this gradient resists the concentration-dependent, inward diffusion of Na^+ .⁵ This state of equilibrium causes the Na^+ channels to close. Shortly after Na^+ enters the cell, K^+ channels begin to open, and the ion rapidly diffuses out of the neuron according to its concentration gradient.

The active removal of intracellular Na^+ by the Na^+ - K^+ pump and the passive diffusion of K^+ outward restore the resting membrane potential. During repolarization, three Na^+ ions leave the cell for each two K^+ ions that enter⁸ (Fig. 10.4).

FIGURE 10.4 Characteristics of the voltage-gated sodium (*top*) and potassium (*bottom*) channels, showing successive activation and inactivation of the sodium channels and delayed activation of the potassium channels when the membrane potential is changed from the normal resting negative value to a positive value. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. St. Louis: Elsevier; 2016:66.)

The sequence of events that results in an action potential results from the passage of ions through pores or “channels” located in the axolemma. These channels, which are composed of globular proteins, have transmural orientation to the phospholipid molecules that constitute the axolemma.⁹ Although K^+ and calcium (Ca^{2+}) channels are important, the Na^+ channels are the most significant and best understood with respect to the initiation and propagation of the action potential.^{3,10-14}

Mechanism of Action

As noted earlier, local anesthetics work by reversibly binding to the voltage-gated sodium channels (Na_v). Sodium channels have three functional states: resting (closed), open, and inactive. The resting state exists when the membrane is at its resting potential. When a nerve is stimulated reversal of the membrane potential occurs until the threshold potential is reached. When this happens a conformational change in the proteins that compose the channel occurs, resulting in the open state. An inactive state, characterized by the return of the Na^+ channel to an impermeable state, follows the open state. This state, which prevents initiation of an action potential, lasts until the restoration of the resting membrane potential.¹⁰ This three-state concept describes the changes in the Na_v that occur during depolarization and repolarization. Local anesthetics preferentially bind to both the open or inactivated states and not to the closed state. This is referred to as the *guarded receptor* or *modulated receptor hypothesis of local anesthetic action*. The open or inactive state may increase the affinity for binding the physical access of the drug to the receptor, or both.^{11,15} In addition, it has long been noted that local anesthetics work faster as the Na_v is repetitively depolarized. This is termed as *use-dependent* or *phasic block*. The more frequently the channel is depolarized, the more time it is available in the open and inactive states and thus available to local anesthetic blockade¹⁶ (Fig. 10.5).

FIGURE 10.5 Resting, activated, and inactivated states of voltage-gated channels, exemplified by the sodium channel. Membrane depolarization causes a rapid transition from the resting (closed) state to the open state. The inactivating particle (part of the intracellular domain of the channel protein) is then able to block the channel. Blocking drugs (e.g., local anesthetics and antiepileptic drugs) often show preference for one of the three channel states, and thus affect the kinetic behavior of the channels, with implications for their clinical application.

Local anesthetics block the propagation of the action potential by binding reversibly to specific receptors within or adjacent to the internal opening of the Na_v channel.¹⁷ Studies have indicated that these receptors, located on the intracellular side of the cell membrane, have a greater affinity for the charged or ionized form of the local anesthetics.^{8,10,18} The uncharged or nonionized portion of the local anesthetic must first penetrate the cell membrane entering the axoplasm before they produce their effects. Fig. 10.6 shows the penetration of local anesthetic into a nerve and subsequent access to the receptor. The sequence is as follows:

FIGURE 10.6 Schematic conceptualization of local anesthetic action. Equilibrium forms outside the nerve between the ionized and nonionized portions. The nonionized portion (LA), which is lipid soluble, enters the nerve. Once inside the axoplasm, the drug equilibrates, and the ionized fraction (LA^+) attaches to the local anesthetic receptor on the inside of the sodium channel. LA , Nonionized form of the local anesthetic; LA^+ , ionized form.

1. Almost all clinically useful local anesthetics (except benzocaine) are tertiary amines and when injected will exist in both nonionized (lipid soluble) and ionized (water soluble) forms according to their particular pK_a (negative logarithm of the acid ionization constant), and the pH of the tissue or compartment they are in.
2. Local anesthetics must gain access to the interior of the neuron to reach their receptor. This occurs by the diffusion of the lipid soluble nonionized fraction across the cell membrane.
3. Once inside the neuron, a new equilibrium forms between ionized and nonionized fractions. The ionized fraction binds to the receptor on the inside of the Na_v .

Benzocaine is a secondary amine and thus is permanently nonionized or neutral. It penetrates the lipid bilayer and can directly inhibit the Na_v without entering the axoplasm first.¹²

Local anesthetics have additional effects on G-protein-coupled

receptors affecting intracellular calcium signaling pathways. The inflammatory modulating action of local anesthetics may result from interruptions in these pathways. The antiinflammatory response to local anesthetics also occurs resulting from suppression of polymorphonuclear leukocyte priming, which prevents overactive inflammatory responses without impairing host defenses or suppressing normal inflammation.^{16,19}

It must be noted that many questions remain as to the mechanism of the clinical effects of local anesthetics in different types of nerve blocks. Different receptors may be involved in their action in peripheral nerves as opposed to spinal or epidural effects.²⁰

Nerve Fiber Sensitivity and Differential Block

It has been observed that nerves functionally have different sensitivity or rates of effect when exposed to local anesthetics. For example, in most major nerve blocks loss of autonomic function occurs first, followed in sequence by perception of superficial pain, touch, and temperature, motor function, and proprioception.²¹ This phenomenon is termed *differential block*. Seen clinically an excellent example of differential block occurs with the use of bupivacaine. When administered by epidural for labor pain, this local anesthetic spares motor function and provides adequate analgesia.^{22,23}

Essential to the understanding of differential block is the concept that the diameter and myelination of nerve fibers influence the sensitivity to local anesthetics. For simplicity nerve fibers are separated into three groups—A, B, and C—on the basis of diameter.^{24,25}

The A fibers are further divided into four subgroups known as *alpha*, *beta*, *gamma*, and *delta* fibers. The alpha fibers are the largest in diameter (12 μm to 20 μm) and the most heavily myelinated; they have the fastest conduction velocity of all the fibers, including B and C fibers. Alpha fibers are responsible for motor functions and proprioception. The A beta (5 μm to 12 μm) and A gamma fibers (3 μm to 6 μm) have conduction velocities second only to A alpha fibers. The A beta fibers provide motor function, touch, and pressure sensation; the A gamma fibers innervate muscle spindles and are responsible for reflexes. The A delta fibers provide pain and temperature sensation. These fibers have a smaller diameter (1 μm

to 5 μm) and slower conduction velocity than other A fibers. The beta, gamma, and delta fibers are all myelinated to a similar extent.²⁶

B fibers have a similar diameter (less than 3 μm) to A delta fibers; however, they exhibit slower conduction velocity and less myelination than the A fibers. These fibers constitute the preganglionic autonomic nerves. The C fibers, which conduct pain and temperature impulses, are the smallest of all fibers (0.3 μm to 1.3 μm) and have the slowest speed of conduction. These are the only fibers that are unmyelinated.⁸ Nerve fiber characteristics and local anesthetic sensitivity are summarized in [Table 10.1](#).

TABLE 10.1

Nerve Fiber Characteristics and Sensitivity to Local Anesthetics

Fiber Type	Function	Diameter (μm)	Myelination	Anesthetic Block Onset
Type A				
Alpha ($A\alpha$)	Proprioception, motor	6–22	Heavy	Last
Beta ($A\beta$)	Touch, pressure	6–22	Heavy	Intermediate
Gamma ($A\gamma$)	Muscle tone	3–6	Heavy	Intermediate
Delta ($A\delta$)	Pain, cold temperature, touch	1–5	Heavy	Intermediate
Type B				
	Preganglionic autonomic vasomotor	< 3	Light	Early
Type C				
Sympathetic	Postganglionic vasomotor	0.3–1.3	None	Early
Dorsal root	Pain, warm and cold temperature, touch	0.4–1.2	None	Early

It was first believed that nerve fiber diameter was the sole determinant of differential blockade.²⁷ This assumption came from the results of isolated in vitro studies performed only on myelinated nerves. Subsequent isolated studies on the small, unmyelinated C fibers revealed that they were more resistant to blockade than the larger A delta or B fibers.⁸

This apparent inconsistency can possibly be explained by the concept of conduction safety. This concept refers to the voltage change needed for the propagation of the action potential along the nerve. This voltage change is significantly greater than the action potential threshold and provides a safety factor for impulse conduction. Gissen et al.²⁸ defined this safety factor as the “ratio

between the magnitude of the action potential and the magnitude of the critical membrane potential.” Research has indicated that the margin of safety for transmission is greater in small, slow fibers than in large, fast fibers.

Lastly, differential block may be influenced by the rate of diffusion of local anesthetic molecules across multilayered lipoprotein membranes of the myelin sheath. For example, the clinical resistance to blockade observed in A fibers may be the result of a slower onset resulting from a greater diffusion barrier. As discussed in more detail later, diffusion can be influenced by such factors as the pK_a and the concentration of the local anesthetic, in addition to the pH of the surrounding tissue and nerve fiber.²⁸

As the preceding discussion indicates, the concept of differential block is more complex than originally proposed. Future research will probably indicate that an isolated mechanism does not explain this phenomenon, but rather several factors interact to produce the effect.²²

Chemical Structure of Local Anesthetics

The local anesthetics used clinically for neural blockade are aminoesters or aminoamides and are similar in chemical structure. In general, these drugs have three characteristic segments: (1) an intermediate ester or amide carbon group separates (2) an unsaturated (aromatic) ring system from (3) an amine end (Fig. 10.7). The aromatic ring provides lipophilic characteristics, whereas the tertiary/quaternary amine gives hydrophilicity to the molecule. The amine portion is able to become ionized in physiologic pH and thus hydrophilic.

FIGURE 10.7 Core structure for local anesthetics, which includes a benzene ring and a quaternary amine separated by an intermediate carbon group. The bond between the benzene ring and the carbon group determines whether the drug is an amide or an ester.

Chemically the major difference among local anesthetics is in their ester or an amide linkage that binds the aromatic ring to the amine group. This linkage is responsible for the classification of these drugs as either esters or amides. The type of linkage is important clinically because it has implications for metabolism,

duration, and allergic potential (Fig. 10.8). Box 10.1 lists the local anesthetics according to chemical class. An easy method for remembering which chemical class a local anesthetic falls into is that the esters have one letter *i* in their generic name and the amides have two. The chemical structures are important in determining the pharmacologic effects of these drugs. Minor chemical alterations to drugs within these two “bond-related” groups can result in significant changes in drug potency, speed of onset, duration of action, and potential for producing differential block (Fig. 10.9).^{5,16,29} These changes are discussed in detail as the specific pharmacologic factors associated with local anesthetics are noted. Table 10.2 summarizes the clinical differences between the ester and amide local anesthetics.

TABLE 10.2

Clinical Differences Between the Ester and Amide Type Local Anesthetics

Esters	Amides
Ester metabolism is catalyzed by plasma and tissue cholinesterase via hydrolysis; occurs throughout the body and is rapid.	Amides are metabolized in the liver by CYP1A2 and CYP3A4 and thus a significant blood level may develop with rapid absorption.
Although local anesthetic allergy is uncommon, esters have a higher allergy potential, and if patients exhibit an allergy to any ester drug, all other esters should be avoided.	Allergy to amides is extremely rare; there is no cross allergy among the amide class or between the ester and amide agents.
Ester drugs tend to be shorter acting due to ready metabolism; tetracaine is the longest acting ester.	Amides are longer acting because they are more lipophilic and protein bound and require transport to the liver for metabolism

Pharmacodynamics and Pharmacokinetic Concepts

An important difference to note when describing the pharmacokinetics of local anesthetics is intuitive yet bears discussion. Unlike most medications, these agents are meant to remain localized in the area of injection or application. The higher the concentration (number of molecules) of drug injected that remain in the area of the nerve or nerves to be blocked, the faster the onset of action. If multiple nerves are being blocked, a greater intensity may also be evident. Therefore systemic absorption away from the deposition site results in the offset and termination of drug effect, rather than the onset as with most other drugs. Factors that affect absorption, such as the vascularity and blood flow of the injection area, lipid and protein binding, and addition of vasoconstrictors, greatly influence duration of action. The same local anesthetic dose and concentration injected in different areas of the body, with or without added epinephrine, can result in vastly different durations of action. Absorption also influences toxicity. The slower a local anesthetic is systemically absorbed, the less likely that high blood levels and therefore central nervous system (CNS) or cardiac toxicity will result. Drug metabolism and elimination more readily “keep up” with absorption, ensuring that toxic blood levels are avoided. A conceptual kinetic depiction of the fate of an injected local anesthetic is given in [Fig. 10.10](#).

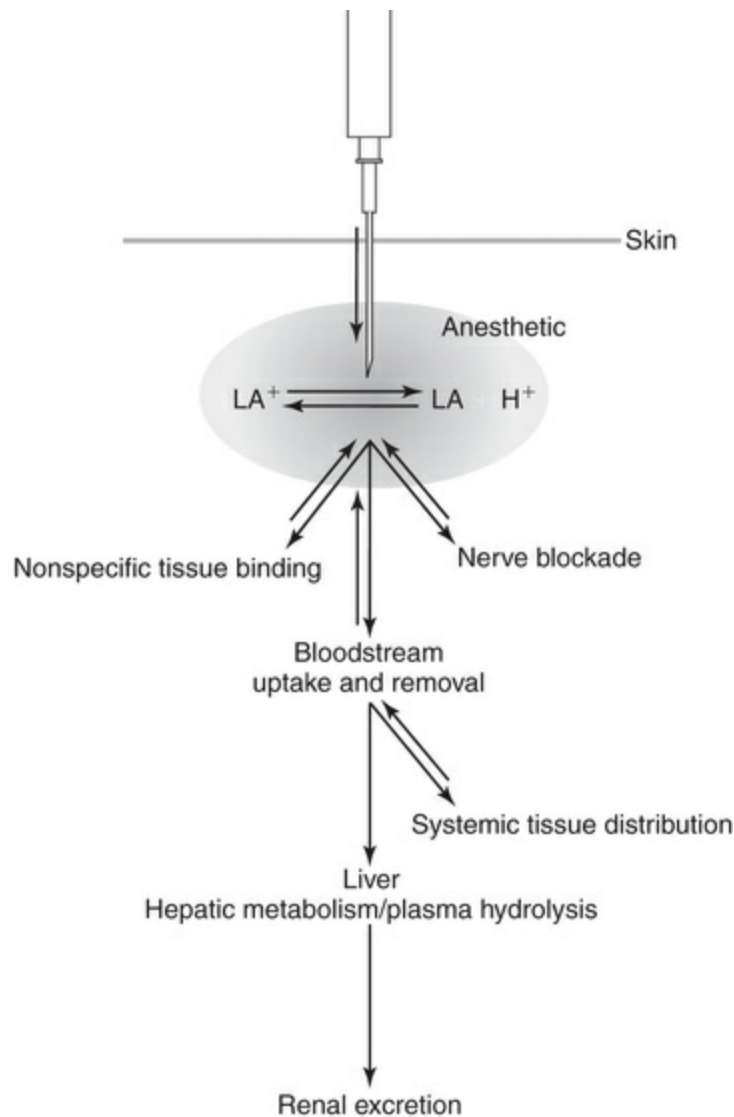

FIGURE 10.10 Representation of the fate of a local anesthetic injected into tissue.

Potency

There is a strong relationship between the lipid solubility of local anesthetics and their potency.^{28,29} This finding is understandable considering that the axolemma and myelin sheath are composed primarily of lipids^{29,30}; therefore, lipid-soluble drugs pass more readily through the nerve membrane. Larger, more lipid-soluble local anesthetics are relatively water insoluble, highly protein bound, and less readily washed out from nerves and surrounding tissues. They bind to Na_v channels with a higher affinity than agents with lower lipid solubility. Increased lipid solubility correlates with increased protein binding, increased potency, longer

duration of action, and a higher tendency for severe cardiac toxicity.^{12,29} It follows that fewer molecules or lower concentrations of these drugs are required for the production of blockade than if nonlipid-soluble anesthetics are used.³¹ Changes in either the aromatic or amine moieties of the local anesthetic molecule can affect the lipid-water partition coefficient. In the amide series, for example, the addition of a butyl group to the amine end of mepivacaine leads to the formation of bupivacaine. Bupivacaine is twenty-sixfold as lipid soluble and fourfold as potent as mepivacaine. In the case of the esters the addition of a butyl group to the aromatic end of procaine produces tetracaine, which is considerably more lipid soluble and potent than procaine.¹⁶

Factors other than lipid solubility can affect potency. For example, the potency of local anesthetics as demonstrated in isolated in vitro studies is not always the same as that observed in vivo. The discrepancy between in vitro and in vivo findings may be the result of many factors, including the vascular and tissue distribution properties of the drug.³²⁻³⁵

Duration of Action

The duration of action of local anesthetics demonstrates a relationship to protein binding and lipid solubility.^{29,36} In theory, drugs that have a high affinity for protein and lipids attach more firmly to these substances in the vicinity of the Na_v channel receptor. This means that the drug remains in the channel and surrounding areas for a longer time producing prolonged conduction blockade.²⁹

It appears therefore that there is a correlation between the degree of protein binding and duration of the local anesthetic. The addition of larger chemical radicals to the amide or aromatic end of the drugs results in greater protein binding. The duration is directly proportional to plasma protein binding, presumably because the local anesthetic receptor on the neural membrane is also composed of protein.^{3,5,37} It has been posited that local anesthetics that have increased protein-binding properties (e.g., ropivacaine 94%, bupivacaine 97%) produce longer-duration anesthesia as a consequence of more efficient binding of the anesthetic to the Na_v

channel.³⁸ For example, bupivacaine is more than 90% bound to plasma protein; however, its homologue, mepivacaine, is only 65% bound.³⁶ The duration of action of bupivacaine is significantly longer than for mepivacaine. Local anesthetics are weak bases and bind mainly to α_1 -acid glycoprotein (AAG). Secondary binding to albumin also occurs.

As in the case of potency, the effect local anesthetics have on the vasculature at the injection site influences the duration of action. This is discussed in detail in the section on vasomotor action and absorption.

Onset of Action

As stated previously local anesthetics must diffuse through the axolemma before they can interact with receptors. How readily they diffuse through the nerve membrane depends on their chemical structure, lipid solubility, and state of ionization. Of these, ionization is the most important because the charged or ionized form of a drug does not penetrate membranes well.^{30,32,37} In other words, the more ionized a local anesthetic, the slower it will penetrate a nerve.

Local anesthetics are bases. The pK_a of a drug is the pH at which 50% of the drug is in the charged or ionized, and water soluble form, whereas the remaining half is uncharged or nonionized, and lipid soluble. A basic drug becomes predominantly ionized if it is placed in an environment with a pH that is significantly less than its pK_a . Therefore drugs that have a greater pK_a are ionized to a greater extent at body pH than those with a lower pK_a . For example, if lidocaine (pK_a 7.74) is placed in plasma (pH 7.4), 65% of the drug is ionized, and 35% remains nonionized. Similarly, if tetracaine (pK_a 8.6) is placed in plasma, 95% of the drug becomes ionized, and 5% remains nonionized.²⁹

Because their ionization is less, local anesthetics with lower pK_a (7.6 to 7.8), such as lidocaine, mepivacaine, and prilocaine tend to have a more rapid onset of action than drugs with a greater pK_a (8.1 to 8.6), such as bupivacaine, tetracaine, and procaine. Chloroprocaine is one exception; it has a high pK_a but retains a

rapid onset, probably because of the clinical use of high concentrations of the drug, which attenuates the ionization effect. In general, the closer the pK_a is to pH 7.4, the more rapid the onset. Some researchers downplay the role of pK_a on onset. They note that onset is slower the more lipid soluble the drug.³⁰

The classification presented in Table 10.3 assists in the selection of an appropriate drug with respect to pharmacokinetic properties.³⁹

TABLE 10.3

Classification of Local Anesthetics Based on Onset, Duration of Action, and Potency

Characteristics	Drug (Generic Name)	Common Brand Name	Onset	Duration of Action (min)
Low potency, short duration of action	procaine	Novocaine	Slow	60–90
	chloroprocaine	Nesacaine	Fast	30–60
Intermediate potency, duration	mepivacaine	Carbocaine	Fast	120–240
	lidocaine	Xylocaine	Fast	90–120
High potency, long duration	tetracaine	Pontocaine	Slow	180–600
	bupivacaine	Marcaine, Sensorcaine	Slow	180–600
	ropivacaine	Naropin	Slow	180–600

Vasomotor Action and Absorption

All local anesthetics except cocaine, ropivacaine, and lidocaine produce relaxation of vascular smooth muscle.^{33,40} The resultant vasodilation increases blood flow to the tissue in which the drug is deposited. This results in an increase in the drug's absorption, which limits its duration of action and increases the probability of toxic effects. It is interesting to note that ropivacaine and lidocaine are the only parenterally administered local anesthetics with mild vasoconstrictive properties.⁴⁰ Cocaine also has vasoconstrictive properties because of its ability to block reuptake of norepinephrine. It is used only topically.

All local anesthetics are not affected equally when epinephrine is added to the solution. There is a definite benefit in extending the duration of analgesic effects with both short- and intermediate-acting agents. The prolongation of the duration with long-acting drugs is less well defined.⁴⁰

The speed of absorption and entry of the local anesthetic into the systemic circulation obviously has significant implications for toxicity. Absorption of drugs generally occurs in the following order of rapidity: interpleural blocks greater than intercostal greater than caudal greater than epidural greater than brachial plexus greater than sciatic-femoral and subcutaneous blocks.¹⁶ Thus blood levels measured after an interpleural block will be higher with a greater potential for toxicity than with a subcutaneous block.

The total dose of local anesthetic, rather than the volume or concentration, linearly determines the peak plasma concentration.⁴¹ For example, 400 mg of lidocaine yields the same peak plasma concentration regardless of whether 40 mL of a 1% or 80 mL of a 0.5% is injected.

Local anesthetic additives include the α_2 -adrenergic agonists clonidine and dexmedetomidine, opioids, sodium bicarbonate, ketorolac, dexamethasone, and hyaluronidase. These are variously added to increase the safety, quality, intensity, duration, and rate of onset of anesthesia, and also reduce blood loss. α_2 -Adrenergic agonists such as clonidine and dexmedetomidine have local anesthetic properties and can alter the nerve block characteristics.⁴¹⁻⁴³ The addition of 100 mcg of clonidine to a local anesthetic solution prolongs the duration of the long-acting agents approximately 100 additional minutes with minimal side effects. The effect is produced by inhibition of the hyperpolarization-activated cation current (I_h current). This current normally restores nerves from the hyperpolarized state to resting potential. The effect is more pronounced in C-fibers (sensory) than $A\delta$ (motor). That makes the effects mostly sensory specific. Cost has limited the routine use of clonidine. The use of dexmedetomidine for peripheral nerve blockade is currently being investigated and is not approved for use in the United States.⁴⁰

The addition of a vasoconstrictor (e.g., epinephrine) to local anesthetics can reduce the rate of vascular absorption allowing more of the drug to stay in the local area where it was injected. The availability of the drug for neuronal uptake is increased resulting in a longer and more profound block. Of importance, the slower rate of absorption also attenuates the peak plasma concentration of the drug, thereby reducing systemic toxicity. The magnitude of this

effect depends on the drug, dose, and concentration of both the local anesthetic and the vasoconstrictor, in addition to the site of injection.⁷ For example, addition of epinephrine to mepivacaine prolongs the time to maximum arterial plasma drug concentration in all situations; however, adding epinephrine to a 2% solution used for an intercostal block has the greatest effect.⁴⁴

Epinephrine does not prolong the duration of blockade to the same extent with all local anesthetics. For example, it prolongs the duration for local infiltration, peripheral nerve block, and epidural anesthesia with procaine, mepivacaine, and lidocaine.^{30,45-48} Research indicates that adding epinephrine to lidocaine solutions increases the intensity and duration of block.⁴⁸ The early increase in intensity is not matched with an increase in intraneural lidocaine content at these early times, although the prolonged duration of block by epinephrine appears to correspond to an enlarged lidocaine content in a nerve at later times, as if a very slowly emptying "effector compartment" received a larger share of the dose. The increase in early analgesia without increased lidocaine content may be explained by a pharmacodynamic action of epinephrine that transiently enhances potency of lidocaine, but also by a pharmacokinetic effect that alters the distribution of the same net content of lidocaine within the nerve. In the case of prilocaine and bupivacaine, infiltration and peripheral nerve blocks are prolonged with epinephrine, whereas no significant effect occurs with epidural anesthesia.⁴⁹ The rationale for this discrepancy might be that epidural fat significantly absorbs ropivacaine and bupivacaine because of their high lipid solubility. These drugs are released slowly from the fat deposit, which could prolong the block.^{47,49-51} This process overrides the effects of epinephrine on duration of action. In addition, the drug concentration can contribute to the differential effect seen with epinephrine. For example, epinephrine can prolong epidural blocks with 0.125% or 0.25% bupivacaine when used in patients in labor.^{50,51} Conversely, epinephrine has less effect with the epidural administration of 0.5% or 0.75% bupivacaine.^{52,53}

The addition of epinephrine does not attenuate the peak plasma level of all local anesthetics; for example, epinephrine significantly reduces the peak plasma concentration of lidocaine and

mepivacaine regardless of the site of administration. On the other hand, epinephrine does not significantly affect the peak plasma level of prilocaine or bupivacaine after epidural anesthesia. The lack of effect seen with prilocaine may be explained by its slower absorption and rapid tissue redistribution. In the case of bupivacaine, it may be explained by the significant lipid solubility and uptake in the epidural adipose tissue.²⁸ There is some controversy as to whether epinephrine may produce neurotoxicity when added to local anesthetics. Some clinicians only recommend its use for nerve blocks done without ultrasound guidance or where the needle tip and local anesthetic spread are not adequately visualized as a safety measure to detect intravascular injection.^{40,41}

Studies that have compared vasoconstrictors conclude that epinephrine is superior to drugs such as phenylephrine and norepinephrine in producing vasoconstriction with local anesthetics.^{54,55} The usual concentration of epinephrine used for this purpose is 1:200,000 or 5 mcg/mL.

Miscellaneous Factors That Influence Onset and Duration

Local anesthetics are basic drugs. As discussed previously, they have both water- and lipid-soluble properties. Factors that raise the pH of their environment increase their lipid solubility, and conversely, lower pH environments, result in increased water solubility. These changes to pH result in altered proportions of lipid- and water-soluble fractions of the drugs, which may have clinical consequences. At times the term used for this phenomenon is *ion trapping*. Ion trapping results from changes in pH in relationship to the pK_a of the agent. Instances in which ion trapping may have clinical consequences are noted in [Box 10.2](#).

Ion Trapping: Clinical Situations in Which Differences Between pK_a and pH May Affect Patient Response

- In the event of local anesthetic overdose, associated respiratory depression may occur resulting in hypoxia and acidosis. The

acidosis resulting from hypoxia may increase the ionized fraction of local anesthetic within the cerebral circulation, thereby decreasing the ability of the anesthetic to cross the blood-brain barrier, leave the brain, and reenter the systemic circulation. This phenomenon may prolong and enhance the central nervous system toxicity of local anesthetics.

- Local anesthetic accumulation in the fetal circulation is enhanced by the fact that fetal pH is lower than maternal pH, which may result in high fetal levels of local anesthetics.
- Local anesthetics injected into acidotic, infected tissues are rendered ineffective because of the loss of lipid solubility. The lipid solubility of local anesthetics is diminished in an acidotic environment because of an increased concentration of the ionized, water-soluble form of the drug. The loss of lipid solubility prevents absorption into the nerve, thereby preventing access to the site of action.
- Carbonation of local anesthetics speeds the onset and intensity of action of neural blockade. Carbon dioxide readily diffuses into the nerve, lowering the pH within the nerve. The lipid-soluble form of local anesthetic, after passing through the neuronal membrane, receives protons from the intraneuronal environment and ionizes. An increase in the ionized fraction within the neuron produces a higher concentration of the active form of the anesthetic available at the sodium channel, the site of action. This practice has been largely abandoned in modern clinical practice.
- Commercially available local anesthetics are prepared in a slightly acidic formulation that improves the stability of the drug by increasing the concentration of the ionized, water-soluble form of the drug. Addition of sodium bicarbonate to the local anesthetic mixture increases the pH of the solution, thereby increasing the concentration of the nonionized, lipid-soluble form of the drug. Improving the lipid solubility of the local anesthetic improves diffusion of the local anesthetic through the neuronal membrane, leading to a more rapid onset of action. This seems to be most effective in epidural blocks and least effective in

peripheral blocks.

Local anesthetics have been carbonated to speed onset. In isolated nerve preparations, carbonation gives a more rapid onset and greater intensity of block.⁵⁶ Diffusion of carbon dioxide through the nerve membrane can lower the intracellular pH. When local anesthetics accompany this process, they become more ionized within the neuron; this results in an increase in the concentration of the drug in the ionized form at the intracellular binding site.

Controversy exists concerning whether carbonation improves onset time in the *in vivo* situation.⁵⁷ Separate double-blind studies of lidocaine and bupivacaine have failed to yield positive results.⁵⁸ This inconsistency may exist because the injected carbon dioxide is rapidly buffered *in vivo*, so intracellular pH is not greatly affected.^{57,58} This practice has been largely abandoned in modern clinical practice.

The addition of sodium bicarbonate to local anesthetics is widely used in epidural anesthesia to speed onset of sensory and motor block.⁵⁹⁻⁶¹ The effects of the addition of sodium bicarbonate to peripheral blocks is unclear.⁴⁰ In theory the mechanism is that addition of bicarbonate increases the pH of the local anesthetic solution resulting in the presence of more drug in the nonionized state. As stated previously this form of the drug readily diffuses across the cell membranes and would therefore speed onset. Studies done with bupivacaine and lidocaine have indicated that this alteration does facilitate the onset and prolong duration of action.^{59,60} Other researchers, however, have noted variable effects on onset and duration depending on whether epinephrine was contained in the solution.⁶¹

The major limitation to the addition of bicarbonate is the precipitation that can occur in the local anesthetic solution. It also should be noted that the amount of bicarbonate that can be added without precipitation depends on whether the epinephrine is commercially or “freshly” mixed.⁵⁹ Manufacturers acidify local anesthetic solutions to increase solubility and stability (the free base is more susceptible to photodegradation and aldehyde formation), which results in a longer shelf-life. For example, the pH range of plain lidocaine is 6.5 to 6.8, compared with 3.5 to 4.5 for

preparations that contain epinephrine. The lower pH is used with epinephrine because of the instability of this compound in alkaline solutions.

Another benefit of alkalization is that it may result in less pain or stinging on injection. The mechanism of action for this effect could be more complex than just an increase in pH. It may be that the nociceptive nerve fibers may not be as sensitive to the nonionized form of the drug. It also is possible that the nonionized drug diffuses so rapidly through the tissue and axolemma that a sensory block occurs almost instantaneously.^{62,63}

The addition of hyaluronidase to local anesthetics as a spreading factor facilitates the diffusion of the drugs in tissues. This additive accomplishes this effect via the hydrolysis of hyaluronic acid, which is a glycosaminoglycan found extensively in the interstitial matrix and basement membranes of tissue. Hyaluronic acid is the main component of interstitial gel, which inhibits the spread of substances through tissue.⁶⁴ It has long been used in ophthalmic blocks to improve quality, speed onset, limit the acute increase in intraocular pressure with periorbital injections, and reduce the incidence of postoperative strabismus.⁶⁵ It has also been suggested that hyaluronidase reduces hematoma size if a needle that is used with the regional technique punctures a major blood vessel. Other common uses are to facilitate the spread of fluids during hypodermoclysis and radiopaque agents in subcutaneous urography.⁶⁴ The addition of hyaluronidase can result in certain undesirable effects, such as the initiation of allergic reactions, a shortening of the duration of anesthetic action, and an increase in drug toxicity.⁶⁶⁻⁶⁸ A new human recombinant product Hylenex is now available that may improve the safety profile.⁶⁹ Currently available hyaluronidase products are listed in [Table 10.4](#). Off-label use for cosmetic applications, to reduce edema, epidural adhesions, and chronic lower back pain have led to an increased interest in this agent.⁶⁴

TABLE 10.4
Available Formulations of Hyaluronidase

Drug	Source	Dosing

Vitrase Amphadase Hydase Hylenex	Lyophilized, Bovine Bovine Bovine Human (recombinant)	A wide range of doses are used depending on the type of regional block and the goals; the dose can vary from 0.75 to 300 units/mL.

Data from Dunn AL, et al. Hyaluronidase: a review of approved formulations, indications, and off-label use in chronic pain management. *Expert Opin Biol Ther.* 2010;10:127–131; Adams L. Adjuvants to local anaesthesia in ophthalmic surgery. *Br J Ophthalmol.* 2011;95:1345–1349.

Most current local anesthetics possess either a fast onset but intermediate duration or a slow onset and long duration. Clinicians frequently mix local anesthetics to obtain a more rapid onset and a long duration of action. The use of intermediate-acting mepivacaine combined with long-acting bupivacaine for an ultrasound-guided interscalene block has been reported.⁷⁰ Onset was not improved compared to bupivacaine alone, but duration was longer than mepivacaine alone. The duration was shorter than bupivacaine alone. In general, studies indicate a faster onset can be achieved but duration of the block may be decreased.^{71,72} Some clinicians have suggested that the use of combinations reduces the risk of toxicity; however, drug errors may increase when using more complex dosing schemes. In addition, the toxicity of local anesthetic combinations appears to be additive.^{73–75} The authors suggest that the increased use of ultrasound-guided techniques allows for the use of lower doses and more precise deposition of drug, which may diminish the use of combined local anesthetics.⁷⁰

Distribution

The absorption or injection of local anesthetics into the systemic circulation results in rapid distribution throughout the body. Distribution results in a rapid decrease in the plasma concentration as the drug moves into highly perfused tissue. Rapid distribution into the brain and heart can be a concern because this can lead to systemic toxicity. A secondary, slower disappearance follows, which reflects a combination of distribution into tissues with a more limited blood supply, drug metabolism, and excretion.

Although local anesthetics are distributed throughout the body, their concentration varies in different tissues. Immediately after vascular uptake, more greatly perfused tissues, such as the brain,

heart, and lungs, receive more of these drugs than do less perfused tissues. Once equilibration occurs, the local anesthetic leaves the highly perfused tissue and is deposited in tissue with less perfusion. As with many drugs, as they redistribute in the body over time, muscle tissue receives the greatest amount of local anesthetic from redistribution.

The distribution process varies significantly with different local anesthetics. For example, the disappearance rate of prilocaine is more rapid than that of mepivacaine or lidocaine. Ropivacaine also has a shorter half-life than bupivacaine. Distribution of the ester local anesthetics is similar to the amides; however, their rate of metabolism in plasma is very rapid, resulting in much lower and shorter duration systemic plasma concentrations.¹⁶

Metabolism

The metabolism of local anesthetics differs according to their chemical structure as either amides or esters. Plasma cholinesterase catalyzes the hydrolysis of ester local anesthetics. The hydrolysis occurs through the action of cholinesterase in plasma, red blood cells, and the liver.⁷⁶⁻⁷⁸ The plasma half-lives of procaine and chlorprocaine are shorter than 1 minute. The rapid rate of clearance of these drugs significantly reduces the potential of toxicity. Conversely, hydrolysis of tetracaine is slower and it has limited clinical use (Table 10.5). Saturated, inhibited, or genetically atypical plasma cholinesterase can significantly prolong the plasma half-life of ester local anesthetics.^{76,79} This would have little effect on duration of the ester agent because absorption away from the site of injection would occur as usual; however, this effect could theoretically increase the chance for systemic toxicity. For example, atypical plasma cholinesterase has been shown to significantly reduce the rate of procaine metabolism.⁸⁰

TABLE 10.5
Clearance Half-Life of Local Anesthetics

Drug	Clearance (L/min)	Half-Life (min)
Chlorprocaine	N/A	6
Procaine	N/A	6

Tetracaine	N/A	20
Cocaine	N/A	42
Prilocaine	2.84	90
Lidocaine	0.95	90
Mepivacaine	0.78	114
Bupivacaine	0.47	210
Ropivacaine	7.2	114

N/A, Not applicable. The ester compounds are rapidly broken down in the plasma and tissue so clearance is not a factor.

Adapted from Malamed SF, ed. *Handbook of Local Anesthesia*. 6th ed. St. Louis: Elsevier; 2013:27.

Metabolism of the amide local anesthetics occurs primarily in the liver predominantly by microsomal cytochrome P-450 enzymes CYP1A2 and CYP3A4.⁸¹ Table 10.6 presents pharmacokinetic data for the amide local anesthetics.¹⁶

TABLE 10.6

Pharmacokinetics of Amide Local Anesthetics

Drug	Half-Life Alpha (min)	Half-Life Beta (min)	V _{dss} (L)	Clearance (L)
Prilocaine	0.5	90	261	2.84
Lidocaine	1	90	91	0.95
Mepivacaine	0.7	114	84	0.75
Bupivacaine	2.7	210	72	0.47
Ropivacaine	2.7	114	66.9	0.73

V_{dss}, Volume of distribution at steady state.

Hepatic clearance is a function of the hepatic extraction ratio and hepatic blood flow and is the primary factor that determines the rate of elimination of amide local anesthetics. The hepatic extraction ratio is dependent on the ratio of free to protein-bound drug and represents the activity level specific to the liver for removing a drug from plasma. This ratio indicates the percentage of drug removed with each pass through the liver. The clearance of drugs that have higher hepatic extraction ratios depends on adequate hepatic blood flow. Hepatic enzyme activity is important when drugs with lower ratios such as bupivacaine are used.⁸² Pathologic conditions that influence hepatic function may prolong the elimination half-life of these drugs by a reduction in hepatic blood flow, enzyme activity, or both. For example, lidocaine has a plasma half-life of 1.6 hours; however, in severe hepatic disease, its half-life is 4.9 hours. This probably results from both an enzymatic and a perfusion effect.

Flow-limited clearance is affected by upper abdominal and laparoscopic surgery, inhalation anesthetics, hypovolemia, and congestive heart failure. Heart failure significantly reduces the rate of elimination of lidocaine because of a concomitant reduction in hepatic blood flow.⁸³ Clinically, hepatic dysfunction does not necessitate a reduction of dose for a single injection nerve block. Doses of amides used in continuous infusions or repeat blocks should be reduced 10% to 50%.⁸⁴

Only 1% to 5% of the injected dose of local anesthetic is accounted for by unchanged renal and hepatic excretion. However, the inactive, more water-soluble metabolites of local anesthetics appear in the urine. Although renal dysfunction affects the clearance far less than hepatic failure, it can result in the accumulation of potentially toxic metabolites.⁸⁵ It may also affect protein binding to both AAG and albumin. Some authors have suggested a 10% to 20% reduction in patients with severe renal disease.⁸⁶

Pregnancy

The use of local anesthetics in pregnancy deserves some special pharmacokinetic and pharmacodynamic consideration. Clinical observations and studies both indicate that the spread and depth of spinal and epidural anesthesia are increased in pregnant women. Spread of neuraxial anesthesia increases during pregnancy as a result of decreases in thoracolumbar cerebral spinal fluid (CSF) volume and increased neural susceptibility to local anesthetic. At first this was thought to be the result of only mechanical factors produced by a gravid uterus. For example, mechanical factors result in dilation of epidural veins, which leads to narrowing of the epidural and subarachnoid space, thereby reducing the dose requirement.⁸⁷ However, hormonal changes appear to also play a role because there is a greater segmental spread of local anesthetics administered in the epidural space during the first trimester of pregnancy when little compression is evident.⁸⁸ A relationship appears to exist between the progesterone level in CSF and an increased segmental spread and sensitivity of nerves to these drugs. Studies performed on isolated nerves taken from pregnant animals demonstrate more sensitivity to local anesthetic block than in

nonpregnant animals.^{89,90}

Local Anesthetics and Tumor Recurrence

It has been suggested after several small retrospective studies that regional or local anesthesia may improve patient survival and the disease free interval after cancer surgery. A number of prospective randomized controlled trials are ongoing, which may clarify this possible action.⁹¹⁻⁹³ The potential mechanisms of the antimetastatic effects include both direct and indirect effects of local anesthetics. Direct effects include interference with tumor promoting pathways, and direct toxic effects on tumors when used for local infiltration. Indirect effects result from a reduction of the perioperative stress response and the preservation of the immune response.¹³

Local Anesthetic Systemic Toxicity

Local anesthetic systemic toxicity (LAST) is a serious but rare consequence of regional anesthesia. It most commonly results from an inadvertent vascular injection or absorption of large amounts of drug from certain nerve blocks requiring large volume injections. It can also occasionally result from continuous infusion and accumulation of drug and metabolites over many days. The subsequent high systemic blood levels lead to LAST.

When inadvertent systemic delivery or rapid absorption of large quantities of local anesthetic occurs, the voltage-gated sodium, potassium and calcium channels in excitable tissues of the central nervous and cardiac system are depressed. Normal functioning of the central nervous system involves both excitatory and inhibitory neurons. As LAST progresses, the inhibitory neurons are blocked first. This lack of inhibition on the excitatory neuron is thought to be the mechanism of the observed seizure. The functioning of the heart depends on mechanisms similar to that of the neuron. Blockade of the cardiac ion channels will affect initiation and propagation of the contraction, and repolarization. A toxic level of local anesthetic results in decreased contractility and several arrhythmias, the first of which is commonly bradycardia. Ventricular fibrillation is the most serious of the arrhythmias.

With respect to the extent of compromise, the type of local anesthetic plays a role. Shorter-acting lidocaine is less cardiotoxic than the longer-acting and more potent bupivacaine. Most reported deaths related to LAST involve bupivacaine. The difference between short-acting and longer-acting agents may be related to their physical properties. The more potent agents are more lipid soluble and protein bound. As such, the duration of blockade of any voltage-gated channel is probably longer and thus the recovery is delayed. The newer agents ropivacaine and levobupivacaine were developed to address this issue of cardiotoxicity. These agents are accepted as safer; however, care should be taken when using large doses of any local anesthetic.⁹⁴

Widespread attention to this adverse effect is attributed to Albright, who wrote an editorial in 1979 outlining the risks of

bupivacaine use in intravenous regional blocks.⁹⁵ Subsequently, 49 cases of cardiac toxicity from local anesthetics were reported to the Food and Drug Administration (FDA).⁹⁶ Worldwide concern followed with a renewed research and clinical interest and safety recommendations.⁸⁴ The American Society of Regional Anesthesia and Pain Medicine (ASRA) Panel on Local Anesthetic Systemic Toxicity has reevaluated the available research and clinical data from 1979 to 2009 and issued recommendations regarding prevention, diagnosis, and treatment of this complication. A review of local anesthetic systemic toxicity cases since publication of the ASRA recommendations was reported in 2015.⁹⁷ Many traditional concepts were reevaluated in light of new data, and practice advisories were formulated. Fortunately the incidence is dropping as awareness, new practice techniques, and new drugs are instituted.⁹⁸

Incidence and Clinical Presentation

Standard randomized controlled trials of LAST are obviously not ethical, therefore our knowledge is primarily derived from epidemiologic studies, case reports, and animal research. Data from animal and laboratory studies can vary widely depending on the model used, so comparisons and extrapolation to clinical situations can be difficult.

There has been a significant reduction in the incidence of LAST since the 1980s.⁹⁹ The estimate of clinically important LAST is from 7.5 to 20 occurrences per 10,000 peripheral nerve blocks and approximately 4 per 10,000 epidurals.⁸⁴ This is a dramatic drop, for example, from the previously reported toxicity of 100 per 10,000 epidurals.¹⁰⁰ Peripheral nerve blocks (PNB) traditionally have a higher incidence of LAST because of the large volumes of local anesthetic drugs administered compared to epidurals. A 2016 evaluation of 80,661 PNBs was reported.^{101,102} This represents the largest cohort of these regional blocks ever analyzed. There were no cases of cardiac arrest and three cases of seizures caused by LAST. The incident rate of 0.4 per 10,000 fits well into a pattern of continually improving patient safety for regional anesthesia. This safety improvement is attributed to the widespread adoption of enhanced safety measures, namely ultrasound guided regional

anesthesia, aspirating before injection, incremental injection, lower local anesthetic doses and use of a test dose. Added safety measures included performing the blocks with the patients either awake or sedated with meaningful contact maintained to allow early identification of LAST, and the use of midazolam, which may have increased the potential seizure threshold.¹⁰¹⁻¹⁰³

As mentioned earlier, ASRA has evaluated data from 1979 to 2009 and identified 93 separate LAST events. The classic typical clinical presentation of LAST is a progression of subjective symptoms of CNS excitation such as agitation, tinnitus, circumoral numbness, blurred vision, and a metallic taste followed by muscle twitching, unconsciousness, and seizures and with very high drug levels, cardiac and respiratory arrest (Fig. 10.11). The sequence occurs because the inhibitory pathways in the brain are affected first, leaving unopposed excitation. This is sometimes referred to as *disinhibition*. As the blood (therefore brain) levels increase, the more resistant excitatory pathways are inhibited, leading to unconsciousness and coma.⁸⁴ This was the presentation in approximately 60% of cases, although the types of CNS symptoms varied greatly. An atypical presentation was evident in approximately 40% of the patients. This was defined as LAST that is delayed for more than 5 minutes or with isolated cardiovascular symptoms alone. Most of the atypical presentations were for delayed symptoms.^{98,99,104}

FIGURE 10.11 Classically reported sequence of clinical signs after increased central nervous system concentration

of lidocaine. CVS, Cardiovascular system.

The most common regional block techniques associated with LAST were epidural (33%), axillary (17%), and interscalene (13%). Seventy-seven cases followed a single injection and 14 occurred with continuous infusion. Two cases involved both continuous infusions with a supplementary single injection. Of the continuous infusion cases, half were pediatric cases. Fifty-two events were related to bupivacaine (55%), 28 to ropivacaine (30%), 4 to levobupivacaine (4%), and 9 were attributed to other local anesthetics (11%). The patient characteristics were as follows: 63% female; 16% under 16 years old; 29% older than 60 years; five newborns receiving epidural anesthesia, and 37% of all patients had significant comorbidities such as diabetes, renal failure, or isovaleric acidemia.¹⁰⁴

The timing of the onset of symptoms after a single injection varied from 30 seconds to 60 minutes (Fig. 10.12). It is usually very rapid. In over half the cases, it happened in less than 50 seconds, and 75% of the cases occurred within 5 minutes of injection. The onset of symptoms following continuous infusion occurred hours or days after starting the drug.¹⁰⁴

FIGURE 10.12 The timing for onset of signs of local anesthetic systemic toxicity after a single injection of local anesthetic (from a total of 77 incidents). (Data from Di Gregorio G, et al. Clinical presentation of local anesthetic systemic toxicity: a review of

published cases, 1979 to 2009. *Reg Anesth Pain Med.* 2010;35:181–187;

anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin.*
2011;29:233–242.)

As mentioned previously, there were 67 additional LAST events reported between March 2010 and March 2014. Fifty cases of toxicity occurred after a single injection of local anesthetic, whereas in eight cases, LAST symptoms arose during continuous infusion. In seven cases, toxicity followed topical administration. Two cases resulted from inadvertent intravascular injection. The most frequently reported regional technique associated with LAST was interscalene block (23%), followed by epidural/caudal block (16%), and dorsal penile block (13%). The remaining 22% of those cases received a single local anesthetic injection for local field infiltration anesthesia.

Sixty-nine percent of the events occurred in an operating room. The remaining cases occurred in an office or other locations. Twenty percent of the patients were older than 60 years, 30% were younger than 16 years, and 22% were in their first year of life. As expected, the most common signs and symptoms of LAST involved the CNS and the cardiovascular (CV) system. Seizures and loss of consciousness were the most frequent CNS manifestations, and these findings are consistent with the data from the past three decades. When CNS and CV symptoms were combined, they most commonly progressed from CNS to CV abnormalities, but this was not the rule, confirming that toxicity may take different forms.⁹⁷

Central Nervous System and Cardiovascular Signs of Toxicity

The newly evaluated data point to a more varied presentation of toxicities. Symptoms of CNS toxicity occurred in 89% of cases either alone (45%) or together with significant cardiovascular symptoms (44%) (Fig. 10.13). The spectrum of CNS signs of toxicity is given in Fig. 10.14. It is interesting to note that the most frequent symptom was seizures (68%), whereas only 18% exhibited the typical prodromal symptoms. The spectrum of cardiovascular signs of

toxicity are given in Fig. 10.15. The most common involved various arrhythmias.¹⁰⁴

FIGURE 10.13 The frequency of symptoms and signs referable to cardiovascular (CV), central nervous system (CNS), or both is given for the 93 cases in this review. (Data from Di Gregorio G, et al. Clinical presentation of local anesthetic systemic toxicity: a review of published cases, 1979 to 2009. *Reg Anesth Pain Med* 2010;35:181–187; Neal JM, et al. Prevention of Local Anesthetic Systemic Toxicity

Adaptation of suggested safety steps such as the use of test doses, incremental injection with frequent aspiration, and the use of pharmacologic markers such as epinephrine or fentanyl have lowered the incidence of LAST in recent years. Additional practices that have been suggested to improve safety include limiting the total dose of local anesthetic by restricting the use of 0.75% bupivacaine in obstetrics. The clinical principle in any regional technique is to use the lowest dose possible (the product of the concentration and volume) to produce a satisfactory block.¹⁰⁵ The use of generalized maximum recommended doses has been questioned.⁸⁶ Systemic blood levels of the same dose of anesthetic vary greatly depending on the area of blockade, technique, and specific drug. Blood levels are difficult to predict when dosing on a milligram per kilogram basis. Body weight as a guide should be used only in pediatric patients (Table 10.7). The use of ultrasound-guided techniques has been evaluated with regards to improved patient safety. Evidence supports the concept that ultrasound guidance is effective in reducing the incidence of local anesthetic systemic toxicity. There is also a lower predicted frequency of pneumothorax. Ultrasound guidance does not affect the incidence of peripheral nerve injury associated with regional anesthesia. There is a reduced incidence and intensity of hemidiaphragmatic paresis with ultrasound-guided supraclavicular blocks.^{106,107} The current ASRA recommendations for recognizing, preventing, and treatment of LAST are given in Box 10.3.¹⁰⁵ Further recommendations for preventing LAST are noted in Box 10.4.

TABLE 10.7**Local Anesthetic Agents Used Commonly for Infiltrative Injection**

Agent	Duration of Action	Maximum Dosage Guidelines (Total Cumulative Infiltrative Injection Dose Per Procedure*)
Esters		
Procaine (Novocain)	Short (15–60 min)	7 mg/kg; not to exceed 350–600 mg
Chloroprocaine (Nesacaine)	Short (15–30 min)	Without epinephrine: 11 mg/kg; not to exceed 800 mg total dose With epinephrine: 14 mg/kg; not to exceed 1000 mg
Amides		
Lidocaine (Xylocaine)	Medium (30–60 min)	Without epinephrine: 4.5 mg/kg; not to exceed 300 mg
Lidocaine with epinephrine	Long (120–360 min)	With epinephrine: 7 mg/kg
Mepivacaine (Polocaine, Carbocaine)	Medium (45–90 min), Long (120–360 min with epinephrine)	7 mg/kg; not to exceed 400 mg
Bupivacaine (Marcaine)	Long (120–240 min)	Without epinephrine: 2.0 mg/kg; not to exceed 175 mg total dose
Bupivacaine with epinephrine	Long (180–420 min)	With epinephrine: 2.5 mg/kg Not to exceed 225 mg total dose
Prilocaine (Citanest)	Medium (30–90 min)	Body weight less than 70 kg: 6 mg/kg; not to exceed 500 mg
Ropivacaine (Naropin)	Long (120–360 min)	3 mg; not to exceed 200 mg for minor nerve block with or without epinephrine

*Nondental use; administer by small incremental doses; administer the smallest dose and concentration required to achieve desired effect; avoid rapid injection.

Box 10.3

American Society of Regional Anesthesia and Pain Medicine Checklist for Managing Local Anesthetic Systemic Toxicity

For patients experiencing signs or symptoms of local anesthetic systemic toxicity (LAST), the pharmacologic treatment of LAST is different from other cardiac arrest scenarios.

- Get help.
- Initial focus:
- *Airway management:* ventilate with 100% oxygen.

- *Seizure suppression: benzodiazepines are preferred.*
- *Basic and Advanced Cardiac Life Support (BLS/ACLS) will require adjustments of medications and perhaps prolonged effort.*
- Infuse 20% lipid emulsion (values in parenthesis are for a 70-kg patient).
- Bolus 1.5 mL/kg (lean body mass) intravenously over 1 min (\approx 100 mL).
- Continuous infusion at 0.25 mL/kg per min (\approx 18 mL/min; adjust by roller clamp)
- Repeat bolus once or twice for persistent cardiovascular collapse.
- Double the infusion rate of 0.5 mL/kg per min if blood pressure remains low.
- Continue infusion for at least 10 min after attaining circulatory stability.
- Recommended upper limit: approximately 10 mL/kg lipid emulsion over the first 30 min.
- Avoid vasopressin, calcium channel blockers, β -blockers, or local anesthetic.
- Reduce individual epinephrine doses to less than 1 mcg/kg.
- Alert the nearest facility having cardiopulmonary bypass

capability.

- Avoid propofol in patients having signs of cardiovascular instability.
- Post LAST events at www.lipidrescue.org and report use of lipid to www.lipidregistry.org.

Be Prepared

- We strongly advise that those using local anesthetics (LAs) in doses sufficient to produce systemic toxicity (LAST) establish a plan for managing this complication. Making a local anesthetic toxicity kit and posting instructions for its use are encouraged.

Risk Reduction (Be Sensible)

- Use the lowest dose of LA necessary to achieve the desired extent and duration of block.
- Local anesthetic blood levels are influenced by site of injection and dose. Factors that can increase the likelihood of LAST include advanced age, heart failure, ischemic heart disease, conduction abnormalities, metabolic (e.g., mitochondrial) disease, liver disease, low plasma protein concentration, metabolic or respiratory acidosis, and medications that inhibit sodium channels. Patients with severe cardiac dysfunction, particularly very low ejection fraction, are more sensitive to LAST and also more prone to receive “stacked” injections (with resulting elevated LA tissue concentrations) because of slowed circulation time.
- Consider using a pharmacologic marker and/or test dose, for example, epinephrine 5 mcg/mL of LA. Know the expected response, onset, duration, and limitations of a “test dose” in identifying intravascular injection.
- Aspirate the syringe prior to each injection while observing for blood.

- Inject incrementally, observing for signs and querying frequently for symptoms of toxicity between each injection.
- Use ultrasound guidance for the local anesthetic injection

Detection (Be Vigilant)

- Use standard American Society of Anesthesiologists (ASA) monitors.
- Monitor the patient during and after completing the injection, as clinical toxicity can be delayed up to 30 min or longer after tumescent procedures.
- Consider LAST in any patient with altered mental status, neurologic symptoms, or cardiovascular instability following a regional anesthetic.
- Central nervous system signs (may be subtle or absent):
 - Excitation (agitation, confusion, muscle twitching, seizure)
 - Depression (drowsiness, obtundation, coma, apnea)
 - Nonspecific (metallic taste, circumoral numbness, diplopia, tinnitus, dizziness)
- Cardiovascular signs (often the only manifestation of severe LAST):
 - Initially may be hyperdynamic (hypertension, tachycardia, ventricular arrhythmias), then:
 - Progressive hypotension

- Conduction block, bradycardia, or asystole
- Ventricular arrhythmia (ventricular tachycardia, torsades de pointes, ventricular fibrillation)
- Sedative hypnotic drugs reduce seizure risk, but even light sedation may abolish the patient's ability to recognize or report symptoms of rising LA concentrations.

Treatment

Maintain and secure the airway; 100% oxygen.

- Timing of lipid infusion in LAST is controversial. The most conservative approach, waiting until after ACLS has proven unsuccessful, is unreasonable because early treatment can prevent cardiovascular collapse. Infusing lipid at the earliest sign of LAST can result in unnecessary treatment because only a fraction of patients will progress to severe toxicity. The most reasonable approach is to implement lipid therapy on the basis of clinical severity and rate of progression of LAST.
- There is laboratory evidence that epinephrine can impair resuscitation from LAST and reduce the efficacy of lipid rescue. Therefore it is recommended to avoid high doses of epinephrine and use smaller doses, for example, 1 mcg/kg for treating hypotension.
- Propofol should not be used when there are signs of cardiovascular instability. Propofol is a cardiovascular depressant with lipid content too low to provide benefit. Its use is discouraged when there is a risk of progression to cardiovascular collapse.
- Consider drawing blood to measure LA plasma concentration if there is no delay to definitive treatment.
- Transfer to a clinical area with appropriate monitoring, equipment, and staff for > 12 hr monitoring.

- Regular clinical review to exclude pancreatitis, including serial amylase or lipase for 2 days.
- Report cases and use of ILE to www.lipidrescue.org.

American Society of Regional Anesthesia and Pain Medicine checklist for managing local anesthetic systemic toxicity: 2012 version, *Reg Anesth Pain Med*, 2012;37:16–18; El-Boghdadly K, Chin KJ. Local anesthetic systemic toxicity: Continuing Professional Development. *Can J Anaesth*. 2016;63:330–349.

Box 10.4

Recommendations for Preventing Local Anesthetic Systemic Toxicity (LAST)

- There is no single measure that can prevent LAST in clinical practice.
- Use the lowest effective dose of local anesthetic (dose = product of volume × concentration).
- Use incremental injection of local anesthetics—administer 3 mL to 5 mL aliquots, pausing 15 to 30 seconds between each injection.
- When using a fixed needle approach, for example, landmark paresthesia-seeking or electrical stimulation; time between injections should encompass one circulation time (approximately 30–45 sec); however, this ideal may be balanced against the risk of needle movement between injections. Circulation time may be increased with lower extremity blocks. Use of larger dosing increments would dictate the need for longer

intervals to reduce the cumulative dose from stacked injections before an event of LAST.

Incremental injection may be less important with ultrasound guidance given that frequent needle movement is often used with the technique.

- Aspirate the needle or catheter before each injection, recognizing that there is approximately a 2% false-negative rate for this diagnostic intervention.
- When injecting potentially toxic doses of local anesthetic, use of an intravascular marker is recommended. Although epinephrine is an imperfect marker and its use is open to physician judgment, its benefits likely outweigh its risks in the majority of patients:
- Intravascular injection of epinephrine 10 to 15 mcg/mL in adults produces a 10-beat or greater heart rate increase, or a 15 or greater mm Hg systolic blood pressure (SBP) increase in the absence of β blockade, active labor, advanced age, or general/neuraxial anesthesia.
- Intravascular injection of epinephrine 0.5 mcg/kg in children produces a 15 or greater mm Hg increase in SBP.
- Appropriate subtoxic doses of local anesthetic can produce subjective symptoms of mild systemic toxicity (e.g., auditory changes, excitation, metallic taste) in unpremedicated patients.
- Fentanyl 100 mcg produces sedation if injected

intravascularly in laboring patients.

- Ultrasound guidance may reduce the frequency of intravascular injection, but actual reduction of LAST remains unproven in humans. Individual reports describe LAST despite the use of ultrasound-guided regional anesthesia. The overall effectiveness of ultrasound guidance in reducing the frequency of LAST remains to be determined.

ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med.* 2010; 35:152–161; El-Boghdadly K, Chin KJ. Local anesthetic systemic toxicity: Continuing Professional Development. *Can J Anaesth.* 2016;63:330–349.

Diagnosis and Treatment of Local Anesthetic Systemic Toxicity

Prompt recognition and treatment are essential to minimizing adverse outcomes of LAST. Airway management remains the primary intervention because preventing hypoxia and acidosis are essential first steps. As noted in [Box 10.2](#), acidosis may enhance toxicity by ion trapping local anesthetic in the brain. Seizure suppression is essential to facilitate immediate airway control and prevent or reduce metabolic acidosis. Benzodiazepines are considered the drugs of choice because they are anticonvulsant without causing significant cardiac depression. When benzodiazepines are not available, small doses of propofol may be appropriate. Succinylcholine may be useful to suppress intractable seizure-induced tonic-clonic muscle activity in spite of the lack of CNS effects. Cardiovascular support is essential to maintaining adequate coronary perfusion. The local anesthetics do not irreversibly damage the cardiac cells. Avoiding tissue hypoxia is essential in reversing the progression of toxic cardiac events.¹⁰⁸

Local anesthetic cardiotoxicity, especially with bupivacaine, involves both electrophysiologic disturbances and depression of contractility. The electrical disturbances appear to occur at lower doses and are more contributory to poor outcomes than contractile depression, but differences among specific local anesthetics exist.¹⁰⁹

Lipid emulsion therapy is recommended as a standard part of LAST resuscitation. There is some evidence that it is able to restore spontaneous circulation without the use of vasopressors. In fact, large doses of vasopressors may decrease the effectiveness of lipid emulsions.¹¹⁰ Vasopressors may be required to maintain adequate blood pressure, but they can worsen local anesthetic-induced arrhythmias. Small doses of epinephrine, less than 1 mcg/kg, are recommended. Vasopressin should be avoided even though it is now part of Advanced Cardiac Life Support guidelines.¹⁰⁸

As noted previously, lipid emulsion therapy for LAST is the newest and most promising therapy that has emerged. Both laboratory and clinical use has shown it to be instrumental in facilitating successful recovery. The exact mechanisms for the beneficial effects is not clear. The mechanisms of action of lipid infusion can be broadly separated into intracellular (metabolic, signaling), intravascular (partitioning, sink), and membrane (channel) effects.

Six mechanistic actions may contribute to lipid resuscitation including: (1) capture of local anesthetic in the blood (lipid sink); (2) increased fatty acid uptake by mitochondria (metabolic effect); (3) interference with local anesthetic binding of sodium channels (membrane effect); (4) activation of serine/threonine kinase (Akt) cascade leading to inhibition of GSK-3, which is glycogen synthase kinase (cytoprotection); (5) promotion of calcium entry via voltage-dependent calcium channels (ionotropic/inotropic effect); and (6) accelerated shunting (pharmacokinetic effects).¹¹¹⁻¹¹⁴ Lipid emulsion is also recommended in pregnant patients.¹¹⁵ It is also being used for a variety of drug overdoses in emergency situations.¹¹⁶ The recommendations for diagnosing LAST are given in [Box 10.5](#).⁹⁸ Treatment recommendations are given in [Box 10.6](#).¹⁰⁶ A detailed [Box 10.5](#) suggestion for administering lipid emulsion is given in [Box 10.7](#)

Recommendations for Diagnosing Local Anesthetic Systemic Toxicity (LAST)

- Classic descriptions of LAST depict a progression of subjective symptoms of central nervous system (CNS) excitement (e.g., agitation, auditory changes, metallic taste, or abrupt onset of

psychiatric symptoms) followed by seizures or CNS depression (e.g., drowsiness, coma, or respiratory arrest). Near the end of this continuum, initial signs of cardiac toxicity (e.g., hypertension, tachycardia, or ventricular arrhythmias) are supplanted by cardiac depression (e.g., bradycardia, conduction block, asystole, decreased contractility). However, there is substantial variation in this classic description, including the following:

- Simultaneous presentation of CNS and cardiac toxicity
- Cardiac toxicity without prodromal signs and symptoms of CNS toxicity
- Thus the practitioner must be vigilant for atypical or unexpected presentation of LAST.
- The timing of LAST presentation is variable. Immediate (less than 60 sec) presentation suggests intravascular injection of local anesthetic (LA) with direct access to the brain, whereas presentation that is delayed 1 to 5 minutes suggests intermittent or partial intravascular injection, delayed circulation time, or delayed tissue absorption. Because LAST can present more than 15 minutes after injection, patients who receive potentially toxic doses of LA should be closely monitored for at least 30 minutes after injection.
- Case reports associate LAST with underlying cardiac, neurologic, pulmonary, renal, hepatic, or metabolic disease. Heightened vigilance is warranted in these patients, particularly if they are at the extremes of age.
- The overall variability of LAST signs and symptoms, timing of onset, and association with various disease states suggests that practitioners should maintain a low threshold for considering the

diagnosis of LAST in patients with atypical or unexpected presentation of CNS or cardiac signs and symptoms after receiving more than a minimal dose of LA.

Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin.* 2011;29:233–242; El-Boghdadly K, Chin KJ. Local anesthetic systemic toxicity: Continuing Professional Development. *Can J Anaesth.* 2016;63:330–349.

Box 10.6

Recommendations for Treatment of Local Anesthetic Systemic Toxicity (LAST)

- If signs and symptoms of LAST occur, prompt and effective airway management is crucial to preventing hypoxia and acidosis, which are known to potentiate LAST.
- If seizures occur, they should be rapidly halted with benzodiazepines. If benzodiazepines are not readily available, small doses of propofol are acceptable. Future data may support the early use of lipid emulsion for treating seizures.
- Although propofol can stop seizures, large doses further depress cardiac function; propofol should be avoided when there are signs of cardiovascular compromise. If seizures persist despite benzodiazepines, small doses of succinylcholine or similar neuromuscular blocker should be considered to minimize acidosis and hypoxemia.
- If cardiac arrest occurs, we recommend standard advance cardiac life support with the following modifications:
- If epinephrine is used, small initial doses (10 mcg to 100 mcg boluses in adults) are preferred. Administration should be preceded by initiation of intravenous lipid emulsion therapy.

- Vasopressin is not recommended.
- Avoid calcium channel blockers, β -adrenergic receptor blockers and sodium channel blockers.
- If ventricular arrhythmias develop, amiodarone is preferred; treatment with local anesthetics (lidocaine or procainamide) is not recommended.
- Lipid emulsion therapy:
- Consider administering at the first signs of LAST, after airway management.
- Dosing

Bolus 1.5 ml/kg over 1 min (100 mL in a 70 kg patient) followed by a continuous infusion at 15 ml/kg per hr.

If persistent cardiovascular instability or deterioration after 5 minutes:

Repeat the same bolus up to two further times.

Double the infusion rate to 30 ml/kg per hr.

Continue infusion for 10 min after return of cardiovascular stability Maximum 30 min cumulative dose of 10 ml/kg.

- Propofol is not a substitute for lipid emulsion.

- Failure to respond to lipid emulsion and vasopressor therapy should prompt institution of cardiopulmonary bypass. Because there can be considerable lag in beginning cardiopulmonary bypass, it is reasonable to notify the closest facility capable of providing it when cardiovascular compromise is first identified during an episode of LAST.

Other Adverse Effects

Allergic Reactions

True allergic reactions to local anesthetics are rare, making up no more than 1% of reactions.¹¹⁷ The frequency is decreasing with the lower use of the ester-type local anesthetics. Adverse reactions are most commonly as a result of anxiety, panic attacks, intravascular injection, vasovagal responses, or epinephrine. A 2012 literature

review of local anesthetic reactions identified 23 case series involving 2978 patients. Twenty-nine of these patients had true immunoglobulin E (IgE) mediated reactions to local anesthetics resulting in a prevalence of 0.97%.¹¹⁸ Local anesthetics can, however, produce allergic, hypersensitivity, and anaphylactic reactions. The use of ester local anesthetics is associated with a greater incidence of allergic reactions than the use of amides. This is likely because esters are derivatives of and metabolized to para-aminobenzoic acid (PABA), which is an allergenic compound.¹¹⁹ Allergy to local anesthetics may be caused by methylparaben, paraben, or metabisulfite used as preservatives. In 1984 the FDA mandated removal of methylparaben from single-dose local anesthetic cartridges commonly used in dentistry which greatly reduced allergic reactions. Sulfites are antioxidants used to stabilize epinephrine in local anesthetic solutions. They are not typically used when the local anesthetic does not contain epinephrine. Sulfites have been involved in nonIgE-mediated hypersensitivity reactions, particularly in patients with asthma. Because testing is very inconsistent, it is difficult to know the role sulfites may play in reactions attributed to a local anesthetic preparation.^{120,121} Preservative-free solutions are available but not commonly used. Cross-reactivity among the ester-type local anesthetics is high. Allergy to the amides remains extremely rare. Cross-reactivity within the amides as a class is extremely rare and between esters and amides is absent.¹²² A thorough history of allergy may be difficult because many patients call all local anesthetic drugs "Novacaine." They may not be aware of the specific agent administered. Clinicians use amides when possible because the incidence of allergy is extremely low, and they are not cross-reactive with other amides or esters. If a true allergy is suspected, referral to an allergist for skin testing and incremental dose challenges is necessary.^{117,123,124}

Methemoglobinemia

Methemoglobinemia is a disorder characterized by high concentrations of methemoglobin (MetHb) in the blood, which can lead to tissue hypoxia. The ferrous form of hemoglobin (Fe^{2+}) is oxidized to the ferric form (Fe^{3+}). Methemoglobin is an oxidized

		tachycardia
7.5–10.5 g/dL	50–70	Coma, seizures, arrhythmias, acidosis

From Cortazzo JA, Lichtman AD. Methemoglobinemia: a review and recommendations for management. *J Cardiothorac Vasc Anesth.* 2014; 28:1043–1047.

Box 10.8

Clinical Clues to the Diagnosis of Methemoglobinemia in the Anesthetized Patient

1. Hypoxia that does not improve with increased fraction of inspired oxygen (FiO_2).
2. Abnormal coloration of blood.
3. Physiologically appropriate partial pressure of arterial oxygen (PaO_2) on blood gas sample with low pulse oximeter saturation — “saturation gap”.
4. New-onset cyanosis and/or hypoxia after ingestion of an agent with oxidative properties.

From Cortazzo JA, Lichtman AD. Methemoglobinemia: a review and recommendations for management. *J Cardiothorac Vasc Anesth.* 2014; 28:1043–1047.

Benzocaine and benzocaine-containing mixtures are widely used for topical anesthesia. The FDA has issued multiple safety bulletins warning of benzocaine-induced methemoglobinemia.¹²⁹ In a 2006 communication the FDA reported 247 cases of methemoglobinemia from benzocaine sprays including three deaths. Since then the number of cases has continued to rise. The development of methemoglobinemia does not seem to be dose related. Symptoms appear within minutes up to 2 hours after benzocaine use. Benzocaine sprays are marketed as different brand names such as Cetacaine, Hurricaine, Exactacain, and Topex. A 2011 safety bulletin warned of serious adverse events associated with over-the-counter benzocaine gels, sprays, and liquids. They are applied to the throat

and gums for pain relief. The cases were primarily in teething children less than 2 years old. Benzocaine gels and liquids are marketed under the names Anbesol, Hurricaine, Orajel, Baby Orajel, Orabase, and some store brands. Benzocaine should not be used in children under 2 years old.

Prilocaine can produce methemoglobinemia because of one of its metabolites o-toluidine, which oxidizes hemoglobin to methemoglobin. The tendency of prilocaine to produce methemoglobin is dose related. Current recommendations are that prilocaine should not be used in children younger than 6 months old, in pregnant women, or in patients taking other oxidizing drugs. The dose should be limited to 2.5 mg/kg.^{130,131} The treatment for elevated methemoglobin is methylene blue, which is initiated at a rate of 1 to 2 mg/kg intravenously over 3 to 10 minutes. If the methemoglobin level is greater than 50% or the clinical condition worsens, then the higher dose of methylene blue 2 mg/kg can be given initially. The dose can be repeated if symptoms fail to improve or high methemoglobin levels persist. A level of methemoglobin greater than 70% may require transfusion or dialysis. Recognition is critical because a delay in treatment can lead to cardiopulmonary compromise, neurologic sequelae, and even death.^{128,132}

Local Tissue Toxicity

Cauda equina syndrome (CES) manifests as bowel and bladder dysfunction with various degrees of bilateral lower extremity weakness and sensory impairment. There are multiple causes for CES, ranging from neural element compression from hematoma, abscess, or herniated intervertebral discs, to poorly understood presentations associated with normal clinical settings. Known risk factors for anesthetic-related CES are supernormal doses of intrathecal local anesthetic and/or the maldistribution of local anesthetic spread within the intrathecal space. Cases of CES have been associated with previously undiagnosed spinal stenosis. In theory, a tight spinal canal may lead to pressure-induced spinal cord ischemia, or limit normal local anesthetic distribution within the intrathecal sac thereby exposing the cauda equina to high drug concentrations. Either of these conditions could promote local

anesthetic neurotoxicity and could be exacerbated by additional compromise of the spinal canal, as may occur with nonneutral surgical positioning **Box 10.9** shows the ASRA recommendations regarding CES.¹³³ Past formulations of chloroprocaine were reported to produce prolonged CES when large doses were given by inadvertent intrathecal injection.^{16,134–136} The neurotoxicity was thought to be caused by a combination of large intrathecal doses, low pH, and the preservative sodium metabisulfite. Controversy remains as to whether transient neurologic symptoms (TNS) after spinal anesthesia are a form of local anesthetic neurotoxicity with the use of preservative free intrathecal 2-chloroprocaine. Spinal 2-chloroprocaine remains off-label in the United States.^{137–139}

American Society of Regional Anesthesia Recommendations for Minimizing Cauda Equina Syndrome

These recommendations are intended to encourage optimal patient care but cannot ensure the avoidance of adverse outcomes. As with any practice advisory recommendation these are subject to revision as knowledge advances regarding specific complications.

- Initial dosing or redosing of subarachnoid local anesthetic in addition, maldistribution (usually sacral) of local anesthetic spread should be ruled out before redosing single-injection or continuous subarachnoid blocks (Class I).
- The risks and benefits of neuraxial techniques should be considered in patients known to have moderate-to-severe spinal stenosis, especially if within the vertebral territory of the intended injection (Class II).
- The incidence of TNS after 40 to 50 mg intrathecal 2-chloroprocaine seems to be remarkably low. The number of 2-chloroprocaine spinal anesthetics reported in the literature is insufficient to determine the risk for CES or other manifestations of neurotoxicity (Class III).
- Physically and temporally separate disinfectant use from block trays and instruments during neuraxial procedures. Allow the

solution to completely dry on skin before needle placement (2–3 min). Care should be taken to avoid needle or catheter contamination from chlorhexidine spraying or dripping, or from applicator device disposal, onto aseptic work surfaces (Class II).

TNS, Transient neurological symptoms.

From Neal JM, et al. The second ASRA practice advisory on neurologic complications associated with regional anesthesia and pain medicine: executive summary 2015. *Reg Anesth Pain Med*. 2015;40:401–430.

Lidocaine has been associated with CES when used for continuous spinal anesthesia, and it is no longer used in this anesthetic technique in the United States.^{140,141} Single dose spinal administration of lidocaine has also been implicated in TNS, which results in back and lower extremity pain for up to 5 days postoperatively. No permanent problems occur. Symptoms include a burning, aching, cramplike and radiating pain in the anterior and posterior aspect of the thighs. Pain radiates to the lower extremities, and lower back pain is common. Other anesthetics have been implicated, but it is much more prevalent following spinal lidocaine.¹⁴² Surgical positioning may be a factor as well.¹⁴³ The exact mechanism is unclear. Newer techniques and agents other than lidocaine are being used now and this has diminished this problem as a clinical issue.¹⁴⁴ Treatment is supportive and should include nonsteroidal antiinflammatory agents when possible.

Clinical Use of Local Anesthetics

Topical Anesthesia

Anesthesia with a number of diverse topical formulations is used for a variety of clinical applications. These include decreasing the pain of venipuncture, circumcision, dressing changes, dentistry, minor surgical procedures, laser procedures, and multiple injection regional blocks. Some available products are listed in [Table 10.9](#) and described hereafter.^{145,146}

TABLE 10.9

Topical Anesthesia Products

Product	Composition	Time to Efficacy	Occlusion	Potential
TAC	0.5% tetracaine, 1 : 2000 epinephrine, and 11.8% cocaine	30 min	No	Seizures; cardiac arrest
LET	0.5% tetracaine, 1 : 2000 epinephrine, and 4% lidocaine	15–30 min	No	None
Topicaine	4% lidocaine	30 min	No	Contact dermatitis
EMLA	2.5% lidocaine and 2.5% prilocaine	30 min to 2 hr	Yes	Contact dermatitis; methemoglobinemia
LMX 4/5	4% or 5% liposomal lidocaine	15–40 min	No	None
BLT	20% benzocaine, 6% lidocaine, and 4% tetracaine	15–30 min	No	None

Cocaine

Cocaine is derived from the coca plant and is the only naturally occurring local anesthetic. Other unique properties include the ability to block the monoamine transporter in adrenergic neurons. The neuronal transporter is responsible for the termination of the action of catecholamines. This catecholamine reuptake blockade results in significant vasoconstriction. This action in the CNS also

accounts for cocaine's analeptic actions. It is used primarily for topical anesthesia of the nose and throat. A maximum of 5 mL of 4% solution or 200 mg should be used. It is frequently administered with other epinephrine-containing preparations so arrhythmias, hypertension, and tachycardia may occur. Caution is advised for possible drug interactions in patients taking other catecholamine-enhancing drugs such as tricyclic antidepressants or monoamine oxidase inhibitors.^{147,148}

Eutectic Mixture of Local Anesthetics

Eutectic mixture of local anesthetics (EMLA) is a mixture of lidocaine and prilocaine that is applied to the skin as either a cream or patch. A eutectic mixture of chemicals has a lower melting point and solidifies at a lower temperature when combined.

Pharmacokinetic studies indicate that satisfactory dermal analgesia is achieved 1 hour after application with an occlusive dressing; maximal analgesia occurs 2 to 3 hours after application.¹⁴⁵ When EMLA is applied to areas of abnormal skin (e.g., where psoriasis or eczema is present), absorption is faster, plasma levels are higher, and the duration of anesthesia is shorter. Systemic absorption of lidocaine and prilocaine is dependent on the duration and surface area of application. Toxicity is more likely to occur in infants and small children than in adults. Guidelines for the use of EMLA are given in [Table 10.10](#).

TABLE 10.10
Guidelines for Application of EMLA

Age and Body Weight Requirement	Maximum Total Dose of EMLA	Maximum Application Area
0–3 months or less than 5 kg	1 g	10 cm ²
3–12 months and more than 5 kg	2 g	20 cm ²
1–6 years and less than 10 kg	10 g	100 cm ²
7–12 years and more than 20 kg	20 g	200 cm ²

EMLA, Eutectic mixture of local anesthetics.

Data from Kaweski S. Plastic Surgery Educational Foundation Technology Assessment Committee: topical anesthetic creams. *Plast Reconstr Surg*. 2008;121:2161–2165.

Tetracaine, Epinephrine, and Cocaine

Three available agents—tetracaine, epinephrine, and cocaine (TAC)—have been combined for use on traumatic lacerations. The relative concentration of each component is as follows: tetracaine 1%, epinephrine 1:200, and cocaine 4%. This combination has been as effective as infiltration of local anesthetics for the closure of certain types of laceration. Tetracaine and cocaine can produce excellent topical anesthesia, and cocaine and epinephrine result in vasoconstriction at the site of application. TAC is much more expensive to administer than lidocaine. The drug combination in TAC can produce significant toxicity.¹⁴⁵

Local Wound Infiltration

Pain can be effectively alleviated with local anesthetics; however, their clinical usefulness is limited by their relatively short duration of action. Even long-acting local anesthetics such as bupivacaine and ropivacaine have durations less than 8 to 16 hours. Wound infiltration prior to closing is a common practice for immediate short-term postoperative pain relief. Direct application of local anesthetic and opiate drugs via continuous infusion indwelling catheters provides long-term analgesia. Wound catheters are commonly placed in the subcutaneous, fascial, intraarticular, pleural, and periosteal areas. Local anesthetic systemic toxicity has not been reported.¹⁴⁹⁻¹⁵¹ Problems associated with the use of indwelling catheters are blockage or breakage, migration away from the intended area, and infection. When intraarticular bupivacaine is used in high concentrations for long periods, chondrotoxicity has been reported.¹⁵²

Sustained Release of Local Anesthetics

A sustained-release formulation of the local anesthetic bupivacaine that does not require an indwelling catheter to achieve a long duration of action is available. Bupivacaine extended-release liposome injection, Exparel, consists of bupivacaine encapsulated in DepoFoam. It provides continuous and extended postsurgical analgesia for up to 72 hours.¹⁵³ It is marketed as a 20 mL single use

vial, 1.3% (13.3 mg/mL). The maximum dosage should not exceed 266 mg (20 mL, 1.3% of undiluted drug). It is indicated for single-dose administration into the surgical site to produce postsurgical analgesia.^{154,155}

Tumescent Anesthesia

Tumescent local anesthesia (TLA) involves the use of lidocaine, sodium bicarbonate, and epinephrine diluted in normal saline to provide anesthesia for liposuction.^{156,157} The term tumescent refers to the physical appearance of tissues after the instillation of large volumes. Very low concentrations (0.05–0.1%) of lidocaine, mixed with epinephrine are used. Common preparations involve the dilution of 500 to 1000 mg to 1000 mL of normal saline. Epinephrine (0.5 mg to 1 mg), and sodium bicarbonate are added to the preparation. The volume of tumescent anesthesia solution used is determined by the achievement of palpable tumescence (uniform swelling) of the surgical field. The maximum dose of lidocaine in TLA can approach 35 to 55 mg/kg. Peak serum levels occur 12 hours postinfiltration, and complete elimination is usually within 36 hours. Strict adherence to liposuction guidelines has minimized adverse reactions from this technique.^{94,158} Specific regional anesthetic techniques and blocks are discussed in detail in [Chapters 49](#) and [50](#).

Summary

Local anesthetic techniques are becoming more commonplace in outpatient procedures, obstetrics, and pain services. A thorough understanding of the pharmacologic properties of local anesthetics is essential in order to administer and manage local, topical, and regional anesthesia appropriately. The selection of a drug with an appropriate dose, concentration, time to onset, and duration of action for a selected regional technique is critical for a clinically successful block. A thorough evaluation of the data on local anesthetic systemic toxicity has led to new insights into the clinical presentation, prevention, and treatment of this adverse event. Lipid resuscitation is expected to offer a new and efficacious approach to clinical management of this problem. Continued efforts to develop new drugs and formulations of existing agents will broaden our ability to address pain management needs.

Opioid and Non-opioid Analgesics

John J. Nagelhout

In the past, opium was used as a topical, intravenous, and inhaled analgesic. One of the earliest uses of opium is found in Greek literature dating from 300 BC. Opium sponges, referred to as *soporific sponges*, were used for the control of pain as early as the 14th century. An attempt to administer opioids by the intravenous route was attributed to Elscholtz in 1665, approximately 200 years before the invention of the syringe and needle. The first attempt to administer an opium vapor by inhalation was documented in 1778. It was not until 1853, when the syringe and needle were introduced into clinical practice by Wood, that an accurate dose of opioid could be administered intravenously.

In 1803, Sertürner reported the isolation of a pure substance from opium that he named *morphine*, after Morpheus, the Greek god of dreams. Other opium alkaloids were soon discovered—codeine by Robiquet in 1832 and papaverine by Merck in 1848. Abuse of opium and isolated alkaloids led to the synthetic production of potent analgesics. The goal of synthetic manufacture of analgesics was the creation of potent analgesics that would have high specificity for receptors, were not addictive, and were free of side effects. Synthetic production led to the development of opioid agonists, partial agonists, agonists-antagonists, and antagonists.^{1,2}

Opioids

Opioid is a term used to refer to a group of drugs, both naturally occurring and synthetically produced, that possess opium- or morphine-like properties. Opioids exert their effects by mimicking naturally occurring endogenous opioid peptides or endorphins. *Narcotic* is derived from the Greek word *narkōtikos*, meaning “benumbing,” and refers to potent morphine-like analgesics with the potential to produce stupor, insensibility, and dependence. The term narcotic is not useful in a pharmacologic or clinical discussion because of its legal connotations.

Several systems of classification are used to describe opioids. One common method divides the opioids into four categories: agonists, partial agonists, agonists-antagonists, and antagonists (Table 11.1). Another system of categorization is based on the chemical derivation of the opioids and divides them into naturally occurring, semisynthetic, and synthetic compounds, with each group having subgroups (Box 11.1).³ Other classification systems describe the drugs as either weak or strong or hydrophilic and lipophilic.

Remifentanil

The term *opioid* is derived from the word opium (from *opos*,

Greek for “sap”), an extract from the poppy plant *Papaver somniferum*. The properties of opium are attributable to the 20 different isolated alkaloids, and the alkaloids are divided chemically into two types: phenanthrene (from which morphine and codeine are derived) and benzylisoquinoline (from which papaverine, a nonanalgesic drug, is derived). Modification of the morphine molecule with retention of the five-ring structure results in the semisynthetic drugs heroin and hydromorphone. When the furan ring is removed from morphine, the resulting four-ring synthetic opioid levorphanol is formed. The phenylpiperidines (e.g., fentanyl) and the diphenylheptane derivatives (e.g., methadone) all have only two of the original five rings of the basic morphine molecular structure. A close relationship exists between the stereochemical structure and potency of opioids, with the levo-isomers being the most potent. All opioids, despite the diverse molecular structures, share an *N*-methylpiperidine moiety, which seems to confer analgesic activity.¹ Fig. 11.1 illustrates the structures of the commonly used opioids.

FIGURE 11.1 Selected opioid agonists and antagonists

used as anesthesia adjunct drugs.

Opioid drugs produce pharmacologic activity by binding to opiate receptors primarily located in the central nervous system (CNS), supraspinal and spinal; and in several peripheral sites. These include the gastrointestinal (GI) system, vasculature, lung, heart, and immune systems. Supraspinal analgesia occurs through activation of opioid receptors in the medulla, midbrain, and other areas, which causes inhibition of neurons involved in pain pathways. Spinal analgesia occurs by activation of presynaptic opioid receptors, which leads to decreased calcium influx and decreased release of neurotransmitters involved in nociception. Clinically, supraspinal and spinal opioid analgesic mechanisms are synergistic.³ This explains why opioids such as fentanyl and sufentanil produce more profound analgesia when delivered epidurally than when delivered systemically, despite the similar blood concentrations measured with both routes of administration.^{1,4}

Opiate Receptors

Opiate receptors have been DNA and amino acid sequenced and cloned. The discovery of opioid receptors can be traced back to the 1950s, when pharmaceutical companies were involved in research in anticipation of the development of an effective nonaddictive analgesic. In 1973, the examination of vertebrate species led to the discovery of three opiate receptor classes that mediate analgesia.⁵ Questions emerged as to why the receptors existed, and further research led to the hypothesis that the receptors possess endogenous functions.

After the discovery of opiate receptors in the early 1970s, the search began for endogenous substances that were their agonists. In 1975, three such agonists were identified: enkephalins, endorphins, and dynorphins.⁵ Each group is derived from a distinct precursor polypeptide and has a characteristic anatomic distribution. By the early 1980s, three precursor molecules to these agonists were identified: proenkephalin, pro-opiomelanocortin, and prodynorphin.^{1,5} Opioid peptides share the common amino-terminal sequence of Try-Gly-Gly-Phe-(Met or Leu), which has been

labeled the *opioid motif* or *message* and is necessary for interaction at the receptor site. The peptide selectivity resides in the carboxy-terminal extension, providing the address.¹ Since then, an additional precursor, pronociceptin, that results in nociceptin, has been identified. Endomorphins 1 and 2, which are agonists at μ receptors, have been identified, but the precursor's molecule has not yet been defined.³ In 1975, Hughes and Kosterlitz⁶ identified the first endogenous substance with opioid activity.

Martin et al.⁷ were the first to provide evidence for opiate receptor subtypes (Table 11.2). Their findings provided evidence for the existence of three opiate receptors: mu (μ), kappa (κ), and sigma (σ), named after their respective agonists—morphine, ketocyclazocine, and SK&F 10047. The sigma receptor was later determined not to be an opiate receptor. A delta (δ) receptor was subsequently identified. Each major opioid receptor has a unique anatomic distribution in the brain, spinal cord, and periphery.⁸ Their diversity is greatest in their extracellular loops.¹ A fourth receptor has been cloned and named opiate receptor-like (ORL1) or the nociceptin orphanin FQ peptide receptor (NOP). Because this receptor family awaits further clarification as to its role in pain signaling and does not display opioid pharmacology, discussion of this category is not included here.

TABLE 11.2

Actions Produced at Each Opioid Receptor Subtype

Effects	Mu (μ) Receptor	Kappa (κ) Receptor	Delta (δ) Receptor
IUPHAR name	MOP	KOP	DOP
Analgesia	Supraspinal, spinal	Supraspinal, spinal	Supraspinal, spinal; modulates mu-receptor activity
Cardiovascular	Bradycardia		
Respiratory	Depression	Possible depression	Depression
Central nervous system	Euphoria, sedation, prolactin release, mild hypothermia, catalepsy, indifference to environmental stimulus	Sedation, dysphoria, psychomimetic reactions (hallucinations, delirium)	
Pupil	Miosis	Miosis	
Gastrointestinal	Inhibition of peristalsis, nausea, vomiting		
Genitourinary	Urinary retention	Diuresis (inhibition of vasopressin release)	Urinary retention
Pruritus	Yes		Yes

Physical dependence	Yes	Low abuse potential	Yes
Antishivering		Yes	

DOP, Delta opiate peptide; *IUPHAR*, International Union of Basic and Clinical Pharmacology; *KOP*, kappa opiate peptide; *MOP*, mu opiate peptide.

Opioid receptors are expressed by central and peripheral neurons and by pituitary, adrenal, immune, and ectodermal cells.⁹ As noted previously, there are three main types of opioid receptors in the central nervous system, the mu, delta, and kappa receptors; the endogenous ligands for each receptor are noted in (Table 11.3)¹⁰. They are not generally selective to one receptor subtype.¹¹ Additional receptor types were proposed (sigma, epsilon, orphanin) but are no longer considered opioid receptors. They have several cellular mechanisms. There are seven transmembrane G protein-coupled receptors (GPCRs) that show 50% to 70% homology between their genes.¹² They either act to inhibit adenylyl cyclases and cyclic adenosine monophosphate (cAMP) production, or they directly interact with different ion channels in the membrane. Opioid receptors can modulate pre- and postsynaptic calcium channels, suppressing calcium influx. This causes attenuation of the excitability of neurons and/or reduces the release of pronociceptive neuropeptides. In addition, opioid receptor activation leads to opening of G protein-coupled inwardly rectifying K⁺ (GIRK) channels, thereby preventing neuronal excitation and/or propagation of action potentials.¹³

TABLE 11.3

NC-IUPHAR-Approved Nomenclature for Opioid Peptide Receptors

Current NC-IUPHAR-Approved Nomenclature	Presumed Endogenous Ligand(s)
μ, mu or MOP	β-Endorphin Enkephalins Endomorphin-1 Endomorphin-2
δ, delta or DOP	Enkephalins β-Endorphin
κ, kappa or KOP	Dynorphin A Dynorphin B α-Neoendorphin
NOP	Nociceptin/orphanin FQ (N/OFQ)

Receptors activated by opiate drugs respond physiologically to endogenous opioid peptides; they are therefore opioid peptide receptors, the receptor family being designated by the two-letter abbreviation OP. The well-established Greek

terminology for opioid receptor types using the descriptors μ , δ , and κ is recommended, but where Greek symbols are not permitted or impractical, the use of mu, delta, or kappa, or MOP, DOP, or KOP is permissible.

Adapted from Stein C. Opioid Receptors. *Annu Rev Med.* 2016;67:433–451; Cox BM, et al. Challenges for opioid receptor nomenclature: IUPHAR Review. *Br J Pharmacol.* 2015;172(2):317–323; Cox BM. Recent developments in the study of opioid receptors. *Mol Pharmacol.* 2013;83(4):723–728.

Stimulation of the mu receptor produces supraspinal analgesia, euphoria, a decrease in ventilation, and most of the classic clinical actions of the opioid agonists. Kappa receptor stimulation produces spinal analgesia, sedation, and miosis. Currently, kappa-opioid drugs are being investigated for antiinflammatory actions that reduce disease severity of arthritis and other inflammatory diseases.^{14–18} The delta receptor is responsible for spinal analgesia, responds to enkephalins, and serves to modulate activity of the mu receptors.³ Various subtypes of each of the three opiate receptors have been proposed but have not been well defined.⁸

The mechanism of action of opioid drugs is shown in Fig. 11.2. The endogenous ligands for opioid receptors are noted in Table 11.3.

FIGURE 11.2 Opioid mechanisms of action. The endogenous ligand or drug binds to the opioid receptor and

activates the G protein (3 distinct protein subunits), resulting in multiple effects that are primarily inhibitory. The activities of adenylate cyclase and the voltage-dependent Ca^{2+} channels are depressed. The inwardly rectifying K^+ channels and mitogen-activated protein kinase (MAPK) cascade are activated. *AMP*, Adenosine monophosphate; *ATP*, adenosine triphosphate; *OTFC*, oral transmucosal fentanyl citrate. (From Hemmings Jr. HC, Egan TD. *Pharmacology and Physiology for Anesthesia*. Philadelphia: Elsevier, 2013:255.)

Pharmacokinetics

Pharmacodynamic and pharmacokinetic considerations must be combined to reach an ideal analgesic clinical state. Surgical requirements for analgesic drugs are very different from nonoperative uses. These differences include a much higher analgesic requirement, the coadministration of potent anesthetic and sedative drugs, and the ability to support respirations so that respiratory depression is not an issue until the patient emerges from anesthesia.

In anesthesia, opioids are most commonly administered by the parenteral, intrathecal, and epidural routes. They may also be given by oral, nasal, intramuscular, and transdermal administration. Physicochemical properties of opioids influence their pharmacokinetics. To reach effector sites in the CNS, opioids must cross biologic membranes from the blood to receptors on neural cell membranes. The ability of opioids to cross the blood-brain and placental barriers depends on molecular size, ionization, lipid solubility, and protein binding. The physicochemical characteristics, pharmacokinetic variables, and partition coefficients (octanol and water as a measure of lipid solubility) for several of the commonly used opioid analgesics are summarized in [Table 11.4](#).

TABLE 11.4

Physicochemical Characteristics and Pharmacokinetics

Opioids	pK_a	Percent Nonionized	Protein Binding (%)	V_c (L/kg)	V_d (L/kg)	Clearance (mL/min/kg)	Elimination Half-Life (h)	Partition Coefficient (Octanol/Water)

N/A, Not applicable; V_c , volume of distribution central compartment; V_d , volume of distribution.

The wide variation in dosing of the opioids in anesthesia, depending on the patient and surgical situation, leads to vastly different durations even with the same drug. Fentanyl, for example, can last from 30 minutes to 18 to 24 hours, depending on how it is administered and how much is given. The pharmacokinetic parameters are important, but the context of how they are used in clinical practice is a major factor in the ultimate patient response.

Opioids are modestly absorbed orally. Some opioids undergo extensive first-pass metabolism in the liver, greatly reducing their bioavailability and therapeutic efficacy after oral dosing. Orally administered morphine has limited absorption from the GI tract. Drugs with greater lipophilicity are better absorbed through nasal and buccal mucosa and the skin.

When small doses of the opioids are used, the effects are usually terminated by redistribution rather than metabolism. Larger or multiple doses or continuous infusions are much more dependent on metabolism for offset.¹⁹ Like most drugs, opioids are usually metabolized in the liver to more polar and less active or inactive compounds by both phase 1 and phase 2 processes. Some opioids, such as morphine, have active metabolites such as morphine 6 glucuronide that can prolong the therapeutic effects of the parent compound. The meperidine metabolite, normeperidine, is neurotoxic and may accumulate in the elderly or in patients with decreased renal or hepatic function. This has led to a decline in its use. It is avoided in the elderly or patients with renal or hepatic dysfunction and where chronic use may be needed.¹ The opioid drugs are metabolized by the usual cytochrome enzymes, including CYP3A4, CYP2D6, and CYP2B6.^{20–22} Remifentanil was designed with an ester group in its structure and is metabolized by hydrolysis in the plasma and tissues by nonspecific esterases.

Remifentanil has a low volume of distribution and a large clearance, which results in a short half-life of approximately 10 minutes. Opioids and their metabolites are excreted primarily by the kidneys and secondarily by the biliary system and GI tract.²³ Clinicians become very adept in the art of administering opioids by bolus, incremental injection, or infusion to maximize analgesia during surgery as needed, yet allowing for safe and rapid recovery and residual postoperative analgesia.

Pharmacogenetics

The wide variations in dosing and patient responses have both pharmacodynamic and pharmacokinetic causes. Pharmacogenetics appears to be an important factor as well. Opioids have a narrow therapeutic index, calling for a fine balance between optimizing pain control and sedative effects (without respiratory depression) and recognizing great variability from patient to patient in response and dose requirements. Genetic factors regulating their pharmacokinetics (metabolizing enzymes, transporters) and pharmacodynamics (receptors and signal transduction) contribute to this variability and to the possibility of adverse drug effects, toxicity, or therapeutic failure of pharmacotherapy. Significant variation in conversion of the prodrug codeine into the active metabolite morphine has been noted.²⁴ Polymorphisms in CYP2D6 are responsible for the wide variations among different populations.²⁵

The clinical use of opioids involves knowledge regarding patient characteristics, their perception, severity, and likely duration of pain, lifestyle variables such as smoking habits and alcohol intake, and opioid drug and dosing regimen selection.²⁵ Other factors affecting pharmacokinetics and pharmacodynamics of opioids include age, body weight, renal failure, hepatic failure, cardiopulmonary bypass, acid-base changes, and hemorrhagic shock.

In adults, advancing age requires lower opioid doses for the treatment of postsurgical pain. Pediatric doses can vary widely as well. In addition, in relatively similar patient groups, dosage requirements vary. Aubrun et al.²⁶ reported that in more than 3000 patients, morphine dosage requirements for postoperative hip

replacement therapy varied almost 40-fold. Large variabilities have been reported in cancer patients receiving morphine via various routes.²⁵ Variability is contributed to by inherent pain sensitivity, tolerance, and other factors, including pharmacogenetics influencing the clinical pharmacology of opioids.^{27,28} Some pharmacogenetic influences on the clinical performance of opioids are noted in [Box 11.2](#).

Pharmacogenetics and Opiates

Cytochrome Enzyme Subtype	Clinical Outcome
CYP2D6	Codeine is a prodrug which is metabolized to its active form, morphine. Extensive metabolizers may produce dangerously high levels of morphine. See Chapter 6 . Tramadol is metabolized to its M1 metabolite which is six times more potent than the parent compound. Hydrocodone effectiveness can vary widely depending on the genetic status of the patient which influences mu receptor binding. Oxycodone has significant variation and effectiveness depending on the metabolic genotype.
CYP3A4	Fentanyl, buprenorphine and methadone metabolism vary according to the activity of this enzyme group.
CYP3B6	Women generally have a higher activity of these enzymes which may alter the metabolism of methadone and propofol.
Mu and Kappa receptor variants	Influence the dosing and efficacy of several clinical opioids.

Clinical Effects of Opioids

[Box 11.3](#) Common clinical effects of opioid agonists are listed in [Box 11.3](#).

Common Clinical Effects of Opioid Agonists

Acute	Chronic
Analgesia	Tolerance
Respiratory depression	Physical dependence
Sedation	Constipation
Euphoria	
Dysphoria	
Vasodilation	
Bradycardia	
Cough suppression	
Miosis	
Nausea and vomiting	

Skeletal muscle rigidity	
Smooth muscle spasm	
Constipation	
Urinary retention	
Biliary spasm	
Pruritus, rash	
Antishivering (meperidine only)	
Histamine release	
Hormonal effects	

Central Nervous System Effects: Analgesia, Sedation, and Euphoria

Opiate analgesia results from actions in the CNS, spinal cord, and peripheral sites (Table 11.5). They are most effective for visceral continuous dull pain; however, at high doses they will relieve any pain. They are less effective against neuropathic pain that requires chronic multimodal therapy.²⁹⁻³¹ The sedative and euphoric actions contribute to the feeling of well-being in awake patients. The analgesic effects of opioids come from their ability to (1) directly inhibit the ascending transmission of nociception information from the spinal cord dorsal horn and (2) activate pain control pathways that descend from the midbrain, via the rostral ventromedial medulla to the spinal cord dorsal horn.¹ The effect of opioids on electroencephalographic and evoked-potential activity is minimal; therefore, neurophysiologic monitoring can be conducted during opioid anesthetic techniques. The opiates can increase intracranial pressure if respiratory depression-induced hypercarbia occurs. They have variable effects on cerebral vascular tone depending on the background anesthetic present. Possible untoward CNS effects when the opioids are used in neurosurgery are easily managed by controlling ventilation and maintaining adequate blood pressures.³² The comparative potency of the opioid agonists that are used in anesthesia is as follows: sufentanil > fentanyl = remifentanyl > alfentanil.

TABLE 11.5

Opioid-Mediated Analgesia in the Central Nervous System

Central Nervous System Location	Opioid Receptor
Supraspinal	

Periaqueductal gray area	Mu = kappa > delta
Raphe nuclei	Mu = kappa > delta
Caudal linear	Kappa
Dorsal	Kappa > mu
Median	Mu > kappa
Magnus	Mu > kappa
Pallidus	Delta
Gigantocellular reticular	Mu = kappa = delta
Spinal	
Spinal cord	Mu = delta = kappa
Dorsal root ganglia	Mu = delta = kappa

The sedative and euphoric effects of the opiates vary depending on the agent. Patients will exhibit sedation and euphoria that is different with mu versus kappa agonists. Dysphoria can occur and appears more prominent with drugs that have strong kappa receptor effects or when opioids are taken in the absence of pain. Physical and psychological dependence occur with repeat administration as evidenced by physical withdrawal with abstinence and drug-seeking behaviors.^{1,33} The opiates are not anesthetics, so awareness under anesthesia is a concern when even high doses of opiates are used.^{34,35} Both acute and chronic tolerance occur with the opiates. Cross-tolerance among mu agonists will occur. Usually a decrease in duration is noted first, followed eventually by a decrease in effect. The mechanism of tolerance is complex and does not appear to be due to a change in receptor number. Receptor internalization, activation of *N*-methyl-D-aspartate (NMDA) receptors, second messenger changes, and G-protein uncoupling may all play a role. Hyperalgesia, which may result from chronic administration, may be related to these same mechanisms.^{1,33}

Respiratory Depression

All opiate agonists produce a dose-dependent depression of respirations via effects on mu and delta receptors in the respiratory centers in the brainstem. They reduce the responsiveness of the respiratory centers to increasing carbon dioxide and decreasing oxygen. It requires higher partial pressure of carbon dioxide (PCO₂) levels to maintain normal respiration. Stated in pharmacologic terms, they produce a shift to the right in the CO₂ response curve for respiration. Respiratory rate is affected first, and a classic “narcotized” patient will take slow deep breaths. As doses increase,

apnea is produced. Because both analgesia and respiratory depression are mediated via the same receptors, reversal of respiratory depression with antagonists such as naloxone also reverses analgesia. The goal of most clinical anesthetics is to leave some residual analgesia without respiratory depression upon emergence to address postoperative pain.¹

Miosis

Miosis, or pinpoint pupils, is a prominent action of opioids and is usually present under general anesthesia as a result of the high doses of high potency opiates used. Minimal tolerance develops to this effect. It is produced by effects in the pupillary reflex arc. Opiate depression of inhibitory gamma-aminobutyric acid (GABA) interneurons leads to stimulation of the Edinger Westphal nucleus, which sends a parasympathetic signal via the ciliary ganglion to the oculomotor nerve to constrict the pupil.¹ Clinicians note the degree of miosis as somewhat indicative of the presence of opiates.

Antitussive Effects

The opiates produce cough suppression via a depressant effect on the cough center in the medulla. Protective glottal reflexes are not affected. Although they all produce this effect, codeine and heroin are especially good suppressants. D-isomers such as dextromethorphan are also effective. Anesthetic use of opiates can assist the patient in tolerating airway devices and ventilators.³⁶

Nausea and Vomiting

The emetic effect of the opioids is complex. They elicit nausea and vomiting by stimulating the chemoreceptor trigger zone in the area postrema of the medulla. The dominant receptors in this area are serotonin type 3 (5-HT₃) and dopamine type 2 (D₂). A vestibular component is also probable because the incidence is much higher in ambulatory patients. Nausea and vomiting are rare in the preoperative area and operating room where patients are recumbent. A separate action with higher repeat doses can have an antiemetic effect by depressing the vomiting center. Clinically,

when opiates are used as part of the anesthetic plan, there is an increased incidence of postoperative nausea and vomiting.³⁷ The effect is less frequent with repeat doses although individual patient response is highly variable. Fig. 11.3 depicts the centers in the brain involved with nausea and vomiting and the types of receptors involved.

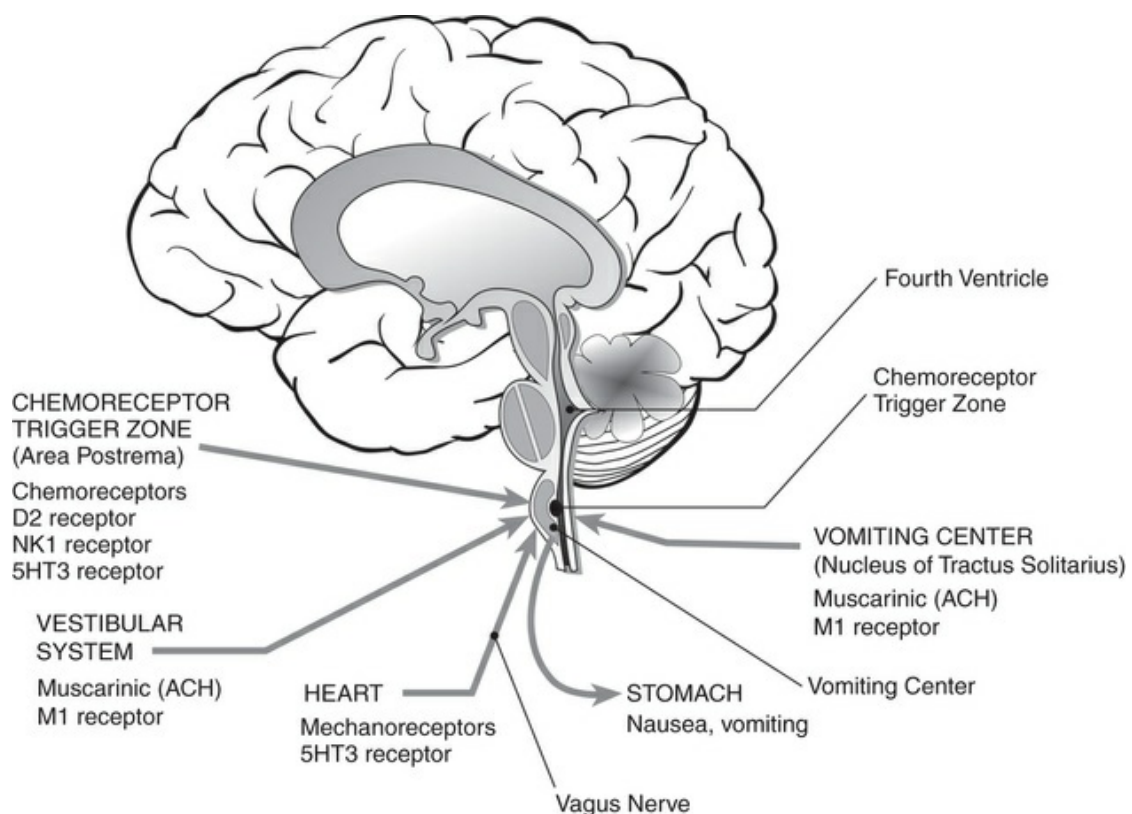

FIGURE 11.3 The vomiting center and chemoreceptor trigger zone are shown. Inputs from sites outside the central nervous system are noted. Type and location of various receptors involved in nausea and vomiting are given. Antiemetic drugs act on these receptor targets. *5HT3*, Serotonin; *ACH*, acetylcholine; *D2*, dopamine receptors; *M1*, muscarinic; *NK1*, neurokinin.

Cardiac Effects

The usual result of anesthetic use of opioids in healthy patients is bradycardia with little effect on blood pressure. Bradycardia results from medullary vagal stimulation.¹ All opioids induce some degree of dose-dependent peripheral vasodilation. Myocardial

contractility, baroreceptor function, and autonomic responsiveness are not affected. Opiate anesthesia is often used in patients with cardiovascular compromise because of this minimal depression. Much of the hypotension produced by morphine, codeine, and meperidine is attributed to histamine release, which is absent with fentanyl, sufentanil, alfentanil, and remifentanil. Histamine₁ and histamine₂ antagonists, when combined, block the cardiovascular effects of vasodilation, tachycardia, and hypotension that results.¹⁹

Opioids usually produce an antidiuretic effect. Opioids that are agonists at kappa receptors can cause diuresis. They decrease tone at the bladder detrusor muscle and constrict the urinary sphincter. This results in urinary retention. Urinary retention is a common side effect with intrathecal and epidural opioid administration.

Muscle Rigidity

Opioids have no major effects on nerve conduction at the neuromuscular junction or at the skeletal muscle membrane. A generalized hypertonus of skeletal muscle can be produced by large intravenous doses of most opioid agonists. Although morphine can produce rigidity, the problem is most often associated with fentanyl, alfentanil, sufentanil, and remifentanil. The difficulty is caused in part by loss of chest-wall compliance and by constriction of pharyngeal and laryngeal muscles. It becomes very difficult to ventilate the patient unless the rigidity is reversed. It is commonly referred to as *tight chest* or *truncal rigidity*. This effect most often occurs during anesthesia induction when high doses of potent opiates are administered rapidly. Remifentanil, which is administered by infusion, may be especially prone to producing this effect. Administration of nitrous oxide also increases the frequency.³⁸ Opioid-induced muscle rigidity is thought to be mediated by central mu receptors interacting with dopamine and GABA pathways. This rigidity is easily reduced or eliminated by the administration of muscle relaxants or naloxone.³⁹

Pruritus

Opiates frequently produce a rash, itching, and a feeling of warmth in the “blush” area of the face, upper chest, and arms. This occurs

with both histamine and nonhistamine-releasing drugs and is especially prominent with neuraxial administration. The mechanism appears to be through central mu receptors and not local histamine release.⁴⁰ Pruritus can be treated with antagonists such as naloxone or naltrexone; however, they also reverse analgesia. Nalbuphine, droperidol, antihistamines, and ondansetron may also be effective. Many clinical pain services have established protocols to treat this problem.^{41,42} The mixed mu/kappa opioid partial agonists seem to be the most effective drugs in relieving neuraxial opioid-induced itch while retaining analgesia.⁴³ In a 2016 review it was noted that nalbuphine is superior to placebo, diphenhydramine, naloxone, or propofol in treating opioid-induced pruritus and should be used as a first-line treatment.⁴⁴

Gastrointestinal Effects

Opioids have multiple effects on the gastrointestinal (GI) function. They decrease gastric motility and intestinal propulsive activity, prolong gastric emptying time, and reduce secretory activity throughout the GI system. This leads to the common problems of opiate-induced constipation and postoperative ileus. Alvimopan (Pamora), methylnaltrexone (Relistor) and naloxegol (Movantik) are locally acting opiate receptor antagonists approved for use in treating these GI side effects. They do not cross biological compartments due to solubility barriers and therefore work locally in the GI system but do not affect centrally produced analgesia.^{45,46} Lubiprostone (Amitiza), a bicyclic fatty acid which activates intestinal chloride channel-2 (ClC-2) in the small intestine, helps to increase fluid secretion and gut motility.⁴⁷⁻⁴⁹

Opioids produce a dose-dependent increase in biliary duct pressure and sphincter of Oddi tone via opioid receptor-mediated mechanisms. They also increase urinary sphincter tone. This has led to a few clinical concerns. The use of opiates for the treatment of biliary or renal colic may be compromised by this action. Meperidine, which produces this effect the least among opiate agonists or nonsteroidal antiinflammatory drugs (NSAIDs), is considered the agent of choice for this situation.⁵⁰ In anesthesia, the use of opiates during surgery may produce false positive

cholangiograms. The clinical relevance of this effect is questionable because the opiates are used routinely without problems.

Endocrine Effects

Opiates reduce the stress response to surgery and have an immunosuppressant effect.³ Endocrinologic effects of opioids include the release of vasopressin and inhibition of the stress-induced release of corticotropin and gonadotropins from the pituitary. Release of thyrotropin from the adrenohypophysis is also inhibited. Basal metabolic rate and temperature may also be decreased in patients receiving chronic opioids, although animal data indicate that acute administration can either systemically or intrathecally increase temperature. Opioids slightly decrease body temperature by resetting the equilibrium point of temperature regulation in the hypothalamus.¹

Opioids and Cancer

Although controversial, mounting data have implicated inhalational anesthesia and opioid analgesia as independent risk factors for cancer recurrence and, conversely, local-regional anesthesia and propofol-based total intravenous anesthesia as having potential “chemopreventative” effects. The immune system plays an important role in controlling cancer. Factors that influence protective antitumor immunity have a significant impact on the course of malignant disease. Opioids are essential for the management of cancer pain, and preclinical studies indicate that opioids have the potential to influence tumor immune surveillance mechanisms. It has been suggested that opioids have a protumor action and may have negative effects on cancer survival. This is due to actions that may promote cancer cell proliferation and migration, immune depression, and angiogenesis or neovascularization. Opioids also inhibit the function of natural killer cells. A definitive conclusion has not been reached. Opioid type and dose, and the underlying disease pathology and organs involved are important factors.⁵¹⁻⁵³ See [Table 46.8](#) for the effects of anesthesia on cancer recurrence.

Neuraxial Effects

The epidural and intrathecal routes have become common for the administration of pain medication. Opioids delivered by epidural or subarachnoid routes behave differently in onset, duration, and side effects than the same drugs given systemically. Pain that is unresponsive to systemic opioids may respond to the same drugs given centrally, reducing some side effects while increasing the incidence of others. Systemic opioids suppress nociception in lamina II and V cells of the dorsal horn of the spinal cord, leaving lamina IV and VI cells, which mediate nonnociceptive information, relatively unaffected.⁵⁴

Spinal administration of opioids is a selective and potent means of producing analgesia. Intrathecal administration allows injection of the opioids directly into the cerebrospinal fluid (CSF), a more efficient method of delivering the drug to the spinal cord opiate receptors. The analgesic response is the result of activity at spinal opiate receptors, especially kappa receptors in the substantia gelatinosa, lamina II of the dorsal horn.⁵⁴ Opioids can be given with local anesthetics or other adjuncts intraoperatively at the initiation of spinal anesthesia or postoperatively for pain control.⁵⁵ Side effects with spinal administration are similar to those described previously with systemic administration, except that pruritus and urinary retention occur with much greater frequency. Less lipid-soluble agents such as morphine and hydromorphone produce a delayed ventilatory depression, the result of migration of opioid via the CSF to the midbrain vestibular centers.

Respiratory depression is the most common serious complication associated with intrathecally and epidurally administered opioids. Two different levels of respiratory depression can occur after neuraxial morphine administration. An early phase observed soon after administration reflects rapid systemic absorption and is similar to parenteral dosing. A later, more insidious depression that occurs over a period of 8 to 12 hours has been related to rostral flow of CSF and delivery of morphine to the brainstem respiratory center.⁵⁶ Awareness of delayed respiratory depression has resulted in increased monitoring of patients and dose reductions, thereby greatly reducing the incidence of serious respiratory depression to that seen with patient-controlled analgesia (PCA) opioids.

Generalized pruritus has been observed with neuraxial morphine and to a lesser extent with other opioids. Mild itching, usually involving the face or chest, is common; however, the intensity of itching can become so annoying that it interferes with sleep. Pruritus is commonly seen with opioids that do not release histamine, such as fentanyl and sufentanil. Pruritus can be treated with antihistamines or with opiate receptor partial agonists or antagonists. The incidence of postoperative nausea and vomiting increases for patients treated with neuraxial opioids. Nausea may result either from the rostral spread of the drug in the spinal fluid to the brainstem or vascular uptake and delivery to the chemoreceptor trigger zone in the area postrema of the medulla.

Urinary retention after spinal opioid analgesia has been related to inhibition of sacral parasympathetic outflow, which results in relaxation of the bladder detrusor muscle and an inability to relax the sphincter.⁵⁴

Opioids with a higher lipid solubility (see [Table 11.4](#)) tend to be rapidly absorbed into the spinal tissues after central administration, resulting in a faster onset of action. However, higher lipid solubility is associated with a small area of distribution of the drug along the length of the spinal cord and therefore a more limited area of analgesia.⁴ Higher lipid solubility is also associated with faster clearance of the drug out of the epidural and intrathecal space, resulting in a shorter duration of action and higher blood concentrations of the opioid.^{54,56} Spinal opioids are advantageous in selective analgesia, which occurs in the absence of motor and sympathetic blockade.

Epidural anesthesia and analgesia have been successfully used in obstetric patients and surgical patients. Epidural doses of opioids, however, are much higher than doses of opioids for intrathecal use. Small portions of epidural opioids cross the dura, enter the CSF, and penetrate spinal tissue in amounts proportional to their lipid solubility. The remaining drug is absorbed by the vasculature, producing plasma levels comparable to those after intramuscular injections and providing supraspinal analgesia.⁵⁶ Neuraxial administration of opioids is a selective and potent means of producing analgesia in many surgical and obstetric procedures.⁵⁷ [Table 11.6](#) gives neuraxial opioid dosages.^{54,56}

TABLE 11.6**Doses of Neuraxial Opioids***

Opioid	Single Dose	Infusion Rate
Epidural		
Morphine	2–5 mg	0.1–1 mg/h
Meperidine	25–50 mg	5–20 mg/h
Methadone	5 mg	0.3–0.5 mg/h
Fentanyl	50–100 mcg	25–100 mcg/h
Sufentanil	25–50 mcg	10–50 mcg/h
Butorphanol	2–4 mg	0.2–0.4 mg/h
Subarachnoid		
Morphine	0.25–0.3 mg	
Meperidine	10 mg	
Fentanyl	10–20 mcg	
Sufentanil	5–10 mcg	

*Doses adjusted for age and level of regional injection.

Opioid Techniques and Delivery

In clinical practice, opioids are used to relieve pain during monitored anesthesia care, regional anesthesia, and as a component of balanced anesthesia, as well as a primary component of general anesthesia. The inclusion of opioids reduces pain and anxiety, decreases somatic and autonomic responses to airway manipulation, improves hemodynamic stability, lowers requirements for inhaled anesthetic agents, and provides postoperative analgesia.⁵⁸

The most common method of administering opioids in the practice of anesthesia is intermittent bolus injection, which although effective for many procedures, produces wide swings in drug plasma concentration. Intermittent periods of deep and light anesthesia are produced. Continuous opioid infusion results in plasma concentration that can be maintained more accurately and consistently. Continuous infusion of opioids is associated with hemodynamic stability, reduces the total necessary dose of opioids, and decreases the need for opioid reversal agents.

Continuous intravenous administration involves the infusion of a loading dose that “fills” the volume of distribution, followed by continuous drug replacement that keeps the volume of distribution “filled” as the drug is eliminated.⁵⁹

$$\text{Loading dose (mcg/kg)} = V_d \text{ (mL/kg)} \times C_p \text{ (mcg/mL)}$$

$$\text{Loading dose (mcg/kg)} = V_d \text{ (mL/kg)} \times C_p \text{ (mcg/mL)}$$

where V_d is volume of distribution, C_p is plasma concentration, and Cl is drug clearance. See [Table 11.4](#) for the V_d and Cl of various opioids.

The rate of continuous infusion does not remain constant, but rather is adjusted to meet the patient's needs and to control varying surgical stimuli. The volume of distribution is decreased for patients with hypovolemia and trauma and for geriatric patients. Factors such as enzyme induction, hepatic failure, and adjunctive drug use are also considered. [Table 11.7](#) provides dose ranges for continuous infusions.

TABLE 11.7
Infusion Rates*

Opioid	Induction (mcg/kg)	Maintenance (mcg/kg per min)
Fentanyl	5–10	0.01–0.05
Sufentanil	1–30	0.005–0.015
Alfentanil	8–100	0.5–3
Remifentanyl	0.5–1	0.05–2

*Doses will vary depending on coadministered drugs, patient characteristics, and surgical procedure.

Continuous intravenous infusion can be administered by gravity flow with a manual control device (e.g., Buretrol), an infusion pump, or a syringe pump. Syringe pumps are advantageous because they are programmed to administer drug in units of micrograms per kilogram per minute. Some advantages of

[Box 11.4](#) Continuous infusion techniques are listed in [Box 11.4](#).

Advantages of Continuous Opioid Infusion

- Hemodynamic stability
- Decreased side effects

- Reduced need for opioid-reversal agents
- Reduced use of vasopressor drugs
- Suppression of cortisol and vasopressin response to cardiopulmonary bypass: stress-free anesthesia
- Reduced total dosage of opioids
- Decreased recovery time

Nonparenteral routes of opioid delivery are also used. Fentanyl is the prototypic opioid for transdermal application. Transdermal administration of fentanyl does not require cooperation from the patient; also in addition, first-phase hepatic metabolism is not a factor, and the route does not produce discomfort. Currently available formulations permit delivery of 25 to 100 mcg per hour for 24 to 72 hours. The transdermal fentanyl patch provides a relatively constant plasma concentration for 72 hours. It is not currently recommended for use in managing postoperative pain.

Rapid-onset opioids provide new options for effective management of pain. There are various formulations of transmucosal immediate-release fentanyl and, although they were originally developed and approved for use in children before painful procedures, are now used in opioid-tolerant adult patients with breakthrough cancer pain. The formulation options include oral lozenge, buccal tablet, buccal film, sublingual tablet, nasal spray, and a sublingual spray; each has practical considerations that vary with the product and route of administration.^{60,61} All have the common advantage of rapid entry into the systemic circulation via transmucosal absorption, avoiding hepatic and intestinal first-pass metabolism and allowing a rapid onset of action that rivals intravenous injections. A high incidence of pruritus is a problematic side effect with transmucosal administration. Fentanyl buccal tablet (FENTORA) is indicated for the management of breakthrough pain in cancer patients who are tolerant to 60 mg or greater of oral morphine equivalents.⁶²

The Food and Drug Administration (FDA) has approved a nasal spray formulation of fentanyl (Lazanda) for management of

breakthrough pain in adult cancer patients who are already receiving and are tolerant to opioid therapy. Nasal administration of sufentanil preoperatively in the pediatric patient has also been studied. The children remained calm, and some experienced somewhat decreased ventilatory compliance. Recovery room time was not increased, and the highest incidence of nausea and vomiting occurred in the group that received the highest dose of sufentanil. Nasal butorphanol is currently available and is widely used in the management of migraine headaches. [Table 11.8](#) compares dosages for various routes of opioid administration.⁶³

TABLE 11.8
Opioid Dose Comparisons

Opioid	Route	Onset	Peak	Duration of Action	Half-Life
Morphine	PO	60 min	30–60 min	4–5 h	Neonates 4.5–13 h
	IM	30–60 min	30–60 min	4–5 h	Adults 3–5 h

Individual Opioids

Agonists

Naturally Occurring Opioids

Morphine.

Morphine, the prototype for opioid agonists, is the most abundant alkaloid in raw opium. The primary therapeutic use of morphine is the abatement of moderate to severe pain. It is more effective in relieving continuous dull pain than sharp intermittent pain. Morphine can be administered via the intramuscular, intravenous, subcutaneous, oral, intrathecal, and epidural routes. Effects of intravenous morphine on the time course of sedation and analgesia occur with sedation first, followed by analgesia.⁶⁴ Morphine-induced sedation, therefore, should not be considered as an indicator of appropriate analgesia. When given intrathecally, morphine has the longest duration of action of the specific opioids. Morphine is among the least lipophilic of the opioids, resulting in slow penetration of biologic membranes, less accumulation in lipid membranes or fatty tissues, and slower onset.

Morphine undergoes phase 2 glucuronide conjugation in the liver at both the 3 position (which produces morphine-3-glucuronide, M3G) and the 6 position (which produces morphine-6-glucuronide, M6G).⁶⁵ As a result of the active metabolite, M6G, morphine appears to produce a more prolonged effect, often excessive sedation, in the patient with renal failure. Within the CNS, M6G metabolite is more potent than the parent drug, whereas M3G metabolite is inactive.^{65,66} The greater hydrophilicity of M6G than the parent drug normally impedes its passage into the CNS. However, after chronic administration or in patients with renal failure, M6G, at a high blood level, can enter the CNS.

Morphine produces a nonimmunologic release of histamine from tissue mast cells, resulting in local itching, redness, or hives near the site of intravenous injection or generalized flushing. When sufficient histamine is released, the patient may exhibit signs of decreased systemic vascular resistance, hypotension, and

tachycardia. Localized histamine release after a morphine injection is not uncommon. Morphine is primarily used for preoperative or postoperative pain relief. The delayed onset and peak effects and large patient variability make it less useful for intraoperative use than fentanyl and its analogs.

Codeine.

Considered a weak opioid, codeine is generally not used for treatment of severe pain. Approximately 10% of the administered dose of codeine is O-demethylated to morphine, which accounts for most of its analgesic activity.⁵⁷ It has good antitussive activity, but on a weight basis, codeine is a less potent antitussive than morphine. Combinations of codeine with acetaminophen remain very popular as prescribed analgesics. Codeine toxicity due to extensive conversion of the prodrug into morphine is discussed in the pharmacogenetics section and in [Chapter 6](#).

Semisynthetic Opioids

Hydromorphone.

Derived from morphine in the 1920s, hydromorphone has a pharmacokinetic profile similar to that of morphine but it is more potent. Hydromorphone is absorbed from the oral, rectal, and parenteral sites. Because of its lipid solubility, it is sometimes used instead of morphine for epidural or spinal administration when a wide area of analgesia is needed.⁶⁷ Studies performed on parenteral hydromorphone relative to morphine tend to demonstrate similar analgesia and side-effect profiles. Because of the lack of any known active metabolites, it is often recommended for patients with renal failure.¹ It is available in high potency and sustained release preparations.

Synthetic Opioids

Methadone.

Introduced in the 1940s, methadone is used primarily for relief of chronic pain, treatment of opioid abstinence syndromes, and

treatment of heroin addiction. Compared to other common opioids, it is well absorbed orally and produces less euphoria. Supplied as a racemic mixture of two optical isomers, most of methadone's activity comes from the l-isomer. Unlike most opioids, it has a long half-life, allowing for less frequent dosing. It has a prolonged effect in part due to extensive protein binding (90%) with slow release and a lower intrinsic ability of the liver to metabolize it. It also has the advantage of a high bioavailability and no active metabolites. Disadvantages include accumulation and a longer time to reach steady state than other opioids.⁶⁸

Meperidine.

Meperidine is a synthetic mu-receptor agonist. It is structurally similar to atropine and has an atropine-like antispasmodic effect. After demethylation in the liver, meperidine is partially metabolized to normeperidine, which is half as analgesic as meperidine but lowers the seizure threshold and induces CNS excitability. Normeperidine's elimination half-life is significantly longer than that of meperidine. With accumulation of normeperidine, subjects may experience a CNS excitation characterized by tremors, muscle twitches, and seizures. Because of accumulation of normeperidine, limitations on its use should be considered in patients with renal failure and for chronic use in cancer patients who may require high doses. There is a significant drug interaction that can occur between meperidine and the first-generation monoamine oxidase (MAO)-inhibiting drugs isocarboxazid (Marplan, others), phenelzine (Nardil, others), and tranylcypromine (Parnate, others). Hyperthermia, seizures, and death have been reported.⁶⁰⁻⁷¹ See [Chapter 14](#) for further discussion of meperidine drug interactions.

Meperidine is effective in reducing shivering from diverse causes, including general and epidural anesthesia.⁷² This appears to result from kappa receptor stimulation. It reduces or eliminates visible shivering, as well as the accompanying increase in oxygen consumption.³³ Anesthetic uses of meperidine have declined in recent years due to the availability of safer, more convenient techniques.

Alfentanil.

After bolus injection, alfentanil has a more rapid onset of action and shorter duration than fentanyl, even though it is less lipid soluble. The high nonionized fraction (90%) of alfentanil at physiologic pH and its small volume of distribution increase the amount of drug available for binding in the brain. Although alfentanil is effective epidurally, the duration of analgesia is short, and for this reason, it has never achieved popularity. Alfentanil is metabolized in the liver by oxidative N-dealkylation and O-demethylation in the cytochrome P-450 system, and the inactive metabolites are excreted in the urine. Alfentanil has great patient-to-patient variability, as seen in the original studies, in which a high coefficient of variation was reported. Erythromycin has been shown to prolong the metabolism of alfentanil and interact with alfentanil to produce clinical symptoms of prolonged respiratory depression and sedation. Its popularity in current practice is limited.

Fentanyl.

Fentanyl is the most widely used opioid analgesic in anesthesia. A single administered dose of fentanyl has a short duration of action (approximately 20 to 40 minutes). It produces a profound dose-dependent analgesia, ventilatory depression, and sedation. The action of a single dose of fentanyl is terminated by redistribution. The high lipid solubility of fentanyl allows for rapid tissue uptake.¹⁹ Fentanyl and its derivatives all undergo significant first-pass uptake in the lungs with temporary accumulation before release. When fentanyl is given in multiple doses or as a continuous infusion, the termination of action reflects elimination but not redistribution. Clearance of fentanyl is dependent on hepatic blood flow. Fentanyl is metabolized by N-dealkylation and hydroxylation to inactive metabolites that are eliminated in urine and bile. Fentanyl elimination is prolonged in the elderly and the neonate.

Initially used intravenously during surgery, fentanyl has many other uses. It is administered for intrathecal, epidural, and postoperative PCA intravenous use. Fentanyl transdermal patches deliver 75 to 100 mcg/h, resulting in peak plasma concentrations in approximately 18 hours because a subcutaneous depot of drug must be saturated before the drug is consistently absorbed into the

bloodstream.¹⁹ The dose remains stable during the presence of the patch. After removal, the decline in blood concentration follows an apparent 17-hour half-life; the true elimination half-life of fentanyl remains at approximately 3 hours, but continued absorption from the subcutaneous depot during elimination makes it appear longer.

Remifentanil.

Remifentanil use in anesthesia has increased tremendously as new applications are being discovered for its unique profile.^{73,74} Its rapid onset and ultra-short duration, titratability, and simple metabolism make it very convenient for many modern clinical perioperative situations. Remifentanil is a moderately lipophilic, piperidine-derived opioid with an ester link. The addition of the ester group allows the drug to be easily and rapidly metabolized by blood and tissue esterases. Kinetic studies indicate that the drug has a small volume of distribution (V_d 0.39 ± 0.25) and an elimination half-life of 8 to 20 minutes. It is metabolized by hydrolysis catalyzed by general esterase enzymes to a less active compound. It is not dependent on cholinesterase enzyme for metabolism and therefore is not influenced by quantitative or qualitative changes in cholinesterase. Succinylcholine metabolism does not influence remifentanil breakdown.

Because of the potential for respiratory depression and muscle rigidity, bolus dosing in the preoperative or postoperative care unit is not recommended. Due to its unique metabolic pathway, remifentanil has a short duration of action, a precise and rapid titratable effect because of rapid onset, and noncumulative effects and results in rapid recovery after discontinuation of its administration by infusion. However, because of the rapidity of emergence from remifentanil anesthesia, it is important to develop and start a plan for alternative analgesic therapy in the postoperative period.⁷⁵

The commercial preparation of remifentanil is a water-soluble, lyophilized powder that contains a free base and glycine as a vehicle to buffer the solution. Because of potential glycine neurotoxicity, remifentanil should not be administered epidurally or intrathecally.¹

Sufentanil.

Sufentanil is the most potent of the phenylpiperidines and is used for situations in which profound analgesia is required, such as in cardiac or other major surgical procedures. The patients are usually in-hospital patients requiring significant analgesia and postoperative care. Sufentanil is a mu agonist that produces effective analgesia via both the intravenous and intrathecal routes. It has a high lipophilicity and potency and a shorter elimination half-life than fentanyl. Hepatic clearance of sufentanil approaches liver blood flow. Sufentanil metabolism involves O-demethylation and N-dealkylation, with minimal amounts being excreted unchanged in the urine.

The effects of age on the distribution and elimination of sufentanil are reflected in a decrease in the initial volume of distribution for the elderly. The reduced volume of distribution of sufentanil in elderly patients is associated with increased respiratory depression.

Tramadol.

Tramadol is a synthetic codeine analog that is a weak mu opioid receptor agonist, with analgesic effects produced by inhibition of norepinephrine and serotonin neuronal reuptake as well as presynaptic stimulation of 5-hydroxytryptamine release. Tramadol is a racemic mixture; the (+) enantiomer binds to the mu receptor and inhibits serotonin uptake, whereas the (-) enantiomer inhibits norepinephrine uptake and stimulates α_2 -adrenergic receptors. It has an elimination half-life of 5 to 6 hours and is an effective analgesic for the treatment of mild to moderate pain. Tramadol can cause seizures and possibly exacerbate them in patients with predisposing factors. Tramadol-induced analgesia is not entirely reversed by naloxone, but tramadol respiratory depression can be reversed. In overdose situations, most of the toxicity is related to the amine uptake inhibition rather than to opioid effects.¹

Partial Agonists and Agonists-Antagonists

Buprenorphine.

Buprenorphine, a synthetic derivative, is a potent partial agonist opioid that binds mainly to the mu receptors.⁷⁶ Its slow dissociation from the receptor is a result of its long duration of action (approximately 8 hours). Its high affinity for the mu receptor accounts for the reduced ability of naloxone to reverse the effects of buprenorphine. Clinically significant respiratory depression can occur with therapeutic doses. Buprenorphine exhibits a ceiling effect in which an increase in the dose does not increase respiratory depression; this is believed to result from the fact that the drug's antagonistic effects become more apparent at higher doses. It also has minimal effect on GI motility and smooth muscle sphincter tone. A transdermal system of buprenorphine was developed for treatment of moderate to severe cancer pain.⁷⁷ Administered transdermally, it provides analgesia and has a low incidence of adverse events.

Butorphanol.

Butorphanol, a highly lipophilic opioid, acts as an agonist at the kappa receptors and as a weak antagonist at mu receptors. It is more potent than morphine in the production of analgesia. It produces respiratory depression, but its ceiling effect is below that of mu agonists. Intranasal butorphanol is used for the treatment of migraine headaches and postoperative pain. Butorphanol has also been studied for epidural use, although it tends to produce significant sedation. It has been shown to be effective in the treatment of postoperative shivering, but the mechanism of this effect is unknown.

Nalbuphine.

Nalbuphine has the ability to reverse respiratory depression that results from opioid use and to maintain analgesia. Nalbuphine acts as both an agonist and an antagonist at the opioid receptors. Nalbuphine's analgesic response is equal to that of morphine. Nalbuphine provides an agonist effect at the kappa receptors and an antagonist effect at the mu receptors. A ceiling effect for respiratory depression and difficulty with reversal with naloxone has been demonstrated with both nalbuphine and butorphanol.⁷⁸ Nalbuphine has been used to antagonize pruritus induced by

epidural and intrathecal morphine. Nalbuphine effectively antagonizes fentanyl-induced respiratory depression, maintains analgesia, and does not produce adverse circulatory changes.

Antagonists

Naloxone.

Naloxone, an oxymorphone derivative, is a pure opioid antagonist. Naloxone blocks the opioid receptor sites and reverses respiratory depression and opioid analgesia. The reversal of respiratory depression and analgesia occurs as a result of competitive antagonism at the mu, kappa, and delta receptors. The duration of action of naloxone is less than that of most opioid agonists, allowing the return of respiratory depression in some patients treated with naloxone. Naloxone is effective only when it is administered intravenously or intramuscularly.

Naloxone may antagonize intrinsic analgesic systems, as evidenced by its ability to blunt the placebo effect and inhibit the analgesia of electroacupuncture. Studies have demonstrated that naloxone's effect on reversing the effects of morphine is, in fact, titratable. Administration of low doses of naloxone can reverse the side effects of epidural opioids while preserving some of the analgesic effects.

The effects of naloxone use range from discomfort to pulmonary edema to sudden death. Pulmonary edema after naloxone administration has been observed in patients with a documented history of cardiovascular disease. Prough et al.⁷⁹ reported two cases of acute onset of pulmonary edema in young male patients who received either 100 or 200 mcg of naloxone. The report discusses the ability of naloxone to inhibit endogenous pain suppression pathways and to allow unopposed noradrenergic transmission from medullary centers that can produce neurogenic pulmonary edema. Neurogenic pulmonary edema results from an increase in catecholamine levels in healthy patients, as well as in patients with a history of cardiovascular disease. Cautious titration of naloxone is of paramount importance. Andree⁸⁰ reported two cases of sudden death after naloxone administration. This study suggests that naloxone produces increases in blood catecholamine levels that

predispose patients to ventricular fibrillation and subsequent cardiac arrest.

Naloxone is undergoing renewed interest as a rescue drug for opioid overdose. The recent increase in deaths from opioid overdose has led to new formulations and delivery vehicles which can be used by first responders and friends and relatives of intravenous drug abusers. The FDA has approved an intranasal formulation of naloxone (Adapt) for emergency treatment of opioid overdose. It is also available as an autoinjector formulation (Evzio) for intramuscular or subcutaneous administration.⁸¹

Nalmefene.

Structurally similar to naloxone, nalmefene (Revex) is a long-acting parenteral opioid antagonist. It has an elimination half-life of approximately 10 hours (compared with naloxone's half-life of 1 hour) and a duration of action of 8 hours when it is given in the usual doses.⁸² The clinical effects of nalmefene are similar to those of naloxone.

Reversal of postoperative respiratory depression is accomplished with the administration of nalmefene 0.1 to 0.5 mcg/kg titrated at 2- to 5-minute intervals. In acute opioid overdose, it is recommended that 0.5 to 1.6 mcg be given intravenously. Administration of doses higher than 1.6 mcg does not elicit additional effects and is not recommended. As with all antagonists, slow titration of small doses may minimize side effects. As with naloxone, nalmefene should not be administered to opioid-dependent patients.⁸³

Naltrexone.

As a synthetic congener of oxymorphone, naltrexone has antagonist and receptor-binding properties similar to those of naloxone but higher oral efficacy and longer duration of action. Its activity is the result of both the parent drug and its 6-beta metabolite. The parent and metabolite have half-lives of 6 and 13 hours, respectively. Naltrexone has a duration of action of approximately 24 hours. An extended release formulation is routinely used in alcohol withdrawal programs.⁸⁴

Naltrexone is administered to patients addicted to opioids so that the euphoric effects of opioids can be prevented. When doses

greater than 100 mg are administered to the opioid-addicted patient, plasma concentrations are reached within 2 hours, and the agent's half-life is approximately 10 hours. Naltrexone produces an active metabolite with a half-life even longer than that of naltrexone.¹

Non-Narcotic Analgesics

The nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen (paracetamol outside the United States) are primarily used in anesthesia as postoperative pain medications. Aspirin is used as an antiplatelet drug for cardiac patients and is rarely given as an analgesic. They are effective for mild to moderate pain. Acetaminophen, ibuprofen, and ketorolac are available as intravenous preparations and are used for select intraoperative and postoperative applications. The mechanism of both the NSAIDs and acetaminophen is inhibition of the cyclooxygenase enzymes, which prevents the production of prostaglandins and thromboxanes. Some important differences exist. The NSAIDs are analgesic, antipyretic, and antiinflammatory, whereas acetaminophen is analgesic and antipyretic, but only minimally antiinflammatory. In anesthetic uses more than one or two doses are rarely given so many of the adverse effects of chronic administration are not a concern.^{85,86} Table 11.9 lists the doses of the commonly used oral NSAIDs.

TABLE 11.9
Commonly Used Oral Nonsteroidal Anti-Inflammatory Drugs

Generic name	Trade name	Adult dosage
Acetaminophen	Tylenol	500–1000 mg q 4 h
Acetylsalicylic acid	Aspirin	325–650 mg q 4 h
Celecoxib	Celebrex	200 mg q 12 h
Choline magnesium trisalicylate	Trilisate	500–750 mg q 8–12 h
Diclofenac sodium	Voltaren	25–75 mg q 8–12 h
Diflunisal	Dolobid	250–500 mg q 8–12 h
Etodolic acid	Lodine	200–400 mg q 6 h
Fenoprofen calcium	Nalfon	200 mg q 4–6 h
Flurbiprofen	Ansaid	100 mg q 8–12 h
Ibuprofen	Motrin	400–800 mg q 6–8 h
Indomethacin	Indocin	25–50 mg q 8–12 h
Ketoprofen	Orudis	25–75 mg q 6–8 h
Ketorolac	Toradol	10 mg q 6–8 h

Meclofenamate sodium	Meclomen	50 mg q 4–6 h
Meloxicam	Mobic	7.5–15 mg QD prn
Naproxen	Naprosyn	275–500 mg q 8–12 h
Phenylbutazone	Butazolidin	100 mg q 6–8 h
Piroxicam	Feldene	10–20 mg once daily
Salsalate	Disalcid	500 mg q 4 h
Sulindac	Clinoril	150–200 mg q 12 h
Tolmetin	Tolectin	200–600 mg q 8 h

Ketorolac.

Ketorolac (Toradol) is an intravenous NSAID that has been used for many years in anesthesia. It is very effective for mild to moderate pain. It can be administered via both intramuscular and intravenous routes. The primary advantages over the opioids are the very low incidence of nausea and vomiting and lack of respiratory depression. It is frequently given near the end of surgical procedures such as laparoscopy to provide postoperative analgesia. It is also used for minor procedures where avoiding opioids is desirable. The usual dose is 30 to 60 mg either intramuscularly (IM) or intravenously (IV). The onset is 30 minutes and the duration of action is 4 to 6 hours.⁸⁷ It should not be used in atopic or asthmatic patients, in the elderly, or in patients with renal or GI dysfunction or bleeding disorders.

Bone healing is delayed by the NSAIDs and many clinicians do not use them as analgesics in orthopedic procedures. Prolonged administration of NSAIDs has been shown to interfere with a successful bone healing response, but prevailing evidence supports the view that NSAID administration is safe in the setting of anticipated primary bone healing (absolute stability) and during the first week of healing via callous formation (secondary bone healing). NSAIDs inhibit bone formation via blockage of mesenchymal stem cells chondrogenic differentiation, which is an important intermediate phase in normal endochondral bone formation.⁶⁴ Bleeding may also be a problem in intracranial surgery.^{88,89}

Ibuprofen.

An intravenous formulation of ibuprofen (Caldolor) is available as

an analgesic and antipyretic. Its clinical effects are similar to ketorolac. The usual dose is 400 to 800 mg IV over 30 minutes. Onset is 30 minutes and duration is 4 to 6 hours.^{90,91} Contraindications and precautions are similar to ketorolac.

Acetaminophen.

Acetaminophen (Ofirmev) is available as an IV analgesic and antipyretic drug for use in both adults and children over 2 years old. It also has a significant opiate sparing effect. Acetaminophen does not exhibit the significant GI and cardiovascular side effects associated with NSAIDs. The dose in patients over 13 years old is 1000 mg infused over 15 minutes. The dose in children is 15 mg/kg. Onset is approximately 10 minutes with a peak effect in 1 hour. The duration of action is 4 to 6 hours.^{92,93} Side effects are rare. Hepatotoxicity is a concern with acetaminophen but not expected with doses less than 4000 mg/day.

Summary

Opioids are a group of drugs that bind to receptor sites in the CNS, supraspinal and spinal, and at peripheral sites, producing morphine-like effects. Opioid analgesia results from the inhibition of nociceptive reflexes and the release of neurotransmitters. Because of their multiplicity of sites and mechanisms of action, opioids are a uniquely valued means for analgesia and anesthesia. Opioids are used for preoperative medication, as induction agents, as maintenance anesthetics, and for treatment of postoperative pain. The newer methods of opioid delivery have been growing in popularity. Opioids provide the anesthesia practitioner with a multitude of delivery modalities.

Neuromuscular Blocking Agents, Reversal Agents, and Their Monitoring

John J. Nagelhout

The neuromuscular blocking drugs (NMBDs) are an integral part of anesthesia practice. They allow for easy airway and operative field manipulation, which is essential in today's sophisticated and complex surgical environment. As with many other types of anesthetic drug components, no single agent or agents are ideal in all situations. For example, the development of a rapid onset, ultrashort-acting, nondepolarizing replacement for succinylcholine has eluded researchers for decades. In addition, reversal of the NMBDs is complex, and residual paralysis in the postanesthesia care unit (PACU) remains a problem. Despite these challenges, our knowledge regarding the safe use of these drugs in anesthesia continually evolves. This chapter updates the clinician with the latest information and concepts on the use of these drugs in modern clinical practice.

History

In the nineteenth century, Claude Bernard, a famous French physiologist and philosopher, carried out experiments with curare, then in use by the Amazonian Indians of South America.¹ He noted that animals the Indians hunted for food were paralyzed by arrows poisoned with curare and subsequently died of asphyxiation.² Bernard's experiments with the poison the Indians tipped their arrows with formed the basis for our ideas of the neuromuscular junction, neuromuscular transmission, and neuromuscular pharmacology.³ Indeed, curare had been used since 1857 as an anticonvulsant treatment in tetany and other types of spastic disorders.⁴

Laewen also described the use of curare in anesthetized humans in a German report in 1912.³ For readers who are interested in historical aspects of this topic, a fascinating and more complete report of the earliest work of these and other researchers, beginning as early as the year 1548, is available in an outstanding review article by Bisset.⁵

In 1936, Dale et al. found that acetylcholine (ACh) was the chemical neurotransmitter that activated the postjunctional muscle membrane receptors after excitation of the nerve terminal.⁵ This finding contradicted the once widely held theory that direct electrical transmission from the nerve to the muscle occurs.⁶ This discovery provided the impetus for further research concerning pharmacologic agents that could either enhance the action of ACh or prevent it, thereby causing a temporary and reversible state of therapeutic paralysis.

Griffith and Johnson⁷ of Montreal, Canada, are universally acknowledged as the persons responsible for the introduction of neuromuscular blockers into anesthetic practice. Their groundbreaking report laid the foundations for other studies that followed. Within a year of their study, Cullen reported on the use of curare in 131 general anesthetic procedures. His only report of an adverse reaction dealt with a 44-year-old woman who experienced "complete paralysis and severe salivation," accompanied by muscular twitching.⁴

Despite initial successes with the neuromuscular blockers, an early study nearly doomed their use before they became widely accepted. Henry Beecher and Donald Todd, two physicians in the anesthesia department of Harvard Medical School, reviewed 599,548 anesthetic procedures administered at 10 institutions between 1948 and 1952. As part of this review, they examined the death rate in patients receiving *curares* (the term by which they described any neuromuscular blocking agent, including tubocurarine chloride, decamethonium bromide, succinylcholine chloride, gallamine triethiodide, and dimethyl-tubocurarine [*d*-tubocurarine] iodide). Beecher and Todd⁸ found that the overall death rate for persons treated with neuromuscular blockers was 1 : 370, compared with a death rate of 1 : 2100 in patients who did not receive these agents.

After reviewing the conditions of the patients; the educational background and training of the practitioners who administered the anesthetic (e.g., physician, nurse anesthetist, or physician-in-training); the size of the institution; the sexes, races, and ages of the patients; and numerous other combinations of these factors, the investigators reached the following conclusions:

[I]n our judgment the situation is one where neither experience of individual nor experience of institution appears to protect. This adds up to evidence that neither mistakes nor preventable error of any kind are involved in the main, but rather the inherent toxicity of the "curares" themselves.⁸

In the litigious environment of modern anesthetic practice, such a statement may have ended the administration of these agents. It would certainly have slowed their development. The positive attributes of the agents, however, were discussed later in the same paper, as Beecher and Todd added this caveat:

Having presented the foregoing evidence and comment, one can ask what, then, is to be done about these agents? Are they to be banned as a practical solution of the problem? We believe not. These data strongly suggest that great caution in the use of muscle

*relaxants should be exercised, that the agents available at present be considered as on trial, and that they be employed only when there are clear advantages to be gained by their use, that they not be employed for trivial purposes or as a corrective for generally inadequate anesthesia.*⁸

Beecher and Todd's admonition still echoes through the halls of anesthetic practice today. Although the safety and efficacy of neuromuscular blocking agents have markedly increased, the sage advice is still germane for the practitioner: Neuromuscular blocking agents, like all anesthetic agents, are best used where and when they are indicated. Nevertheless, as one leg of the anesthetic objectives that includes anesthesia, analgesia, amnesia, and muscle relaxation, neuromuscular blockade has become an integral part of most modern anesthetic techniques. A broad spectrum of these agents now exists, although no single agent has all of what would be the ideal properties. Their individual pharmacokinetic and pharmacodynamic attributes enable the anesthetist to tailor the use of the agent to the physiologic needs of the patient and the requirements of the surgeon.

Monitoring of Neuromuscular Blockade

Monitoring of neuromuscular blockade should be the standard during most anesthetics when a relaxant is administered. Combining objective data from nerve monitoring with clinical signs of paralysis offers obvious advantages when dosing relaxants intraoperatively and assessing postoperative recovery. An important anesthetic discussion has been taking place on the gap between the scientific knowledge on effective monitoring and use of muscle relaxants in anesthesia and actual current clinical practice.⁹⁻¹² Expert consensus strongly recommends the routine monitoring of neuromuscular block in the perioperative period as a safety issue. They feel this guides intraoperative relaxant dosing by avoiding overparalysis and helps reduce the incidence of residual weakness in the PACU. An extensive survey of clinicians in the United States¹³ and Europe indicate that many practitioners are not using these monitors in everyday practice.¹⁴⁻¹⁶ Several explanations are given: the current quantitative monitors are cumbersome and difficult to use, qualitative monitoring is unreliable, residual paralysis is not a problem in their practice, and clinical signs can be used to assess paralysis in most patients, among others. Survey respondents felt that the incidence of residual paralysis in their practice was usually less than 1%. Objective studies estimate the incidence as high as 52%.^{13,17} The discrepancy may exist because most patients recover safely in spite of residual paralysis and their problem is not noticed. Many patients may have had some difficulty or discomfort but manage to compensate until full recovery occurs and do not need specific interventions. There is no question however, that residual paralysis in the PACU represents a significant potential hazard for airway complications and aspiration. A complete discussion of neuromuscular blockade reversal is later in this chapter.

The response to a peripheral nerve monitor indirectly infers the relaxation of musculature. The neuromuscular monitor is an electrical device that delivers a series of electric shocks or impulses

to the patient through electrodes applied to the skin near a nerve. There are several methods for monitoring neuromuscular blockade intensity, including acceleromyography (AMG), electromyography (EMG), phonomyography (PMG), mechanomyography (MMG), and kinemyography (KMG). Visual and tactile response to evoked electrical stimulus as assessed by the clinician, or by qualitative monitoring, is the most common method. On activation of the stimulator, various predictable muscle contraction patterns are visible in the presence and absence of neuromuscular blockers. Quantitative monitoring, in which the stimulator is coupled with a displacement transducer as a movement measuring device and a number value is displayed, is preferred but less common. Quantitative monitoring can be accomplished with MMG, AMG, KMG, or EMG.⁹

Depolarization and contraction of a muscle are caused by an action potential traveling along the course of a nerve. As the impulse reaches the motor endplate, ACh is released across the synaptic cleft. It subsequently travels toward the receptor sites on the muscle membrane, resulting in depolarization and subsequent contraction of the muscle.² The stimulator elicits the same activity, which makes it useful for the monitoring of neuromuscular blockade (Fig. 12.1).

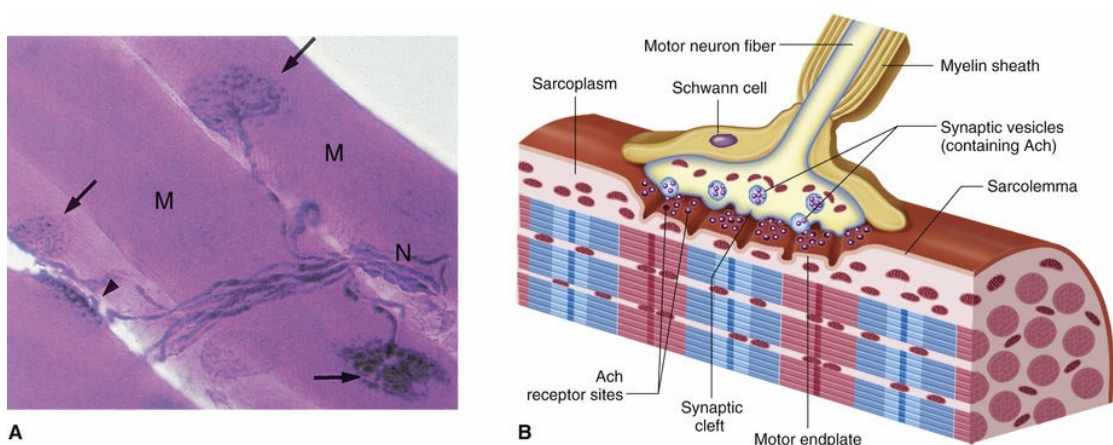

FIGURE 12.1 Neuromuscular junction (NMJ). **A**, Micrograph showing four neuromuscular junctions (NMJs). Three are surface views (*arrows*) and one is a side view (*arrowhead*). *N*, Nerve fibers; *M*, muscle fibers. **B**, This sketch shows a side view of the NMJ. Note how the distal end of a motor neuron fiber forms a synapse, or “chemical

junction,” with an adjacent muscle fiber. Neurotransmitter molecules (specifically, acetylcholine [ACh]) are released from the neuron's synaptic vesicles and diffuse across the synaptic cleft. There they stimulate receptors in the motor endplate region of the sarcolemma. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 9th ed. St. Louis: Elsevier; 2016:367.)

The proper administration of neuromuscular blocking agents (NMBAs) is essential for patient safety and efficient perioperative workflow. Inadequate doses of NMBAs may result in complications during surgical procedures because of unexpected patient movement and a less than ideal operative field. In contrast, overdosage may result in residual paralysis in the postoperative period, increasing morbidity and the need for labor-intensive interventions (e.g., mechanical ventilation).

Contraction of the adductor muscle of the thumb via stimulation of the ulnar nerve is the preferred site for determining the level of neuromuscular blockade. It is usually accessible and convenient. Disposable electrodes are applied over the ulnar nerve. The distal electrode is placed over the proximal flexor crease of the wrist, and the other electrode is placed over and parallel to the carpi ulnaris tendon. On stimulation of these electrodes with the monitoring device, adduction of the thumb is visible. When access to the arm and hand is not practical, other monitoring sites include the nerves of the foot and the facial nerve. Facial nerve monitoring generally involves stimulation of the temporal branch of the facial nerve that supplies the orbicularis oculi muscle around the eye or the corrugator supercilii that moves the eyebrow when frowning.^{17,18} The facial and ulnar nerves sites are shown in [Figs. 12.2](#) and [12.3](#), respectively. [Table 12.1](#) gives a comparison of the ulnar and facial nerve monitoring sites.

FIGURE 12.2 Facial neuromuscular blockade testing.

FIGURE 12.3 Ulnar neuromuscular blockade testing.

TABLE 12.1**A Comparison of Neuromuscular Monitoring Sites**

Monitoring Site	Response	Comments
Ulnar nerve innervation of the adductor pollicis	Thumb adduction	Usually have easy access Best site to measure recovery
Facial nerves	Eyelid and eyebrow movement	Easily accessed when arm is not available Best site to measure onset Corrugator supercilii is more resistant to relaxants than the orbicularis oculi

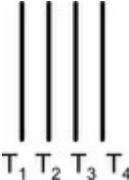

A few contrasting factors involving blood flow versus muscle sensitivity must be considered when assessing paralysis and interpreting responses from the ulnar nerve or face. During onset of a relaxant, the muscle group sensitivity exhibits the following pattern: The eye muscles are the most sensitive and are the first group to be affected, followed by the extremities, the trunk of the body (with the neck and chest first), then abdominal muscles, and, lastly, the diaphragm. During recovery, muscle function returns in the opposite pattern with the diaphragm first and the eye muscles last. Blood flow, however, is greater to the head, neck, and diaphragm, so more of the drug is distributed to these areas upon initial distribution and onset. Additionally, there is a difference in sensitivity to relaxants between various muscles surrounding the eye. The corrugator supercilii is more resistant than the orbicularis oculi to NMBAs. Distinguishing between the effects of drugs on these two muscles is very difficult clinically. When monitoring in the face, with its many small nerves and muscles, it is difficult to ensure that only a single nerve is being stimulated and accordingly, that only one muscle is contracting. This may lead to twitches of the relatively resistant corrugator supercilii muscle to be counted, even in the absence of a twitch by the orbicularis oculi muscle.¹⁷

Due to these conflicting influences, the facial nerves should be used when assessing relaxant onset. Blood, thus drug, distribution to the facial muscles mirrors distribution in the larynx and diaphragm where relaxation is required for intubation and airway manipulation. Recovery is best measured in the hand. The hand muscles are more sensitive to relaxant than the diaphragm, so if recovery is evident in the hand, the larynx, and the diaphragm, the upper airway muscles will be recovered as well.¹⁷⁻¹⁹

Tests of Neuromuscular Function

There are five clinical tests of neuromuscular function: single twitch, train-of-four (TOF), double-burst stimulation (DBS), tetanus, and posttetanic count (PTC). The TOF, DBS, and tetanic stimulation are the most commonly used.²⁰ The ability to evaluate muscle function with each mode of stimulation varies (Table 12.2).

TABLE 12.2
Common Neuromuscular Monitoring Tests

Monitoring Test	Definition	Comments	Stimulation Characteristics
Single twitch	A single supramaximal electrical stimulus ranging from 0.1–1.0 Hz	Requires baseline before drug administration; generally used as a qualitative rather than quantitative assessment	
Train-of-four	A series of four twitches at 2 Hz every ½ second for 2 sec	Reflects blockade from 70–100%; useful during onset, maintenance, and emergence Train-of-four ratio is determined by comparing T ₁ –T ₄	
Double-burst stimulation	Two short bursts of 50 Hz tetanus separated by 0.75 sec	Similar to train-of-four; useful during onset, maintenance, and emergence; may be easier to detect fade than with train-of-four; tactile evaluation	
Tetanus	Generally consists of rapid delivery of a 30-, 50-, or 100-Hz stimulus for 5 sec	Should be used sparingly for deep block assessment; painful	
Posttetanic count	50-Hz tetanus for 5 sec, a 3-sec pause, then single twitches of 1 Hz	Used only when train-of-four and double-burst stimulation is absent; count of less than eight indicates deep block, and prolonged recovery is	

A brief explanation of the concept called *fade* is required to understand the responses to nerve monitoring. Fade is the inability to sustain a response to repetitive nerve stimulation and is seen in several of the clinically used monitoring tests. This is a sign of drug-induced muscle paralysis. Fade occurs because the nondepolarizing drugs block presynaptic ACh receptors (AChRs) in addition to their classic antagonist effect at postsynaptic ACh neuromuscular junction sites. The function of presynaptic AChRs is to facilitate the release of ACh from the nerve terminal via a positive feedback mechanism. During high impulse rates of nerve stimulation, this positive feedback mechanism prevents the decrease (fade) of transmitter release. The facilitated ACh release associated with this positive feedback mechanism is blocked by the relaxants.²¹ This inhibition is detected as fade during the use of the monitoring tests as described hereafter.

Single Twitch

The first (and simplest) type of stimulation is a single twitch at 0.1 to 1 hertz (Hz) for 0.1 to 0.2 milliseconds (ms). These impulses can be delivered automatically every second, every 10 seconds, or manually, depending on the sophistication of the neurostimulating apparatus.

Unless you have a comparison twitch response before any relaxant is given, this test simply indicates whether 100% paralysis is present. If the patient's muscle moves when stimulated, less than 100% muscle paralysis exists. If no movement is detected, 100% paralysis is present.

Train-of-Four

The second and most widely used means of stimulation is the TOF, which delivers four separate stimuli every 0.5 seconds at a frequency of 2 (Hz) for 2 seconds. A comparison is made of the four stimulated responses. Each of the four twitch responses are referred to as T_1 through T_4 , respectively. Upon the onset of paralysis with a nondepolarizing relaxant, there is a progressive diminution of the twitch responses with visible fade. Fade refers to the fact that each

of the successive twitch responses from T_1 through T_4 is smaller. When partial paralysis is present yet all four twitch responses can be elicited, with fade from T_1 through T_4 , an assessment can be made regarding the size of T_4 compared to T_1 . This $T_4:T_1$ ratio is referred to as the *train-of-four ratio*, or TOFR. TOF testing can aid in approximating the degree or percent of paralysis present. It is most sensitive between 70% and 100% paralysis. The fourth twitch (T_4) disappears first, which represents a block of 75% to 80%. Progressive disappearance of the third twitch (T_4 and T_3 absent) indicates 80% to 85% block. When three twitches are abolished (T_4 , T_3 , and T_2 are absent), 90% to 95% neuromuscular blockade is present. When 100% paralysis is achieved, no responses can be elicited. [Fig. 12.4](#) correlates the responses to TOF stimulation with the approximate degree of paralysis present. Intraoperatively, the ideal degree of paralysis necessary for any procedure with sufficient anesthetic depth is 85% to 95%. That correlates with 1 to 2 twitch responses present upon TOF stimulation. Avoiding total 100% paralysis intraoperatively ensures a successful operative procedure while avoiding overdosing of the relaxant. Less total relaxant administered lessens the chances of residual paralysis upon reversal.²²

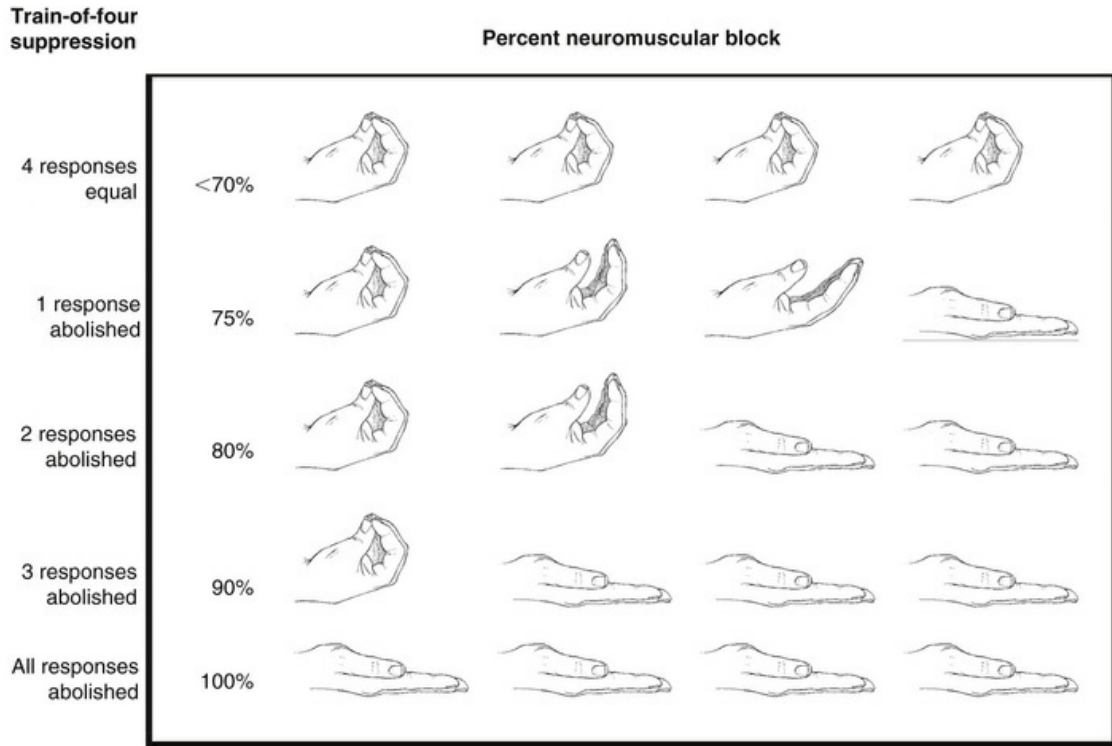

FIGURE 12.4 Train-of-four test.

A representative assessment of the TOF test during onset and recovery of a nondepolarizing relaxant is shown in [Figs. 12.5](#) and [12.6](#), respectively.

FIGURE 12.5 Characteristic train-of-four response during onset of a nondepolarizing muscle relaxant.

FIGURE 12.6 Characteristic train-of-four response during recovery from a nondepolarizing muscle relaxant.

Double-Burst Stimulation

Double-burst stimulation was conceptualized as an analog to TOF with some improvements. It consists of two short bursts of a 50-Hz tetanus separated by 0.75 seconds. The use of DBS seems to improve the ability to detect residual paralysis during recovery. The suggestion is that DBS relies on the direct comparison of the muscle contraction in response to two rapidly sequential minitetanics bursts, rather than the indirect comparison of the fourth twitch with the first twitch as in the TOFR. It is thought that the comparison of the fourth to the first twitches when assessing the TOFR is hindered by the second and third twitches that provide no useful information. Evaluating two rather than four twitch responses facilitates detection of fade. Tactile evaluation is suggested to improve the ability to detect fade. Responses are similar to the TOF. Fade of the second impulse is comparable to a TOFR of less than 0.6 and indicates significant paralysis.¹⁹ A comparison is shown in [Fig. 12.7](#).^{20,23,24}

FIGURE 12.7 A comparison of responses to double-burst (DBS) and train-of-four (TOF) stimulation during recovery from a nondepolarizing muscle relaxant.

Tetanus

Tetanus consists of continuous electrical stimulation for 5 seconds at 50 or 100 Hz. The 100-Hz current is more reliable for detecting fade but is not always specific.^{19,25} If the muscle contraction produced is sustained for the entire 5 seconds of stimulation without fade, significant paralysis is unlikely. If fade is present, clinically significant block remains.^{20,26} The higher intensity of stimulation produced by tetanic frequencies as compared to TOF, DBS, or a single twitch makes it useful when other tests such as TOF or DBS are equivocal. The test is painful and should not be repeated too often in order to avoid muscle fatigue.

Posttetanic Count

The PTC was rarely used clinically but is undergoing a newfound interest since the introduction of sugammadex. Several sugammadex dosing regimens are based on the PTC and will be discussed under reversal drugs. It is only performed when there is no response to any of the commonly used tests due to the presence of 100% paralysis. Because you are already aware that the patient is completely paralyzed, the value of the PTC is to attempt to give a rough time estimate as to when recovery may occur. The PTC mode involves the use of a 50-Hz tetanic stimulation for 5 seconds, followed in 3 seconds by a series of single 1-Hz twitch stimulations.²⁴ An understanding of the phenomenon of posttetanic potentiation (also referred to as *posttetanic stimulation* or *facilitation*) is necessary to comprehend the PTC test. When the 50-Hz tetanus is applied, there is no response because the patient is completely blocked. Application of the 50-Hz tetanus, however, transiently mobilizes excesses of ACh so that after a 3-second pause, you are able to produce a short series of single-twitch responses in the hand. Because they only occur after a tetanic stimulation and not before, this single-twitch response is termed *posttetanic potentiation*. This extra ACh will, in effect, “transiently reverse” the relaxant by

competing for the receptor at the local monitoring site. This augmented response will only last several seconds until the excess ACh dissipates. The number of twitches elicited is counted. The higher the count, the less intense the block. The usual count is between 0 (deep block) and 8 (less intense block where TOF response should return). With rocuronium, for example, neostigmine reversal of an intense block where the PTC was 1 to 2 takes more than 50 minutes.^{27,28} At a PTC of 6 to 8, reversal should occur in less than 10 minutes.

Neuromuscular monitoring terminology and tests are summarized in [Box 12.1](#), [Fig. 12.2](#), and [Table 12.3](#). Some key points related to successful use of tests of neuromuscular transmission are given in [Box 12.2](#).²⁹

Commonly Used Neuromuscular Terminology

- *Onset time*: Time from drug administration to maximum effect
- *Clinical duration*: Time from drug administration to 25% recovery of the twitch response
- *Total duration of action*: Time from drug administration to 90% recovery of twitch response
- *Recovery index*: Time from 25% to 75% recovery of the twitch response
- *Train-of-four ratio*: Compares the fourth twitch of a TOF with the first twitch; when the fourth twitch is 90% of the first, recovery is indicated

TOF, Train-of-four.

TABLE 12.3

Key Points Related to Tests of Neuromuscular Transmission and Reversal

Acceptable	Approximate Percent
------------	---------------------

Test	Acceptable Clinical Result to Suggest Normal Function	of Receptors Occupied When Response Returns to Normal Value	Comments, Advantages, and Disadvantages
Tidal volume	At least 5 mL/kg	80	Necessary, but insensitive as an indicator of neuromuscular function
Single-twitch strength	Qualitatively as strong as baseline	75–80	Uncomfortable; need to know twitch strength before relaxant administration; insensitive as an indicator of recovery, but useful as a gauge of deep neuromuscular blockade
Train-of-four (TOF)	No palpable fade	70–75	Uncomfortable, but more sensitive as indicator of recovery than single twitch; used as a gauge of depth of block by counting the number of responses perceptible
Sustained tetanus at 50 Hz for 5 sec	At least 20 mL/kg	70	Very uncomfortable, but a reliable indicator of adequate recovery
Vital capacity	At least 20 mL/kg	70	Requires patient cooperation, but is the goal for achievement of full clinical recovery
Double-burst stimulation	No palpable fade	60–70	Uncomfortable, but more sensitive than TOF as an indicator of peripheral function; no perceptible fade indicates TOF of at least recovery of 60%
Inspiratory force	At least –40 cm H ₂ O	50	Difficult to perform with endotracheal intubation, but a reliable gauge of normal diaphragmatic function
Head lift	Must be performed unaided with patient supine and sustained for 5 sec	50	Requires patient cooperation, but remains the standard test of normal clinical function
Hand grip	Sustained at a level qualitatively similar to preinduction	50	Sustained strong grip, though also requires patient cooperation; is another good gauge of normal function
Sustained bite	Sustained jaw clench on tongue blade	50	Very reliable with patient cooperation; corresponds with TOF of 85%

Modified from Miller RD. Neuromuscular blocking drugs. In Miller RD, Pardo M, eds. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier; 2011:158.

Box 12.2

General Guidelines for Successful Neuromuscular Monitoring

- Objective (quantitative) monitoring of neuromuscular function should be used when possible.
- Peripheral nerve stimulator units should display the delivered current output, which should be at least 30 mA.

the extremities, trunk (from the neck muscles downward through the intercostals), abdominal muscles, and finally the diaphragm. Recovery returns in the opposite manner. Protective reflex muscles of the pharynx and upper esophagus recover later than the diaphragm, larynx, hands, or face.

- Monitoring of the facial nerve for determination of onset and readiness for intubation may be preferable to monitoring of the ulnar nerve.
- Monitoring of the offset and recovery from neuromuscular blockade is probably better at the ulnar nerve.
- Tactile evaluation of train-of-four (TOF) and double-burst stimulation (DBS) fade reduces but does not eliminate the incidence of postoperative residual paralysis compared with the use of clinical criteria to assess readiness for tracheal extubation.
- Adequate spontaneous recovery should be established before pharmacologic antagonism of neuromuscular blocking drug (NMBD) block with anticholinesterases. This requirement does not apply to reversal with sugammadex.
- When there is only one response to TOF stimulation, successful reversal may take as long as 30 minutes.
- At a TOF count of two or three responses, recovery usually takes 4 to 15 minutes after intermediate-acting drugs and may take up to 30 minutes after administration of the long-acting relaxant pancuronium.
- When the fourth response to TOF stimulation appears, adequate recovery can be achieved within 5 minutes of reversal with neostigmine or 2 to 3 minutes after use of edrophonium.
- When the fourth twitch of the TOF returns, the train-of-four ratio (TOFR) may be determined. Compare the size of the fourth twitch (T_4) with the size of the first twitch (T_1), using $T_4:T_1$ as a ratio. The timing of tracheal extubation should be guided by

quantitative monitoring tests such as TOF greater than 0.9 or DBS₃ greater than 0.9.

Depolarizing Agents

Succinylcholine Chloride

Succinylcholine chloride (Anectine, Quelicin, and others) is very familiar to every clinician, having been a standard for several decades of practice. Although its widespread use in clinical anesthesia represents the standard of care for a variety of situations, opinions regarding its use remain divided because of some of its untoward effects.

Stephen Thesleff at the Karolinska Institute in Stockholm was one of the pioneers who introduced the drug into clinical practice to induce neuromuscular paralysis in humans. Initial description of the neuromuscular blocking properties of succinylcholine is credited to Daniel Bovet. (Bovet was awarded the Nobel Prize for Physiology and Medicine in 1957 for his discovery of synthetic compounds that act on the vascular system and skeletal muscle.)³⁰ The first use of succinylcholine in the United States occurred in 1952. Foldes et al.³¹ described this agent in the following manner:

*Compared to other muscle relaxants used in anesthesiology, succinylcholine possesses several advantages, the outstanding one, in our experience, being its easy controllability, which permitted almost instantaneous changes in degree of muscular relaxation. With succinylcholine, both increasing and decreasing muscular relaxation took less than a minute.*³¹

The disadvantages of succinylcholine have been well recorded through years of clinical experience. It has no action in the ganglionic nicotinic receptors but may cause bradycardia by an action on cardiac cholinergic muscarinic receptors.^{32,33} Prolonged neuromuscular blockade can result from excessive doses of succinylcholine in patients with atypical, inhibited, or deficient levels of plasma cholinesterases.^{3,32}

Succinylcholine is the only remaining depolarizing muscle relaxant licensed for use in the United States. Remembering the composition of the drug is helpful in better understanding its

effects and side effects. Succinylcholine results from the joining of two ACh molecules and is represented by the chemical formula $C_{14}H_{30}N_2O_4$. Although succinylcholine mimics the action of ACh by depolarizing the motor endplate, its degradation is distinct. In contrast with the degradation of ACh by acetylcholinesterase (AChE), succinylcholine is hydrolyzed by plasma cholinesterase (pseudocholinesterase). The popularity of this muscle relaxant is rooted in its unique ability to provide a quick onset and short duration of effect. A bolus of 0.5 to 1.5 mg/kg is the recommended dose for adequate adult paralysis and relaxation for intubation.³⁴ The dose of succinylcholine that provides the desired paralytic effect in 95% of the population (ED_{95} [(effective dose, 95% response)]) is approximately 0.30 mg/kg.³⁵

Pharmacokinetics

Onset.

Succinylcholine has an extremely rapid onset and remains the gold standard against which other agents are compared. In general, muscle relaxants exhibit an inverse relationship between potency and onset speed. The lower the potency, the faster the speed. A lower potency drug requires larger doses so a muscle gradient will be achieved more quickly.³⁶ A typical intubating dose of 1 to 1.5 mg/kg results in a maximum suppression of muscle twitch and good to excellent intubating conditions within 1 to 1.5 minutes of administration.^{34,37,38} Onset of action of succinylcholine at the larynx with administration of 1 mg/kg is 34 seconds.^{39,40} The onset as measured at peripheral sites such as the adductor pollicis is slightly longer at 1 minute.⁴¹ The rapid onset of succinylcholine is based on its action as an initial agonist at the nicotinic receptor, rather than as a competitive antagonist. Succinylcholine works by activating the muscle-type nicotinic cholinergic receptors, followed by desensitization.³³ This action results in the need for significantly less drug at the receptor site to produce neuromuscular block. In contrast, most NMBAs require 75% or more receptor occupancy for clinically useful paralysis to result. Variable onset must be considered in patients with altered physiology. Patients with atypical plasma cholinesterase may exhibit prolonged onset after

succinylcholine administration.⁴² A summary of the dose, onset, and duration of the neuromuscular blocking drugs is given in [Table 12.4](#).

TABLE 12.4
Neuromuscular Blocking Agents: Dose, Onset, and Duration*

Agent	ED ₉₅ (mg/kg)	Intubating Dose (mg/kg)	Time to Onset	Duration of Action (min)
Succinylcholine (Anectine)	0.3	1–1.5	30–60 sec	Ultrashort, 5–15
Mivacurium (Mivacron)	0.08	0.25	2–3	Short, 15–20
Atracurium (Tracrium)	0.15	0.5	2–4 min	Intermediate, 30–60
Cisatracurium (Nimbex)	0.05	0.1	2–4 min	Intermediate, 30–60
Rocuronium (Zemuron)	0.3	0.6–1	1–1.5 min	Intermediate, 30–60
Vecuronium (Norcuron)	0.05	0.1	2–4 min	Intermediate, 30–60
Pancuronium (Pavulon)	0.05	0.08–1.8	2–4 min	Long, 60–90

* All data for adult patients without significant disease.

ED₉₅, Effective dose for 95% paralysis.

Duration.

The plasma half-life of succinylcholine is 2 to 4 minutes.⁴³ The clinical duration of succinylcholine (i.e., the length of time during which its clinical effects can be recognized) is generally 5 to 10 minutes, with full recovery evident at 12 to 15 minutes. Twitch recovery of 25%, as measured by the laryngeal adductor pollicis responses, is 4.3 minutes, whereas 90% to 95% twitch recovery has been reported to occur in 8 minutes.³⁹ In a 2015 study of 1630 patients given a 1 mg/kg dose, average duration was 7.3 minutes. A duration greater than 10 minutes was noted in 16% of patients. Independent risk factors associated with prolonged duration included physical status, sex, age, hepatic disease, pregnancy, history of cancer, and use of etomidate or metoclopramide.⁴⁴

Elimination.

Succinylcholine is degraded via hydrolysis by plasma cholinesterases. These enzymes, although found in the plasma, are produced by the liver. Initially, hydrolysis results in the transformation of succinylcholine into succinylmonocholine and choline ([Fig. 12.8](#)). Succinylmonocholine is further degraded by

plasma cholinesterase into succinic acid and choline. Succinylcholine metabolism is so rapid that only 10% of the injected dose ever reaches the neuromuscular junction.³⁰ A summary of the elimination routes for the neuromuscular blocking drugs is given in Table 12.5.

FIGURE 12.8 Metabolism of succinylcholine.

TABLE 12.5

Neuromuscular Blockers: Elimination Mechanism

Agent	Elimination Mechanism	Comments
Atracurium	Hofmann elimination; nonspecific esterases	Non-organ-dependent elimination produces consistent duration in patients with significant hepatic and renal disease, as well as the elderly
Cisatracurium	Hofmann elimination; nonspecific esterases	Similar to atracurium but without the histamine release
Rocuronium	Hepatic; renal	May be prolonged with hepatic and renal disease
Vecuronium	Renal (20–30%); hepatic (40–80%)	May be prolonged with hepatic disease
Pancuronium	Renal primarily; some hepatic	May be prolonged with renal disease
Succinylcholine	Plasma cholinesterase	Prolonged in patients with cholinesterase deficiency
Mivacurium	Plasma cholinesterase	Prolonged in patients with Cholinesterase deficiency

Central Nervous System

Like all muscle relaxants, succinylcholine contains a quaternary ammonium in its structure, rendering it water soluble in the body. It does not therefore pass the blood-brain barrier and has no direct central nervous system (CNS) effects. Succinylcholine indirectly increases intracranial pressure (ICP), and therefore concern has always existed as to the appropriateness of its use in certain neurosurgical procedures and in patients with brain pathology and increased ICP.³⁹ Research conducted in animals shows a small and transient rise of 10 to 15 mm Hg for 5 to 8 minutes after administration.⁴³ The rise is associated with an increased cerebral blood flow, muscle spindle afferent activity, and electroencephalogram arousal. Fasciculation of the neck muscles causing jugular vein stasis appears to be a factor.⁴⁵ The ICP effects are blocked by pretreatment with a small dose of nondepolarizing relaxant.⁴⁶ In clinical practice, the administration of succinylcholine is preceded by an anesthetic induction agent that lowers ICP, so that may help counteract this effect as well. Nevertheless, the routine use of succinylcholine in neurosurgery has declined. It remains widely used, with nondepolarizing relaxant and lidocaine pretreatment, for emergency procedures requiring rapid airway control via rapid sequence induction.^{32,47}

Cardiovascular System

Succinylcholine usually results in slight tachycardia; however, sudden abrupt bradycardia may result from repeat dosing in adults and any dose in children. Many types of arrhythmias have been reported. The bradycardia results from autonomic ganglia and parasympathetic muscarinic receptor stimulation. Another possible mechanism for the bradycardia associated with succinylcholine administration is thought to be related to its metabolite, succinylmonocholine, which causes stimulation of cholinergic receptors in the sinoatrial node.⁴⁸

An intubating dose of succinylcholine increases serum potassium levels by 0.5 to 1 mEq/L.⁴³ Although this may not be significant in the normokalemic patient, it may be life threatening in patients with preexisting hyperkalemia.⁴⁹ Gronert⁵⁰ presents a case that involved an 11-year-old girl who experienced cardiac arrest after receiving succinylcholine. Her cardiac arrest and eventual death were directly attributed to a high potassium release after the succinylcholine administration (10.2 mEq/L). The exaggerated potassium release after the succinylcholine administration in this case was determined to be related to a familial myopathy evidenced by extremely high patient levels of creatine kinase. Succinylcholine administration, hyperkalemia, and myopathy are discussed later. Some clinicians believe that a second dose of succinylcholine indicated by any event should be preceded by intravenous (IV) atropine or glycopyrrolate for its anticholinergic effects; however, others do not.⁴⁹

Hepatic System

Cholinesterase enzyme subtypes are produced in the liver. Pseudocholinesterase (PChE) degrades succinylcholine; therefore, certain types of liver damage may prolong the effects of the drug.⁴⁸ Ester compounds like succinylcholine are metabolized by adding water, in a process referred to as *hydrolysis*. The basic reaction is $\text{ESTER} + \text{H}_2\text{O} \leftrightarrow \text{ACID} + \text{ALCOHOL}$. Three esterase enzymes that can act as catalysts for these hydrolysis reactions exist in the plasma: cholinesterase, paraoxonase, and albumin esterase. Paraoxonase and albumin esterase are frequently referred to as

nonspecific esterases. Additionally, red blood cells (RBCs) contain two esterase enzymes in their cytosol. One is referred to as *RBC esterase*, *esterase D*, or *S-formylglutathione*, and the other is AChE in small amounts.⁵¹

Cholinesterase is a generic term used for a family of related enzymes that hydrolyze choline esters at a faster rate than other esters under optimal conditions. The major function of cholinesterase is to terminate the action of ACh at cholinergic nerve endings in synapses or in effector organs.⁵² Two subtypes of cholinesterase exist in the human body, with several variations and a confusing set of names. One type of cholinesterase is acetylcholinesterase, AChE, also known as *true*, *specific*, *genuine*, and *type I cholinesterase*. This enzyme is found in erythrocytes, nerve endings, the lungs, the spleen, and the gray matter of the brain. It is a membrane-bound glycoprotein and exists in several molecular forms. The other subgroup pseudocholinesterase, PChE, also known as *plasma*, *serum*, *benzoyl*, *false*, *butyryl*, *nonspecific*, and *type II cholinesterase*, exists in plasma and has more than 11 isoenzyme variants. PChE is also present in the liver, smooth muscle, intestines, pancreas, heart, and white matter of the brain.

Measurements of PChE activity can serve as a sensitive measure of the synthetic capacity of the liver. In the absence of known inhibitors, any decrease in activity reflects impaired synthesis of the enzyme. A moderate decrease (30% to 50%) is seen in acute hepatitis and long-standing chronic hepatitis, whereas a severe decrease (50% to 70%) is seen in advanced cirrhosis and in some carcinomas with metastases to the liver. Decreased levels of PChE are also found in pregnant women and newborns and in patients with acute infections, pulmonary embolism, muscular dystrophy, myocardial infarction, and after certain surgical procedures.⁴⁸ Essentially normal levels are noted in patients with mild cirrhosis or obstructive jaundice. Increased levels have been observed in cases of nephrotic syndrome, thyrotoxicosis, and hemochromatosis, in obese patients with diabetes, and in patients with anxiety and other psychiatric states. Patients generally develop neuromuscular symptoms at approximately 60% of normal activity, and serious neuromuscular effects are seen at approximately 20% of normal activity. Reference intervals are 2900 to 7100 units/L, although they

vary with the analysis method.⁵³

Table 12.6 lists some common anesthesia-related drugs that undergo hydrolysis, along with the enzyme catalyst involved.

TABLE 12.6

Common Esterase-Dependent, Anesthesia-Related Drugs

Drug	Enzyme
Succinylcholine	Pseudocholinesterase
Mivacurium	Pseudocholinesterase
Ester local anesthetics:	Pseudocholinesterase
Cocaine	
Procaine	
Chlorprocaine	
Tetracaine	
Neostigmine	Pseudocholinesterase
Edrophonium	Pseudocholinesterase
Atracurium	Nonspecific esterases (plasma)
Cisatracurium	Nonspecific esterases (plasma)
Remifentanyl	Nonspecific esterases (plasma)
Esmolol	Nonspecific (RBC esterases) plasma
Clevidipine	Nonspecific esterases (plasma)

MOC, Methoxycarbonyl; RBC, red blood cell.

Genetic Variants of Pseudocholinesterase and the Dibucaine Inhibition Test

Some patients exhibit genetic variations in PChE that result in a prolonged response and apnea when the patient is exposed to succinylcholine. Although such individuals may lead a normal life in every other respect, their atypical variants of cholinesterase are unable to hydrolyze certain ester-containing drugs in the usual fashion. The most frequent variations in the PChE gene are the atypical (A) and Kalow (K) variants. The K variant is the most common mutation and is present in 25% of Caucasians.⁵⁴ Over 75 mutations in the coding sequence have been reported; however, most are extremely rare.^{53,55,56} The fluoride resistant (F), silent (S), and K variants are not tested for clinically because of assay difficulty and lack of clinical relevance. Phenotype-genotype concordance studies have been reported that allow detailed genetic mapping and clinical data to be evaluated.⁵³

In the usual clinical scenario, a patient completes surgery and is

unable to breathe. Muscle relaxation cannot be successfully reversed. If succinylcholine was used to facilitate intubation, differential diagnosis leads the anesthesia provider to conclude that a potential atypical pseudocholinesterase may be present.⁵⁷⁻⁵⁹ The patient is taken to the PACU, placed on a ventilator, sedated, and monitored until the succinylcholine wears off. Sedation is important because these patients have a high risk of being awake and paralyzed.⁶⁰ The patient recovers and is subsequently discharged, but, prior to discharge, a blood sample is taken to perform a dibucaine inhibition test to help determine (1) whether an atypical enzyme was present and (2) the cause of the prolonged apnea. The dibucaine number and enzyme activity are both determined. By treating the patient's serum with dibucaine and measuring the residual PChE activity compared with the PChE of an untreated sample, the metabolic sensitivity to succinylcholine can be measured. The patient is contacted postdischarge and counseled as appropriate, according to the findings. The administration of whole blood, fresh frozen plasma, or purified human cholinesterase has been suggested as a treatment for the prolonged apnea. Although they may be successful, there are additional transfusion risks and cost issues.⁴⁸ It is safer to let the effects of succinylcholine dissipate on their own with sedation and ventilation as noted earlier.

Dibucaine is an amide local anesthetic that inhibits typical or usual PChE but not atypical PChE. For example, the normal dibucaine number of 80 means that 80% of the PChE activity was inhibited by dibucaine. If a dibucaine number of 20 is obtained, the patient has atypical enzyme because dibucaine did not inhibit the patient's enzyme activity. If a patient experiences prolonged apnea after succinylcholine administration, it is imperative to differentiate between an atypical genetic variant of PChE or simply low levels of normal PChE enzyme. Possible interpretations of a dibucaine test

Box 12.3 are given in [Box 12.3](#).

Dibucaine Inhibition Test Outcomes

1. Low dibucaine number + slightly lower activity = atypical enzyme and prolonged apnea
2. Normal dibucaine number + low activity = normal enzyme with

low levels present and prolonged apnea

3. Low dibucaine number + very low activity = possible rare variant-type enzyme with very low levels present and prolonged apnea
4. Normal dibucaine number + normal activity = normal enzyme and amount (Another reason for the prolonged apnea must be investigated.)

Patients with acute or chronic liver disease, organophosphate poisoning, or chronic renal disease, patients in the late stages of pregnancy, and those undergoing estrogen therapy may have markedly decreased PChE activities but normal enzyme. PChE phenotype interpretation is based on the total PChE activity and the percent of inhibition caused by dibucaine (Table 12.7).

TABLE 12.7

Select Inherited Variants of Plasma Cholinesterase

PChE Variant	Genetic Label	Frequency (%)	Population Incidence	Enzyme Activity	Duration of Succinylcholine
Usual	Homozygote U	96	Normal	Normal	Normal; dibucaine number 70–80
–	Heterozygote U/A	3	1 in 480	Decreased	Slightly prolonged; dibucaine number 50–69
Atypical	Homozygote A	0.3	1 in 3200	Decreased by 70% or more	Significantly prolonged; dibucaine number 16–30
Fluoride	Homozygote F	0.03	Extremely rare	Decreased by 60%	Moderately prolonged
Silent	Homozygote S	0.04	Extremely rare	No activity	Significantly prolonged

PChE, Plasma cholinesterase.

Gene sequencing combined with biochemical testing can provide patients and their families with a comprehensive assessment of the likelihood of this type of event.^{53,54,56}

Renal System

Succinylcholine may be used in surgical patients with renal disease when preoperative potassium levels are normal. The use of succinylcholine in patients with elevated preoperative potassium

levels is contraindicated.⁶¹ Patients with renal failure and end-stage renal disease are frequently dialyzed prior to surgery, so as long as the serum potassium is within normal limits, succinylcholine may be used safely.⁶² Patients with renal disease may have lower cholinesterase levels.⁶³

Effects in Special Populations

Elderly Patients.

The onset of succinylcholine may be slightly prolonged in the elderly due to a slower circulation time, but the clinical relevance is minimal.⁶⁴ Reduced plasma cholinesterase levels in elderly men may allow for a reduced dose of succinylcholine. A unique possible drug interaction has been noted in elderly patients taking, donepezil (Aricept), rivastigmine (Exelon), or galantamine (Razadyne). These are anticholinesterase drugs used to treat Alzheimer disease and select forms of dementia. They increase ACh levels in the CNS and are referred to as *cognitive enhancers*. Theoretically, the inhibition of cholinesterase produced by these agents may prolong the action of succinylcholine. The amount of systemic cholinesterase inhibition, however, does not produce **Box 12.4** significant prolongation of succinylcholine⁶⁵ (Box 12.4).

Drugs That May Inhibit Cholinesterase

Agents Used to Treat Alzheimer disease

- Donepezil (Aricept)
- Rivastigmine (Exelon)
- Galantamine (Razadyne)—herbal medicine also available over the counter

Obese Patients.

No contraindication to the use of succinylcholine exists in obese patients. The utility of rapid-sequence induction in anesthetic management of the obese patient makes its use common.⁶⁶ The recommended dose of succinylcholine is 1.0 mg/kg, based on total

body weight, to produce excellent intubating conditions.⁶⁷ In a 2003 study by Brodsky and Foster,⁶⁸ succinylcholine was given to 14 morbidly obese patients (body mass indices ranging from 35.8 to 58) who underwent laparoscopic gastric bypass surgery. The authors administered doses ranging from 120 to 140 mg and successfully intubated all of the patients. Only 2 of the 14 patients complained of postoperative myalgia. Dosing should be based on total body weight. Because succinylcholine is water soluble, it would seem that doses based on lean body weight would suffice. Morbidly obese patients have increased fluid compartments and pseudocholinesterase levels, however, and require higher doses to ensure adequate paralysis.^{69,70}

Pediatrics.

In children, succinylcholine is used only in emergency situations to secure an airway. Routine use in elective procedures was abandoned in the early 1990s, owing to several widely reported cases of severe hyperkalemia and rhabdomyolysis in what appeared to be healthy children. The cases involved routine procedures in children with undiagnosed Duchenne muscular dystrophy (DMD).⁷¹⁻⁷⁵ This is an X chromosome–linked disorder with onset of symptoms usually around 5 years of age. Patients exhibit a typical progression of weakness and atrophy that starts in the legs and pelvis, spreads to the shoulders and neck, and finally involves the upper extremities and respiratory muscles. Life expectancy is rarely more than 30 years; death is often a consequence of cardiac and respiratory diseases. Children with DMD frequently require orthopedic surgery for repair of scoliosis or contractures.^{76,77}

The Food and Drug Administration (FDA), in conjunction with the anesthesia community, placed the following warning on the use of succinylcholine:

RISK OF CARDIAC ARREST FROM HYPERKALEMIC RHABDOMYOLYSIS.

There have been rare reports of acute rhabdomyolysis with

hyperkalemia followed by ventricular dysrhythmias, cardiac arrest, and death after the administration of succinylcholine to apparently healthy children who were subsequently found to have undiagnosed skeletal muscle myopathy, most frequently Duchenne muscular dystrophy.

This syndrome often presents as peaked T-waves and sudden cardiac arrest within minutes after the administration of the drug in healthy appearing children (usually, but not exclusively, males, and most frequently 8 years of age or younger). There have also been reports in adolescents.

Therefore, when a healthy appearing infant or child develops cardiac arrest soon after administration of succinylcholine not felt to be due to inadequate ventilation, oxygenation, or anesthetic overdose, immediate treatment for hyperkalemia should be instituted. This should include administration of intravenous (IV) calcium, bicarbonate, and glucose with insulin, with hyperventilation. Due to the abrupt onset of this syndrome, routine resuscitative measures are likely to be unsuccessful. However, extraordinary and prolonged resuscitative efforts have resulted in successful resuscitation in some reported cases. In addition, in presence of signs of malignant hyperthermia, appropriate treatment should be instituted concurrently.

Since there may be no signs or symptoms to alert the practitioner to which patients are at risk, it is recommended that the use of succinylcholine in children should be reserved for emergency intubation or instances where immediate securing of the airway is necessary (e.g., laryngospasm, difficult airway, full stomach) or for intramuscular use when a suitable vein is inaccessible.⁷⁸

Because neither succinylcholine nor halothane is routinely used in children, the incidence of masseter spasm and malignant hyperthermia has decreased. Older studies have been reported in which jaw-opening ability and the presence or absence of masseter

spasm, often considered a precursor of malignant hyperpyrexia, were studied. Research was conducted on 63 children anesthetized with halothane, then relaxed with succinylcholine, pancuronium, or vecuronium. Although vecuronium and pancuronium did not cause problems with jaw opening, succinylcholine was associated with this problem, and some of the succinylcholine patients were difficult to intubate.⁷⁸ Masseter spasm was noted to be more frequent in children administered succinylcholine concomitantly with halothane, compared with children who received succinylcholine and thiopental.^{36,79}

A random sample of 6500 anesthetic records (53% of 12,169 anesthetic procedures performed) was reviewed. Fifteen cases of masseter spasm were identified. In each case, the patient underwent halothane induction and was then given succinylcholine intravenously. Seven of the 15 cases of masseter spasm developed in children between ages 8 and 10 years.⁸⁰ Researchers noted an increased incidence of masseter spasm in children with strabismus who were anesthetized with halothane and received IV succinylcholine. Of 1468 halothane anesthetic procedures, 15 cases of masseter spasm were discovered, and of these 15 cases, 6 occurred in the 211 patients with strabismus.⁸¹

In current practice, masseter spasm, although rare, is seen in adults during anesthesia induction and often in emergency rooms or critical care units during emergency airway management.^{82,83} Common side effects of succinylcholine and contraindications for its use are noted in [Table 12.8](#) and [Box 12.5](#), respectively.

TABLE 12.8
Side Effects of Succinylcholine

Side Effect	Probable Cause
Hyperkalemia	Normally, serum K ⁺ is increased by up to 0.5 mEq/L secondary to potassium leaking from the depolarized muscle; in up-regulated patients, levels may rise much higher
Dysrhythmias	Tachycardia (usually mild) is the most common effect; bradycardia secondary to hyperkalemia, especially with repeat doses, can occur (Wide electrocardiographic complexes leading to cardiac arrest have been seen in children with Duchenne muscular dystrophy and other muscle disorders)
Myalgia	Secondary to fasciculation, even though some patients complain of muscle pain without having shown visible evidence of fasciculation
Myoglobinemia	Rare complication after extensive fasciculation or in malignant hyperthermia
Elevated intragastric	Secondary to transient contraction of abdominal muscles during fasciculation; however, elevations of intragastric pressure seen after succinylcholine are not

pressure	clinically relevant; less significant than occur with CO ₂ insufflation during laparoscopic procedures
Elevated intracranial pressure (ICP)	Postulated to be secondary to fasciculation, increased central venous pressure; associated with increased cerebral blood flow secondary to muscle-spindle afferent activity and actions on peripheral neuromuscular junctions ICP effects can be blocked by pretreatment with a small dose of nondepolarizing relaxant and the usual initial administration of an induction agent; may safely be used in neurosurgical procedures)
Elevated intraocular pressure (IOP)	Increases IOP within 1 minute and peaks at an increase of 9 mm Hg within 6 min after administration; increase is a vascular event, with choroidal vascular dilation or a decrease in drainage secondary to elevated central venous pressure, temporarily inhibiting the flow of aqueous humor through the canal of Schlemm; generally considered safe in ocular emergencies
Malignant hyperthermia	Associated with a genetic predisposition; mechanism by which succinylcholine triggers the syndrome is not understood
Masseter spasm	Seen in anesthetic and emergency use; sometimes followed by malignant hyperthermia

CO₂, Carbon dioxide; K⁺, potassium.

Box 12.5

Contraindications to the Use of Succinylcholine

- Hyperkalemia
- Burn patients with injuries of over 35% total body surface area (TBSA), third-degree burn
- Severe muscle trauma
- Neurologic injury (e.g., paraplegia, quadriplegia)
- Hyperkalemia resulting from renal failure
- Severe sepsis (e.g., abdominal)
- Muscle wasting, prolonged immobilization, extensive muscle denervation
- Malignant hyperthermia
- Duchenne muscular dystrophy

- Selected muscle disorders (see [Table 12.9](#))
- Should be used in children under 8 years old only in emergency situations; not for routine intubation
- Genetic variants of pseudocholinesterase
- Allergy

Other Factors

Intraocular Pressure.

Intraocular pressure (IOP) is known to increase by 5 to 15 mm Hg for as much as 10 minutes after succinylcholine administration.^{43,84} The average is approximately 10 mm Hg for approximately 6 minutes. The exact mechanism of this increase is unknown. Some feel that tonic contractions of the extraocular muscles via fasciculation may explain this IOP increase. It is now thought, however, that succinylcholine-induced IOP increase is a vascular event, with choroidal vascular dilation or a decrease in drainage secondary to elevated central venous pressure temporarily inhibiting the flow of aqueous humor through the canal of Schlemm.⁸⁴

This rise in IOP with succinylcholine administration is significantly less than the IOP increase associated with coughing or bucking. Patients who receive succinylcholine and are intubated 1 minute after its administration had IOPs that were not significantly higher than baseline. There are no documented reports of the extrusion of globe contents following the use of succinylcholine in open-eye emergency procedures. A 2006 review has essentially refuted the issue of eye damage after succinylcholine administration in open-globe injuries. It appears as a theoretical but not a clinical concern. Securing the airway remains the primary issue.^{36,43,84} A thorough discussion of the use of succinylcholine and eye injuries is found in [Chapter 44](#).

Hyperkalemia.

Succinylcholine administration results in a transient hyperkalemia.

A 0.5- to 1-mEq/L increase in serum potassium levels within 3 minutes after administration is usual. The effects were reported as lasting fewer than 10 to 15 minutes.⁶¹

A muscle receives signals to perform various functions from action potentials. As the action potential traverses the neuron, an influx of sodium and release of potassium occur. This mechanism of potassium release during normal muscle signaling is the same mechanism by which serum potassium increases because of the depolarization associated with receiving succinylcholine.⁶¹

Hyperkalemia may be profound in certain patients. In a review, Martyn and Richtsfeld⁸⁵ noted that lethal hyperkalemic responses to succinylcholine continue to be reported, although the mechanisms have not been completely elucidated. In the normally innervated mature muscle, AChRs are located only in the junctional area. But in certain pathologic states—including upper or lower motor denervation, infection, direct muscle trauma, muscle tumor, muscle inflammation, burn injury, immobilization, and prolonged chemical denervation by muscle relaxants, drugs, or toxins—there is an up-regulation (increase) of AChRs spreading throughout the muscle membrane. There is also an additional expression of two new isoforms of AChRs. The depolarization of these AChRs by succinylcholine and its metabolites leads to potassium efflux from the muscle and severe hyperkalemia. The nicotinic (neuronal) $\alpha 7$ AChRs, which are also in muscle, are depolarized not only by Ach and succinylcholine but by choline. Persistent choline stimulation may play a critical role in the hyperkalemic response to succinylcholine in patients with up-regulated AChRs.⁸⁵ Pathologic conditions with the potential for producing hyperkalemia

associated with succinylcholine use are listed in [Box 12.6](#).

Pathologic Conditions with Potential for Hyperkalemia with Succinylcholine

- Upper or lower motor neuron defect
- Spinal cord trauma
- Prolonged chemical denervation (e.g., muscle relaxants, magnesium, clostridial toxins)

- Direct muscle trauma, tumor, or inflammation
- Select muscular dystrophies and myopathies
- Thermal trauma
- Disuse atrophy
- Stroke
- Tetanus
- Severe infection

Succinylcholine has been implicated in hyperkalemia after its administration to burn patients; therefore it is contraindicated in these patients.⁸⁶ Receptor up-regulation resulting from thermal trauma has been associated with several documented cases of cardiac arrest involving succinylcholine administration.⁵⁰ Indeed, plasma potassium levels as high as 15 mEq/L have been reported after the administration of succinylcholine, with this effect occurring 4 to 10 days after the burn and lasting for years.⁸⁷ The burn injury–related increase of AChRs is probably related to inflammation and local denervation of muscle. Major third-degree burns involving extensive body surface area may up-regulate AChRs throughout the body because of the extent and direct inflammation and injury to muscle. Hyperkalemia after burn injury to a single limb (8% body surface area) has been observed, indicating that burn size alone is not the only contributing factor. It is generally reported that the administration of succinylcholine to a burn patient more than 24 hours after the burn is unsafe; however, others note that succinylcholine can be safely used with burn patients for several days after the burn, because receptor up-regulation does not begin until 24 to 48 hours after the burn.^{88,89} Martyn recommends avoidance of succinylcholine, starting 48 hours after injury.⁸⁹ Changes in responses to both succinylcholine and the nondepolarizing agents have been noted for years after a major burn injury. Immobilization due to contractures may play a role. Succinylcholine should never be used in these patients,

regardless of the time postburn.^{84,90}

Treatment of succinylcholine-induced hyperkalemia involves the emergency administration of drugs that promote the cellular uptake of potassium; these include insulin with glucose, catecholamines, and sodium bicarbonate.

The use of various muscle relaxants in patients with muscle disorders is reviewed in [Table 12.9](#).

TABLE 12.9
Anesthetic Considerations in Patients With Muscle Disorders

Muscle Disorder	Succinylcholine	Nondepolarizing Muscle Relaxant	Regional Anesthesia	Volatile Anesthetic	Malignant Hyperthermia (MH) Risk
Dystrophinopathies (Duchenne and Becker muscular dystrophy)	Contraindicated	Increased sensitivity	Yes	No; may produce significant rhabdomyolysis	Weak evidence of susceptibility
Myasthenia gravis	Prolonged duration if anti-cholinesterase (ACHE) continued; Sensitive if ACHE discontinued	Increased sensitivity	Yes	Yes	Not susceptible
ALS (amyotrophic lateral sclerosis); Lou Gehrig disease	Contraindicated	Increased sensitivity	Yes	Yes	Not susceptible
Lambert-Eaton syndrome	Contraindicated	Increased sensitivity	Yes	Yes	Not susceptible
Guillain-Barre syndrome	Contraindicated	Increased sensitivity	Yes	Yes	Not susceptible
Charcot Marie tooth disease	Contraindicated	Increased sensitivity	Controversial	Yes	Not susceptible
Mitochondrial myopathy	Contraindicated	Variable sensitivity	Yes	Yes	Not susceptible

Myotonic dystrophy	Contraindicated	Increased sensitivity	Yes	Controversial	Not susceptible
Multiple sclerosis	Contraindicated	Increased sensitivity	Epidural safe; spinal controversial	Yes	Not susceptible
Critical illness polyneuropathy and critical illness myopathy	Contraindicated	Variable resistance	Avoided unless major risk for gen. anesthesia	Yes	Not susceptible
Central core disease	Contraindicated	Increased sensitivity	Yes	Avoid	Susceptible
Hyperkalemic periodic paralysis	Contraindicated	Increased sensitivity	Yes	Avoid	Not susceptible
McArdles disease	Contraindicated	Variable sensitivity	Yes	Avoid	Weak evidence susceptible
Friedreich's ataxia	Contraindicated	Variable sensitivity	Yes, but may be difficult due to severe scoliosis	Yes	Not susceptible
Chronic inflammatory demyelinating polyneuropathy	Contraindicated	Increased sensitivity	Avoid	Yes	Not susceptible
Huntington disease	Yes, but may have low levels or fluoride resistant genotype pseudochoolinesterase	Normal response	Yes	Yes	Not susceptible

Recommendations for anesthesia and perioperative management of patients with neuromuscular disorders. *Minerva Anesthesiol*. 2013;79(4):419–433; Gurnaney H, et al. Malignant hyperthermia and muscular dystrophies. *Anesth Analg*.

Malignant Hyperthermia.

Malignant hyperthermia (MH) is a pharmacogenetic skeletal muscle disorder triggered by volatile anesthetics, succinylcholine, and stress. Succinylcholine is absolutely contraindicated in patients with known or suspected MH or who have MH in their families.⁹¹ The mechanism for the possible triggering action remains unclear.⁹² Mutations in the skeletal muscle ryanodine receptor gene may result in altered calcium release from sarcoplasmic reticulum stores, giving rise to MH. Patients who develop MH show signs such as muscle rigidity, rhabdomyolysis, increased carbon dioxide production, convulsions, metabolic acidosis, tachycardia, and a rapid increase in temperature.^{93–95} A complete discussion of the physiologic and treatment aspects of MH can be found in [Chapter 36](#).

Myalgias and Fasciculations.

Postoperative muscle pain, particularly in the subcostal region, trunk, neck, upper abdominal muscles, and shoulders, is a common occurrence after succinylcholine administration.⁹⁶ A meta-analysis that included 52 randomized clinical trials found several interesting results.⁹⁷ The incidence of succinylcholine-induced myalgia is high, and symptoms sometimes last for several days. Small doses of nondepolarizing muscle relaxants, approximately 10% to 30% of the ED₉₅, reduce the incidence of fasciculations and myalgia, although pretreatment side effects occur. Higher doses of succinylcholine decrease the risk of myalgia compared with lower doses, and opioids do not have any impact. There is no clear direct relationship between succinylcholine-related fasciculation and myalgia. Pretreatment with sodium channel blockers (i.e., lidocaine) or nonsteroidal antiinflammatory drugs (diclofenac and aspirin) may prevent myalgia.

Myalgias are generally attributed to the occurrence of fasciculations resulting from repetitive firing of the motor nerve terminals, which causes uncoordinated muscle contractions. Patients who experience muscle pain most often are women and those persons who rarely participate in muscular activity.

Conversely, patients at extremes of age, as well as pregnant patients, are least affected. Postoperative myalgias associated with succinylcholine increase in severity with early ambulation, which may consequently delay postoperative healing.⁹⁶

Prevention is the key to avoiding postoperative muscle pain. Although not always effective, the incidence of myalgia is greatly reduced with nondepolarizer pretreatment. Use of no more than 10% of the ED₉₅ is safe and effective and will avoid most of the difficulties of the patient experiencing weakness prior to loss of consciousness. Effective and equivalent doses have been reported as 0.04 mg/kg rocuronium, 1.5 mg atracurium, and 0.3 mg vecuronium.^{98,99}

Phase II Block.

Administration of large doses of succinylcholine results in an alteration in the characteristics of the block.⁴⁹ Succinylcholine produces specific unique responses to nerve stimulation when compared with the nondepolarizing agents. These include a sustained response to tetanic stimulation, no fade with TOF or DBS, and no posttetanic potentiation. [Figs. 12.9](#) and [12.10](#) show the characteristic TOF responses during onset and recovery from succinylcholine-induced block, respectively. [Box 12.7](#) compares the characteristics of depolarizing and nondepolarizing neuromuscular blockade. Large doses of succinylcholine cause changes that resemble more of a nondepolarizing block, as evidenced by fade in response to tetanic stimuli, TOF, and DBS, the appearance of posttetanic potentiation, and theoretically, antagonism with drugs such as neostigmine. This is commonly referred to as a *desensitization*, *dual*, or *phase II block*. Some experts do not use these terms interchangeably.⁴⁸

FIGURE 12.9 Characteristic train-of-four response during the onset of succinylcholine.

FIGURE 12.10 Characteristic train-of-four response during recovery from succinylcholine.

Box 12.7

Characteristics of Neuromuscular Blockade

Depolarizing (Phase I) Block

- Muscle fasciculation precedes onset of neuromuscular blockade
- Sustained response to tetanic stimulation
- Absence of posttetanic potentiation, stimulation, or facilitation
- Lack of fade to tetanus, train-of-four, or double-burst stimulation
- Block antagonized by prior administration of nondepolarizer as pretreatment (approximately 20% more succinylcholine required)

- Block potentiated by anticholinesterase drugs

Nondepolarizing (Phase II) Block

- Absence of muscle fasciculation
- Appearance of tetanic fade and posttetanic potentiation, stimulation, or facilitation
- Train-of-four and double-burst fade
- Reversal with anticholinesterase drugs
- In rare cases may be produced by an overdose and desensitization with succinylcholine at doses greater than 6 mg/kg

As explained earlier, tetanic fade is caused by an interaction with cholinergic presynaptic receptors mediating positive feedback–induced ACh release from the motor nerve end.^{33,85} The finding that high doses of succinylcholine inhibited presynaptic $\alpha_3\beta_2$ AChRs (i.e., the compound behaved like a nondepolarizing relaxant) may help explain how high or repeated doses of succinylcholine result in a nondepolarizing type of block (phase II block) characterized by fade and posttetanic potentiation.¹⁰⁰ The exact mechanism is unclear; however, an electrical imbalance caused by repeated opening of junctional channels has been proposed.⁴⁸ Development of a desensitization block is a historic discussion because doses exceeding 6 to 8 mg/kg are required, and high doses, as seen with succinylcholine infusions, are no longer used in current practice.

Nondepolarizing Agents

The efficacy of the nondepolarizing relaxants is similar, so the choice of one drug over another is largely made on other factors. Specific patient characteristics, type of surgical procedure, pharmacokinetics, and side-effect profile guide the selection of an individual relaxant for a given situation. The intermediate duration nondepolarizing relaxants are almost exclusively used in current clinical practice.

Rocuronium Bromide

Rocuronium is the most widely used nondepolarizing relaxant in the United States.¹³ The introduction of vecuronium and atracurium, both of which were marketed as intermediate-acting NMBAs, improved the flexibility of the clinician in matching the agent to the expected duration of surgery.¹⁰¹ Slow onset, solution stability, and histamine release remained problems to be overcome.¹⁰² Rocuronium (Zemuron) has been developed to partially fill this void. It combines a duration and cardiovascular profile comparable to those of vecuronium, with an onset that is only slightly longer than that of succinylcholine.¹⁰¹⁻¹⁰³

A derivative of vecuronium, rocuronium bromide is chemically designated as 1-[17 β -(acetyloxy)-3 α -hydroxy-2 β -(4-morpholinyl)-5 α -androstane-16 β -yl]-1-(2-propenyl) pyrrolidinium bromide, and it has one-seventh to one-eighth the potency of its derivative.^{38,49,103} It is a monoquaternary structure that also shares its aminosteroid structure with pancuronium¹⁰⁴ (Fig. 12.11). The pH of rocuronium is adjusted to 4.0, and the agent contains no preservative. It exists in a solution that is stable at room temperature for up to 30 days.¹⁰⁵

FIGURE 12.11 Chemical structures of nondepolarizing muscle relaxants.

Results of clinical studies of both healthy children and healthy adults suggest an ED₉₅ of approximately 0.3 mg/kg.³⁷ Its steady-state volume of distribution in healthy adults is 207 (14) mL/kg and is slightly smaller for children ages 4 to 8 years. Rocuronium is approximately 46% bound to human plasma proteins, somewhat less than other neuromuscular blockers. This decreased plasma protein binding may lead to a slightly more rapid onset because more unbound drug is readily available at the neuronal binding sites.¹⁰⁶

Pharmacokinetics

Onset.

Rocuronium is the drug of choice and is widely used as the NMBA for rapid sequence induction (RSI) when succinylcholine is contraindicated. A disadvantage of using rocuronium during RSI is its long duration of action.^{107,108}

Administration of rocuronium with doses ranging from 0.6 to 1.2 mg/kg provides good to excellent intubating conditions within 45 to 90 seconds.^{39,109,110} A meta-analysis noted that although rocuronium 1.2 mg/kg produces excellent intubating conditions, succinylcholine is superior in achieving excellent and clinically acceptable intubating conditions. It also has a shorter duration of action which is clinically advantageous.^{111,112} The onset of muscle relaxants is related to potency. The less potent an agent, the faster the onset. Rocuronium has an onset of action that is inversely proportional to its potency,¹⁰³ and it is less potent than other steroidal-based neuromuscular blockers.^{113,114} This decreased potency allows a larger mass of drug at the prejunctional and postjunctional cholinergic receptors.^{39,113} This large drug mass at the receptor site yields a faster onset.^{115,116}

One method used clinically to accelerate the onset of rocuronium when administering it to intubate during RSI is referred to as *priming*. Priming involves giving 10% of the calculated intubating

dose prior to inducing anesthesia. After a period of 1 to 3 minutes, the patient is anesthetized, and the remaining rocuronium is given. Giving a small portion of the relaxant dose in this manner speeds the onset by valuable seconds.¹¹⁷⁻¹¹⁹ Priming, however, produces respiratory distress in 10% of the patients in which it is used.¹²⁰

Duration.

Rocuronium is classified as an intermediate duration relaxant.⁴¹ In usual ED₉₅ doses, it lasts 30 to 60 minutes. The duration of action is similar to that of vecuronium, and its duration depends, like that of any other agent, on the dose administered.³⁸ An intubating dose of 0.6 to 1 mg/kg provides a clinical duration of 30 to 90 minutes.^{38,39} The administration of 0.6 mg/kg resulted in 10% recovery of T₁ within 27.2 (5.5) minutes, whereas 25%, 75%, and 90% recovery of T₁ occurred in 31.1 (5.6) minutes, 39.3 (6.2) minutes, and 41.2 (6.1) minutes, respectively.¹²¹ Recovery of the TOF ratio to 0.8 when rocuronium was administered with sevoflurane, isoflurane, and propofol occurred in 103 (30.7), 69 (20.4), and 62 (21.1) minutes, respectively.¹²²

Elimination.

Rocuronium undergoes both hepatic and renal elimination. The primary means of rocuronium elimination is biliary elimination of unchanged drug. It also undergoes deacetylation via the liver.¹²¹⁻¹²³ Renal excretion accounts for 33% of elimination.⁴⁹ Plasma levels of rocuronium follow a three-compartment open model. This results in extensive redistribution after IV injection. Therefore, before elimination occurs, serum levels of the drug are low enough to result in substantial recovery.³⁷ The elimination half-life of rocuronium is 60 to 120 minutes. The elimination half-lives of the agent in children, normal adults, and elderly persons are 38.3 minutes, 56 minutes, and 137 minutes, respectively.^{113,124} Patients with significant liver or kidney disease will have a prolonged effect.^{52,63}

Vecuronium Bromide

Vecuronium bromide (Norcuron) is a potent nondepolarizing

neuromuscular blocker. Studies comparing vecuronium with pancuronium, its predecessor, found vecuronium to be 1.5 times more potent than its parent compound.¹²⁵ Both agents were developed by manipulation of the steroid nucleus. The molecule was successfully altered from bisquaternary pancuronium to a monoquaternary compound, creating an agent with a more rapid onset and a shorter duration. Vecuronium is more lipophilic than pancuronium, although it is still predominantly a hydrophilic compound. This change in its solubility is thought to be the cause of its differing pharmacokinetic profile.^{126–128}

It is chemically designated as piperidinium 1-[(2 β , 3 α , 5 α , 16 β , 17 β)-3, 17-bis(acetyloxy)-2-(1-piperidinyl) androstan-16-yl]-1-methyl bromide¹²⁷(see Fig. 12.11).

Vecuronium is available as a 10- or 20-mg, sterile, nonpyrogenic powder for IV use only. Once reconstituted, the solution has a pH of 4.0 and is stable for 24 hours at 25°C.¹²⁷ Miller et al.¹²⁶ constructed dose-response curves to derive the ED₉₅, which they found to be 0.03 mg/kg. The agent has a steady-state volume of distribution of 0.21 to 0.27 L/kg.¹²⁸

Pharmacokinetics

Onset.

Vecuronium has an onset of action that is 1.5 times that of pancuronium, a proportion similar to that of its potency.^{129,130} At a dose of twice the ED₉₅, 0.1 mg/kg, the maximum suppression of muscle twitch occurs within 3 minutes of administration. The onset varies with the concurrent anesthetic administered and is inversely proportional to the dose.¹³¹ With balanced anesthesia, a 0.1-mg/kg dose of vecuronium resulted in an onset of 3.1 minutes, whereas in patients receiving isoflurane, nitrous oxide–oxygen (N₂O–O₂) anesthesia, the onset time decreased to 1.8 minutes.^{128,132–134}

Duration.

Duration of action varies with the type of anesthetic being administered and the dose of the agent. This phenomenon has been noted with other nondepolarizing agents, as well as with

vecuronium.¹³⁴ The duration is 36.2 ± 6.4 minutes after a dose of 0.1 mg/kg in patients undergoing intravenous anesthesia.¹³² The time from 25% twitch recovery to 75% twitch recovery at a dose of 0.1 mg/kg was 11 to 12 minutes and the duration 30 to 45 minutes.

Elimination.

Vecuronium is eliminated via hepatic and renal mechanisms. Vecuronium undergoes elimination via an orthodox three-compartment model. Because it is more lipophilic than other agents in its class, vecuronium does not depend solely on the kidneys for elimination. Only 20% to 30% of the administered dose is recovered unchanged in the urine within 24 hours.¹²⁶ A major portion of the dose, 40% to 80%, is taken up by the liver and excreted in bile.¹³⁰ Small amounts of its metabolites (3-hydroxy, 17-hydroxy, and 3,17-hydroxy) can be detected by thin-layer chromatography. The 3-desacetyl metabolite is thought to have approximately 50% the potency of vecuronium.⁹ It is avoided in critical care units for long-term administration because of accumulation. Reported elimination half-lives range from 51 to 90 minutes in healthy adults. Total clearances have been reported from 3 to 5.6 mL/kg per min.^{125,135,136}

Pancuronium Bromide

Pancuronium bromide was first synthesized for Organon in England in 1966. Researchers, especially Lewis et al., were searching for an agent that was nondepolarizing, had a rapid onset, had an intermediate duration of action, was easily reversed, and had no significant unwanted side effects.⁶ After clinical use by Baird and Reid in 1967 in Europe, the agent was introduced in the United States in 1972.¹³⁷⁻¹⁴⁰

The chemical designation of pancuronium bromide is $2\beta, 16\beta$ -dipiperidine- 5α -androstane- $3\alpha, 17\beta$ -diol diacetate dimethobromide (see Fig. 12.11). It has a volume of distribution of 0.18 to 0.26 L/kg; is an odorless, white, crystalline powder; and has a melting point of 215°C . Extensive testing revealed an effective dose of 0.02 to 0.05 mg/kg in mice, rats, rabbits, cats, and dogs.⁶ Further research determined the ED_{95} of pancuronium to be 0.075 mg/kg in humans.^{135,136}

Pharmacokinetics

Onset.

The mean time to depression of twitch to 5% of control values after a dose of twice the ED₉₅ (0.14 mg/kg) is 4.4 (0.5) minutes.¹⁴¹ At a dose of 1.5 ED₉₅, which is estimated as 0.08 mg/kg, an onset time to 90% blockade was 2.3 ± 0.3 minute.^{142,143}

Duration.

Pancuronium is a long-acting nondepolarizer that does not release histamine.¹³⁸ At an ED₉₀ dose of 0.062 mg/kg, the mean duration of blockade was 109 minutes.¹⁴⁴ The average duration is 60 to 90 minutes.

Elimination.

Pancuronium is excreted mainly via the kidney. Thirty-five percent of the drug is also released in the bile.⁹³ Up to 24 hours after the injection of pancuronium, anywhere from 43% to 67% of unchanged drug may be found in the urine.¹⁴⁰ Its half-life is prolonged and clearance is reduced in patients with renal failure.¹⁴⁵ A summary of the selected properties of the neuromuscular blocking agents is given in [Table 12.10](#).

TABLE 12.10

Summary of Select Properties of Neuromuscular Blocking Agents

Classification	ED ₉₅ (mg/kg)	Intubating Dose Usually 2– 3 × ED ₉₅ (mg/kg)	Onset	Duration	Metabolism	Elimination		Automatic Ganglia Effect (SNS & PNS)
						Kidney (%)	Liver (%)	
Ultrashort								
Succinylcholine (Anectine, Quelicin)	0.3	1–1.5	30–60 sec	5–10 min	Plasma cholinesterase	< 2	0	Stimulates
Intermediate								
Atracurium (Tracrium)	0.15	0.5	2–4 min	30–60 min	Hofmann elimination, nonspecific esterase	10–40 metabolites	0	0

					hydrolysis				
Cisatracurium (Nimbex)	0.05	0.1	2–4 min	30–60 min	Hofmann elimination, nonspecific esterase hydrolysis	Up to 77 metabolites	0	0	
Rocuronium (Zemuron)	0.3	1	1–3 min	30–60 min	Hepatic and renal	10–30	70–90	0	
Vecuronium (Norcuron)	0.05	0.1	2–4 min	30–60 min	Hepatic and renal	40–50	50–60	0	

Atracurium Besylate

Atracurium (Tracrium) was developed as a result of a joint venture between the Department of Pharmaceutical Chemistry at the University of Strathclyde and Wellcome Research Laboratories.¹⁴⁶ The objective of the investigators was to develop an agent with the following characteristics:

- Competitive bisquaternary neuromuscular blocker
- Highly selective in action
- Degradable without renal or hepatic intervention^{146,147}

The resulting agent was a bisquaternary competitive neuromuscular blocker in the form of a besylate salt.^{126,146}

Atracurium is classified as a benzyliisoquinolinium and is designated as 2,2'-[1,5-pentanediy]bis[oxy(3-oxo-3,1-propanediyl)] bis[1-[(3,4-dimethoxyphenyl) methyl]-1,2,3,4-tetrahydro-6,7-dimethoxy-2-methylisoquinolinium] dibenzenesulfonate. (see Fig. 12.11). The pH of atracurium is adjusted to 3.25 to 3.65, and the agent contains the preservative benzyl alcohol. Atracurium loses potency at the rate of 6% per year when it is refrigerated at 5°C. At room temperature, the agent degrades approximately 5% per month, and its recommended unrefrigerated shelf life is 14 days. It was developed with an intermediate duration in mind, and it spontaneously degrades to inactive products. It is well absorbed intravenously, with an ED₉₅ of 0.10 to 0.25 mg/kg.^{126,148}

Atracurium is rapidly distributed throughout the extracellular space after IV injection and has a volume of distribution of 153 (13) mL/kg. It is approximately 82% protein bound and does not distribute into the fat, because it is ionized.¹⁴⁹ Obese patients who received atracurium according to ideal body weight demonstrated no difference in recovery indices or recovery times when compared

with control patients of normal weight because of the agent's lack of organ dependency for elimination.¹⁵⁰⁻¹⁵² The chemical structure of atracurium besylate is shown in Fig. 12.11.

Pharmacokinetics

Onset.

As expected, atracurium has an onset time that is inversely proportional to dosage, in the range of 1.2 to 2.8 minutes. When various doses of atracurium were given to 70 patients anesthetized with fentanyl, thiopental, and N₂O-O₂ anesthesia, clinical effects were seen at doses of 0.3 to 0.6 mg/kg. Other investigators, however, have found the onset to be longer, in the range of 2.31 to 3.55 minutes.^{131,132,153}

Duration.

The duration of atracurium increases as its dose increases. Duration of maximum effect and duration to 95% recovery of peak contraction are reported in the range of 5.6 to 69.5 minutes.^{132,154,155} On average, as an intermediate relaxant, the duration of action is 30 to 60 minutes.

Elimination.

The development of atracurium arose from the discovery of the plant *Leontice leontopetalum* and one of its components, designated *petaline*. This component was similar to tubocurarine and was observed to undergo an unexpectedly facile degradation in mild alkali by the well-known Hofmann elimination pathway, with loss of water and formation of a tertiary base.¹⁴⁸ Stenlake's pursuit of this research led to the development of atracurium, which does not rely on any organ system for its breakdown and elimination. Study of the clinical pharmacology of atracurium reveals that its molecules decompose by Hofmann elimination, as well as by nonspecific ester hydrolysis.^{146,148,150,156}

Hofmann elimination is a temperature- and pH-dependent breakdown of the drug molecule. In the vial, atracurium is at room temperature in an acidic medium. When injected, the pH rises to blood pH of 7.4, and the temperature increases to body

temperature. These increases in pH and temperature allow the Hofmann elimination to ensue. Atracurium degrades via Hofmann elimination (10% to 40%). In mild alkaline states, fission occurs at the quaternary nitrogen position, and laudanosine is subsequently released.^{156,157} The agent then degrades further. Ester hydrolysis also occurs, and it is catalyzed by nonspecific esterases into a quaternary alcohol and a quaternary acid.^{146,156} These metabolites are excreted primarily in bile and urine.

Cisatracurium Besylate

The most notable of the ten stereoisomers of atracurium, cisatracurium besylate (Nimbex) has gained popularity in the clinical arena since the mid-1990s. It is a nondepolarizing muscle relaxant, three times more potent than atracurium with a slower onset of action. The agent is available as a sterile, nonpyrogenic aqueous solution in 5-, 10-, and 20-mL vials. The pH is 3.25 to 3.65, and the concentration is 2 mg/mL (except in the 20-mL vial, in which the concentration is 10 mg/mL for convenience in the intensive care unit setting).¹⁵⁸ Advantages of cisatracurium include maintenance of cardiovascular stability, nonorgan-dependent elimination, and a lack of histamine release after injection.^{159,160}

Pharmacokinetics

Onset.

Cisatracurium is regarded as intermediate in its onset and duration of action. In adults the ED₉₅ is 0.05 mg/kg during N₂O-O₂ opioid anesthesia.¹⁶¹ It has been noted to be five times more potent than rocuronium, with a slower onset of action, longer duration, and slower spontaneous recovery.^{162,163} An IV bolus of 0.1 mg/kg (twice the ED₉₅) produces desired levels of relaxation within 3.1 minutes.¹⁶⁴ Doses of three to four times the ED₉₅ (0.15 to 0.2 mg/kg) decrease the mean time of onset to 3.4 and 2.8 minutes, respectively.¹⁶⁵

Duration.

After doses of three to four times the ED₉₅, the average time for the first twitch in a TOF to recover to 25% of control is 65 minutes.¹⁶⁶

Further studies report that the duration of cisatracurium with an intubating dose of 0.25 mg/kg is 55 to 75 minutes. Full recovery at the aforementioned dose occurs in 75 to 100 minutes. Additional sources report the duration as 55 to 61 minutes.¹⁶⁷

Elimination.

Cisatracurium, like atracurium, undergoes Hofmann elimination (which is pH and temperature dependent) in the plasma and tissues. Hofmann elimination accounts for 77% of total body clearance, and nonspecific esterases are responsible for 23% of total body clearance. Of the organ-dependent clearance, 16% occurs through renal pathways.¹⁶⁸ Studies have demonstrated a half-life of approximately 26 to 36 minutes, with an increase in the rate of degradation as pH increases.¹⁶⁹ As with atracurium, one of the metabolites of cisatracurium is laudanosine along with acrylates. However, cisatracurium liberates one-fifth as much laudanosine as atracurium.¹⁷⁰

Mivacurium Chloride

Mivacurium (Mivacron) was marketed as the first “short-acting” NMBA. The drug company that marketed it in the USA stopped in 2006 due to manufacturing issues. A new company plans to reintroduce it in 2016. Its chemical formula is (R-(R*, R*-(E)))-2,2'-((1,8-dioxo-4-octene-1,8-diyl) bis(oxy-3,1-propenediyl) bis(1,2,3,4-tetrahydro-6,7-dimethoxy-2-methyl-1-(3,4,5-trimethoxyphenyl) methyl) isoquinolinium) chloride. Mivacurium is classified as a benzylisoquinolinium and consists of a mixture of three different isomers. Perioperative relaxation is achieved with a dose of 0.05 mg/kg. The ED₉₅ of mivacurium is 0.08 mg/kg. Its degradation by plasma cholinesterase provides it with a short duration^{48,171} (see Fig. 12.11).

Pharmacodynamics

Onset.

The times to 90% suppression of first twitch (T1) in American Society of Anesthesiologists Physical Classification I or II (ASA I or

II) adults has been studied. Those receiving a dose of 0.20 mg/kg achieved this 90% reduction in 2.2 (0.8) minutes, whereas in those receiving a dose of 0.25 mg/kg, onset times decreased to 1.5 (0.8) minutes. The onset time of mivacurium in healthy adults receiving 0.18 mg/kg along with nitrous-oxide–opioid anesthesia was 3.7 minutes.¹⁷² The onset of mivacurium using the adductor muscles of the larynx, as well as the adductor pollicis, was determined to be 2.5 (0.7) minutes at the vocal cords and 4 (1.3) minutes at the adductor pollicis with a dose of 0.07 mg/kg.¹⁷³

Duration.

Mivacurium chloride was developed specifically to fill the niche between the ultrashort-acting succinylcholine and intermediate-acting agents. The duration of mivacurium is 15 to 20 minutes, approximately twice that of succinylcholine, and is dose related. The time to 25%, 75%, and 95% spontaneous recovery of T1 was measured in patients who received nitrous oxide–opioid anesthesia after an infusion dose of 10 mcg/kg per min. These patients recovered in 6.9 (1.6), 11.5 (1.8), and 14.7 (2.8) minutes, respectively.¹⁷⁴

Elimination.

Like that of succinylcholine, mivacurium's degradation by plasma cholinesterase results in its short action. The rate of degradation has been found to be 50% to 90% to that of succinylcholine.⁴⁸ Mivacurium is metabolized into two molecules of a quaternary alcohol and a dicarboxylic acid, and these metabolites are subsequently eliminated in the bile and urine. Any disease process that interferes with the production of this enzyme results in the prolongation of action of this agent.¹⁷⁵

Mivacurium should not be administered to patients with atypical plasma cholinesterase. Patients with a deficiency of plasma cholinesterase exhibit prolonged blockade. Patients who are heterozygous for the atypical plasma cholinesterase gene experienced recovery times that were prolonged approximately 50% compared with those in patients without the gene. Patients who had a homozygous occurrence of the atypical plasma cholinesterase gene experienced significantly prolonged recovery

times as well. Renal excretion via the urine results in the elimination of up to 7% of mivacurium.¹⁷⁶

Pharmacodynamic Summary.

The onset time of mivacurium is dose dependent and ranges from 1.5 minutes with 0.25 mg/kg up to 4 minutes with 0.15 mg/kg. The duration of mivacurium is 15 to 20 minutes. The metabolites of mivacurium are excreted in the urine, after the agent itself has been broken down by plasma cholinesterases. Prolonged paralysis after a test dose of 30 mcg/kg in a patient with a previously known plasma cholinesterase deficit has been reported.⁶⁰

Nondepolarizing Agents' Effect on Various Organ Systems

Central Nervous System

All muscle relaxants are quaternary ammonium compounds and therefore water soluble at physiologic pH. As such, they are unable to cross physiologic barriers such as the blood-brain, placental, and gastric, and therefore have no CNS effects.

Cardiovascular System

The NMBAs have no direct effect on cardiac muscle. Any cardiovascular changes that occur with the administration of a muscle relaxant are caused by indirect actions such as histamine release or effects on the autonomic nervous system. Of the current nondepolarizing relaxants, only atracurium, mivacurium and pancuronium exhibit any cardiac effects. Atracurium and mivacurium are associated with increases in heart rate and decreases in blood pressure at usual clinical doses due to histamine release.^{177,178} Systolic and diastolic pressures significantly decrease, and cardiac output was significantly increased at 2, 5, and 10 minutes after a bolus dose. The increase in cardiac output is the result of a markedly decreased systemic vascular resistance. Nearly all of the hemodynamic changes associated with the administration of atracurium and mivacurium have been linked to the release of histamine.⁴⁸ Administration of cisatracurium does not result in

histamine release. The effects of stimulation of histamine receptors and the resulting effects are listed in [Box 12.8](#).

Effects of Stimulation of Histamine Receptors by Neuromuscular Blockers

H ₁ Receptors	H ₂ Receptors
Increased capillary permeability	Increased gastric acid production
Bronchoconstriction	Systemic and cerebral vasodilation
Intestinal contraction	Positive inotropic effects
Negative dromotropic effects	Positive chronotropic effects

Atracurium and mivacurium release modest amounts of histamine. Slight histamine release may occur with succinylcholine. The amount of histamine release is dependent on dose and speed of injection.

With endogenous histamine release, all receptor responses are elicited.

Prophylaxis against histamine release requires administration of both H₁- and H₂-receptor blockers.

H, Histamine.

Pancuronium produces tachycardia. Significant increases in heart rate 3 minutes after the administration of the agent were noted in patients with coronary artery disease who were scheduled for coronary artery bypass graft and who received a dose of 0.1 mg/kg, despite administration of narcotics. Increases in heart rate are often accompanied by mild increases in mean arterial pressure. The tachycardia results from a vagolytic and an indirect sympathomimetic action. The other steroidal relaxants, vecuronium and rocuronium, have no significant cardiac effects at clinical doses.⁴⁸ The cardiovascular effects of the neuromuscular blocking agents are summarized in [Box 12.9](#).

Cardiac Effects of Neuromuscular Blocking Drugs

- Atracurium and mivacurium cause histamine release and may produce hypotension and tachycardia.
- Pancuronium is vagolytic and causes slight catecholamine release

(indirect sympathomimetic), producing tachycardia.

- Succinylcholine usually results in slight tachycardia. Repeat dosing in adults and any dose in children may produce sudden, abrupt bradycardia. Many types of arrhythmias have been reported.

Hepatic System

The steroidal relaxants rocuronium, vecuronium, and pancuronium are affected by changes in hepatic status. They are primarily eliminated by a combination of liver metabolism and biliary and renal excretion, and therefore their duration of action is prolonged in patients with hepatic disease. Vecuronium, which is metabolized in the liver, has been administered to patients with hepatic disease.^{179–183} Lebrault et al.,¹⁷⁹ for example, compared patients with cirrhosis who received 0.2 mg of vecuronium per kilogram with healthy control patients and found that elimination half-life was prolonged approximately 60%. This effect resulted in a time to return of 50% twitch height of 130 minutes in the cirrhotic group, compared with 62 minutes in healthy patients. Differences in clearance among alcoholic patients with liver disease are dose dependent and usually not significant.¹⁸³ Rocuronium and pancuronium have an increased volume of distribution and elimination times, resulting in significantly longer durations.^{179–182} The duration of action of rocuronium, as well as the onset, is typically prolonged in patients with hepatic disease such as cirrhosis. Patients with hepatic dysfunction demonstrate an elimination half-life that is increased to 173 minutes, compared with the normal 60 to 120 minutes. This supports the finding that the route of plasma clearance of rocuronium is predominantly hepatic with much of the drug excreted being unchanged in bile.¹⁸⁴ Cautious dosing is warranted, along with vigilant monitoring of neuromuscular function in these patients.

An active desacetyl metabolite results from the breakdown of each of the steroidal relaxants. These metabolites exhibit relaxant activity and accumulate with prolonged use. Although this does not pose a problem perioperatively, prolonged paralysis and myopathies in patients with multiorgan failure in critical care units

has been a problem with multiday use. Practice guidelines for sustained neuromuscular blockade in critically ill adults and children have been published.¹⁸⁵⁻¹⁸⁷ Nondepolarizing relaxants are used in intensive care to immobilize patients for procedural interventions, decrease oxygen consumption, facilitate mechanical ventilation, reduce intracranial pressure, prevent shivering, and manage tetanus and acute respiratory distress syndrome (ARDS). Emerging data may support the use of cisatracurium in select patients with ARDS.^{188,189} Cisatracurium may be kinetically preferred for patients with organ dysfunction. Close monitoring with peripheral nerve stimulation is recommended, with sustained use of nondepolarizing relaxants to avoid drug accumulation and minimize the risk for adverse drug events. Reversal of paralysis is best achieved by discontinuing therapy.¹⁸⁸

Atracurium and cisatracurium are not affected by changes in liver function and are the agents of choice for use in patients with liver disease because of their unique method of metabolism, specifically their breakdown pathway via Hofmann elimination and nonesterase-dependent hydrolysis.¹²⁶ Cisatracurium is preferred for its lack of histamine release. The pharmacokinetics of atracurium in patients with hepatic and renal disease was compared with those in nonimpaired control subjects. No differences in plasma elimination half-lives were noted.^{139,190} The effect of atracurium infusions in patients with fulminant hepatic failure who were awaiting liver transplantation, as well as during liver transplantation, has been studied. Plasma clearances and half-lives were similar to those reported in healthy individuals, and no cumulative effects were noted.^{182,183}

Renal System

The steroidal relaxants rocuronium, vecuronium, and pancuronium are affected by changes in renal status. Because all three drugs depend to varying degrees on renal and hepatic elimination, their duration of action is prolonged in patients with decreases in renal function. Pancuronium is largely (80% to 85%) dependent on renal elimination, which is markedly decreased in patients with chronic renal failure and therefore leads to the prolongation of neuromuscular blockade.¹⁹¹ A small portion of rocuronium is

excreted unchanged in the urine, resulting in a prolonged elimination half-life in patients with renal disease.¹⁸⁴ The onset time of rocuronium is not affected by renal failure.

Atracurium and cisatracurium are considered the agents of choice in patients with renal disease. Onset and duration are not affected by changes in renal function. Doses of three times the ED₉₅ (0.15 mg/kg) of cisatracurium were given to 39 patients with decreased renal function, all of whom were induced with fentanyl and thiopental. Onset time, mean arterial blood pressure, heart rate, and time to recovery of 25% T₁ were assessed, and there was no significant variation in the drug effects compared with patients with normal renal function.¹⁹²

Effects in Special Populations

Elderly Patients.

The onset times of the NMBAs are generally delayed in the elderly due to slower circulation times and other kinetic changes associated with aging.¹⁹³ This is true for all relaxants. The dosing interval and duration of action of the steroidal relaxants rocuronium, vecuronium, and pancuronium are prolonged in the elderly due to decreased hepatic and renal clearance and an increased volume of distribution.^{193–196} The duration of atracurium and cisatracurium is not affected by aging, making these the most predictable NMBAs in the elderly.

Obese Patients.

The use of the NMBAs in obese patients raises some special clinical considerations. Obese patients require a rapid-sequence induction more frequently than nonobese patients, owing to their higher risk for gastroesophageal reflux disease and pulmonary aspiration. A difficult airway is more often encountered. It is especially important to ensure full reversal of the relaxant actions in this patient group because of the higher occurrence of breathing abnormalities and lung compromise. Sleep apnea syndrome and the associated anesthetic management must be considered.^{197–200} The duration of action of the steroidal relaxants rocuronium, vecuronium, and

pancuronium are all prolonged. This is likely due to a decrease in elimination.

The kinetics of atracurium and cisatracurium are not significantly changed in obese patients, making these the most reliable agents. Cisatracurium is preferred for its lack of histamine release. Several authors recommend that to avoid overdosing, NMBA should be dosed at ideal body weight, except for succinylcholine, which is given according to total body weight.^{69,70,199,201–204.}

Pediatrics.

When compared with adults, several differences exist among neonates, infants, and children in relation to their response to NMBAs. A more complete discussion of neonatal and pediatric pharmacology is given in [Chapters 52](#) and [53](#). A few general observations can be made here. The neuromuscular junction is incomplete at delivery and continues to mature throughout infancy.²⁰⁵ The sensitivity to any relaxant may change from birth through childhood. Neonates and infants have a higher volume of distribution and differences in redistribution, elimination, and metabolic rates, which vary with age. Young children appear to be more sensitive to nondepolarizing drugs than adults. There is age-related variability in the required dose of an NMBA. The ED₉₅ is the lowest in neonates due to the immaturity of the neuromuscular junction. It is higher in children 3 to 10 years old and increases further toward adult doses in children 13 years and older. The increased volume of distribution (Vd) from an expanded extracellular fluid volume (ECF) in neonates means a similar initial dose (per kilogram) is given to neonates and teenagers. Children tend to require larger doses than adults. The reason for the larger dose requirement in children is unclear but it may be the result of increased muscle bulk.^{206,207}

The onset of action for NMBAs is faster in neonates than it is in older children and adults due to a greater cardiac output per kilogram. The duration of action of the intermediate NMBAs is longer in infants younger than 10 months of age than in children 1 to 5 years of age. Recovery is faster in children than adults.^{206,207}

Other Factors

Hypothermia.

The importance of keeping the patient's core body temperature normothermic cannot be overstated. Hypothermic patients exhibit a prolonged duration of action to all muscle relaxants. This is due to decreased metabolism and delayed hepatic and renal clearance.⁴⁸ Severe (but not mild) hypothermia makes it more difficult to antagonize a neuromuscular block.^{208–210}

Allergy.

The role of muscle relaxants in perioperative anaphylaxis is well established. It primarily follows anesthetic induction but may occur during emergence with sugammadex. It is an IgE-mediated pathological mechanism. Neuromuscular blocking agents and antibiotics are the most common drugs involved. Latex allergy now occurs infrequently. The initial diagnosis is presumptive, whereas the etiological assessment is linked to the clinical presentation, tryptase levels, and skin test results. Because anaphylaxis presents with significant hypovolemia and vasoplegia, aggressive fluid therapy and epinephrine are the cornerstones of management.^{211–214}

Succinylcholine and rocuronium are the most frequently NMBAs involved, and pancuronium and cisatracurium are the least. Cross-sensitization among the different agents is common and is more frequent with aminosteroid than with the benzyloquinoline drugs.^{215,216} Quaternary and tertiary ammonium ions in the relaxant molecules are the main component of the allergenic sites on the reactive drugs. The flexibility of the chain between the ammonium ions, as well as the distance between the substituted ammonium ions, might be of importance during the elicitation phase of IgE-mediated reactions. Flexible molecules, such as succinylcholine, are considered more potent in stimulating sensitized cells than rigid molecules, such as pancuronium.²¹⁷ The rate of NMBA anaphylaxis shows marked geographical variation, suggesting that there may be external or environmental factors involved. Ammonium ions are found in a wide variety of chemical structures, including prescription and over-the-counter medications and common household chemicals. Epidemiological studies have shown a possible link to the consumption of pholcodine, a nonprescription antitussive drug used outside of the United States, which contains a

tertiary ammonium ion, and an increased incidence of NMBA anaphylaxis. This link has prompted the withdrawal of pholcodine in some countries.^{218,219} Skin testing and follow-up guidelines have been published.²²⁰⁻²²² A complete discussion of anaphylaxis management and anesthesia is given in [Chapter 46](#).

Reversal of Neuromuscular Blockade

Complete and effective reversal of the action of the muscle relaxants is one of the most important aspects of clinical practice. Incomplete relaxant reversal and the resulting difficulties continue to be a challenge. The use of nerve stimulators and our knowledge of relaxant pharmacology continue to evolve; however, a significant incidence of postoperative residual paralysis stubbornly remains. Three anticholinesterase agents for reversal of the relaxants are available, although neostigmine is used overwhelmingly. Edrophonium may be used when a faster onset is desired, but its efficacy is less than that of neostigmine. This lower effectiveness limits its use to situations in which significant recovery has already occurred. Pyridostigmine is largely historical and rarely used. It is available for treatment of myasthenia gravis. Fortunately, a new paradigm is unfolding with the introduction of the selective relaxant binding agent (SRBA) sugammadex.²²³

A thorough evaluation of the current data on the clinical use of relaxants and their reversal has been reported and discussed in several publications.^{9,12,13,20,22} The criteria for determination that successful recovery has taken place have been clarified and factors that can affect recovery have been noted. The decision faced by the clinician at the end of a procedure involves determining when the relaxant effects have dissipated and the patient can safely control his or her own airway. A convenient and reliable bedside clinical test for evaluating reversal is needed but not yet available. A number of factors combining objective monitoring with clinical signs must be obtained to assure safe recovery. Several studies have indicated that the incidence of residual paralysis may be as high as 63.5%. The RECITE (Residual Curarization and its Incidence at Tracheal Extubation) study was a prospective observational study completed in 2015 at eight hospitals in Canada investigating the incidence and severity of residual neuromuscular blockade (NMB). They found that the incidence of residual NMB, defined as a TOF ratio less than 0.9, was 63.5% at tracheal extubation and 56.5% at arrival at the PACU.²²⁴ Other studies have noted similar results.²²⁵ Residual paralysis may be evident even up to 4 hours after use of

an intermediate relaxant.^{226,227} This phenomenon is frequently referred to as *recurarization*, implying that adequate reversal was obtained but the drug effect was reestablished. This term is a misnomer because the noted effect is most likely unrecognized residual paralysis. Reversal should not be attempted unless spontaneous recovery of 1 to 2 twitches of the TOF has occurred because the block may be too deep to obtain adequate reversal.⁹⁻¹² Many clinicians recommend that 4 twitches of the TOF be evident prior to reversal.²²⁷ A TOFR of 0.7 along with additional clinical signs such as strong hand grip and 5-second head lift were used as criteria for adequate reversal for many years. It has since been shown that a TOFR of 0.9 should be the standard attained because even small degrees of residual block increase the incidence of adverse respiratory events and may increase longer-term morbidity as well.^{228,229} This is due to previously unrecognized decreases in airway patency and swallowing unless a TOFR of 0.9 is present. An increased incidence of adverse effects such as hypoxia, hypercarbia, atelectasis, and airway obstruction may occur in the PACU.^{211,230,231} This is especially true in higher risk or elderly patients. A study by Murphy et al.²³² suggests the incidence of significant respiratory adverse events in the PACU is 0.8%. Quantitative monitoring should be the gold standard because qualitative assessments of the signs of recovery are frequently misinterpreted by even the most experienced clinicians. It can be difficult to detect subtle differences in fade of TOF and tetanus with subjective qualitative tests.²³³ Interestingly, many clinicians speculated that the introduction of sugammadex with its high efficacy may reduce the need for neuromuscular monitoring. The opposite has happened. Quantitative monitoring for degree of residual blockade at the end of a procedure is essential for proper administration of sugammadex reversal. Assessment of TOF, and, if no response, the posttetanic count, guide dose selection.

Some adverse effects of residual neuromuscular block are noted

Box 12.10.

Adverse Effects of Residual Neuromuscular Block

Volunteer Studies

- Impairment of pharyngeal coordination and force of contraction
- Swallowing dysfunction/delayed initiation of the swallowing reflex
- Reductions in upper esophageal sphincter tone
- Increased risk of aspiration
- Reductions in upper airway volumes
- Impairment of upper airway dilator muscle function
- Decreased inspiratory airflow
- Upper airway obstruction
- Impaired hypoxic ventilatory drive
- Profound symptoms of muscle weakness (visual disturbances, severe facial weakness, difficulty speaking and drinking), generalized weakness

Clinical Studies in Surgical Patients

- Increased risk of postoperative hypoxemia
- Increased incidence of upper airway obstruction during transport to the postanesthesia care unit (PACU)
- Higher risk of critical respiratory events in the PACU
- Symptoms and signs of profound muscle weakness
- Delays in meeting PACU discharge criteria and achieving actual discharge
- Prolonged postoperative ventilatory weaning and increased

intubation times (cardiac surgical patients)

- Increased risk of postoperative pulmonary complications (atelectasis or pneumonia)

Residual neuromuscular block: lessons unlearned. Part II: methods to reduce the risk of residual weakness. *Anesth Analg*. 2010;111(1):129–140.

General principles for avoiding residual paralysis are given in [Box 12.11](#). Factors influencing the incidence of postoperative residual neuromuscular blockade are shown [Box 12.12](#).

Reversal Considerations in Clinical Practice

Considerations When Return of Muscle Function Is Incomplete

- As with any reversal agent, the ability to counteract a nondepolarizing blocking agent depends on the amount of spontaneous recovery before the administration of a reversal drug.
- Has enough time been allowed for the anticholinesterase to antagonize the block (at least 15 to 30 minutes)?
- Is the neuromuscular blockade too intense to be antagonized?
- Even if recovery appears clinically adequate, a small dose of neostigmine may be prudent if the time since relaxant administration is less than 4 hours.
- Has an adequate dose of antagonist been given?
- Are the other anesthetics and adjunctive agents contributing to patient weakness?
- Has metabolism or excretion of the relaxant been reduced by a

possibly unrecognized process?

- Have acid-base and electrolyte status, temperature, age, drug interactions, and other factors that may prolong relaxant action been contemplated?
- The safest approach when any question as to successful reversal remains is to provide proper sedation and controlled ventilation until adequate recovery is ensured.

Box 12.12

Factors Influencing the Incidence of Postoperative Residual Neuromuscular Blockade

Definition of Residual Neuromuscular Blockade

- Objective train-of-four (TOF) measurements (TOF ratio less than 0.9)
- Clinical signs or symptoms of muscle weakness

Type and Dose of Neuromuscular Blocking Drug (NMBD) Administered Intraoperatively

- Intermediate-acting NMBD
- Long-acting NMBD
- Bolus versus infusion

Use of Neuromuscular Monitoring Intraoperatively

- Qualitative monitoring (TOF and double-burst stimulation studied)

- Quantitative monitoring (acceleromyography studied)
- No neuromuscular monitoring (clinical signs)

Degree of Neuromuscular Blockade Maintained Intraoperatively

- TOF count of 1 to 2
- TOF count of 2 to 3

Amount of Spontaneous Recovery at Time of Reversal

- The greater the extent of spontaneous recovery present, the more effective the reversal

Type of Anesthesia Used Intraoperatively

- Inhalation drugs
- Intravenous anesthesia (total intravenous anesthesia [TIVA])

Type and Dose of Anticholinesterase Reversal Drug

- Neostigmine
- Edrophonium
- Sugammadex

Duration of Anesthesia

Time Interval between Anticholinesterase Administration and Objective Monitoring

- TOF measurements

Patient Factors

- Metabolic derangements in the postanesthesia care unit (PACU) (acidosis, hypercarbia, hypoxia, electrolyte imbalance or hypothermia)
- Organ dysfunction such as renal hepatic cardiac or neuromuscular disease

Drug Therapy in PACU

- Opioids
- Antibiotics
- Lithium
- Magnesium
- Local anesthetics

From Murphy GS, Brull SJ. Residual neuromuscular block: lessons unlearned. Reversal of neuromuscular block. *Br J Anaesth*. 2009;103(1):115–129.

Cholinesterase Inhibitors

The mechanism of action of the cholinesterase inhibitors is primarily the result of its structural relationship and interaction with AChE, a protein with a molecular weight of approximately 320,000 and the capacity to hydrolyze an estimated 300,000 molecules of ACh per minute.²³⁴

Edrophonium, pyridostigmine, and neostigmine all contain an ionized center that actively combines either at the active center or at the site specifically removed from the active center of AChE. Edrophonium is a simple alcohol that contains a quaternary ammonium group.²³⁴ It is considered a reversible inhibitor of cholinesterase because it electrostatically attaches to the anionic site of AChE and is stabilized by hydrogen binding at the esteratic site of the enzyme. Because a true chemical bond is not formed, ACh competes with edrophonium for the binding site of AChE, and therefore it has a shorter duration of action than those of compounds that form a bond.²³⁵

Neostigmine and pyridostigmine are carbamic acid esters of alcohols and contain a quaternary or tertiary ammonium group.²³⁴ These agents form a carbamyl-ester complex at the esteratic site of cholinesterase. This drug-enzyme complex then degrades in the same manner as the ACh-cholinesterase complex. The carbamate group is transferred to AChE, leaving it unable to hydrolyze ACh.⁴⁹

The indirect-acting cholinesterase inhibitors exert their effect by inhibiting AChE, thereby increasing the concentration of endogenous ACh around the cholinergic receptors.²³⁴ They act as alternative substrates for the enzyme. This provides a twofold mechanism in the reversal of neuromuscular blockade. First, increasing the concentration of ACh in the junctional cleft changes the agonist-antagonist ratio, thereby increasing the likelihood that the ACh will reoccupy the receptor site once occupied by the neuromuscular blocker, as well as occupying sites not previously engaged. Second, the life of the ACh within the cleft is increased. The increased concentration of ACh prolongs the time it remains in the cleft, allowing time for the antagonist dissociation and the reactivation of the receptor site. Evidence also suggests that these

agents have direct influences on neuromuscular transmission independent of enzyme inhibition. These include at least three distinct although possibly interacting mechanisms, including a weak agonist action, the formation of desensitized receptor complex intermediates, and the alteration of the conductance properties of active channels.²³⁶

Although the result of inhibition of AChE is the same when edrophonium, neostigmine, or pyridostigmine is administered, the means by which these agents accomplish the task varies. Edrophonium binds reversibly with the negatively charged enzyme site by electrostatic attraction of its positively charged nitrogen. This effect prevents catalytic binding with ACh for the short time that edrophonium occupies the binding site. Although the duration of receptor site occupation is short for edrophonium, the duration of its effects is prolonged by the fact that once it leaves the receptor site, it finds another to occupy and continues with this process until eliminated.²³⁷

Enzymatic inactivation is accomplished by neostigmine and pyridostigmine. Electrostatic interaction between the ionized centers of drug and enzyme takes place initially as with edrophonium. This phenomenon then leads to a hydrolytic chemical reaction in which a shift in covalent bonds occurs, resulting in the formation of a carbamylated enzyme. This methyl-carbamyl AChE is much more stable and resistant to hydrolysis than the acetyl enzyme, resulting in an enzyme that is incapable of inactivating ACh.

These differences in chemical deactivation of AChE result in differing pharmacokinetic profiles. Edrophonium, neostigmine, and pyridostigmine are all quaternary ammonium compounds that are poorly lipid soluble. At moderate doses, penetration through lipid barriers (e.g., gastrointestinal tract, placenta, and blood-brain barrier) is minimal if present at all.

Edrophonium is the most rapid acting of these agents, with an onset time of 30 to 60 seconds after IV administration and a duration of 5 to 10 minutes. Intramuscular administration results in an onset of 2 to 10 minutes.²³⁸ Renal excretion accounts for approximately 75% of the edrophonium eliminated, although in the absence of renal function, hepatic metabolism accounts for the

inactivation of 30% of the injected dose; this amount undergoes conjugation to inactive edrophonium glucuronide. The elimination half-life of edrophonium is 110 minutes in the healthy patient and 304 minutes in the anephric patient. The volume of distribution is 1.1 and 0.7 L/kg in normal and anephric patients, respectively.

Although similar in structure and mechanism of AChE deactivation, neostigmine is more potent than pyridostigmine and has a more rapid onset of action. After IV administration of neostigmine, onset occurs within 4 to 8 minutes. Duration of action is 0.5 to 2 hours, although other sources suggest durations from 60 minutes to 4 hours. Renal excretion accounts for roughly 50% of the neostigmine eliminated, primarily by glomerular filtration. The remaining 50% of the neostigmine dose is hydrolyzed by plasma esterases and hepatic metabolism to 3-hydroxyphenyltrimethyl ammonium (3-OH PPM) and conjugated 3-OH PPM. These metabolites have approximately one-tenth the activity of the parent compounds and are renally eliminated. The elimination half-life of neostigmine is 70 to 80 minutes, increasing to 181 to 183 minutes in anephric patients. The volume of distribution of 0.7 L/kg in healthy patients increases to 0.8 L/kg in those with renal failure.^{234,237} Successful reversal is usually attained in 10 to 30 minutes. In a much discussed report published in 2015, it was noted that there is a dose dependent increase in postoperative respiratory complications when doses of neostigmine exceed 60 mcg/kg. These doses are in the upper range of recommended neostigmine dosing. Neostigmine-induced partial neuromuscular transmission block may explain adverse respiratory outcomes in patients who received high-dose neostigmine after recovery of neuromuscular transmission. They caution that neostigmine does not reverse deep neuromuscular blockade. Administration to patients who present with deep neuromuscular blockade can result in incomplete reversal. Furthermore, it may lead to anesthesia providers falsely believing their patients to have safe return of muscular function.^{239,240}

The pharmacology of the reversal agents is summarized in [Table 12.11](#). The common clinical signs of muscle recovery after administration of a muscle relaxant are listed in [Box 12.13](#). Some considerations that apply when reversal is incomplete are noted in

Box 12.10. Factors that may prolong paralysis are listed in Box 12.14.

TABLE 12.11

Commonly Used Anticholinesterase, Anticholinergic, and Select Relaxant Binding Agents

Agent	Dose Range	Onset (min)	Duration	Comments
Neostigmine	25–75 mcg/kg	5–15	45–90 min	Most commonly used reversal agent; may increase incidence of postoperative nausea and vomiting
Edrophonium	500–1000 mcg/kg	5–10	30–60 min	Not recommended for deep block; rapid onset, short duration
Atropine	15 mcg/kg	1–2	1–2 hr	Should be combined with edrophonium because of more rapid onset
Glycopyrrolate	10–20 mcg/kg	2	2–4 hr	Less initial tachycardia than atropine; no central nervous system effects; most frequently used
Sugammadex	2–16 mg/kg	1–2	2–16 hr	Selective relaxant binding agent; up to 16 mg/kg has been safely used

Box 12.13

Common Clinical Signs of Recovery from Neuromuscular Blockers

- Adequate tidal volume and rate
- Respirations smooth and unlabored
- Opens eyes widely on command; no diplopia
- Sustained protrusion and purposeful movement of tongue
- Effective swallowing and sustained bite
- Able to sustain head or leg lift for at least 5 seconds (In small children, a strong knee-to-chest movement is equivalent.)
- Arm lift and touch the opposite shoulder
- Strong, constant hand grip
- Effective cough
- Adequate vital capacity of at least 15 mL/kg

- Adequate inspiratory force of at least 25 to 30 cm H₂O negative pressure
- Sustained tetanic response to 50 Hz for 5 seconds
- Train-of-four ratio greater than 0.9 with no fade
- No fade to double-burst stimulation

Box 12.14

Factors That May Prolong Paralysis

Pathophysiologic Causes

Acid maltase deficiency

Adrenocortical dysfunction

Acute intermittent porphyria

Amyotrophic lateral sclerosis

Anoxia and ischemia

Carcinomatous polyneuropathy

Cholinesterase deficiency or genetic variance

Compressive neuropathy

Critical illness polyneuropathy

Diphtheria

Eaton-Lambert syndrome

Guillain-Barré syndrome

Hypokalemia and hypocalcemia

Hypomagnesemia
Hypophosphatemia
Hypothermia
Motor neuron disease
Multiple sclerosis
Muscular dystrophy
Myasthenia gravis
Myotonic syndromes
Neurofibromatosis
Nonspecific nutritional deficiency
Poliomyelitis
Pyridoxine abuse
Polymyositis
Renal failure (variable prolongation)
Respiratory acidosis
Sepsis
Thiamine deficiency
Tick bite paralysis
Trauma
Vitamin E deficiency
Wound botulism

Pharmacologic Causes

Aminoglycoside toxicity

Penicillin toxicity

Steroid myopathy

Antihypertensives

Calcium channel blockers

β -blockers

Furosemide

Antidysrhythmics

Quinidine

Procainamide

Local anesthetics in large doses

Antibiotics

Aminoglycoside antibiotics

Polymyxin B

Clindamycin

Tetracycline

Miscellaneous Drugs

Cyclosporine

Steroids

Volatile anesthetics

Dantrolene

Magnesium

Lithium

Azathioprine

Organophosphate (poisoning)

Anticholinergics

Atropine or glycopyrrolate are used in combination with neostigmine or edrophonium to prevent the parasympathomimetic side effects of the anticholinesterase drugs. If given alone, neostigmine and the other anticholinesterase drugs would cause severe vagal effects due to the systemic buildup of acetylcholine. These would include bradycardia and arrhythmias, hypotension, bronchoconstriction, hypersalivation, diarrhea, and an increase in postoperative nausea and vomiting. Glycopyrrolate is used more often because it produces less initial tachycardia and has no CNS effects. The antimuscarinic can be given first or the glycopyrrolate and neostigmine may be mixed in the same syringe.

Anticholinergic, *antimuscarinic*, and *parasympatholytic* are three common terms used to describe compounds that originate from alkaloids of the belladonna plant. Each group name divides these compounds into subgroups that have a more similar mechanism of action. For the purposes of this section, all of the compounds are referred to as *antimuscarinics*. Atropine (*dl*-hyoscyamine) is the prototype of this group, and many of the currently available products are structural derivatives obtained both naturally and synthetically.²⁴¹ Atropine is found in the plant *Atropa belladonna*, or deadly nightshade, and in *Datura stramonium*, also known as *jimson weed*.¹⁴⁹ Preparations of these plants have been used by clinicians for centuries; belladonna was used as a poison during the time of the Roman Empire and in the Middle Ages. In 1867, Bezold and Bloebaun began to study the cardiac effects of bella donna's vagal inhibition, and in 1931 Mein isolated atropine in the pure form.²⁴

Atropine and scopolamine are naturally occurring tertiary amines. Semisynthetic congeners of the belladonna alkaloids represented by glycopyrrolate are usually quaternary ammonium derivatives. These quaternary ammonium derivatives often have potent peripheral effects without CNS activity.

All the antimuscarinics are absorbed orally to some extent, although this route is often unpredictable. Intramuscular or IV administration is usually the route used. Scopolamine has the additional advantage of transdermal absorption. Atropine is well

absorbed from the gastrointestinal tract by inhalation via endotracheal administration and by IV and intramuscular routes. Given orally, 90% of the dose is absorbed and reaches peak plasma levels within 1 hour. Intramuscular and IV administration results in peak plasma levels within 30 minutes and 2 to 4 minutes, respectively. Atropine is well distributed throughout the body. It crosses both the blood-brain barrier and the placental barrier. Both the kidneys and liver aid in the elimination of atropine. Although elimination is biphasic, the terminal half-life is 2 to 3 hours. Metabolism by the liver results in several metabolites: tropic acid, tropine, and glucuronide conjugates. Approximately 30% to 50% of a dose is excreted unchanged in the urine. Small amounts of atropine may also be eliminated in expired air as carbon dioxide and in feces.²⁴¹

Glycopyrrolate is a quaternary ammonium compound whose ionization limits gastrointestinal absorption, blood-brain barrier, and placental penetration. After IV administration, glycopyrrolate has an onset of 1 minute. Intramuscular and subcutaneous administration results in an onset of 15 to 30 minutes. Vagal blockade can persist for 2 to 3 hours. Serum levels of glycopyrrolate decline quickly, and less than 10% of the drug remains in the serum after 5 minutes. Glycopyrrolate is excreted in feces and urine, primarily as an unchanged drug. Small amounts are metabolized to inactive metabolites. Eighty-five percent of an IV dose is excreted in the urine within 48 hours.¹⁴⁹

Atropine and glycopyrrolate are commonly administered to prevent the muscarinic effects of anticholinesterase inhibitors. Atropine induces its vagolytic effect more rapidly than glycopyrrolate. Atropine appears to be somewhat better suited for use with edrophonium, whereas the onset times of glycopyrrolate and neostigmine are more closely matched. When administered with edrophonium, the usual recommended dose of atropine is 7 mcg/kg.¹⁴⁹ With 0.5 to 2.5 mg of neostigmine, the recommended dose of atropine is 0.6 to 1.2 mg, and that of glycopyrrolate is 0.2 to 0.6 mg.²⁴¹ (See [Chapter 13](#), [Table 13.6](#) for a comparison of the anticholinergics.)

Selective Relaxant Binding Agents—

Sugammadex

Sugammadex (Bridion) is the first selective relaxant binding agent (SRBA) to be introduced as a reversal for clinical neuromuscular blockade. The name sugammadex is a contraction of sugar and gamma-cyclodextrin. It is a modified gamma-cyclodextrin that works by encapsulating and forming very tight water-soluble complexes at a 1 : 1 ratio with steroidal neuromuscular blocking drugs. Once encapsulation occurs, it does not dissociate and the sugammadex-relaxant complex is excreted in the urine. Reversal occurs independent of the depth of block; therefore, even deep blockade can be reversed with the appropriate dose. The concentration of free muscle relaxant falls rapidly, and muscle strength is reestablished. It is most effective reversing rocuronium, vecuronium, and pancuronium, in that order. It does not affect the benzylisoquinolines atracurium and cisatracurium.^{242,243} Used in appropriate doses, sugammadex can reverse any depth of rocuronium or vecuronium block within 3 minutes.

Pharmacokinetics

Sugammadex is biologically inactive. The pharmacokinetics of sugammadex show a linear dose relationship in doses up to 8.0 mg/kg. Clearance is approximately 120 L per minute and the volume of distribution is 18 liters. The elimination half-life is 2.3 hours. Up to 80% of an administered dose of sugammadex is eliminated in the urine within 24 hours. Sugammadex does not bind to plasma proteins or erythrocytes. Due to the dependence on renal elimination, the drug should be avoided in patients with significant renal disease.^{237,243}

Clinical Use

The dosage range of sugammadex varies from 2 to 16 mg/kg according to the depth of blockade at the time of reversal. Sugammadex comes in 2 or 5 mL vials. There is 100 mg/mL. Monitoring for twitch responses to determine the timing and dose for sugammadex administration is essential. The drug is administered as a single bolus injection. A dose of 2 mg/kg is

recommended if spontaneous recovery has reached the reappearance of the second twitch in response to TOF stimulation. A dose of 4 mg/kg is recommended if spontaneous recovery of the twitch response has reached 1 to 2 PTC and there are no twitch responses to TOF stimulation. A dose of 16 mg/kg is recommended if there is a clinical need to reverse neuromuscular blockade soon (approximately 3 minutes) after administration of a single dose of 1.2 mg/kg of rocuronium.²⁴⁴⁻²⁴⁶ A suggested dosing strategy for reversal is given in [Table 12.12](#).

TABLE 12.12
Reversal Strategy

Nerve Stimulator Test	Response and Depth of Block	Reversal
Posttetanic count	Profound (count < 3)	Sugammadex 4–16 mg/kg
	Deep (count > 3)	Sugammadex 4 mg/kg
TOF count	Intermediate (TOF count 1–3)	Sugammadex 2–4 mg/kg
	Recovery (TOF count 4)	
	With fade	Neostigmine 60 mcg/kg
	No fade	Neostigmine 30 mcg/kg
TOF ratio	Recovery (TOF count 4)	
	TOF ratio 0–0.8	Neostigmine 30–60 mcg/kg
	TOF ratio > 0.9	Neostigmine 30 mcg/kg or no reversal

TOF, Train-of-four.

Sugammadex appears to be safe and well tolerated. The most commonly reported adverse drug reactions include nausea, vomiting, allergy, hypertension and headache.²⁴⁴ Anaphylaxis has been reported and it is the reason approval was initially delayed by the FDA. It occurs within five minutes of administration.^{244,247-249}

Patients using hormonal contraceptives must use an additional, nonhormonal method of contraception for the next 7 days following sugammadex administration due to an interaction which interferes with contraceptives. An increase in the coagulation parameters activated partial thromboplastin time (aPTT) and prothrombin time/international normalized ratio [PT(INR)] of up to 25% for up to 1 hour has been reported. In patients undergoing major orthopedic surgery of the lower extremity who were concomitantly treated with heparin or low molecular weight heparin for thromboprophylaxis, increases in aPTT and PT(INR) were observed in the hour following a 4 mg/kg dose. Sugammadex is not

recommended for use in patients with severe renal impairment, including those requiring dialysis.²⁴⁴

In the rare event that neuromuscular block needs to be reestablished, a benzylisoquinoline such as atracurium, mivacurium, or cisatracurium should be given. Succinylcholine is not affected.²⁴⁶ Recurarization is rare but has been reported.²⁵⁰

Summary

Like every other agent used in the practice of anesthesia, neuromuscular blocking agents are useful tools in the hands of skilled clinicians. It should go without saying that these agents should never be administered without first appropriately sedating the patient. The exception is if the patient's condition is so marginal that even the most careful use of sedation could increase the chance for morbidity or death. The decision to use neuromuscular blockers in the absence of sedation should be made only after the most careful and thorough consideration. Prevention of movement should provide the surgeon with the optimum field on which life-saving skills can be practiced.

Autonomic and Cardiac Pharmacology

John J. Nagelhout

Cardiovascular medicine continues to be one of the most rapidly changing specialties in modern clinical practice. Management guidelines are continuously being refined as data from large-scale clinical trials are reported. The number of patients requiring noncardiac surgery who have had coronary interventions is increasing. Many patients have complex management plans that require consultation with their cardiologists. Providing high-quality anesthetic care involves continuous monitoring of all the body's systems, with a special emphasis on the cardiovascular status of the patient. Complex anesthetic plans and invasive surgical intervention can produce profound stress on patients' cardiovascular balance and require careful manipulation of vital signs. The array of diagnostic tests, monitors, and drugs available makes a thorough understanding of autonomic and cardiac pharmacology essential. A well-devised treatment plan will make the anesthetic course flow smoothly. Intraoperative planning for the immediate and late postoperative periods is critical to avoiding untoward outcomes. The number and variety of medications in a patient's profile require a delicate balance between the anesthetic requirements and maintaining a successful continuum of therapy for the long-term needs of the patient. This chapter presents a broad overview of the many autonomic and cardiovascular medicines that may be encountered during the perioperative period, and their important anesthetic considerations.

Autonomic Drugs—Sympathomimetic Amines

The sympathomimetic amines include the three naturally occurring catecholamines epinephrine, norepinephrine, and dopamine and a number of synthetic agents such as phenylephrine and dobutamine. These drugs are used in a variety of situations, including the treatment of anesthesia-induced hypotension, bradycardia, anaphylaxis, shock, heart failure, and cardiac resuscitation.

The basic structure of the sympathomimetic amines is β -(3,4-dihydroxyphenyl)-ethylamine. This structure consists of a substituted benzene ring and an ethylamine side chain.¹ The effects elicited by this pharmacologic class are the result of the stimulation of β -adrenergic, α -adrenergic, and dopamine adrenergic receptors. The innervation of the effector organs by the autonomic system is outlined in [Table 13.1](#).

TABLE 13.1
Typical Autonomic Influences on Peripheral Effector Organs

Organ System	Sympathetic Effect	Adrenergic Receptor Type	Parasympathetic Effect	Cholinergic Receptor Type
Eye				
Radial muscle, iris	Contraction (mydriasis)	α_1		
Sphincter muscle, iris			Contraction (miosis)	M ₃ , M ₂
Ciliary muscle	Relaxation for far vision	β_2	Contraction for near vision (accommodation)	M ₃ , M ₂
Heart				
Sinoatrial node	Increase in heart rate	β_1	Decrease in heart rate	M ₂
Atria	Increase in contractility and conduction velocity	β_1	Decrease in contractility	M ₂
Atrioventricular node	Increase in automaticity and conduction velocity	β_1	Decrease in conduction velocity; atrioventricular block	M ₂
His-Purkinje system	Increase in automaticity and conduction velocity	β_1	Little effect	M ₂
Ventricle	Increase in contractility, conduction velocity, automaticity	β_1	Slight decrease in contractility	M ₂
Blood Vessels				
Arteries				
Coronary	Constriction; dilation		None	—

		$\alpha; \beta_2$		
Skin and mucosa	Constriction	$\alpha_1; \beta_2$	None	—
Skeletal muscle	Constriction; dilation	$\alpha_1; \beta_2$	None	—
Cerebral	Constriction (slight)	α_1	None	—
Pulmonary	Constriction; dilation	$\alpha_1; \beta_2$	None	—
Abdominal viscera	Constriction; dilation	$\alpha_1; \beta_2$	None	—
Salivary glands	Constriction and reduced secretions	$\alpha_1; \alpha_2$	Dilation and increased secretions	M_3
Renal	Constriction; dilation	$\alpha_1, \alpha_2; \beta_1, \beta_2$	None	—
Veins	Constriction; dilation	$\alpha_1, \alpha_2; \beta_2$	None	—
Lung				
Tracheal and bronchial smooth muscle	Relaxation	β_2	Contraction	M_2, M_3
GI Tract				
Motility and tone	Decrease	$\alpha_1, \alpha_2; \beta_1, \beta_2$	Increase	M_2, M_3
Sphincters	Contraction	α_1	Relaxation	M_3, M_2
Secretion	Inhibition	α_2	Stimulation	M_3, M_2
Gallbladder and ducts	Relaxation	β_2	Contraction	M
Kidney				
Renin secretion	Increase	β_1	None	—
Urinary Bladder				
Detrusor	Relaxation	β_2, β_3	Contraction	M_3, M_2
Trigone and sphincter	Contraction	α_1	Relaxation	M_3, M_2
Uterus	Contraction (pregnant)	α_1	None	—
	Relaxation (pregnant and nonpregnant)	β_2		
Liver	Glycogenolysis and gluconeogenesis; increased blood sugar	$\alpha_1; \beta_2$		
Pancreas				
Islets (β cells)	Decreased insulin secretion	α_2	None	—
	Increased insulin secretion	β_2	None	—
Adipocytes	Lipolysis	$\alpha_1; \beta_1, \beta_2, \beta_3$	None	—

α , Alpha receptor; β , beta receptor; *GI*, gastrointestinal; *M*, muscarinic receptor.

The efficacy of a particular sympathomimetic amine depends on its concentration at the receptor site, its affinity for specific receptors, and the population of receptors available for binding. The effects of the common autonomic drugs are summarized in [Table 13.2](#).

TABLE 13.2
Effects of Autonomic Drugs

Organ Systems	α -Agonists	α -Blocker	β -Agonists	β -Blocker	Cholinergic Agonists
---------------	--------------------	-------------------	-------------------	------------------	----------------------

Eye	Mydriasis	Miosis (slight)	NCRE	↓ Intraocular pressure	Miosis, ↓ intraocular pressure
Heart					
Rate	Bradycardia (reflex)	Tachycardia (reflex)	Tachycardia	Bradycardia	Bradycardia
Contractility	NCRE	Slight increase (reflex)	↑	↓	↓ (slight)
Conduction velocity	NCRE	NCRE	↑	↓	↓
Blood (vessels)	Vasoconstriction	Vasodilation	Vasodilation	Vasoconstriction	NCRE
Lungs	NCRE	NCRE	Bronchodilation	Bronchoconstriction	Bronchoconstriction
GI Tract	↓ Motility and secretion	NCRE	↓ Motility and secretion	NCRE	↑ Motility and secretion
Uterus	Contraction	NCRE	Relaxation	NCRE	NCRE
Liver	↑ Blood sugar	NCRE	↑ Blood sugar	Hypoglycemia	NCRE

↑, Increase; ↓, decrease; *GI*, gastrointestinal; *NCRE*, no clinically relevant effect.

Epinephrine

Epinephrine, one of the naturally occurring catecholamines, is the final product in the chain of catecholamine synthesis. (See [Chapter 37](#) for a complete description of catecholamine synthesis.) Although both epinephrine and norepinephrine have agonistic activity at both α - and β -receptors, norepinephrine has minimal β_1 activity in low doses, whereas epinephrine strongly stimulates both β_1 - and β_2 -receptors.

Epinephrine is useful not only in the treatment of anaphylaxis and cardiopulmonary resuscitation, but also its combination of α and β effects make it an appropriate choice for the treatment of some shock states that involve both poor tissue oxygen delivery and hypotension. In small doses, epinephrine may well be useful as a sympathomimetic agent in patients unresponsive to indirect-acting agents and in those in whom simultaneous β_1 (cardiac stimulation) and β_2 -receptor stimulation (vasodilation) may be helpful. With epinephrine, the dominance of α or β effects is dose-related.

Epinephrine's β_1 effect produces marked positive inotropic (force of contraction), chronotropic (heart rate), and dromotropic (conduction velocity) actions. It should be noted that as heart rate,

left ventricular stroke work, stroke volume, and cardiac output increase, so does myocardial oxygen consumption. In addition, the corresponding increased automaticity of all foci, including ectopic foci, may lead to arrhythmia. Marked vigilance must be maintained in an effort to ensure that an imbalance of myocardial oxygen supply and demand does not occur. It should be recalled that epinephrine administration can both increase myocardial demand and decrease myocardial supply.

Beneficial effects of β_2 stimulation include bronchodilation, vasodilation, and stabilization of mast cells, with a resultant decrease in histamine release. Concurrently, α stimulation promotes a decrease in bronchial secretion. The net effect is a decrease in airway resistance, with an improvement in oxygenation.

With low doses of epinephrine (10 mcg/min), the peripheral vasculature promotes the redistribution of blood flow to skeletal muscle, thereby producing a decrease in systemic vascular resistance. As the dose of epinephrine is increased, the α effect predominates, with resultant vasoconstriction and an increase in systemic pressures. The systolic pressure is increased, whereas the diastolic pressure remains relatively unchanged, with a resultant increase in pulse pressure. It should be noted that, if the coronary arteries are not obstructed, autoregulation increases oxygen delivery to meet the increased demand.² However, in the presence of a coronary artery lesion, oxygen delivery may be insufficient to meet demand, and myocardial ischemia results.³

The increased α effect that occurs with greater doses of epinephrine also results in renal and splanchnic vasoconstriction. Renal vascular resistance, and ultimately renal blood flow, are decreased. β Stimulation leads to activation of the renin-angiotensin system (RAS), and also to an increase in lipolysis, glycogenolysis, gluconeogenesis, ketone production, and lactate release by skeletal muscle. Insulin secretion is inhibited by an overriding β_2 stimulation. Epinephrine-induced β_2 stimulation also can cause transient hyperkalemia as potassium follows glucose out of hepatic cells. This is followed by a longer hypokalemia as β_2 stimulation then forces this extracellular potassium into red blood cells.⁴

Norepinephrine

Norepinephrine is a potent vasopressor. Although it is not as potent as epinephrine in stimulating α -receptors in equal doses, it has little β_2 activity at low doses, and the end result is, for the most part, unopposed α stimulation. The chronotropic effect seen with β_1 stimulation is generally absent with norepinephrine in low doses, because of the increase in systemic vascular resistance, which induces reflex vagal activity.

The aforementioned combination of adrenergic stimulation results in a decrease in vital organ flow; however, coronary artery perfusion may be increased because of the increase in diastolic pressure. Renal vascular resistance is increased, and urine output may fall. An increase in preload may be seen, because norepinephrine is a venoconstrictor.^{5,6}

Both norepinephrine and dopamine are used as first-line therapy for shock. There is an ongoing debate as to whether either one is superior. A 2016 meta-analysis suggests that they are equally effective, although dopamine produces more adverse events such as arrhythmias, and possibly increased mortality.⁷ Norepinephrine is generally used in patients with adequate cardiac output but low systemic vascular resistance. In this group of patients, however, the underlying problem of peripheral tissue perfusion-oxygenation may be exacerbated by the intense norepinephrine-induced peripheral vasoconstriction, even if adequate blood pressure has been achieved.

Norepinephrine does have some generalized metabolic effects, such as a decrease in insulin production, but these metabolic effects are present to a lesser degree than those seen with epinephrine. Adverse effects are usually a result of the intense vasoconstriction associated with norepinephrine.

Dopamine

Dopamine is an endogenous central and peripheral neurotransmitter that is derived from dopa in the chain of catecholamine synthesis. Pharmacologically, dopamine stimulates dopamine receptors, β -receptors, and α -receptors in a dose-dependent manner because of differing receptor affinities.

Dopaminergic receptors are stimulated with low doses of less than 2 mcg/kg per min. At moderate doses of 2 to 5 mcg/kg per min, β effects are elicited, and α effects are seen with high infusion rates of greater than 10 mcg/kg per min. Dopamine also has an indirect sympathomimetic effect, eliciting the release of norepinephrine via β_1 stimulation.⁸

Norepinephrine is now considered first-line therapy for a patient in shock. Some clinicians have found dopamine to have a poor response in cases of gram-negative sepsis, because the sensitivity of β -receptors is diminished due to a down-regulation.^{9,10}

During surgery and anesthesia, dopamine is administered for its dopaminergic effect. The stimulation of dopamine receptors in the renal artery promotes an increase in renal blood flow and a resultant increase in glomerular filtration rate and urine output. However, the benefits of so-called “renal” dopamine are in doubt, and many clinicians have abandoned the practice.¹¹⁻¹⁴ The urine output increases, but long-term morbidity and mortality do not improve. Dopamine also inhibits aldosterone, resulting in an increase in sodium excretion and urine output.

Dopamine has been implicated in several cases of severe limb ischemia. If dopamine is administered through a peripheral line, increased vigilance in pediatric patients and in patients with any type of vascular disease such as diabetes, atherosclerosis, or Raynaud phenomenon is advised. The presence of an arterial line in the affected limb also increases the incidence of limb ischemia with concurrent dopamine infusion. Other metabolic and central nervous system (CNS) effects, similar to those seen with epinephrine but less extensive, have been attributed to dopamine administration.⁴

The monoamine oxidase enzymes metabolize dopamine; therefore, the effects of dopamine can be prolonged in patients receiving a monoamine oxidase inhibitor. Tricyclic antidepressants may also augment the activity of sympathomimetic drugs.

Isoproterenol

Isoproterenol is a synthetic catecholamine with the same underlying chemical structure as the endogenous catecholamines. It

is a potent nonselective agonist of β_1 - and β_2 -receptors, but has no agonistic activity at α -receptors or dopamine receptors. The use of isoproterenol has been limited since the emergence of dobutamine and milrinone. In current practice, it is occasionally used in the treatment of bradycardia with heart block and *torsades de pointes* ventricular tachycardia.¹⁵ Isoproterenol is also used after heart transplant for chronotropic support.¹⁶

The profound β_1 stimulation induced by isoproterenol results in positive inotropic and chronotropic effects. In combination with the peripheral β_2 -induced vasodilation and resultant drop in systemic vascular resistance, an increase in cardiac output is seen. However, the positive inotropic and chronotropic effects dramatically increase myocardial oxygen consumption, which may already be compromised by the β_2 -induced peripheral vasodilation, causing a decrease in diastolic blood pressure, and ultimately a decrease in coronary artery perfusion. These effects are especially detrimental in patients with coronary artery disease. Isoproterenol is also a potent bronchial dilator and pulmonary vasodilator.

The detrimental effects of isoproterenol on the heart, such as excessive tachycardia, induction of myocardial ischemia, and arrhythmia production, are the major factors limiting its use for the treatment of significant heart block unresponsive to atropine. Other side effects are similar to those seen with epinephrine, but occur to a lesser extent.

Dobutamine

Dobutamine is a synthetic sympathomimetic amine. It is a modification of isoproterenol, but its use is much more widespread. Dobutamine is used primarily as a β_1 -agonist, with some β_2 effects.^{17,18} Dobutamine induces a strong inotropic response with minimal chronotropy. It also produces a slight drop in systemic vascular resistance, owing to peripheral vasodilation. The resultant increase in cardiac output compensates for the decrease in systemic vascular resistance, and the blood pressure increases or, at low doses, remains relatively unchanged. Pulmonary artery pressure decreases, and an increase in left ventricular stroke work index is observed.¹⁹

The positive inotropic effects, coupled with the lack of chronotropy and maintenance of normal blood pressure, have made this agent an option in cardiogenic and septic shock and in select patients with mild heart failure.²⁰ It is also frequently used for heart stimulation for cardiac stress testing.¹⁵ Evidence indicates significant adverse effects when dobutamine is used in cardiac surgery, and clinicians have stopped using it for inotropic support in this situation.²¹

Direct-Acting α -Agonists

α_1 -Agonists

Phenylephrine

Phenylephrine (Neo-Synephrine) is the most commonly employed pure α -agonist. Phenylephrine has strong α -stimulating effects, with virtually no β stimulation. A sharp rise in blood pressure is produced as a result of a significant increase in peripheral resistance, secondary to the α_1 stimulation. A reflex bradycardia can be elicited secondary to baroreceptor stimulation. Careful titration of intravenous (IV) phenylephrine boluses is necessary to avoid large changes in blood pressure and decreases in heart rate. The onset of action of IV phenylephrine is immediate, with the duration of action ranging from 5 to 20 minutes. Because of its vasoconstricting effects, phenylephrine is used topically to prevent nosebleeds during nasal intubation or to reduce bleeding during ear, nose, and throat surgery. It is also used as a mydriatic in ophthalmology. Severe hypertension may occur however and careful dose titration should be observed. Judicious use of other agents such as oxymetazoline or epinephrine is an alternative.²²⁻²⁴

Other Inotropes

Vasopressin

Arginine vasopressin is an endogenous hormone that is produced in the hypothalamus, stored in the posterior pituitary, and released from the magnocellular neurons of the hypothalamus. It functions to control osmoregulation, and its release is stimulated by increased osmolality and hypovolemia. Arginine vasopressin is also referred to as *antidiuretic hormone*. Vasopressin deficiency and down-regulation of vasopressin receptors are common in septic shock.²⁵ Vasopressin is a potent vasoconstrictor; however, it selectively dilates renal afferent, pulmonary, and cerebral arterioles. Low-dose vasopressin infusion (0.03 to 0.04 units/min) increases blood pressure, urine output, and creatinine clearance and decreases the

dosage of norepinephrine required to maintain blood pressure in patients with septic shock. It is mostly used as an add-on therapy with catecholamine vasopressors. Increases in blood pressure occur in the first hour of administration, and the catecholamine vasopressor can then be titrated down. In a randomized trial, low-dose vasopressin added to norepinephrine was not significantly better than as-needed norepinephrine alone, although added vasopressin may be useful in patients with less severe shock. Complications of vasopressin include gastrointestinal ischemia, decreased cardiac output, skin or digital necrosis, and cardiac arrest (especially at doses greater than 0.04 units/min).²⁶⁻²⁸ Vasopressin agonists such as terlipressin and desmopressin have a variety of uses, including bleeding reduction, antidiuresis in diabetes insipidus, and treatment of enuresis.²⁹

Phosphodiesterase Inhibitors

Milrinone.

The phosphodiesterase 3 (PDE 3) inhibitors, also known as *nonglycoside noncatecholamines*, include milrinone (Primacor). They differ structurally and functionally from catecholamines, and are generally used as alternatives or adjuncts to the standard inotropes in cardiac surgery and heart failure.³⁰⁻³³

Phosphodiesterases are a group of enzymes that play a role in a variety of physiologic actions. Eleven subfamilies have been identified.³⁴ They break down the second messengers cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) in various cells. PDE 3 inhibitors such as milrinone prevent the breakdown of cAMP, and thus enhance its action. Milrinone induces positive inotropic action and vasodilation without producing tachycardia. It is occasionally referred to as an *inodilator*.³⁵ Milrinone substantially improves left ventricular function in association with an acceleration of calcium uptake by the sarcoplasmic reticulum. This acceleration appears to result from an inhibition of membrane-bound PDE 3 in the sarcoplasm, which induces a local elevation of cAMP. This allows for the buildup of cAMP and a subsequent increase in the uptake of intracellular calcium. Adrenergic receptors are not used to achieve the inotropic

effect. It follows that these drugs retain their inotropic effect even in the presence of β -blocking agents or during β -receptor down-regulation, situations that are frequently encountered in patients with heart failure. Therefore, by virtue of their alternative pathway, PDE 3 inhibitors may be used to augment the effect of direct-acting β -agonists such as dobutamine or dopamine. Milrinone improves weaning of high-risk patients from cardiopulmonary bypass.^{32,33}

These agents act as vasodilators because of the differential mechanism of cAMP action in the smooth muscle versus the myocardium. In the smooth muscle, cAMP causes an efflux of calcium, with a resultant relaxation of the muscle and vasodilation. The clinical result is a decrease in both preload and afterload. This effect, along with the absence of an associated increase in heart rate, probably contributes to the absence of an increase in myocardial oxygen consumption. Sildenafil (Viagra, Revatio) is a PDE 5 inhibitor that produces vasodilation and is used to treat pulmonary arterial hypertension. Pulmonary vasodilation reduces the workload of the right ventricle and improves symptoms of right-sided heart failure.

Milrinone enhances diastolic function, increases cardiac output, and decreases pulmonary wedge pressure. Side effects can include arrhythmias. Elimination is via the kidney; therefore, milrinone should be used with caution in patients with renal failure because of the potential for life-threatening arrhythmias. The current manufacturer's recommendation for the administration of milrinone is an IV loading dose of 50 mcg/kg, administered slowly over 10 minutes to avoid hypotension, followed by an infusion of 0.5 mcg/kg as needed. [Table 13.3](#) outlines the current vasopressors and some of their uses.

TABLE 13.3
Vasopressor Agents

Mixed Function Agonists

Ephedrine

Ephedrine is a synthetic noncatecholamine sympathomimetic commonly used in anesthesia practice. It stimulates both α - and β -receptors directly, and it indirectly causes release of endogenous catecholamines, leading to multiple mechanisms of action. It has both central and peripheral actions. Ephedrine's effects are similar to those seen with epinephrine; however, they are more moderate and are not accompanied by a dramatic increase in serum glucose concentrations. The duration of action of ephedrine is also longer than that of epinephrine, owing to its lack of a basic catechol structure; this characteristic makes it resistant to metabolism by monoamine oxidase.¹⁵

Ephedrine produces dose-related increases in blood pressure, cardiac output, heart rate, and systemic vascular resistance. Ephedrine is often the first sympathomimetic chosen to alleviate hypotension because of the cardiac-depressant effects of anesthetic agents and the vasodilation resulting from spinal anesthesia. Ephedrine, when administered intravenously in doses ranging from 5 to 25 mg, has an immediate onset and a duration of action of 15 minutes to 1.5 hours, depending on dose. This drug should be used cautiously in patients with questionable coronary perfusion, because myocardial oxygen consumption may increase more dramatically than anticipated as a result of ephedrine's positive inotropic effect. In obstetrics, ephedrine had long been considered the drug of choice to address maternal hypotension after regional anesthesia because it was felt to maintain uterine blood flow better than phenylephrine. Newer data are questioning this long-standing practice, and phenylephrine is now recommended over ephedrine.³⁶⁻³⁸ Ephedrine produces increases in fetal metabolic rate, leading to fetal acidosis due to β stimulation, and phenylephrine does not.³⁹ As with any indirect-acting agent, tachyphylaxis may develop with subsequent dosing, because catecholamine stores become depleted.⁴⁰ Ephedrine also may be administered by oral, intramuscular, or subcutaneous routes.

Selective β_2 -Agonists

The β_2 -agonists include albuterol (Proventil, Ventolin, others), levalbuterol (Xopenex), pirbuterol (Maxair), and salmeterol (Serevent). These “selective” β_2 -agonists are effective in treating obstructive airway diseases such as asthma, chronic obstructive pulmonary disease, and acute bronchospasm. Long-acting formulations include formoterol (Foradil) and salmeterol (Serevent).^{41,42}

The selectivity of these agents for β_2 -receptors results in the desired response of bronchodilation and a lower incidence of the undesired β_1 responses of tachycardia and arrhythmia. None of these agents, however, are completely selective. These agents are available in aerosol form, and it is widely accepted that aerosol delivery is as effective as subcutaneous or other means of administration. Drugs of this class also have an increased duration of action because of their noncatecholamine structure; this renders them resistant to methylation by catechol-*O*-methyltransferase (COMT). Two puffs of nebulized or metered-dose inhaler–administered albuterol or salmeterol 10 to 15 minutes before exercise have been shown to have similar efficacy in preventing exercise-induced asthma.⁴³

Chronic use of these agents can result in tachyphylaxis secondary to down-regulation (i.e., diminished quantity) of β -receptors. Increased hyperresponsiveness of the airway also has been suspected with chronic use of these agents. A black box warning about a higher risk of asthma-related death was added to the package inserts of all preparations containing a long-acting β_2 -agonist. If the addition of formoterol or salmeterol to an inhaled corticosteroid is found to improve symptomatic control, it is safer to give formoterol or salmeterol in the form of a combination inhaler.^{44,45}

The β_2 -agonists have been administered to delay premature labor, although their use has declined dramatically because of a high frequency of adverse events and a lack of efficacy. This is referred to as a *tocolytic effect*. Uterine relaxation is achieved through an increase in cAMP levels; this decreases intracellular

calcium levels and ultimately diminishes the level of actin-myosin coupling.^{46–48} Doses of selected vasoactive drugs are listed in [Table 13.4](#). For a complete discussion of tocolysis, see [Chapter 51](#). Mirabegron (Myrbetriq) is a β_3 agonist that inhibits the detrusor muscle and is used for overactive bladder.

TABLE 13.4
Doses of Select Vasoactive Drugs

Drug	Bolus Dose	Infusion Dose Rate	Comments
Calcium chloride (CaCl ₂) or gluconate	500–1000 mg (chloride)		Onset: < 1 min Peak effect: < 1 min Duration: 10–20 min
Dobutamine (Dobutrex)	500–2000 mg (gluconate)	2–20 mcg/kg per min	Onset: 1–2 min Peak effect: 1–10 min Duration: 10 min
Dopamine		1–2 mcg/kg per min (renal doses) 2–10 mcg/kg per min (cardiac doses) 10–20 mcg/kg per min (vasopressor doses)	Onset: 2–4 min Peak effect: 2–10 min Duration: < 10 min
Ephedrine	5- to 10-mg incremental doses		Dilute to 5 or 10 mg/mL Onset: < 1 min Peak effect: 2–5 min Duration: 10–60 min
Epinephrine	10–100 mcg	0.01–0.03 mcg/kg/min (β doses) 0.03–0.15 mcg/kg per min (α and β doses) 0.15–0.3 mcg/kg per min (α doses)	Onset: < 1 min Peak effect: 1–2 min Duration: 5–10 min
Fenoldopam		0.1–1.6 mg/kg per min	Onset: 4–5 min Peak effect: 7 min Duration: 15 min
Glucagon	1–5 mg over 2–5 min		
Isoproterenol (Isuprel)	1 mL over 1 min <i>after diluting</i> in 10 mL (= 0.02 mg/mL)	0.015–0.15 mcg/kg per min	Onset: < 1 min Peak effect: 1 min Duration: 1–5 min
Milrinone (Primacor)	50 mcg/kg	0.375–0.75 mcg/kg per min	
Nesiritide (Natrecor)		0.01 mcg/kg per min	Onset: 15 min

			Peak effect: 1 h Duration: 60 min
Norepinephrine (Levophed)		0.01–0.2 mcg/kg per min	Onset: < 1 min Peak effect: 1–2 min Duration: 2–10 min
Phentolamine	5 mg (50–100 mcg/kg); repeat as required	1–10 mcg/kg per min	Onset: 1–2 min Peak effect: 2 min Duration: 10–15 min
Phenylephrine (Neo-Synephrine)	40–100 mcg	0.15–0.75 mcg/kg per min	Onset: < 1 min Peak effect: 1 min Duration: 15–20 min
Sodium nitroprusside (Nitropres)		0.1–10 mcg/kg per min	Onset: < 1 min Peak effect: 1–2 min Duration: 1–10 min
Vasopressin (Pitressin)	10–20 units	0.1–1.0 units/min	Onset: 1–5 min Peak effect: 5 min Duration: 10–30 min

α_2 -Agonists

Clonidine

Clonidine (Catapres) is a presynaptic α_2 -agonist. Clonidine decreases blood pressure by acting as an agonist at peripheral presynaptic α_2 -receptors and central α_2 -receptors. Stimulation of the peripheral presynaptic α_2 -receptors causes inhibition of catecholamine release, with subsequent vasodilation. Stimulation of the central α_2 -receptors, which is considered the main antihypertensive mechanism of action, results in diminished sympathetic outflow and a resultant decrease in circulating catecholamines and renin activity. It is usually reserved for short-term oral treatment of severe hypertension as an add-on drug.⁴⁹ Rebound hypertension, seen after abrupt discontinuation of clonidine use, is a major concern. The resultant increase in catecholamine levels manifests as tachycardia and hypertension.

Continuing the medication throughout the perioperative period is essential. Tapering the dose and discontinuation may occasionally be indicated. Patches may also be used during surgery to prevent withdrawal.

Clonidine is available in oral, transdermal, and epidural forms. The transdermal form is frequently encountered and is administered at a fixed rate for a period of 1 week. Additional uses of clonidine include use as a premedicant sedative, as an analgesic in combination with opiates for epidural treatment of severe pain (Duraclon), and for suppression of alcohol withdrawal symptoms.⁵⁰ Clonidine is used as part of a catecholamine suppression test in the diagnosis of pheochromocytoma.

Dexmedetomidine

Dexmedetomidine is an α_2 -agonist that is marketed for short-term sedation in critical care. It is used as an adjunct to anesthesia in a variety of situations.⁵¹ Dexmedetomidine provides dose-dependent sedation, analgesia, sympatholysis, and anxiolysis without significant respiratory depression. The side effects are predictable from the pharmacologic profile of α_2 -adrenoceptor agonists, and include hypotension, bradycardia, oversedation, and delayed recovery. Dexmedetomidine is discussed in detail in [Chapter 9](#). The mechanism of presynaptic α_2 -agonism is shown in [Fig. 13.1](#).

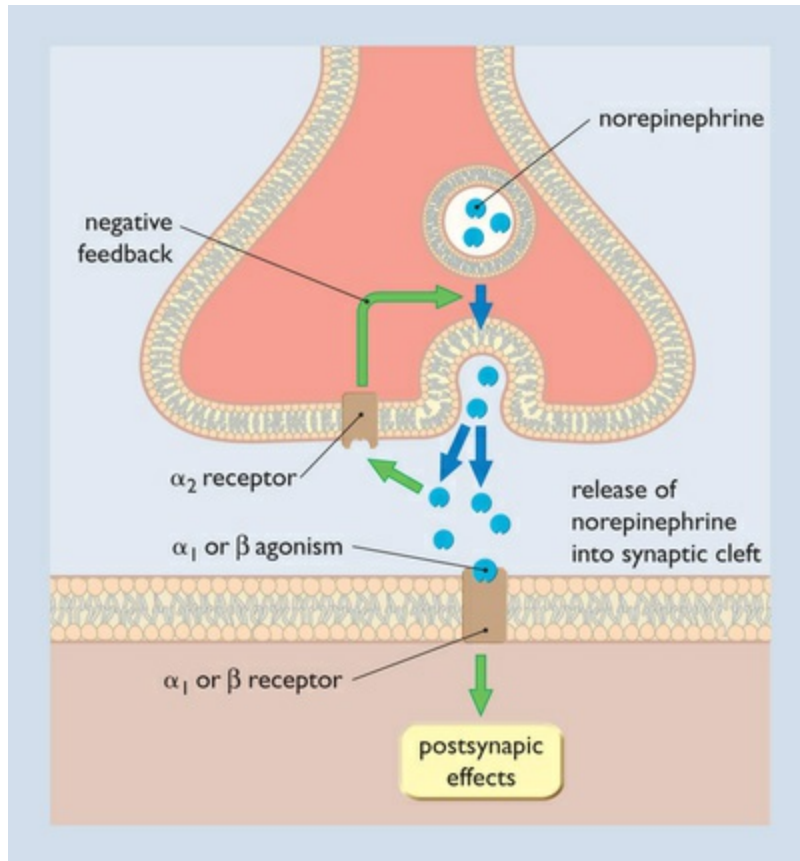

FIGURE 13.1 Presynaptic α_2 -agonism. (From Page C, et al. *Integrated Pharmacology*. 3rd ed. Edinburgh: Mosby; 2006:420.)

α -Receptor Antagonists

The α -receptor antagonists are used for treatment of hypertension, benign prostatic hyperplasia (BPH), pheochromocytoma, Raynaud phenomenon, and ergot alkaloid toxicity.⁴⁰ Common side effects include orthostatic hypotension and baroreceptor-mediated reflex tachycardia, which may make them somewhat difficult to use in the treatment of hypertension in the ambulatory patient. In addition, because of the significantly longer duration of action of the α -receptor antagonists, other agents are considered more predictable for treating emergent episodes of hypertension.

Phenoxybenzamine

Phenoxybenzamine (Dibenzylamine) is a halo alkylamine with both α_1 - and α_2 -blocking activity. Phenoxybenzamine binds to α -receptors noncompetitively and irreversibly, and its action is terminated only by metabolism of the drug and generation of new α -receptors. Clinically, this drug is used preoperatively in patients with pheochromocytoma to decrease the response to endogenous catecholamines. The preoperative course is started 1 to 3 weeks before surgery, with the oral dosage titrated up to 40 to 120 mg in two or three divided daily doses. It may be combined with the tyrosine hydroxylase inhibitor metyrosine (Demser).

Phenoxybenzamine also prevents the sympathomimetic response expected from phenylephrine. The response to norepinephrine is limited to its β_1 -agonist activity, and treatment with epinephrine may show “epi-reversal,” which is an enhanced β_2 response with a worsening of hypotension and tachycardia. The primary side effect is orthostatic hypertension. Nasal stuffiness has been frequently associated with phenoxybenzamine use.^{15,52}

Phentolamine

Phentolamine, an imidazole, is a competitive antagonist of α_1 - and α_2 -receptors. It has a rapid onset after IV administration and a much shorter duration of action when compared with

phenoxybenzamine. It can be used for the short-term control of hypertension in patients with pheochromocytoma. The recommended dose is 1 to 5 mg by slow IV push. Phentolamine has also been used to treat local infiltrations of vasoconstricting agents. Phentolamine (5–10 mg) can be mixed with 10 mL of normal saline and injected directly into the site of the infiltration.⁵²

Prazosin and Other α -Receptor Antagonists

Prazosin (Minipress), doxazosin (Cardura), and terazosin (Hytrin) are selective α_1 -antagonists used in the treatment of chronic hypertension and BPH. Their lack of α_2 -blocking activity indicates that they have no effect on norepinephrine levels. Therefore, selectivity for α_1 -receptors leaves the inhibitory action of α_2 -receptors on norepinephrine release intact, and less norepinephrine-induced tachycardia results than when a nonselective α -antagonist is used. Prazosin induces vasodilation in both arterioles and veins. Peripheral vascular resistance and cardiac preload and afterload are diminished. The drugs are administered orally, and orthostatic hypotension can be a major side effect.

Tamsulosin (Flomax), alfuzosin (Uroxatral), and silodosin (Rapaflo) are α_1 -selective antagonists that produce relaxation of the bladder neck and prostate, helping relax smooth muscle tone and relieve obstructive urinary symptoms. They are commonly used with 5α -reductase inhibitors such as finasteride (Proscar) and dutasteride (Avodart) for the treatment of BPH. Because they do not antagonize β -receptors, there is a decreased risk of hypotension.⁵³ Tamsulosin, and other α -antagonists, have been noted to produce floppy iris syndrome, which may complicate cataract surgery. Discontinuing them prior to surgery is not required, as long as the ophthalmologist is aware of their administration.^{54,55}

Droperidol

Droperidol (Inapsine), a butyrophenone, is used as an antiemetic in anesthesia practice. It produces both dopamine and α -adrenergic blockade, and thus small reductions in blood pressure may occur,

especially in volume-depleted patients. The use of droperidol has decreased markedly as a result of the black box warning required by the US Food and Drug Administration (FDA) as part of the package insert for this drug. Use of droperidol has been associated with prolongation of the corrected Q-T interval in certain patients, increasing the probability of the development of torsades de pointes, which has led to serious morbidity and death. There has been considerable debate regarding the relationship between the anesthetic administration of droperidol in very low doses as an antiemetic and the complications described.⁵⁶ Little doubt remains, however, that the potential for administrative and legal difficulties added to issues of patient safety have led to significant changes in the pattern of use of this drug.^{57,58} A 12-lead electrocardiogram is required by the FDA prior to the use of droperidol. Off-label use of very low doses as an antiemetic may still be useful. Evidence suggests that the serotonin type 3 receptor antagonists have a similar frequency of Q-T interval prolongation.^{56,59}

β-Adrenergic Blocking Agents

The β-blockers are one of the most widely prescribed classes of drugs. Common applications for these agents include the treatment of angina pectoris, hypertension, postmyocardial infarctions, supraventricular tachycardias (including Wolff-Parkinson-White syndrome), and atrial fibrillation (AF); the suppression of increased sympathetic activity (e.g., as occurs with intubation); the management of hypertrophic obstructive cardiomyopathies and congestive heart failure (CHF); the treatment of migraine headaches; and the preoperative preparation of hyperthyroid patients. They are also effective in the treatment of digitalis-induced arrhythmias and in the management of select atrial and ventricular arrhythmias.⁶⁰ β-blockers also prevent detrimental cardiac remodeling, which occurs in many cardiac diseases.⁶¹

The use of perioperative β-blockade in high-risk patients is discussed as follows and in [Chapter 28](#).

The β-blockers are structurally related to isoproterenol. They bind β-receptors in a competitive manner and prevent the actions of catecholamines and other β-agonists. Because these agents are competitive antagonists, if an agonist is present in sufficient concentration at the receptor, the blocking actions of the β-antagonists can be overcome.

The β-blockers are subdivided on the basis of their selectivity for cardiac β₁-receptors and other notable clinical differences, such as their ability to induce vasodilation by additional mechanisms or whether they have partial agonist activity. [Table 13.5](#) lists the β-blockers according to classification subtype.⁶²

TABLE 13.5

Antihypertensive Drugs

Drug	Daily Adult Maintenance Dosage	Frequent or Severe Adverse Effects
Angiotensin-Converting Enzyme (ACE) Inhibitors		
Benazepril (Lotensin)	10–80 mg in one or two doses	Cough; hypotension, particularly with a diuretic or volume depletion; rash; acute renal failure with bilateral renal artery stenosis or stenosis of the artery to a solitary kidney;

		angioedema; hyperkalemia if also taking potassium supplements or potassium-sparing diuretics; loss of taste, usually not severe; blood dyscrasias and renal damage rare, except in patients with renal dysfunction; increased fetal mortality with second- and third-trimester exposure; may decrease excretion of lithium
Captopril (Capoten)	12.5–150 mg in two or three doses	
Enalapril (Vasotec)	2.5–40 mg in one or two doses	
Fosinopril (Monopril)	10–80 mg in one or two doses	
Lisinopril (Prinivil or Zestril)	5–40 mg in one dose	
Moexipril (Univasc)	7.5–30 mg in one or two doses	
Perindopril (Aceon)	4–8 mg in one or two doses	
Quinapril (Accupril)	5–80 mg in one or two doses	
Ramipril (Altace)	1.25–20 mg in one or two doses	
Trandolapril (Mavik)	1–8 mg in one or two doses	
Angiotensin-Receptor Antagonists		
Azilsartan (Edarbi)	80 mg once a day	Similar to ACE inhibitors, but do not cause cough
Candesartan (Atacand)	8–32 mg in one dose	
Eprosartan (Teveten)	400–800 mg in one or two doses	
Irbesartan (Avapro)	150–300 mg in one dose	
Losartan (Cozaar)	25–100 mg in one or two doses	
Olmesartan (Benicar)	20–40 mg in one dose	
Telmisartan (Micardis)	40–80 mg in one dose	
Valsartan (Diovan)	80–320 mg in one dose	
β-Adrenergic Blocking Drugs		
Atenolol (Tenormin)	25–100 mg in one or two doses	Fatigue; depression; bradycardia; decreased exercise tolerance; congestive heart failure; aggravate peripheral arterial insufficiency; aggravate allergic reactions; bronchospasm; mask symptoms of and delay in recovery from hypoglycemia; Raynaud phenomenon; insomnia; vivid dreams or hallucinations; acute mental disorder; impotence; increased serum triglycerides
Betaxolol generic	5–40 mg in one dose	
Bisoprolol (Zebeta)	5–20 mg in one dose	

Metoprolol (Lopressor, Toprol-XL)	50–200 mg in one or two doses Extended release 25–400 mg once	
Nadolol (Corgard)	20–320 mg in one dose	
Propranolol (Inderal)	40–240 mg in two doses	
Timolol generic	10–60 mg in two doses	
β-Adrenergic Blocking Drugs With Intrinsic Sympathomimetic Activity		
Acebutolol (Sectral)	200–1200 mg in one or two doses	Similar to other β -adrenergic blocking drugs but with less resting bradycardia and fewer lipid changes; acebutolol has been associated with positive antinuclear antibody test and occasional drug-induced lupus
Penbutolol (Levitol)	10–80 mg in one dose	
Pindolol generic	10–60 mg in two doses	
α- and β-Blockers		
Carvedilol (Coreg)	12.5–50 mg in two doses	Similar to other β -adrenergic blocking drugs, but more orthostatic hypotension; no effect on serum lipids
Labetalol generic	200–1200 mg in two doses	
β-Blocker With Vasodilating Nitric Oxide Mediated Activity		
Nebivolol (Bystolic)	5–40 mg once	Vasodilator due to nitric oxide-mediated action
Thiazide-Type Diuretics (Usually Once Daily)		
Chlorothiazide (Diuril)	125–500 mg once	Hyperuricemia; hypokalemia; hypomagnesemia; hyperglycemia; hyponatremia; hypercholesterolemia; hypertriglyceridemia; pancreatitis; rashes and other allergic reactions; sexual dysfunction; photosensitivity reactions; may decrease excretion of lithium
Hydrochlorothiazide (Microzide)	12.5–50 mg once	
Chlorthalidone (Thalitone)	12.5–50 mg once	
Indapamide, generic	1.25–5 mg once	
Metolazone (Zaroxolyn)	1.25–5 mg once	
Loop Diuretics		
Bumetanide generic	0.5–2 mg in two doses	Dehydration; circulatory collapse; hypokalemia; hyponatremia; hypomagnesemia; hyperglycemia; metabolic alkalosis; hyperuricemia; blood dyscrasias; rashes; lipid changes as with thiazide-type diuretics
Ethacrynic acid (Edecrin)	25–100 mg in two or three doses	
Furosemide (Lasix)	20–320 mg in two doses	
Torsemide (Demadex)	5–20 mg in one or two doses	
Potassium-Sparing Diuretics		
Amiloride (Midamor)	5–10 mg in one or two doses	Hyperkalemia; GI disturbances; rash; headache
Triamterene	50–150 mg in	Hyperkalemia; GI disturbances; nephrolithiasis

(Dyrenium)	one or two doses	
Aldosterone Antagonists		
Spirololactone (Aldactone)	12.5–100 mg in one or two doses	Hyperkalemia; hyponatremia; mastodynia; gynecomastia; menstrual abnormalities; GI disturbances; rash
Eplerenone (Inspra)	25–100 mg in one or two doses	Hyperkalemia; hypernatremia
Calcium Channel Blockers		
Diltiazem (Cardizem CD)	120–360 mg in one dose	Dizziness; headache; edema; constipation (especially verapamil); AV block; bradycardia; heart failure; lupus-like rash
(Tiazac)	120–540 mg in one dose	
Verapamil (Calan)	120–480 mg in one or two doses	
(Calan SR)	120–480 mg in one or two doses	
(Isoptin SR)	120–480 mg in one or two doses	
(Verelan)	120–480 mg in one dose	
(Covera HS)	180–540 mg in one dose	
Dihydropyridines		
Amlodipine (Norvasc)	2.5–10 mg in one dose	Dizziness; headache; peripheral edema (more than with verapamil and diltiazem; more common in women); flushing; tachycardia; rash; gingival hyperplasia
Felodipine (Plendil)	2.5–10 mg in one dose	
Isradipine (DynaCirc, DynaCirc CR)	5–10 mg in two doses	
Nicardipine, generic Nicardipine, extended release (Cardene SR)	60–120 mg in two or three doses	
Nifedipine (Adalat CC, Procardia XL)	30–90 mg once	
Nisoldipine (Sular)	17–34 mg once	
α-Adrenergic Blockers		
Prazosin (Minipress)	1–20 mg in two or three doses First dose is 1 mg at bedtime	Syncope with first dose; dizziness and vertigo; headache; palpitations; fluid retention; drowsiness; weakness; anticholinergic effects; priapism
Terazosin (Hytrin)	Maintenance: 1–20 mg once First dose is 1 mg at bedtime	Both similar to prazosin, but with less hypotension after first dose
Doxazosin (Cardura)	1–2- mg in once dose First day: 1 mg at	

	bedtime	
Central α-Adrenergic Agonists		
Clonidine (Catapres)	0.1–0.6 mg in two or three doses	CNS reactions similar to methyl dopa, but more sedation and dry mouth; bradycardia; heart block; rebound hypertension (less likely with patches); contact dermatitis from patches
(Catapres TTS)	One patch weekly (0.1–0.3 mg/day)	Similar to clonidine
Guanfacine, generic	1–3 mg in one dose	Drowsiness; sedation, fatigue; depression; dry mouth; heart block; autoimmune disorders, including colitis, hepatitis, hepatic necrosis; Coombs-positive hemolytic anemia; lupus-like syndrome; thrombocytopenia; red cell aplasia; impotence
Methyl dopa generic	250 mg to 2 g in two doses	
Direct Vasodilators		
Hydralazine generic	40–200 mg in two to four doses	Tachycardia; aggravation of angina; headache; dizziness; fluid retention; nasal congestion; lupus-like syndrome; hepatitis
Minoxidil generic	2.5–40 mg in one or two doses	Tachycardia; aggravation of angina; marked fluid retention; pericardial effusion; hair growth on face and body
Renin Inhibitor		
Aliskiren (Tekturna)	150–300 mg once daily	First direct renin inhibitor for treatment of hypertension; avid binding of renin and long half-life could lead to hypotension unresponsive to discontinuing drug

AV, Atrioventricular; CNS, central nervous system; GI, gastrointestinal.

From: Drugs for Hypertension. *Med Lett Drugs Ther.* 2017;59(1516):41–48.

The degree of receptor selectivity is important, because antagonism of β_1 -receptors results in lowered heart rate, decreased myocardial contractility, and diminished atrioventricular conduction velocity; it also has beneficial effects with regard to decreasing myocardial oxygen consumption and the treatment of arrhythmias. However, antagonism of β_2 -receptors can result in adverse effects such as bronchoconstriction, hypoglycemia, and peripheral vasoconstriction. It is important to note that, as the dose of the selective β -blockers is increased, the degree of selectivity is diminished.

Some of the β -blockers act as partial agonists, and as such, possess intrinsic sympathomimetic activity (ISA). A partial agonist does not stimulate β -receptors to the extent that a full agonist does, and in the presence of a full agonist, the partial agonist acts as a competitive antagonist. It follows that β -blockers with ISA competitively antagonize the effects of a full agonist (e.g., endogenous catecholamines released during times of maximal sympathetic tone) down to the activity level of its partial agonist component. ISA minimizes the risk of bronchoconstriction in

patients with reactive airway disease who require β -blockade. Pindolol, acebutolol, penbutolol, and carteolol are β -adrenergic blocking agents that possess ISA.

Membrane-stabilizing activity is another property of some β -blockers. These agents diminish arrhythmogenicity by exerting a quinidine-like effect in the heart. However, membrane-stabilizing activity is seen only with high drug concentrations.⁶³ Propranolol and pindolol are two β -blockers with membrane-stabilizing activity. Labetalol and carvedilol are mixed β - and α -receptor antagonists; the added α -receptor blockade makes them vasodilators. Nebivolol (Bystolic) is a new cardioselective β -blocker approved for the treatment of hypertension. It is unique in that it has nitric oxide (NO)-mediated vasodilating properties.⁶⁴

Some potential problems with β -adrenergic blocking agents have already been mentioned. β -blockade can result in both bronchospasm and the development of overt cardiac failure in some high-risk patients receiving high doses or IV administration. Other potential problems arise with β_2 -receptor blockade in patients with peripheral vascular disease and Raynaud phenomenon, because of the possible potentiation of peripheral vasoconstriction. In diabetic patients, signs of hypoglycemia may be masked, and the patient's ability to increase serum glucose levels may be impaired. Serum potassium levels may also become elevated with β_2 -blockade, because uptake into skeletal muscle is inhibited. In patients whose heart rate is controlled to maintain cardiac output, β -blockade may have a significant impact on blood pressure.

The β -receptors are considered to be "labile" receptors—that is, they are subject to significant up- and down-regulation. Long-term therapy with β -blockers leads to up-regulation of β -receptors or an increase in the absolute number and activity of receptors. This phenomenon is suspected to be the underlying cause of the withdrawal syndrome seen with abrupt discontinuation of β -adrenergic antagonist use. Raynaud phenomenon is characterized by increased sympathetic activity for up to 2 days. Obviously this means the patient receiving β -blockers should continue to receive them without interruption throughout the perioperative period. The effects of the β -blocking agents on the ischemic heart are summarized in [Fig. 13.2](#).

- A. Negative chronotropic
- B. Negative dromotropic
- C. Negative inotropic
- D. Anti-arrhythmic
- E. Anti-ischemic

FIGURE 13.2 Cardiac effects of β -adrenergic blocking drugs. **A**, Negative chronotropic. **B**, Negative dromotropic. **C**, Negative inotropic. **D**, Antiarrhythmic. **E**, Anti-ischemic.

Anesthetic Uses

Metoprolol, Esmolol, and Labetalol

Three β -adrenergic blocking agents that are available in IV form are especially useful in the perioperative period. They are metoprolol, esmolol, and labetalol. Esmolol has replaced propranolol in most instances of β -blocker application in anesthesia because of its rapid onset, short duration of action, and ease of use. Esmolol has an onset time of 2 minutes and an elimination half-life of approximately 9 minutes. Its rapid onset and short half-life, as well as its duration of action of 10 to 15 minutes, make it easily and reliably titratable in acute-care situations. The recommended IV loading dose of esmolol is 500 mcg/kg; this is followed by an infusion of 100 to 300 mcg/kg per min as needed. Small boluses of 10 to 15 mg may be given with repeat administration, according to patient response. Esmolol is metabolized by nonspecific plasma esterases found in the cytosol of red blood cells. Metoprolol is used after myocardial infarction or in some types of angina and hypertension, once the patient is stable, to normalize vital signs. IV administration of 5-mg doses at 5-minute intervals to a maximum dose of 15 mg is recommended.^{24,62}

Labetalol (Normodyne, Trandate) is classified as a nonselective β -

blocker but is unique in that it also possesses an α -blocking component. It provides β -blockade along with α -blockade in a ratio of 7:1. Unlike the standard β -blocker, labetalol produces vasodilation secondary to its α -blocking properties. This action can be extremely beneficial in situations in which an acute rise in blood pressure could be devastating to the clinical outcome. The usual IV dose of labetalol is 0.25 mg/kg; this dose can be repeated every few minutes as indicated, and followed by an infusion, if indicated, at a rate of 2 mg/min. In clinical practice, a bolus dose of labetalol (5–10 mg) is titrated and repeated on the basis of patient response. Labetalol can have a duration of action ranging from 2 to 6 hours, depending on dose. Because labetalol provides both β - and α -blockade, an adequate heart rate must be present before labetalol can be used in the acute management of hypertension. It is recommended for hypertensive episodes in obstetric patients. Uterine blood flow is not affected in obstetric patients, even in the event of a dramatic decrease in systemic blood pressure. Labetalol undergoes hepatic metabolism and renal elimination.^{62,64,65}

There is a major controversy as to the use of prophylactic use of perioperative β -blockers. Studies are conflicting, and several major studies have been retracted. In 2008, the largest randomized controlled trial of perioperative beta blocker use, PeriOperative ISchemic Evaluation (POISE), indicated that β -blockade offered cardiac protection in coronary heart disease. However, there was a significant increase all-cause mortality, particularly in patients who became septic or hypotensive. There was also a significant increase in strokes, contributed to by hypotension. Hypotension and bradycardia were much more frequent in the β -blocked patients. A meta-analysis of randomized controlled trials (including POISE) showed that some subgroups of patients could benefit from perioperative β -blockade, including those at high risk and those in whom β -blockade was strictly titrated.⁶⁶ The increased mortality risk associated with perioperative β -blockade resulted in a reappraisal of their perioperative use. β -blocker initiation decreased sharply in the second half of 2008 and continued to decrease afterwards. A number of clinicians feel that, until we have new clinical trials showing definitive benefit, their use should be minimal.^{67–69} In 2014, new guidelines were introduced by the

American College of Cardiology/American Heart Association (ACC/AHA) Task Force.^{70,71} The European Society of Cardiology/European Society of Anaesthesiology (ESC/ESA) offered similar guidelines.⁷² Both sets of guidelines strongly recommend continuing treatment in patients currently taking β -blockers. The new guidelines recommend considering starting β -blockers in patients with known ischemic heart disease or myocardial ischemia, and in patients with multiple cardiac risk factors (two, according to the ESC/ESA guidelines and three, according to the ACC/AHA guidelines). The ACC/AHA guidelines suggest that initiating β -blockers in patients with a compelling indication for β -blockers but with no other cardiac risk factor is of uncertain benefit. Both sets of guidelines recommend starting β -blocker therapy well in advance of surgery, preferably more than one day before surgery (ACC/AHA) or between 2 and 30 days before surgery (ESC/ESA). The possibility of harm is emphasized. The ACC/AHA guidelines consider starting β -blockers the day of surgery as potentially harmful, a view endorsed by the ESC/ESA guidelines, with another caveat against initiation of β -blockers in patients undergoing low-risk surgery. The ESC/ESA guidelines recommend using atenolol or bisoprolol as a first choice. Previous guidelines indicated targets for heart rate. Only the ESC/ESA guidelines comment on the need to titrate to resting heart rate 60–70 beats/min and the systolic blood pressure to greater than 100 mm Hg. The ACC/AHA view is that there is insufficient evidence with respect to titration to a specific number.⁷³

A summary of the guidelines to perioperative β -blockade is shown in [Box 13.1](#).^{71–75} β -blockers are contraindicated in patients with asthma, bradyarrhythmias, acute heart failure, or advanced heart block. Researchers investigated whether an α_2 -adrenergic agonist such as clonidine or dexmedetomidine may have some benefit in reducing activation of the sympathetic nervous system during and after noncardiac surgery. They found that administration of low-dose clonidine in patients undergoing noncardiac surgery did not reduce the rate of the composite outcome of death or nonfatal myocardial infarction. There was, however, an increased risk of clinically important hypotension and nonfatal cardiac arrest.⁷⁶ The 2014 ACC/AHA guidelines are quite

clear that α_2 -receptor agonists are not recommended for the prevention of cardiac events. The ESC/ESA guidelines make no specific recommendation, but state that α_2 -receptor agonists should **Box 13.1** not be administered to patients undergoing noncardiac surgery.^{71,72}

Suggestions for Managing Perioperative β -Blockers

β -blockers should be continued in patients undergoing surgery who have been on β -blockers chronically.

It is reasonable for the management of β -blockers after surgery to be guided by clinical circumstances, independent of when the agent was started.

In patients with intermediate- or high-risk myocardial ischemia noted in preoperative risk stratification tests, it may be reasonable to begin perioperative β -blockers.

In patients with three or more revised cardiac risk index (RCRI) risk factors (e.g., diabetes mellitus, heart failure, coronary artery disease, renal insufficiency, or cerebrovascular accident), it may be reasonable to begin β -blockers before surgery.

In patients with a compelling long-term indication for β -blocker therapy but no other RCRI risk factors, initiating β -blockers in the perioperative setting as an approach to reduce perioperative risk is of uncertain benefit.

In patients in whom β -blocker therapy is initiated, it may be reasonable to begin perioperative β -blockers far enough in advance to assess safety and tolerability, preferably more than one day before surgery.

β -blocker therapy should not be started on the day of surgery.

Adapted from Fleisher LA. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines. *J Am Coll Cardiol.* 2014;64(22):e77–137.

Statins

Statins have documented benefits for primary and secondary prevention of cardiovascular disease, and are thought to improve perioperative outcomes in patients undergoing surgery. It is suggested they be prescribed in patients undergoing cardiac or major vascular surgery. Compliance with both antiplatelet and statin therapy in vascular surgical patients is associated with significantly improved long-term survival. There are insufficient data to support a recommendation on perioperative statin therapy for patients undergoing noncardiac surgery.⁷⁷⁻⁷⁹ The new ACC/AHA guidelines recommend continuing statins perioperatively for patients who are currently taking them. The ESA/ESC guidelines agree, and add that continuation of statins should favor drugs with a long half-life or extended release in order to maintain some of statins' effects until oral administration can resume postoperatively.^{71,72}

Antiplatelet Drugs

Many patients with cardiovascular disease or significant risk factors are taking lifelong aspirin. Whether aspirin should be continued or withheld in patients undergoing noncardiac surgery is a common clinical question. Clinicians must balance discontinuing the beneficial antithrombotic effect of aspirin against the possibility of increasing perioperative bleeding. Results from the POISE-2 trial of over 10,000 patients suggest that aspirin administration during the perioperative period does not change the risk of a cardiovascular event, and may result in increased bleeding.⁸⁰ A focused review published in 2015 of the available data suggests that aspirin should not be administered to patients undergoing surgery unless there is a definitive guideline-based primary or secondary prevention indication. Aside from closed-space procedures such as intracranial, middle ear, or posterior eye surgery, intramedullary spine surgery, or possibly prostate surgery, continuation of aspirin administration throughout the perioperative period may be warranted for moderate-risk patients taking lifelong aspirin for a guideline-based secondary but not primary prevention.⁸¹

Cholinergics

Cholinergic agents mimic the actions of the neurotransmitter acetylcholine, but have been developed to differ in terms of comparative nicotinic and muscarinic activity and duration of action. Acetylcholine (Miochol) has no clinical application, owing to its generalized enhancement of cholinergic effects throughout the body and its extremely short duration of action (approximately 1 msec), which is a result of its rapid metabolism by acetylcholinesterase.

Methacholine (Provocholine), carbachol (or carbamylcholine chloride), and bethanechol (or carbamylmethylcholine) are choline esters that have limited clinical application. Methacholine can be used as an aerosol in the diagnosis of reactive airway disease, whereas carbachol, because of its significant muscarinic and nicotinic activity, is used only as a topical ophthalmic solution in the treatment of narrow-angle glaucoma and for inducing miosis during diagnostic testing and surgery. Bethanechol is theoretically useful in instances of ileus and urinary retention, such as in postvagotomy and postpartum patients, respectively. Bethanechol's relative lack of nicotinic activity makes it the most attractive of these three agents, and it is the agent most frequently encountered in clinical practice. Potential side effects of these agents include any cholinergic-induced response such as bradycardia, varying degrees of heart block, hypotension, bronchoconstriction, and an increase in gastric secretions.⁸²

Anticholinergics

The anticholinergics are familiar agents in anesthesia practice. Atropine, scopolamine, and glycopyrrolate are the three anticholinergics used in anesthesia practice. These agents are competitive antagonists of acetylcholine at muscarinic receptors. A comparison of the basic properties of the anticholinergic agents is provided in [Table 13.6](#). Subtypes of muscarinic and nicotinic receptors are summarized in [Tables 13.7](#) and [13.8](#).

TABLE 13.6
Comparative Effects of Anticholinergic Drugs

Effect	Atropine	Scopolamine	Glycopyrrolate
Sedate	+	+++	0
Antisialagogue	+	+++	++
Increase heart rate	+++	+	++
Relax smooth muscle	++	+	++
Mydriasis, cycloplegia	+	+++	0
Prevent motion-induced nausea	+	+++	0
Decrease gastric hydrogen ion secretion	+	+	+

Peripheral neuronal (N _N)	Autonomic ganglia; adrenal medulla	Excitatory; depolarization; firing of postganglion neuron and secretion of catecholamines
Central nervous system (CNS)	CNS; pre- and post-junctional	Pre- and post-synaptic excitation
		Prejunctional control of transmitter release

Atropine

Atropine, a belladonna alkaloid, is the prototype anticholinergic. The anesthetist can use atropine for its antisialagogue effects, for the prevention or treatment of bradycardia, and concurrently with anticholinesterase agents in the reversal of muscle relaxants for preventing the resultant bradycardia from anticholinesterase-induced acetylcholine buildup. The usual adult IV dose for increasing heart rate during anesthesia is 0.4 mg to 0.6 mg, with the time to onset being 1 to 2 minutes. Atropine is a tertiary amine; this allows it to cross the blood-brain barrier freely, and may result in transient bradycardia during onset when low doses are given. However, significant CNS effects are rarely evident at usual clinical doses. Hepatic metabolism accounts for approximately half of a dose of atropine, with the remainder being eliminated unchanged in the urine. The elimination half-life of atropine is approximately 4 hours. Atropine should be avoided in patients with narrow-angle glaucoma, because it increases intraocular pressure. Atropine poisoning or belladonna alkaloid toxicity manifests with extreme antimuscarinic effects, with potential progression to CNS depression and coma. The decades-old mnemonic “red as a beet, blind as a bat, dry as a bone, mad as a hatter, and hot as a hare” was devised to be an easy way to remember the signs and symptoms of belladonna overdose. These include flushing (“red as a beet”); extreme mydriasis (“blind as a bat”); lack of secretions and dry mouth (“dry as a bone”); confusion (“mad as a hatter”); and hyperthermia (“hot as a hare”).⁸²

Scopolamine

Scopolamine (Isopto Hyoscine) is another belladonna alkaloid with anticholinergic effects. Scopolamine is a tertiary amine. Compared with atropine, the CNS effects of scopolamine are much more

pronounced at lower doses, and it does not substantially increase heart rate. It can be used as a preoperative medication, with sedation and amnesia being a desirable effect. Scopolamine also is used to diminish the incidence of postoperative nausea and vomiting. A scopolamine patch (Transderm Scōp) containing a total dose of 1.5 mg is usually applied behind the ear. The patches have an onset of 4 hours and a duration of 3 days.⁸³

Tiotropium

Tiotropium (Spiriva) is a long-acting inhaled muscarinic antagonist that is used as a bronchodilator for patients with chronic obstructive pulmonary disease (COPD). Tiotropium improves lung function and quality of life, and decreases COPD exacerbations, but does not significantly reduce the rate of decline in the forced expiratory volume⁸⁴

Glycopyrrolate

Glycopyrrolate (Robinul), a synthetic quaternary ammonium compound, has become the most frequently used anticholinergic in anesthesia practice. It has excellent antisialagogue activity⁸² and a longer duration of action than belladonna alkaloids. It prevents bradycardia without inducing significant levels of tachycardia. The quaternary ammonium structure of glycopyrrolate prevents it from crossing the blood-brain barrier to any significant degree; therefore, CNS effects are not seen. This is an important advantage of glycopyrrolate, because atropine and scopolamine cross the blood-brain barrier and have CNS effects that can contribute to postoperative delirium.⁸⁵ This property also makes it the agent of choice in obstetrics, because it does not pass the placental barrier. Adult IV doses are generally 0.1 mg to 0.2 mg for antisialagogue activity and for the treatment of bradycardia. Onset of action is rapid, and the duration of action is up to 4 hours. It is used in combination with neostigmine for the reversal of nondepolarizing neuromuscular blockers. Glycopyrrolate produces less tachycardia than atropine in the period leading up to the onset of neostigmine.⁸²

Direct Vasodilators

Within the category of direct vasodilators, sodium nitroprusside, nitroglycerin, and hydralazine are the three drugs most commonly employed (Table 13.9). All three produce direct vasodilation: sodium nitroprusside produces arterial and venous relaxation; nitroglycerin has a greater effect on venous relaxation than on arterial relaxation; and hydralazine produces primarily arterial relaxation. The mechanism of action of all three agents is believed to be primarily an induced increase in the concentration of vascular NO, although that has not been confirmed with hydralazine.⁸⁶ The mechanism of action is depicted in Fig. 13.3. The vasodilators nitroprusside and nitroglycerin are frequently used for controlled hypotension under anesthesia. Combined with the inhalation and IV anesthetics, they facilitate a reduction in blood loss and the need for transfusions during a variety of surgical procedures.⁸⁷ Hydralazine is used in combination with isosorbide dinitrate for the treatment of systolic heart failure in African Americans. It may also serve as an alternative for patients with an intolerance to angiotensin antagonists.⁸⁸

TABLE 13.9

Parenteral Drugs for Treatment of Severe Hypertension

Drug	Class	Route and Dose	Onset	Duration	Comments
Fenoldopam (Corlopam)	Dopamine-1 receptor agonist	IV infusion pump: 0.1–1.6 mcg/kg per min	4–5 min	< 10 min	May cause reflex tachycardia; may increase intraocular pressure
Labetalol (Trandate Normodyne)	α - and β -adrenergic blocker	IV: 20 mg initially, then 40–80 mg every 10 min (300 mg max)	5 min or less	3–6 h	Not for patients with bronchospasm, congestive heart failure, first-degree heart block, cardiogenic shock, or severe bradycardia
Nicardipine (Cardene IV)	Calcium channel blocker	IV: 5 mg/h, increased by 2.5 mg/h every 15 min up to 15 mg/h	1–5 min	3–6 h	May cause reflex tachycardia
Clevidipine (Cleviprex)	Calcium channel blocker	IV infusion: 1–2 mg/h initially; double the dose at 90-s intervals until desired results are achieved (16 mg/h max)	2–4 min	5–15 min	Rapidly degraded by tissue and blood esterases; contraindicated with

					may cause reflex tachycardia
Nitroglycerin	Venous arteriolar vasodilator	IV infusion pump: 5–100 mcg/min	2–5 min	5–10 min	Headache, tachycardia can occur; tolerance may develop with prolonged use
Sodium nitroprusside	Arteriolar and venous vasodilator	IV infusion pump: 0.3–10 mcg/kg per min	Seconds	3–5 min	Thiocyanate or cyanide toxicity with prolonged or too rapid infusion
Esmolol	β -blocker	IV: 500 mcg/kg per min for 1 min titrated to effect, usually 50 mcg/kg per min	1–2 min	5–10 min	Cardioselective; however, use with caution in patients with asthma
Labetalol	Combined α - and β -blocker	5–80 mg bolus titrated to effect; 2 mg/min infusion	1–2 min	3–6 min	Generally used in 5–10 mg incremental doses titrated to effect in the perioperative period

Nitrovasodilators

Sodium Nitroprusside

Sodium nitroprusside is frequently used for the emergent control of hypertension, for inducing hypotension to decrease blood loss during surgical procedures, and for the treatment of acute cardiac disorders. Its rapid onset (within seconds) and its short duration of action (1–3 min) make it unique among agents for the rapid control of blood pressure. Sodium nitroprusside reduces both afterload and preload, which results in a decrease in cardiac filling pressures and an increase in stroke volume and cardiac output. Left ventricular volumes are decreased, and diminished myocardial wall tension should contribute to a decrease in myocardial oxygen consumption.

Usually, sodium nitroprusside is started as an infusion at 0.3 mcg/kg per min and is titrated until a response occurs. An infusion rate of 3 mcg/kg per min is rarely exceeded, but young, normotensive patients may require up to 5 mcg/kg per min to achieve the desired response.^{89,90} The maximum recommended infusion rate is 10 mcg/kg per min. Sodium nitroprusside is mixed with 5% dextrose in water, and the bottle and tubing are covered in a protective wrap, as light causes the sodium nitroprusside to decompose. An infusion pump should always be used with sodium nitroprusside because of its potency and the associated risk of cyanide toxicity.

Cyanide Toxicity.

The chemical structure of sodium nitroprusside contains five cyanide ions, which are released upon metabolism by plasma hemoglobin. One cyanide ion binds methemoglobin to form cyanmethemoglobin, whereas the other four cyanide ions undergo rhodanese-catalyzed conversion to thiocyanate in the liver, with the

thiocyanate undergoing renal elimination. This conversion to thiocyanate requires the cofactor thiosulfate B₁₂. Cyanide toxicity results when this metabolic pathway is quantitatively overwhelmed. Preventing cyanide toxicity from sodium nitroprusside begins with awareness of maximum doses and lengths of administration. In general, when more than 500 mcg/kg of sodium nitroprusside is administered faster than 2 mcg/kg per min, cyanide is generated faster than the patient can eliminate it. Chronic administration should not exceed 0.5 mcg/kg per min. Clinically the development of metabolic acidosis, increased mixed venous oxygen content, tachycardia, and tachyphylaxis during sodium nitroprusside use are signs of cyanide toxicity.

Treatment of cyanide toxicity consists of discontinuing the sodium nitroprusside infusion, administering oxygen, and treating metabolic acidosis. Sodium nitrite 3% at 4 mg/kg to 6 mg/kg can be administered over 3 to 5 minutes to promote the production of methemoglobin so that excess cyanide ions can be bound. Sodium thiosulfate at 150 mg/kg to 200 mg/kg over 15 minutes can be administered every 2 hours as needed; vitamin B₁₂ also can be administered. Hydroxycobalamin can be very effective. Methylene blue at 1 mg/kg to 2 mg/kg may also be useful. A new prodrug, sulfanegen sodium, is also being tested.^{91,92}

Nitroglycerin

Nitroglycerin is used in the treatment of angina pectoris and ischemia under anesthesia and also can be used for lowering blood pressure. It has a rapid onset and short duration so it is easily titratable. Nitroglycerin causes venodilation, with an increase in venous capacitance and a resultant decrease in preload. This results in a lowering of cardiac filling pressures, a lessening of myocardial wall tension, and ultimately a decrease in myocardial oxygen requirements. Nitroglycerin's primary mechanism of action in the relief of angina is a decrease in preload and cardiac work. Some of the larger coronary vessels may become dilated, with a resultant redirection and increase in blood flow to ischemic myocardium. It also relieves coronary spasm. At higher concentrations of nitroglycerin, arterial vasodilation also can occur.⁹³

Use of sublingual nitroglycerin (0.3-mg tablets) up to a total of three tablets is the most efficient treatment for acute angina. Relief is generally achieved in 1 to 2 minutes and lasts up to 30 minutes. IV nitroglycerin also has an onset time of 1 to 2 minutes and duration of action of up to 10 minutes. Nitroglycerin is extensively metabolized in the liver and has a half-life of only 3 minutes.⁸⁸ IV nitroglycerin is used for “unloading” of the heart in CHF and myocardial infarction.⁹⁴ Guidelines suggest that IV infusions should be instituted following three sublingual doses of 0.4 mg every 5 minutes in patients having an ST-segment elevation myocardial infarction (STEMI). Nitroglycerin infusions are usually started at 10 to 20 mcg/min and are titrated up until effective. IV nitroglycerin can also be used for controlled hypotension, but is not as effective as an infusion of sodium nitroprusside. Because nitroglycerin exerts its main effect on venous capacitance, any decrease in blood pressure is more volume-dependent when compared with sodium nitroprusside-induced hypotension. Nitrates should be avoided in patients with a blood pressure less than 90 mm Hg, a heart rate less than 50 bpm or above 100 bpm, and in patients with right ventricular infarction. Of note to the anesthesia provider is the ability of nitroglycerin to relax the smooth muscle of the biliary tract and provide relief from narcotic-induced biliary spasm. Generally, 50 mg of nitroglycerin is mixed with 250 mL of dextrose 5% in water.⁹⁵ For extended coverage, nitroglycerin patches and ointments are also available. A summary of antihypertensive agents dosing information is found in [Table 13.5](#).

Hydralazine

Hydralazine causes direct relaxation of arterial smooth muscle. It can be administered intravenously for the control of hypertension in doses ranging from 2.5 mg to 20 mg. Tachycardia frequently accompanies the decrease in blood pressure, secondary to the preferential reduction in afterload. It is important to remember that the onset of action can occur from 2 to 20 minutes after administration; therefore, adequate time should be allowed before the initiation of repeat dosing so that profound decreases in blood pressure can be prevented. The elimination half-life in plasma is approximately 1 hour, but the duration of vasodilating action can

be as long as 12 hours.⁹⁶⁻⁹⁸ Hydralazine undergoes hepatic metabolism with renal excretion. Acetylation is partly responsible for the metabolism of hydralazine. Slow acetylators may be more prone to a drug-induced lupus syndrome that can result from high serum concentrations of hydralazine during chronic treatment. Hydralazine is used for hypertensive episodes during pregnancy.⁹⁹

Calcium Channel Blockers

The calcium channel antagonists, also referred to as *calcium channel blockers* (CCBs), have proved to be useful pharmacologic agents in the treatment of angina, hypertension, arrhythmias, peripheral vascular disease, esophageal spasm, cerebral vasospasm, and controlled hypotension.¹⁰⁰ There are three chemical classes of CCBs: 1,4-dihydropyridine derivatives such as Nifedipine (Adalat, Procardia); diltiazem (Cardizem), which is a benzothiazepine derivative; and verapamil (Calan, Isoptin), which is a phenylalkylamine derivative.

All CCBs have negative inotropic and chronotropic actions. They are class 4 antiarrhythmics that block calcium channels; therefore, they depress electrical impulses in the sinoatrial (SA) and atrioventricular (AV) nodes. They produce coronary and systemic vasodilation. Different drugs in the three classes vary as to their individual ability to produce each of these effects.⁶³

A discussion of the generalized mechanism of action of the calcium antagonists is necessary for a better understanding of their role. Depolarization of the SA and AV nodes is dependent on the inward flux of calcium during the depolarization phases of the cardiac action potential. Calcium channel antagonists “block” these channels, diminishing the inward flux of calcium and prolonging phase 2, and in this way exert a negative chronotropic effect on the heart. Ventricular pacemaker foci are dependent on the inward flux of sodium, which is minimally (if at all) affected by the calcium antagonists. It then follows that the calcium antagonists are effective in patients with atrial tachyarrhythmias. Verapamil and diltiazem are the most commonly used CCBs as antiarrhythmics. They are effective in treating atrial tachyarrhythmias (including Wolff-Parkinson-White syndrome) and in controlling the ventricular response to AF and flutter. Verapamil is not indicated for the treatment of AF associated with Wolff-Parkinson-White syndrome, nor is it indicated for the treatment of “simple” atrial tachycardia, for which β -blockers may be a better choice.

CCBs also exert a negative inotropic effect on the heart, which can be beneficial in patients with angina. Cardiac contractility is

dependent on the influx of calcium into cardiac cells, and this is slowed by the CCBs. This negative inotropic effect then leads to a decrease in myocardial oxygen consumption. Calcium channel antagonists produce relaxation of vascular smooth muscle, resulting in vasodilation. Systemic vasodilation of both arteries and veins results in a decreased preload and afterload, which contributes to an increase in cardiac output and a decrease in myocardial work and oxygen consumption. The negative inotropic action and vasodilation account for the antihypertensive effect.¹⁰¹ Coronary arteries also are affected, with an increase in coronary blood flow. The CCBs are especially beneficial in the prevention of angina resulting from spasm of the coronary arteries, such as Prinzmetal angina.

Nimodipine has been a long-standing treatment for treatment of cerebral vasospasm associated with neurologic emergencies such as ruptured aneurisms and neurosurgery.¹⁰²⁻¹⁰⁴

Verapamil at 2.5 mg to 10 mg intravenously (dose can be repeated every 30 minutes) can be given for the treatment of atrial tachyarrhythmias. The onset time is up to 10 minutes, and the duration of action ranges from 2 to 4 hours. Verapamil is metabolized hepatically, has an elimination half-life of 4 to 7 hours, and is renally eliminated. Verapamil has been largely replaced by adenosine as the first-line drug of choice in the treatment of supraventricular tachycardias. Nicardipine is also useful as an IV preparation for the treatment of perioperative hypertension.^{105,106} The effects of CCBs on the ischemic heart are summarized in [Fig. 13.4](#).

FIGURE 13.4 Effects of calcium channel blockers on the ischemic heart.

Varying degrees of AV block, myocardial depression, and hypotension are associated with the use of the calcium antagonists. An additive effect should be anticipated if the calcium channel antagonists are used with other cardiodepressant agents such as anesthetics.¹⁰⁷

Clevidipine (Cleviprex) is a dihydropyridine L-type CCB indicated as an IV antihypertensive. It is highly selective for vascular muscle and does not affect myocardial contractility or conduction. Its antihypertensive effect is largely due to arterial vasodilation. Clevidipine is rapidly metabolized by nonspecific esterases in the blood. The terminal half-life is approximately 15 minutes. It is formulated as a lipid emulsion, so careful handling is essential. The starting dose is 1 to 2 mg/h, titrated up to 16 mg/h or less, according to patient response. Onset is 2 to 4 minutes, and duration is 5 to 15 minutes (see [Table 13.9](#)).^{108,109}

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (ACEI) are widely prescribed for the treatment of hypertension, angina, diabetic neuropathy, CHF, and in the management of the postmyocardial infarction patient.^{110,111} These drugs exert their action by inhibiting the angiotensin-converting enzyme (ACE). Along with the angiotensin receptor antagonists (ARAs), they are often described as angiotensin axis–blocking drugs (AABs). A brief description of the RAS is necessary for a full understanding of the actions of the ACE inhibitors ([Fig. 13.5](#)).

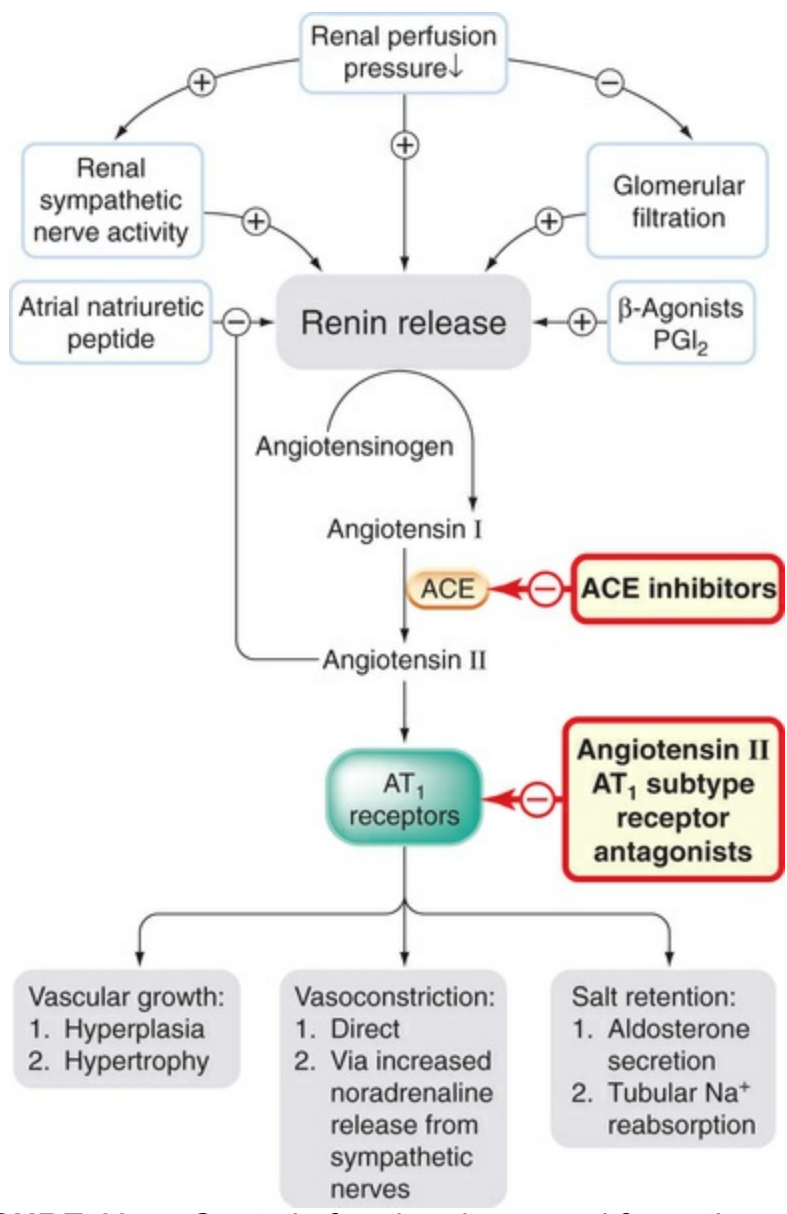

FIGURE 13.5 Control of renin release and formation, and action of angiotensin II. Sites of action of drugs that inhibit the cascade are shown. *ACE*, Angiotensin-converting enzyme; *AT₁*, angiotensin II receptor subtype 1. (From Rang HP, et al. *Rang and Dale's Pharmacology*. 8th ed. Edinburgh: Elsevier; 2016:270.)

Renin, a proteolytic protein, is released from the juxtaglomerular apparatus in the kidney in response to diminished blood pressure. Renin is responsible for the conversion of precursor angiotensinogen, which is released from the liver, to the decapeptide angiotensin I. Angiotensin I is then converted to the octapeptide angiotensin II by the ACE. ACE is primarily located in the endothelial tissue of the lung. Angiotensin II is a potent

vasopressor that also stimulates the release of endogenous norepinephrine and aldosterone. The end result is an increase in peripheral vasoconstriction, with an increase in blood pressure and a resultant decrease in cardiac output. The higher aldosterone level results in increased sodium and water reabsorption, with concomitant secretion of potassium.¹¹⁰ The ACE inhibitors block this action and produce vasodilation. Common ACE inhibitors are listed in [Table 13.5](#). Enalapril is a prodrug, and it undergoes hepatic metabolism to its active form of enalaprilat. Enalaprilat is available for IV administration for use in perioperative hypertension, but it is rarely used. All of these agents are renally eliminated, and their elimination half-lives can be expected to be prolonged in renally compromised patients.

Adverse effects associated with the ACE inhibitors include cough, angioedema, renal failure, hyperkalemia, neutropenia, and proteinuria. The dry cough resulting from the ACE inhibitors occurs in up to 25% of patients, and is the most common reason for discontinuation of the drug. If an ACE inhibitor cannot be tolerated, an angiotensin receptor blocker is substituted. The reason for the cough has been determined, as ACE is also responsible for the metabolism of bradykinin, which is blocked by these drugs. The resulting buildup of bradykinin contributes to the cough.^{112,113}

Angiotensin II Receptor Antagonists

ARAs are a class of drugs that are useful for the treatment of hypertension and CHF. Their pharmacologic actions are similar to the ACE inhibitors, but their mechanism of action is competitive blockade of type 1 angiotensin II (AT_1) receptors (see [Table 13.5](#) and [Fig. 13.5](#)).¹¹⁴ They are effective for lowering blood pressure without the cough and angioedema associated with ACE inhibitors. Unlike the ACE inhibitors, they do not prevent the breakdown of bradykinin, and therefore do not produce cough. There are no IV preparations currently marketed. Due to cost, the ARAs are often reserved for patients who cannot tolerate an ACE inhibitor.⁶⁴

Anesthesia Management of Patients Taking Angiotensin Axis Blockers

There has been a controversy for many years about whether ACE inhibitors or ARAs should be withheld the morning of surgery. The long-term clinical consequences of continuing versus withholding preoperative ACEI/ARAs are unknown. Most, if not all, cardiac medications are continued preoperatively up to and including the day of surgery.¹¹⁵ The ACE inhibitors may result in an increase in refractory hypotension during induction and maintenance of anesthesia if not discontinued prior to surgery. Hypotension usually occurs within 30 minutes of induction of anesthesia. Concurrent diuretic therapy increases hypotensive frequency.¹¹⁶ Even though withholding these medications may decrease hypotensive episodes intraoperatively, some argue that it could lead to a loss of their established long-term benefits and increase the risk for precipitating a withdrawal hypertensive crisis on the day of surgery.¹¹⁷ There are conflicting data regarding the association between perioperative AABs and the development of end-organ damage. There is an increased incidence of acute kidney injury (AKI) in patients on perioperative AABs undergoing vascular surgery, thoracic surgery, and orthopedic surgery. However, the incidence of AKI in patients on perioperative AABs following cardiac surgery has been shown in certain studies to be increased, unchanged, and even decreased.¹¹⁸ Additionally, in a 2015 large retrospective Veterans Hospital study, researchers reported that in patients who had their ARAs withheld prior to surgery, a postoperative delay in resuming the ARA past 2 days postoperatively is strongly associated with an increased 30-day mortality rate, especially in younger patients.¹¹⁹

This phenomenon is sometimes referred to as *vasoplegic syndrome* (VS). VS is defined as unexpected refractory hypotension under general anesthesia with a mean arterial pressure less than 50 mm Hg, a cardiac index greater than 2.5 L/min per m², and a low systemic vascular resistance, despite adrenergic vasopressor administration. It is most commonly seen with cardiac surgery, but

can occur during any anesthetic. The incidence of VS in cardiac surgical patients is 8% to 10%, but may increase to upwards of 50% in patients taking AABs. In cardiac surgical patients with persistent hypotension into the postoperative period, the associated mortality approaches 25%. The proposed mechanism involves selective depression of the three blood pressure support systems: the sympathetic nervous system, renin angiotensin, and vasopressin systems. Sympathetic nervous system depression under anesthesia leaves maintenance of blood pressure dependent on the renin-angiotensin and the vasopressinergic systems. ACEI and ARAs inhibit the RAS, leaving only vasopressin to maintain blood pressure. Other proposed mechanisms for developing refractory hypotension include: cytokine and NO-mediated smooth muscle relaxation, catecholamine receptor down-regulation, cell hyperpolarization, and endothelial injury.^{120,121}

Conventional therapies include decreasing the anesthetic agent, inducing volume expansion, and administering phenylephrine, ephedrine, or glycopyrrolate, as indicated. High doses may be required. If further therapy is needed, then norepinephrine, epinephrine, and dopamine may be used. If they are not effective, the administration of vasopressin may increase blood pressure. A 0.5 to 1.0-unit bolus of vasopressin may be given, followed by an infusion dose of 0.03 units/min of vasopressin or 1 to 2 mcg/kg per hour of terlipressin, as needed. Methylene blue is suggested as a last resort when other interventions fail. A bolus dose of 1 to 2 mg/kg over 10 to 20 minutes followed by an infusion of 0.25 mg/kg per hour for 48 to 72 hours is recommended, with a maximum dose of 7 mg/kg. Methylene blue is believed to interfere with the NO-cGMP pathway, inhibiting the vasodilating effect on smooth muscle.

Catecholamine-Depleting Agents

Catecholamine-depleting agents are rarely encountered in modern anesthesia practice, but the anesthetist should be familiar with their mechanism of action. The classic member of this group is reserpine. Reserpine blocks the uptake of catecholamines into storage vesicles within the presynaptic adrenergic neuron by inhibiting the vesicular monoamine transporter. This exposes the catecholamines to metabolism by monoamine oxidase in the axoplasm. This “catecholamine depletion” is responsible for the antihypertensive action of reserpine.¹²²

Tyrosine Hydroxylase Inhibitors

Metyrosine (Demser) is a tyrosine hydroxylase inhibitor. Tyrosine hydroxylase is responsible for catalyzing the conversion of tyrosine to dopa, and is considered the rate-limiting step in catecholamine synthesis. Inhibition of tyrosine hydroxylase results in a decrease in circulating catecholamine levels. It is used as an add-on drug to the α - and β -blockers for the control of the blood pressure in patients with pheochromocytoma.¹²³

Catechol-O-Methyltransferase Inhibitors

Tolcapone (Tasmar) and entacapone (Comtan) are used for the treatment of Parkinson disease as an adjunct to levodopa or carbidopa therapy. A third drug, nebicapone, is in clinical trials. These drugs are selective and reversible inhibitors of COMT. They enhance the action of levodopa and produce less fluctuation in drug response. There are concerns that COMT inhibitors may interact with various cardiac drugs by reducing their metabolism. Caution should be taken when administering drugs such as isoproterenol, dobutamine, dopamine, norepinephrine, and epinephrine. Reduced doses should be started initially until the response can be assessed.^{124,125}

Cardiac Glycosides

Characterized by the digitalis preparations, the cardiac glycosides have been used to treat CHF for two centuries. The most common preparation used is digoxin. The primary inotropic effect of digitalis is achieved by binding to the α -subunit of the sodium-potassium adenosine triphosphatase (Na/K ATPase) in cardiac cells (the Na/K ATPase is somewhat erroneously referred to as the *sodium/potassium pump*).³⁵ This results in an increase in the concentration of intracellular calcium during systole, which augments myocardial contractility. Normally, the Na/K ATPase exchanges intracellular sodium for extracellular potassium against their concentration gradients. Inhibition of this exchange results in an increase in intracellular sodium, which results in decreased calcium exchange and a higher level of intracellular calcium. The mechanism of action of digitalis is shown in Fig. 13.6. The additional calcium enhances contraction. Digitalis produces an increase in both the diastolic filling and ejection fractions.

FIGURE 13.6 The mechanism of action of digitalis. (1) The sodium-potassium ATPase is inhibited, resulting in increased intracellular sodium; (2) increased intracellular sodium produces a decrease in the exchange of sodium

and calcium; (3) intracellular calcium increases; and (4) muscle contraction is enhanced.

Electrophysiologically, enhancement of vagal tone, another prominent effect of digitalis, results in slowing of the heart rate and prolongation of AV conduction. Because of its vagal effects, digitalis is also used to control the ventricular response to AF and other atrial tachyarrhythmias. The digitalis-induced enhancement of vagal tone leads to slowing of impulse conduction through the AV node and prolongation of the effective refractory period of the AV node. Its use as both an antiarrhythmic and an inotrope has decreased significantly with the introduction of more efficacious and safer drugs.

Digitalis preparations have a narrow therapeutic index, significant variability in action among patients, and several serious side effects. Hypokalemia greatly enhances the effects of digoxin, whereas hyperkalemia has the opposite effect.¹²⁶ A patient with hypokalemia receiving digitalis level within a therapeutic range may show toxic effects. Digoxin serum levels are also mediated by the P-glycoprotein transporter. All known arrhythmias have been attributed to digitalis toxicity. Other signs and symptoms of digitalis toxicity include nausea, vomiting, diarrhea, headache, fatigue, and colored vision. Under anesthesia, the first sign is usually an arrhythmia, frequently premature ventricular contractions. Close monitoring of electrolytes should be performed in digoxin-treated patients receiving preoperative bowel preparation. Calcium administration is contraindicated in digoxin-treated patients, because it may lead to cardiac arrest. The serum levels of potassium and digitalis can be monitored preoperatively in select patients.¹²⁷

Some common mechanisms for drugs affecting the sympathetic nervous system are shown in [Fig. 13.7](#).

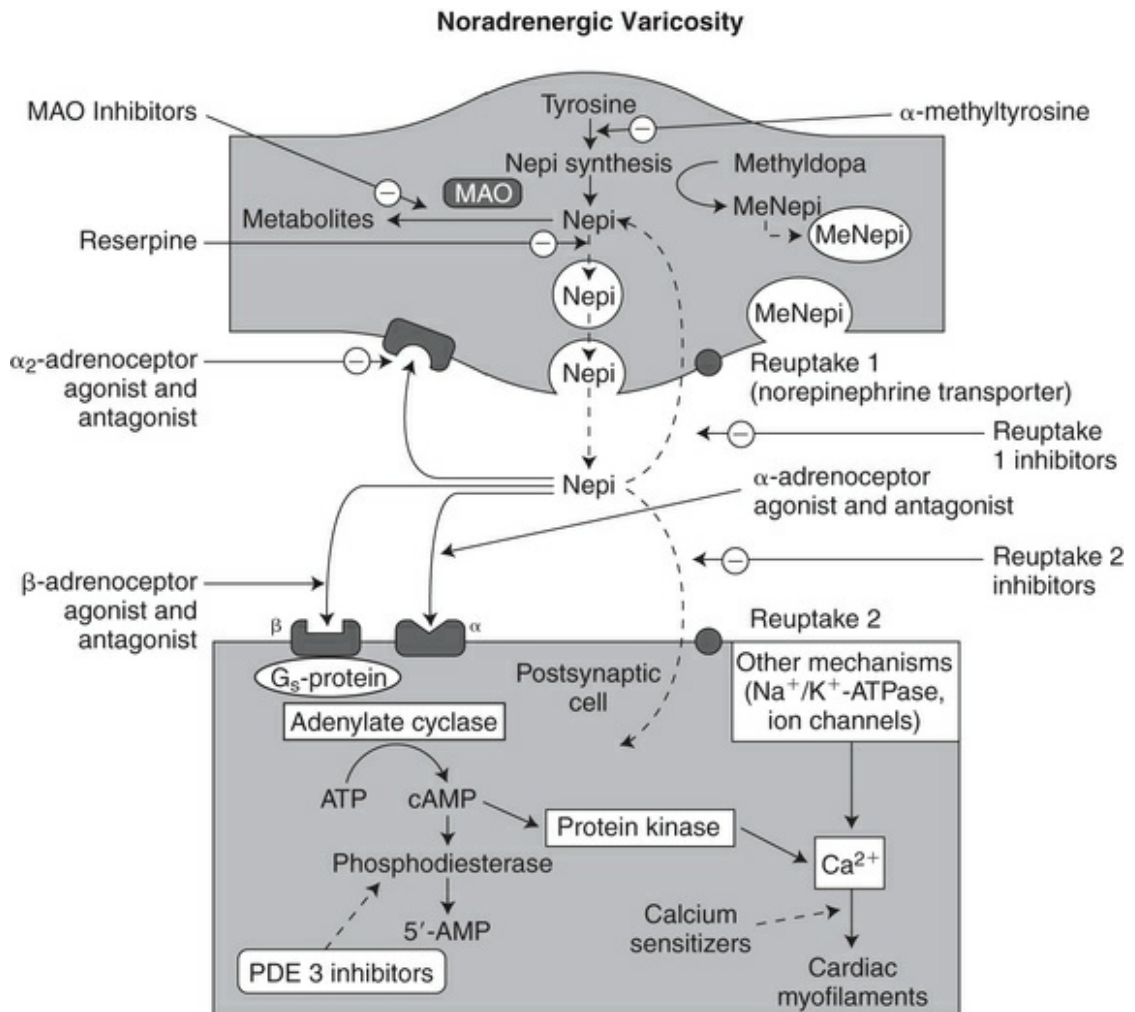

FIGURE 13.7 Common mechanisms for drugs affecting the sympathetic nervous system. *ATP*, Adenosine triphosphate; *5'-AMP*, 5' adenosine monophosphate; *cAMP*, cyclic guanosine monophosphate; *MAO*, monoamine oxidase; *MeNepi*, methylnorepinephrine; *Nepi*, norepinephrine; *PDE 3*, phosphodiesterase 3.

Management of Specific Diseases

In past decades, treatment of cardiovascular diseases under anesthesia was difficult, and options were limited. The lack of specific cardiac drugs and the limited selection of anesthetic agents warranted symptomatic therapy designed to facilitate surgery until the patient was in the postanesthesia care unit. Currently, with the vast array of cardiac drugs, the improved sophistication of anesthetic management, and monitoring that provides extensive hemodynamic information, the anesthesia provider is able to treat patients in a manner that is appropriate for management of their diseases. Therapies can be chosen that fit into a patient's plan of care. The anesthetic process can safely and effectively continue the care management of the individual patient. To assist in predicting possible poor outcomes, ACC/AHA and the European Society of Cardiology have classified the cardiovascular and surgical risks **Box 13.2** and **13.3**).^{128,129}

Clinical Predictors of Increased Perioperative Cardiovascular Risk

Major Risk Factors

Unstable Coronary Syndromes

- Acute or recent myocardial infarction with evidence of important ischemic risk by clinical symptoms or noninvasive study*
- Unstable or severe angina (Canadian class III or IV)

Decompensated Heart Failure

- New York Heart Association functional class IV; worsening or new-onset heart failure

Significant Arrhythmias

- High-grade atrioventricular block

- Mobitz II atrioventricular block
- Third-degree atrioventricular block
- Symptomatic ventricular arrhythmias
- Supraventricular arrhythmias, including atrial fibrillation with an uncontrolled ventricular rate greater than 100 at rest
- Symptomatic bradycardia
- Newly-recognized ventricular tachycardia

Severe Valvular Disease

- Severe aortic stenosis with mean pressure gradient greater than 40 mm Hg; aortic valve area less than 1 cm²; or exhibiting symptoms
- Symptomatic mitral stenosis; progressive dyspnea on exertion; exertional presyncope; or heart failure

Intermediate Risk Factors

- Mild angina pectoris (Canadian class I or II)
- Previous myocardial infarction identified by history or pathologic Q waves
- Compensated or previous heart failure
- Diabetes mellitus (particularly insulin-dependent)
- Renal insufficiency

Minor Risk Factors

- Advanced age
- Abnormal ECG (left ventricular hypertrophy, left bundle-branch

block, ST-T abnormalities)

- Rhythm other than sinus (e.g., atrial fibrillation)
- Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)
- History of stroke
- Uncontrolled systemic hypertension

*The American College of Cardiology National Database Library defines recent myocardial infarction as having occurred more than 7 days, but less than or equal to 1 month (30 days), previously; acute myocardial infarction is defined as having occurred within the last 7 days; may include “stable” angina in patients who are unusually sedentary.

ECG, Electrocardiogram.

Box 13.3

Cardiac Risk Stratification for Noncardiac Surgical Procedures

High (Very Elevated) Risk (Cardiac Risk > 5%)

- Major vascular surgery
- Emergent major operations
- Prolonged procedures with large fluid shifts or significant blood loss

Intermediate (but Elevated) Risk (Cardiac Risk Generally 1% to 5%)

- Carotid endarterectomy
- Endovascular aortic aneurysm repair

- Head and neck surgery
- Intraperitoneal and intrathoracic surgery
- Orthopedic surgery
- Prostate surgery

Low Risk (Cardiac Risk < 1%)

- Superficial procedures
- Cataract surgery
- Breast surgery
- Ambulatory surgery

From Cohn SL. Preoperative evaluation. In: Goldman L, Schafer AL, eds. *Goldman's Cecil Medicine*. 25th ed. Philadelphia: Elsevier; 2016:2611–2618.

The drugs listed for therapy of the cardiovascular disorders that follow are presented not so much for their specific intraoperative use but as a means of continuing the patient's current drug profile. Patient treatment mirrors general nonoperative indications and considerations. Anesthetic techniques take into account the combined effects of cardiac drugs and anesthetic agents when administered together.

Congestive Heart Failure

In the United States, more than 5 million people have chronic CHF, with 600,000 to 700,000 new cases occurring each year. The incidence will undoubtedly increase as the population ages. Heart failure results in more than 1 million hospitalizations each year. It is the most common hospital discharge diagnosis in patients older than 65. More than 280,000 patients die as a direct or an indirect consequence of heart failure each year, and this number has increased sixfold during the past 40 years.¹³⁰ CHF is the only major cardiovascular disorder that is increasing in prevalence, with an

estimated annual cost of \$40 billion. Once cardiac failure has been diagnosed, 5-year survival rates are typically 40% to 50%. Fortunately, data suggest that hospitalization and mortality rates are declining, which may indicate that aggressive intervention and management are yielding positive results.¹³¹ The classification of heart failure is given in [Box 13.4](#).

New York Heart Association Functional Classification for Heart Failure

Class I (Mild)

- No limitation of physical activity.
- Ordinary physical activity does not cause undue fatigue, palpitation, or dyspnea.

Class II (Mild)

- Slight limitation of physical activity.
- Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, or dyspnea.

Class III (Moderate)

- Marked limitation of physical activity.
- Comfortable at rest, but less than ordinary activity causes fatigue, palpitation, or dyspnea.

Class IV (Severe)

- Unable to carry out any physical activity without discomfort.
- Symptoms of cardiac insufficiency at rest.
- If any physical activity is undertaken, discomfort is increased.

Adapted from Januzzi JL, Mann DL. Clinical assessment of heart failure. In Mann DL, et

Heart failure is a major independent predictor of adverse perioperative outcomes in noncardiac surgery.¹³² Mortality estimates range from 10% for elective surgery to as high as 30% in patients undergoing abdominal surgery. In patients with CHF and renal failure undergoing emergency surgery, mortality rates as high as 76% have been reported.¹³³⁻¹³⁵ In a multicenter cohort study of patients undergoing noncardiac surgery from 2005 to 2010, conducted as part of the American College of Surgeons National Surgical Quality Improvement Program, worsening preoperative heart failure was associated with a significant increase in postoperative morbidity and mortality when controlling for other comorbidities. Although these likely have a multifactorial etiology, patients are much more likely to suffer from respiratory, renal, and infectious complications than from cardiac complications.¹³⁶

CHF is a syndrome resulting from a cardiac malfunction that impairs the ability of the heart to eject blood and meet the circulatory demands of the body. It is defined as a complex clinical syndrome that can result from any structural or functional cardiac disorder that interferes with the ability of the ventricle to fill with or eject blood. Alterations associated with CHF include impairment-induced complex changes in the structure of the ventricle, called *ventricular remodeling*, along with hormonal and physiologic alterations.¹³⁷ The chamber dilates, hypertrophies, and becomes more spherical. Substantial evidence suggests that activation of the body's endogenous neurohormonal systems, such as the RAS, plays an important role in cardiac remodeling and the progression of heart failure. Treatment is complex and tailored to the patient's age, current disease state, and associated concurrent disorders. It involves a polypharmaceutical approach that is referred to as *triple therapy*. This includes ACE inhibitors, β -blockers, and diuretics. Statins are usually added as well. Other agents useful in select patients may include digoxin, ARAs, nitrates, nesiritide, aldosterone, and hydralazine. Mechanical support devices may be added as well.¹³⁰

In the perioperative period, anesthesia providers are faced with managing therapy for all degrees of CHF severity. The goal can

range from prevention of symptom progression to surviving an emergency procedure in life-threatening cases. When appropriate, regional nerve block techniques should be considered, but patients may have difficulty lying flat during surgery. No single general anesthetic technique has proven superior. Invasive arterial blood pressure monitoring and transesophageal echocardiography (TEE) are useful for guiding intraoperative decision-making and fluid management. TEE is especially useful in diagnosing whether hypotensive episodes are the result of inadequate circulating blood volume, worsening ventricular function, or arterial vasoconstriction.

Drugs such as the inotropes, phosphodiesterase inhibitors, diuretics, and vasodilators are commonly used intraoperatively in acute episodes (see [Tables 13.3](#) and [13.9](#)).^{127,133,138}

Arrhythmias

The incidence of serious arrhythmias requiring intervention during general anesthesia is relatively low. A large multicenter study found that, not counting simple tachycardia, bradycardia, or clinically minor rhythm disturbances, the frequency of serious arrhythmias was 1.6% in a series of more than 17,000 patients who underwent general anesthesia.¹³⁹ It is surprising that the incidence is not higher, because several contradictory factors are involved. Most drugs given during anesthesia are cardiac depressants; therefore, they tend to be antiarrhythmic. However, patients with multiple drug profiles in combination with the anesthetics may experience drug interactions that lead to rhythm disturbances. Add to these pharmacologic factors the stresses of surgery and anesthesia, and a multitude of effects on cardiac rhythms may be expected.

A report on perioperative arrhythmias noted that the incidence of postoperative arrhythmia after cardiothoracic surgery is approximately 30% to 40%, with postoperative AF being most common.¹⁴⁰ In noncardiothoracic procedures, the incidence ranges from 4% to 20%, depending on the type of surgery performed. Bradyarrhythmias are common after cardiac surgery, and occur most frequently in the early postoperative period. These arrhythmias, in part, are related to the fluctuation in vagal tone

caused by direct surgical injury and local edema. The initial management of patients with perioperative atrial arrhythmia depends on the hemodynamic effect of the arrhythmia on the patient's clinical status. The first step in managing these patients is to eliminate any potential precipitating factors. Multiple studies have demonstrated that β -blockers reduce the risk of AF by up to 61% compared with placebo. Therefore, routine administration of β -blockers after cardiac surgery should be the standard of care to prevent AF. Sustained monomorphic or polymorphic ventricular arrhythmias are uncommon, and occur in approximately 1% to 3% of patients, usually within the first week after surgery.¹⁴⁰

In recent years, new pharmacologic and nonpharmacologic management approaches for cardiac arrhythmias have emerged. New drugs, implantable cardiac devices (ICDs), and ablation therapy are available for managing these disorders. The use of antiarrhythmic drugs in the United States is declining because of the increasing use of ablation therapy and ICDs.⁶³ Some causes of **Box 13.5** perioperative rhythm disturbances are listed in **Box 13.5**.

Causes of Intraoperative Rhythm Disturbances

General Factors

- Advanced age
- Left atrial enlargement
- Heightened adrenergic state
- Drug toxicity (proarrhythmic)
- Hypoxia
- Hypovolemia
- Hemodynamic instability
- Reperfusion after cessation of bypass

- Hypertension
- Hypoglycemia or hyperglycemia
- Pulmonary disease
- β -blocker withdrawal

Structural Heart Disease

- Coronary artery disease
- Myocardial infarction
- Valvular and congenital heart disease
- Cardiomyopathy
- Sick sinus or long Q-T interval syndrome
- Wolff-Parkinson-White syndrome
- Heart disease secondary to systemic disease (e.g., uremia, diabetes)
- Sinus bradycardia
- Atrioventricular node heart block

Transient Imbalance

- Stress: electrolyte or metabolic imbalance
- Laryngoscopy, hypoxia, hypercarbia
- Device malfunction, microshock
- Diagnostic or therapeutic intervention (pacemakers, cardioverter-defibrillators)
- Surgical stimulation

- Central vascular catheters

Adapted from Atlee JL. *Complications in Anesthesia*. 2nd ed. Philadelphia: Elsevier; 2007:319–335; Melduni RM, et al. Management of arrhythmias in the perioperative setting. *Clin Geriatr Med*. 2012;28(4):729–43.

The goal of drug therapy for arrhythmias during anesthesia should be to treat immediate hemodynamic problems and prevent progression of serious arrhythmias. Treatment is similar to that in the nonoperative setting, with the caveat that most therapies should be carefully titrated to avoid unexpected proarrhythmic or excessive hypotensive outcomes. Some cautionary statements should precede any discussion on the use of antiarrhythmic agents during anesthesia:

- The cause of the arrhythmia should be explored before any treatment is instituted. A cardiology consult should be obtained when possible.
- Adequacy of ventilation, depth of anesthesia, acid-base balance, and fluid and electrolyte balance must be verified before appropriate therapy can be formulated.
- Multiple-drug administration, which constitutes modern anesthesia practice, may result in unexpected drug interactions. Analysis of complex arrhythmias with the commonly used three- or five-lead electrocardiograph system during a surgical procedure is less than ideal for proper diagnosis and treatment. Nonetheless, rhythm disturbances that compromise hemodynamic stability or may progress to more severe dysfunction must be addressed.

Classification of antiarrhythmic drugs is given in [Table 13.10](#). Characteristics and treatment for the common arrhythmias are given in [Table 13.11](#).

TABLE 13.10
Classification of Antiarrhythmic Drugs

Class	Electrophysiologic Effect	Drug
I	Depression of phase 0 depolarization (block sodium channels)	
IA	Moderate depression and prolonged	Quinidine, procainamide, disopyramide

	repolarization	
IB	Weak depression and shortened repolarization	Lidocaine, mexiletine, phenytoin, tocainide
IC	Strong depression with little effect on repolarization	Flecainide, propafenone, moricizine
II	β -Adrenergic blocking effects	Esmolol, propranolol, metoprolol, timolol, pindolol, atenolol, acebutolol, nadolol, carvedilol
III	Prolongs repolarization (blocks potassium channels)	Amiodarone, bretylium, sotalol, ibutilide, dofetilide
IV	Calcium channel-blocking effects	Verapamil, diltiazem
Other		Adenosine, adenosine triphosphate, digoxin, atropine

TABLE 13.11
Characteristics of Arrhythmias*

P Waves				QRS Complexes			Ventricular Response to Carotid Sinus Massage
Type of Arrhythmia	Rate (Beats/min)	Rhythm	Contour	Rate (Beats/min)	Rhythm	Contour	
Sinus rhythm	60-100	Regular ⁺	Normal	60-100	Regular	Normal	Gradual slowing and return to form rate
Sinus bradycardia	<60	Regular	Normal	<60	Regular	Normal	Gradual slowing and return to form rate
Sinus tachycardia	100-180	Regular	May be peaked	100-180	Regular	Normal	Gradual slowing and return to form rate
AV nodal reentry	150-250	Very regular except at onset and termination	Retrograde; difficult to see; lost in QRS complex	150-250	Very regular except at onset and termination	Normal	Abrupt slowing caused by termination of tachycardia or no effect
Atrial flutter	250-350	Regular	Sawtooth	75-175	Generally regular in absence of drugs or disease	Normal	Abrupt slowing and return to form rate; flutter remains
Atrial fibrillation	400-600	Grossly irregular	Baseline undulation, no P waves	100-160	Grossly irregular	Normal	Slowing; grossly irregular; remains
Atrial tachycardia with block	150-250	Regular; may be irregular	Abnormal	75-200	Generally regular in absence of	Normal	Abrupt slowing and return

					drugs or disease		to norm rate; tachycardia remain
AV junctional rhythm	40-100 ^S	Regular	Normal	40-60	Fairly regular	Normal	None; may be slight slowing
Reciprocating tachycardias using an accessory (WPW) pathway	150-250	Very regular except at onset and termination	Retrograde; difficult to see; monitor the QRS complex	150-250	Very regular except at onset and termination	Normal	Abrupt slowing; caused termination of tachycardia or no effect
Nonparoxysmal AV junctional tachycardia	60-100 ^I	Regular	Normal	70-130	Fairly regular	Normal	None; may be slight slowing
Ventricular tachycardia	60-100 ^I	Regular	Normal	110-250	Fairly regular, may be irregular	Abnormal, >0.12 sec	None
Accelerated idioventricular rhythm	60-100 ^I	Regular	Normal	50-110	Fairly regular; may be irregular	Abnormal, >0.12 sec	None
Ventricular flutter	60-100 ^I	Regular	Normal; difficult to see	150-300	Regular	Sine wave	None
Ventricular fibrillation	60-100 ^I	Regular	Normal; difficult to see	400-600	Grossly irregular	Baseline undulations; no QRS	None
First-degree AV block	60-100 ^I	Regular	Normal	60-100	Regular	Normal	Gradual slowing; caused sinus
Type 1 second-degree AV block	60-100 ^I	Regular	Normal	30-100	Irregular**	Normal	Slowing; caused sinus slowing and an increase in AV block
Type II second-degree AV block	60-100 ^I	Regular	Normal	30-100	Irregular ^I	Abnormal, >0.12 sec	Gradual slowing; caused sinus slowing
Complete AV block	60-100 ^I	Regular	Normal	<40	Fairly regular	Abnormal, 0.12 sec	None
Right bundle branch block	60-100	Regular	Normal	60-100	Regular	Abnormal, 0.12 sec	Gradual slowing; and retrograde to form rate
Left bundle branch block	60-100	Regular	Normal	60-100	Regular	Abnormal, >0.12 sec	Gradual slowing; and retrograde

goal of less than 150/90 mm Hg and hypertensive persons 30 through 59 years of age to a blood pressure of less than 140/90 mm Hg. The same thresholds and goals are recommended for hypertensive adults with diabetes or nondiabetic chronic kidney disease (CKD) as for the general hypertensive population younger than 60.¹⁴¹

TABLE 13.12

Classification and Management of Blood Pressure for Adults

Blood Pressure Classification	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
Normal	< 120	and <80
Prehypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	≥ 160	or ≥ 100

From Joint National Committee on Prevention, Detection and Treatment of High Blood Pressure: *Seventh Report of the National Committee on Detection, Evaluation and Treatment of High Blood Pressure (JNC-7)* (NIH Publication No. 03-5233). Washington, DC: U.S. Department of Health and Human Services; National Institute of Health; National Heart, Lung and Blood Institute; National High Blood Pressure Education Program, May 2003.

A large number of drugs are available for the treatment of high blood pressure. The main classes of drugs used to treat hypertension include diuretics, CCBs, ACEI, and ARAs.^{142,143} β -blockers are frequently included as initial therapy, but may not be preferred in some hypertensive patients.^{144,145}

JNC 8 notes that there is moderate evidence to support initiating drug treatment with an ACEI, ARA, CCB, or thiazide-type diuretic in the nonblack hypertensive population, including those with diabetes. In the black hypertensive population, including those with diabetes, a CCB or thiazide-type diuretic is recommended as initial therapy. There is moderate evidence to support initial or add-on antihypertensive therapy with an ACEI or ARA in persons with CKD to improve kidney outcomes.¹⁴¹

Most patients with hypertension are taking two or more drugs to control their blood pressure. The most important aspect of treatment is to reduce blood pressure to goal levels, and the specific drug combinations appears to be less important. Unfortunately, despite the remarkable progress in therapy, blood pressure remains inadequately controlled in more than half of patients with

hypertension in the United States.^{146,147}

Drugs available for the treatment of hypertension are listed in [Table 13.5](#). Antihypertensive drugs that are safe for use during pregnancy are listed in [Table 13.13](#).

TABLE 13.13
Antihypertensive Drugs Used in Pregnancy*

Suggested Drug	Comments
Central α -agonists	Methyldopa is the drug of choice
β -Blockers	Atenolol, metoprolol, and labetalol
Diuretics	Diuretics recommended for chronic hypertension if prescribed before gestation or if patients appear to be salt sensitive; diuretics not recommended in patients with preeclampsia
Direct vasodilators	Hydralazine is the parenteral drug of choice, based on its long history of safety and efficacy

* Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers should not be used. Fetal abnormalities and death have been reported.

From Joint National Committee on Prevention, Detection and Treatment of High Blood Pressure: *Seventh Report of the National Committee on Detection, Evaluation and Treatment of High Blood Pressure (JNC-7)* (NIH Publication No. 03-5233). Washington, DC: U.S. Department of Health and Human Services; National Institute of Health; National Heart, Lung and Blood Institute; National High Blood Pressure Education Program, May 2003.

Manipulation of the patient's blood pressure is an ongoing task during anesthesia, and many drugs are available to increase and decrease blood pressure when indicated. Improved monitoring and more sophisticated anesthetic techniques have made control of blood pressure almost routine.

The problem of hypertension has varying significance in preoperative, intraoperative, and postoperative situations. Mild to moderate hypertension probably represents only a minor risk for anesthesia and surgery.¹⁴⁸ Patients with more severe hypertensive episodes are at greater risk and will benefit from acute therapy combined with postoperative long-term follow-up.¹⁴⁹ Hypertensive episodes during the perioperative period occur most often during emergence from anesthesia, and may be associated with pain, airway stimulation, hypoxia-hypercarbia, hypothermia and shivering, bladder distention, withdrawal from preoperative

medications, and intraoperative use of vasopressors. Drugs useful for the treatment of perioperative hypertension are listed in [Table 13.9](#).

Coronary Heart Disease

An estimated 15 million Americans currently have coronary heart disease. Among individuals aged 45 and older, the incidence of stable angina pectoris is approximately 500,000 per year; approximately 65% of these patients are men. Nearly 8 million Americans have prevalent angina pectoris. Although deaths attributable to coronary disease have declined in the United States during the past several decades, ischemic heart disease is now the leading cause of death worldwide, and it is expected that this rate of rise will continue to accelerate as a consequence of the epidemic rise in obesity, type 2 diabetes, and metabolic syndrome. An estimated 7 million patients went to emergency departments in 2010 for chest pain, and approximately 1.5 million of them were hospitalized with the acute coronary syndrome.^{150,151}

The goal of any anesthetic in a cardiac-compromised patient is hemodynamic optimization, tailored to each patient's unique disease and surgical profile. No single anesthetic technique or agent has been shown to be superior.¹⁵² Finding a balance that avoids increases in myocardial work while maintaining proper perfusion is essential.^{153,154}

The causes of coronary artery disease and management of patients with the disorder are discussed in detail in [Chapters 25](#) and [26](#). The classification of angina pectoris is given in [Table 13.14](#).

TABLE 13.14
Classification of Angina Pectoris

Class	New York Heart Association Functional Classification	Canadian Cardiovascular Society Functional Classification	Specific Activity Scale
I	Patients with cardiac disease but without resulting limitations of physical activity. Ordinary physical activity does not cause undue fatigue,	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina with strenuous or rapid or prolonged exertion at work or recreation.	Patients can perform to completion any activity requiring ≥ 7 or more metabolic equivalents, e.g., can carry 24 lb up eight steps; carry objects that weigh 80 lb; do outdoor work (shovel snow, spade soil); do

	palpitation, dyspnea, or anginal pain.		recreational activities (skiing, basketball, squash, handball, jog or walk 5 mph).
II	Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitations, dyspnea, or anginal pain.	Slight limitation of ordinary activity. Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions.	Patient can perform to completion any activity requiring ≥ 5 or more metabolic equivalents but cannot and does not perform to completion activities requiring ≥ 7 or more metabolic equivalents, e.g., have sexual intercourse without stopping, garden, rake, weed, roller skate, dance foxtrot, walk at 4 mph on level ground.
III	Patients with cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.	Marked limitation of ordinary physical activity. Walking one or two blocks on the level and climbing more than one flight in normal conditions.	Patient can perform to completion any activity requiring ≥ 2 or more metabolic equivalents but cannot and does not perform to completion any activities requiring ≥ 5 or more metabolic equivalents, e.g., shower without stopping, strip and make bed, clean windows, walk 2.5 mph, bowl, play golf, dress without stopping.
IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	Inability to carry on any physical activity without discomfort—anginal syndrome may be present at rest.	Patient cannot or does not perform to completion activities requiring ≥ 2 or more metabolic equivalents; cannot carry out activities listed previously (Specific Activity Scale, class III).

From Goldman L, et al. Comparative reproducibility and validity of systems for assessing cardiovascular functional class: advantages of a new specific activity scale. *Circulation*. 1981;64:1227–1234.

Usual pharmacotherapy includes nitrates, β -blockers, CCBs, aspirin, and lipid-lowering or “statin” drugs (Table 13.15). Nitrates are given for symptomatic relief of acute anginal episodes. Positive benefits have been noted for perioperative statin use.¹⁵⁵ Preoperative statin use is associated with reduced cardiac mortality after primary elective coronary artery bypass grafting. Postoperative statin discontinuation is associated with increased in-hospital mortality.¹⁵⁶ The β -blockers, ACEI, and CCBs are listed in Table 13.5. The HMG-CoA (3-hydroxy-3-methylglutaryl-coenzyme A) reductase inhibitors (statins) are listed in Table 13.16.

TABLE 13.15

Drug Therapy for Angina

Drug	Comments
Nitrates	First-line therapy for acute attacks; mechanism is a decrease in oxygen demand via a reduction in preload and some beneficial redistribution in blood flow
β -Blockers	Cornerstone therapy for chronic prophylaxis; decrease cardiac demand via lower heart rate, blood pressure, and contractility
Calcium channel blockers	Especially effective in variant angina and in patients intolerant to β -blockers; reduce preload, afterload, and increase coronary flow
Antiplatelet drugs	Aspirin inhibits platelet and endothelial cyclooxygenase; reduces coronary thrombosis; clopidogrel (Plavix) may be substituted in patients with contraindications to aspirin
Statins	HMG-CoA reductase inhibitors, commonly referred to as <i>statins</i> ; reduce C-reactive protein, thrombogenicity, and adverse cardiac events
Angiotensin-converting enzyme inhibitors	May be useful in patients with coronary artery disease and diabetes or other vascular diseases
Ranolazine	Ranolazine (Ranexa) is usually given in conjunction with the standard antianginal agents; blocks the late inward sodium current reducing intracellular calcium overload

HMG-CoA, 3-Hydroxy-3-methylglutaryl-coenzyme A.

TABLE 13.16

HMG-CoA Reductase Inhibitors (“Statins”)

Drug	Initial Dosage	Maximum Dosage	Comments
Atorvastatin (Lipitor)	10 mg once	80 mg once	Statins are generally tolerated better than other lipid-lowering drugs. Mild transient gastrointestinal disturbances, muscle pain, rash, and headache have occurred. Some patients have reported sleep disturbances. An increase in liver enzymes and creatine phosphokinase may occur with significant myalgia and muscle weakness.
Fluvastatin (Lescol)	20 mg once	40 mg bid	
Lovastatin (Mevacor)	20 mg once	80 mg once	
Pitavostatin (Livalo)	2 mg once	4 mg once	
Pravastatin (Pravachol)	40 mg once	80 mg once	
Rosuvastatin (Crestor)	10 mg once	40 mg once	
Simvastatin (Zocor)	20 mg once	80 mg once	

HMG-CoA, 3-Hydroxy-3-methylglutaryl-coenzyme A.

Preoperative Administration of Cardiac Drugs

Continuation of the patient's cardiac medications throughout the perioperative period is now considered routine practice. This also includes aspirin, which adds little bleeding risk to surgical procedures. It is better to have the patient's disease state under proper control than to discontinue any medications before surgery and risk having the patient in an unstable condition. Withdrawal after abrupt discontinuation of β -blockers and clonidine is especially severe.

Aspirin is recommended as a lifelong therapy that in general should not be interrupted for patients with cardiovascular disease. The abrupt withdrawal of aspirin can cause a platelet rebound phenomenon and prothrombotic state, leading to a major adverse cardiovascular event. A complete discussion of this phenomenon can be found in the earlier section on anesthetic uses of β -blockers.^{80,81}

An estimated 600,000 coronary artery stents are placed annually in the United States for the management of acute and chronic coronary artery disease, and the use of stents continues to grow. The frequency of noncardiac surgery after coronary stenting is estimated to be more than 10% at 1 year and 20% at 2 years.¹⁵⁷ Dual antiplatelet therapy (DAPT) with aspirin and a P2Y₁₂ inhibitor such as clopidogrel (Plavix), prasugrel (Effient), ticagrelor (Brilinta), or cangrelor (Kengreal) is standard at least 6 weeks after placement of bare-metal stents (BMS), 3 to 6 months after myocardial infarction, and at least 12 months after placement of drug-eluting stents (DES). Some patients remain on dual antiplatelet therapy for longer periods. The 2016 update by the ACC/AHA recommends the following: (A) Elective noncardiac surgery should be delayed 30 days after BMS implantation and optimally 6 months after DES implantation because of the risk of in-stent thrombosis and/or bleeding from dual antiplatelet therapy during surgery. (B) In patients treated with DAPT after coronary stent implantation who must undergo surgical procedures that mandate the

discontinuation of P2Y₁₂ inhibitor therapy, it is recommended that aspirin be continued if possible and the P2Y₁₂ platelet receptor inhibitor be restarted as soon as possible after surgery. (C) When noncardiac surgery is required in patients currently taking a P2Y₁₂ inhibitor, a consensus decision among treating clinicians as to the relative risks of surgery and discontinuation or continuation of antiplatelet therapy can be useful. (D) Elective noncardiac surgery after DES implantation in patients for whom P2Y₁₂ inhibitor therapy will need to be discontinued may be considered after 3 months if the risk of further delay of surgery is greater than the expected risks of stent thrombosis. (E) Elective noncardiac surgery should not be performed within 30 days after BMS implantation or within 3 months after DES implantation in patients in whom DAPT will need to be discontinued perioperatively.¹⁵⁸

In surgical patients, antiplatelet therapy should be maintained in all situations in which the risk of surgical bleeding is low, which is usually the case in an ambulatory setting. If this is not possible, aspirin should be continued in the perioperative period, although the management of P2Y₁₂ inhibitors should be individualized according to the individual patient and type of surgery. The exception is surgery in a closed space, such as intracranial procedures; procedures in the posterior eye chamber, middle ear, or intramedullary spine; and possibly transurethral prostatectomy or surgeries associated with massive bleeding and difficult hemostasis.^{159–161} A complete discussion of the anesthesia management of patients on antiplatelet drugs can be found in [Chapter 38](#).

Summary

Both advances in diagnostic and screening tests for heart disease and improvements in cardiac disease management continue to make impressive strides. Angioplasty is more effective and widely available, and electrophysiologic treatment of rhythm disorders is now considered routine. The number and diversity of cardiac medications we encounter in the perioperative period continues to grow in number and complexity. These advances require that anesthesia clinicians stay abreast of ever more complex clinical techniques, but at the same time improve anesthesia quality and safety for our patients.

Perioperative Antibiotics

Surgical site infections (SSI) are a significant burden to the patient and the health care system. They are the most common perioperative infection and the most frequent cause of hospital readmission after surgery, accounting for nearly 20% of unplanned readmissions.¹ There are an estimated 300,000 SSIs annually in the United States. They prolong hospitalization an average of 7 to 10 days, and have an estimated annual incremental cost of \$1 billion. The mortality rate associated with SSI is 3%, with approximately three-quarters of deaths being directly attributed to the infection.² Estimates from 2013 indicate that the average added cost of an SSI is approximately \$21,000.³ Costs can exceed \$41,000 for more complicated deep infections.⁴ An SSI is an infection that occurs somewhere in the operative field following surgery. The Centers for Disease Control and Prevention (CDC) defines SSIs to include both incisional SSI and organ space SSI. Incisional SSI is subdivided into superficial and deep SSI, depending on whether the infection is limited to the skin and subcutaneous tissue only (superficial SSI) or extends into the deeper tissues, such as the fascial and muscular layers of the body wall (deep SSI). Organ/space SSI is an infection that occurs anywhere within the operative field other than where the body wall tissues were incised. Examples include intra-abdominal abscess developing after an abdominal operation, empyema developing after a thoracic operation, and osteomyelitis or joint infection developing after an orthopedic procedure.^{5,6} Risk factors for developing a SSI are listed in [Box 14.1](#). The 10 most common isolates in surgical site and nosocomial infections are listed in [Table 14.1](#). Surgical wound classification is noted in [Table **Box 14.1**](#)

Risk Factors for Surgical Site Infections

Patient-Related

- Age
- Nutritional status

- Diabetes
- Smoking
- Obesity
- Coexistent infections at a remote body site
- Colonization with microorganisms
- Altered immune response
- Length of preoperative stay
- Hypothermia

Operation

- Duration of surgical scrub
- Skin antiseptics
- Preoperative shaving
- Duration of operation
- Antimicrobial prophylaxis
- Operating room ventilation
- Inadequate sterilization of instruments
- Foreign material in the surgical site
- Surgical drains
- Surgical technique
- Poor hemostasis
- Failure to obliterate dead space

- Tissue trauma

Adapted from Young PY, et al. Surgical site infections. *Surg Clin North Am.* 2014;94(6):1245–1264.

TABLE 14.2

Surgical Wound Classification

Class	Type	Description
I	Clean	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow nonpenetrating (blunt) trauma should be included in this category if they meet the criteria.
II	Clean—contaminated	An operative wound in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.
III	Contaminated	Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract, and incisions in which acute, nonpurulent inflammation is encountered are included in this category.

IV	Dirty—infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation.
----	----------------	---

From Young PY, et al. Surgical site infections. *Surg Clin North Am*. 2014;94(6):1245–1264.

Choosing the proper antimicrobial agent is essential. Prophylaxis should be directed against the most likely organism without covering all possible pathogens to decrease drug resistance. A drug for surgical prophylaxis should (1) prevent SSI, (2) prevent SSI-related morbidity and mortality, (3) reduce the duration and cost of health care, (4) produce no adverse effects, and (5) have no adverse consequences for the microbial flora of the patient or the hospital. To achieve these goals, an antimicrobial agent should be (1) active against the pathogens most likely to contaminate the surgical site, (2) given in an appropriate dosage and at a time that ensures adequate serum and tissue concentrations during the period of potential contamination, (3) safe, and (4) administered for the shortest effective period to minimize adverse effects, the development of resistance, and costs.⁷ Some common antimicrobials and their mechanisms are listed in [Table 14.3](#). Antibiotics may be classified as β -lactams or non- β -lactams. These β -lactam drugs include penicillins, cephalosporins, and carbapenems. β -Lactam antibiotics contain a 4-membered β -lactam ring and consist of several classes: the penicillins (penams), cephalosporins (cephems), and the carbapenems, monobactams, oxacephems, and clavams. Non- β -lactam antibiotics, such as macrolides, sulfonamides, quinolones, and aminoglycosides, are different chemically.

TABLE 14.3

Select Antibiotic Classes and General Mechanisms

Target and Group	Drugs	Mechanisms
Cell Wall		
β -Lactams	Penicillins, cephalosporins, carbapenems, monobactams	Inhibition of transpeptidases responsible for peptidoglycan cross-linking \rightarrow loss structural integrity
Glycopeptides	Vancomycin	Inhibition of peptidoglycan cross-linking by steric inhibition \rightarrow loss of structural integrity
Cell Membrane		
Polymyxins	Colistin, polymyxin B	Disruption of outer cell membrane of Gram negative bacteria \rightarrow altered cell membrane permeability
Ribosome		

Aminoglycosides	Gentamicin, tobramycin, amikacin, streptomycin	Binding to 30S ribosomal subunit → inhibition of protein synthesis production of mistranslated proteins
Macrolides	Azithromycin, clarithromycin, erythromycin	Binding to 50S ribosomal subunit → inhibition of protein synthesis
Tetracyclines & Glycylcyclines	Doxycycline, tigecycline	Binding to 30S ribosomal subunit → inhibition of protein synthesis
Lincosamides	Clindamycin	Binding to 50S ribosomal subunit → inhibition of protein synthesis
DNA Synthesis and Structure		
Fluoroquinolones	Ciprofloxacin, levofloxacin, moxifloxacin	Inhibition of bacterial topoisomerases, preventing DNA uncoiling → DNA strand breakage
Antifolates	Trimethoprim/sulfamethoxazole	Sequential inhibition of nucleotide precursors → interruption of DNA synthesis
Nitroimidazoles	Metronidazole	Generation of free radicals → DNA destabilization and strand breakage

Infectious diseases. In Rakei RE, Rakei DP. *Textbook of Family Medicine*. Philadelphia: Elsevier; 2016;183–235; Bratzler DW, et al. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm*. 2013;70(3):195–283.

The Surgical Care Improvement Project (SCIP) is a national quality partnership of organizations interested in improving surgical care by significantly reducing surgical complications.⁸ Since 2006, they have been setting core measures designed to reduce SSIs. The SCIP National Quality Core Measures are evidence-based clinical care guidelines that are audited and reported to a national database and have been used as a quality measure to compare hospitals. Even though they have increased the focus on SSI, there has not been a measurable improvement in infection rates to date.⁹ The surgical care improvement project core performance measures are listed in [Table 14.4](#).

TABLE 14.4
Surgical Care Improvement Project Surgical Site Infection Performance Measures

SCIP INF-1	Prophylactic antibiotic received within 1 h before surgical incision
SCIP INF-2	Proper prophylactic antibiotic selected
SCIP INF-3	Prophylactic antibiotics discontinued within 24 h after surgery end time
SCIP INF-4	Cardiac surgery patients with controlled postoperative blood glucose
SCIP INF-6	Appropriate hair removal
SCIP INF-9	Urinary catheter removed on postoperative day 2
SCIP INF-10	Appropriate perioperative temperature management

SCIP, Surgical care improvement project; *INF*, infection measure.

From Surgical Care improvement project.

Bundled interventions is an approach which attempts to group the best, evidence-based measures into routine care for all patients. It involves preoperative screening, decolonization, and targeted prophylaxis. It includes methods for preoperative removal of hair (where appropriate), rational antibiotic prophylaxis, avoidance of perioperative hypothermia, management of perioperative blood glucose, and effective preoperative bathing and skin preparation.^{10,11} A recent report (2015) from a tertiary medical center on a bundled program in eight intensive care units noted impressive reductions in catheter based infections. They implemented a catheter bundle that included: hand hygiene, provider education, chlorhexidine skin preparation, use of maximum barrier precautions, a dedicated line cart, checklist, avoidance of the femoral vein for catheter insertion, chlorhexidine-impregnated dressings, use of anti-infective catheters, and daily consideration of the need for the catheter.¹² The development of 30-day postoperative infections has been directly linked to bacterial transmission events originating from anesthesia work station reservoirs. Anesthesia providers should consider implementation of measures designed to target attenuation of bacterial transmission occurring during the routine administration of all anesthetics. Evidence suggests that a multimodal approach, including double gloving during airway instrumentation, intraoperative hand hygiene, patient screening and decolonization, and environmental equipment decontamination, as well as improvements in intravascular handling and design, may reduce the risk of postoperative infections.¹³

Drug Administration

β -Lactams work primarily via time-dependent killing, which means the time that the drug concentration exceeds the minimum inhibitory concentration (MIC) of the target organism is the primary determinant of its efficacy. In contrast, fluoroquinolones exhibit concentration-dependent killing. Vancomycin exhibits both types of

effects.¹⁴ It is recommended that administration of the first dose of the prophylactic antibiotic should be 60 minutes before the initial surgical incision to ensure adequate serum and tissue levels. If vancomycin or a fluoroquinolone is used, the infusion should begin within 60 to 120 minutes before the incision because of the prolonged infusion times required for these drugs.⁷ Redosing of antibiotics is recommended at approximately two half-lives of the drug. For cefazolin (Ancef), for example, with an elimination half-life of 1.4 to 2 hours, that would be approximately 4 hours. Because β -lactam antibiotics work on time-dependent killing, some clinicians have suggested continuous IV infusion after an initial loading dose as the suggested method of administering antibiotic prophylaxis.¹⁵ Procedures associated with significant blood loss and replacement may require more frequent redosing. Suggested redosing may occur after every 1500 mL of blood loss, or possibly after exchange of every 30% loss of blood volume.^{15,16} The duration of antimicrobial prophylaxis should be less than 24 hours for most procedures. [Table 14.5](#) lists the common antimicrobial prophylaxis for various surgical procedures.¹⁷

TABLE 14.5
Antimicrobial Prophylaxis for Surgery

Type of Surgical Procedure	Common Pathogens	Recommended Antibiotics	Usual Adult Dosage ¹
Cardiac			
Coronary artery bypass grafting, valve repairs, device implantation	<i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i>	cefazolin	2 g IV ^{4,5}
		OR cefuroxime	1.5 g IV ⁵
Gastrointestinal			
Esophageal, gastroduodenal ; entry into the GI lumen or patients at high risk for infection ⁶	Enteric gram-negative bacilli, gram-positive cocci	cefazolin ^{3,7}	2 g IV ⁴
Biliary tract; open or high-risk laparoscopic ⁸	Enteric gram-negative bacilli, enterococci, clostridia	cefazolin ^{3,7,9}	2 g IV ⁴
Colorectal ¹⁰	Enteric gram-negative bacilli, anaerobes, enterococci	cefazolin	2 g IV ⁴
		+ metronidazole ^{3,7}	0.5 g IV
		OR cefoxitin or cefotetan ^{3,7}	2 g IV
		OR ampicillin/sulbactam ^{3,7,11}	3 g IV
		OR ceftriaxone	2 g IV

		+ metronidazole ^{3,7,12}	0.5 g IV
		OR ertapenem ^{3,7,13}	1 g IV
Appendectomy, nonperforated	Enteric gram-negative bacilli, anaerobes, enterococci	cefoxitin or cefotetan ^{3,7}	2 g IV
		OR cefazolin	2 g IV ⁴
		+ metronidazole ^{3,7}	0.5 g IV
Hernia	Gram-positive cocci	cefazolin ^{2,3}	2 g IV ⁴
Genitourinary			
Cystoscopy alone	Enteric gram-negative bacilli, enterococci	High-risk ¹⁴ only: ciprofloxacin ¹¹	500 mg PO or 400 mg IV
		OR trimethoprim/sulfamethoxazole ¹¹	160/800 mg (1 DS tab) PO
Cystoscopy with manipulation or upper tract instrumentation ¹⁵	Enteric gram-negative bacilli, enterococci	ciprofloxacin ¹¹	500 mg PO or 400 mg IV
		OR trimethoprim/sulfamethoxazole ¹¹	160/800 mg (1 DS tab) PO
Open or laparoscopic surgery ¹⁶	Enteric gram-negative bacilli, enterococci	cefazolin ^{3,7}	2 g IV ⁴
Gynecologic and Obstetric			
Vaginal, abdominal, or laparoscopic hysterectomy	Enteric gram-negative bacilli, anaerobes, Gp B strep, enterococci	cefazolin ^{3,7}	2g IV ⁴
		OR cefoxitin or cefotetan ^{3,7}	2 g IV
		OR ampicillin/sulbactam ^{3,7,11}	3 g IV
Cesarean section	same as for hysterectomy	cefazolin ^{3,7}	2 g IV ⁴
Abortion, surgical	same as for hysterectomy	doxycycline 300 mg	PO ¹⁷
Head and Neck Surgery			
Incisions through oral or pharyngeal mucosa	Anaerobes, enteric gram-negative bacilli, <i>S. aureus</i>	Cefazolin	2 g IV ⁴
		+ metronidazole ^{3,18}	0.5 g IV ⁴
		OR ampicillin/sulbactam ^{3,11,18}	3 g IV
Neurosurgery			
Craniotomy, spinal and CSF-shunting procedures, intrathecal pump placement	<i>S. aureus</i> , <i>S. epidermidis</i> , <i>Propionibacterium acnes</i>	cefazolin ^{2,3}	2 g IV ⁴
Ophthalmic ¹⁹	<i>S. epidermidis</i> , <i>S. aureus</i> , streptococci, enterococci, <i>P. acnes</i> , <i>Corynebacterium spp.</i> , enteric gram-negative bacilli, <i>Pseudomonas spp.</i>	neomycin-gramicidin-polymyxin B, gatifloxacin, or moxifloxacin	1 drop q5-15 min × 5 doses
		± cefazolin	100 mg subconjunctivally at the end of the procedure
Orthopedic			
Spinal, hip fracture, internal fixation, total joint replacement	<i>S. aureus</i> , <i>S. epidermidis</i> , <i>P. acnes</i> (shoulder)	cefazolin ^{2,3,20}	2 g IV ⁴
Thoracic (Noncardiac)			
Lobectomy, pneumonectomy, lung resection, thoracotomy	<i>S. aureus</i> , <i>S. epidermidis</i> , streptococci, enteric gram-negative bacilli	cefazolin ^{2,3}	2 g IV ⁴
		OR ampicillin/sulbactam ^{2,3,11}	3 g IV
Vascular			
Arterial involving a prosthesis, the abdominal aorta, or a groin incision	<i>S. aureus</i> , <i>S. epidermidis</i> , enteric gram-negative bacilli	cefazolin ^{2,3}	2 g IV ⁴
Lower extremity amputation for ischemia	<i>S. aureus</i> , <i>S. epidermidis</i> , enteric gram-negative bacilli, clostridia	cefazolin ^{2,3}	2 g IV ⁴

¹Parenteral prophylactic antimicrobials can be given as a single IV dose begun within 60 minutes before the initial incision. For procedures that exceed 2 half-lives of the drug or those with major blood loss, or in patients with extensive burns, additional intraoperative doses should be given at intervals of about 2 times the half-life of the drug (ampicillin/sulbactam every 2 hours, cefazolin every 4 hours, cefuroxime every 4 hours, ceftiofur every 2 hours, clindamycin every 6 hours, vancomycin every 12 hours) for the duration of the procedure in patients with normal renal function. If vancomycin or fluoroquinolone is used, the infusion should be started within 60 to 120 minutes before the initial incision to have adequate tissue levels at the time of incision and to minimize the possibility of an infusion reaction close to the time of induction of anesthesia.

²Vancomycin (15 mg/kg IV) or clindamycin (900 mg IV) is a reasonable alternative for patients who are allergic to beta-lactams. They only provide coverage against gram-positive organisms; for procedures in which enteric gram-negative bacilli are common pathogens, many experts would add an aminoglycoside (gentamicin, tobramycin or amikacin), aztreonam, or a fluoroquinolone.

³A dose of vancomycin (15 mg/kg) can be given in addition to the recommended antimicrobial(s) in patients colonized with MRSA or in hospitals in which methicillin-resistant *S. aureus* and *S. epidermidis* are a frequent cause of postoperative wound infection. Vancomycin is less effective than cefazolin in preventing surgical site infections due to methicillin-susceptible *Staphylococcus aureus* (MSSA). Vancomycin has activity only against gram-positive bacteria; for procedures in which enteric gram-negative bacilli are common pathogens, many experts would add another drug such as an aminoglycoside (gentamicin, tobramycin or amikacin), aztreonam, or a fluoroquinolone. Rapid IV administration of vancomycin may cause hypotension, which could be especially dangerous during induction of anesthesia. Even when the drug is given over 60 minutes, hypotension may occur; treatment with diphenhydramine (Benadryl, and others) and further slowing of the infusion rate may be helpful. An infusion rate of 10-15 mg/minute (≥ 1 h/1000 mg) has been recommended (T Crawford et al. *Clin Infect Dis* 2012; 54:1474).

⁴Dose for patients who weigh <120 kg; the recommended dose is 3 g for those weighing ≥ 120 kg. Morbidly obese patients may need higher doses.

⁵Some experts recommend an additional dose when patients are removed from bypass during open-heart surgery.

⁶Morbid obesity, GI obstruction, decreased gastric acidity or GI motility, gastric bleeding, malignancy or perforation, or immunosuppression.

⁷For patients who are allergic to beta-lactams, clindamycin (900 mg IV) or vancomycin (15 mg/kg IV) with either gentamicin, aztreonam, or a fluoroquinolone is a reasonable alternative. Fluoroquinolones should not be used for prophylaxis in cesarean section.

⁸Age >70 years, acute cholecystitis, non-functioning gallbladder, obstructive jaundice, common bile duct stones, duration >120 minutes, diabetes, pregnancy, or immunosuppression.

⁹Cefotetan, cefoxitin, and ampicillin/sulbactam are reasonable alternatives.

¹⁰In addition to mechanical bowel preparation, 1 g of neomycin plus 1 g of erythromycin at 1 PM, 2 PM and 11 PM or 2 g of neomycin plus 2 g of metronidazole at 7 PM and 11 PM the day before an 8 AM operation.

¹¹Due to increasing resistance of *Escherichia coli*, local sensitivity profiles should be reviewed before use.

¹²Where there is increasing resistance of gram-negative isolates to first- and second-generation cephalosporins, a single dose of ceftriaxone plus metronidazole may be preferred over routine use of carbapenems.

¹³Ertapenem is FDA-approved for prophylaxis in colorectal surgery. It was more effective than cefotetan in one study, but it was associated with an increased risk of *Clostridium difficile* infection and other adverse effects (KM Itani et al. *N Engl J Med* 2006;355:2640). Routine use could promote carbapenem resistance.

¹⁴Urine culture positive or unavailable, preoperative catheter, transrectal prostatic biopsy, or placement of prosthetic material.

¹⁵Shock wave lithotripsy, ureteroscopy.

¹⁶Including percutaneous renal surgery, procedures with entry into the urinary tract, and those involving implantation of a prosthesis. If manipulation of bowel is involved, prophylaxis is given according to colorectal guidelines.

¹⁷Divided into 100 mg before the procedure and 200 mg after.

¹⁸For patients who are allergic to beta-lactams, clindamycin (900 mg IV) is a reasonable alternative.

¹⁹Preoperative application of povidone-iodine to the skin and conjunctiva is recommended.

²⁰If a tourniquet is to be used during the procedure, the entire dose of antibiotic must be infused before its inflation.

DS, Double strength; GI, gastrointestinal; OR, operating room; PO, per os.

Antibiotic Allergy

Antibiotics account for approximately 15% of anesthesia-related

anaphylactic reactions, with penicillins and cephalosporins being responsible for 70% of these. Penicillin allergy is the most commonly reported drug allergy in the United States. The prevalence of reported penicillin allergy is 10% in the general population. However, more than 90% of these patients are found not to be allergic to penicillin after skin testing. In patients found to have a penicillin allergy, the frequency of positive results on skin testing decreases by 10% per year of avoidance. Therefore, 80% to 100% of patients may test negative for penicillin allergy by 10 years after their reaction. Skin testing for penicillin allergy is safe and reliable for type 1 IgE-mediated reactions. The rate of cephalosporin allergy is approximately 1%. The rate of cross-reactivity between penicillin and cephalosporins is approximately 3%. Cephalosporins and other nonpenicillin β -lactams are widely, safely, and appropriately used in individuals, even in those with a confirmed penicillin allergy. There is little, if any, clinically significant immunologic cross-reactivity between penicillins and other β -lactams.¹⁸⁻²⁰ Cross-sensitivity occurs when the R1 side chains of the penicillins and cephalosporins are similar. That is not the case with cefazolin, which is why many clinicians consider it safe in patients with a penicillin allergy. Cephalosporins with R1 side chains similar to penicillins include cephalexin, cefaclor, and cefadroxil.¹⁴ Reactions to antibiotics can be classified according to the interval between the last administration of the drug and the onset of symptoms. Immediate reactions occurring within an hour of exposure are almost always either IgE-mediated or due to direct stimulation of mast cells. Reactions occurring later than 1 hour probably have multiple mechanisms, including being IgE-mediated or involving cell-mediated reactions. The latter are likely caused by drug-specific T lymphocytes.^{21,22}

Antibiotic-Anesthetic Drug Interactions

Most antibiotics can cause neuromuscular blockade in the absence of neuromuscular blocking agents (NMBAs). The aminoglycosides, polymyxins (lincomycin and clindamycin), and tetracycline antibiotics can potentiate neuromuscular blockade. An interaction between the cephalosporins and penicillins and NMBAs has not been reported. If an interaction is suspected, ventilation should be

controlled until muscle strength spontaneously returns. Calcium should not be given in an attempt to reverse the interaction because the antagonism it produces is not sustained, and it may diminish the antibacterial effect of the antibiotics.²³

Antibiotic Prophylaxis for Surgical and Dental Procedures

The routine use of antibiotic prophylaxis (AP) to prevent endocarditis in patients undergoing surgical or dental procedures is an area of long-standing controversy. Significant differences in recommendations from experts in the United States, United Kingdom, and other countries exist. The National Institute for Health and Clinical Excellence (NICE) in the United Kingdom issued new recommendations in 2006, which eliminated AP altogether. The American Heart Association (AHA) significantly narrowed the indications to high risk groups only.^{24–28} Patients at increased risk of developing infective endocarditis are listed in [Box 14.2](#). Consensus recommendations differ as to the type of procedure, such as gastrointestinal (GI) or dental. [Box 14.3](#) notes the type of procedures in which AP may be appropriate. [Table 14.6](#) lists [Box 14.2](#) antibiotic recommendations for dental AP.^{29,30}

Patients at Increased Risk of Developing Infective Endocarditis

High-Risk

- Patients with a previous history of infective endocarditis
- Patients with any form of prosthetic heart valve (including a transcatheter valve)
- Those in whom prosthetic material was used for cardiac valve repair
- Patients with any type of cyanotic congenital heart disease
- Patients with any type of congenital heart disease repaired with

prosthetic material, whether placed surgically or by percutaneous techniques, for the first 6 months after the procedure or lifelong if a residual shunt or valvular regurgitation remains

- Cardiac transplantation recipients who develop cardiac valvulopathy

Moderate-Risk

- Patients with a previous history of rheumatic fever
- Patients with any other form of native valve disease (including the most commonly identified conditions: bicuspid aortic valve, mitral valve prolapse and calcific aortic stenosis)
- Patients with unrepaired congenital anomalies of the heart valves

Box 14.3

Recommendations for Prophylaxis of Infective Endocarditis in the Highest-Risk Patients According to the Type of At-Risk Procedure

Recommendations

Dental Procedures

Antibiotic prophylaxis should only be considered for dental procedures regarding manipulation of the gingival or periapical region of the teeth or perforation of the oral mucosa.

Antibiotic prophylaxis is not recommended for local anaesthetic injections in noninfected tissues, treatment of superficial caries, removal of sutures, dental x-rays, placement or adjustment of

removable prosthodontic or orthodontic appliances or braces, or following the shedding of deciduous teeth or trauma to the lips and oral mucosa.

Respiratory Tract Procedures

Antibiotic prophylaxis is not recommended for respiratory tract procedures, including bronchoscopy or laryngoscopy or transnasal or endotracheal intubation.

Gastrointestinal or Urogenital Procedures or TOE

Antibiotic prophylaxis is not recommended for gastroscopy, colonoscopy, cystoscopy, vaginal or cesarean delivery, or TOE.

Skin and Soft Tissue Procedure

Antibiotic prophylaxis is not recommended for any procedure.
TOE, Transesophageal echocardiography.

Endorsed by: European Association for Cardio-Thoracic Surgery (EACTS) the European Association of Nuclear Medicine (EANM). *Eur Heart J.* 2015;36(44):3075–3128.

TABLE 14.6

Recommended Prophylaxis for High-Risk Dental Procedures in High-Risk Patients

Situation	Antibiotic	Single-dose 30–60 Minutes Before Procedure	
		Adults	Children
No allergy to penicillin or ampicillin	Amoxicillin or ampicillin*	2 g orally or IV	50 mg/kg orally or IV
Allergy to penicillin or ampicillin	Clindamycin	600 mg orally or IV	20 mg/kg orally or IV

* Alternatively, cephalexin 2 g IV for adults or 50 mg/kg IV for children, cefazolin or ceftriaxone 1 g IV for adults or 50 mg/kg IV for children.

Cephalosporins should not be used in patients with anaphylaxis, angioedema, or urticarial after intake of penicillin or ampicillin due to cross-sensitivity.

From Habib G, et al. 2015 ESC Guidelines for the management of infective endocarditis: the Task Force for the Management of infective endocarditis of the European Society of Cardiologist (ESC). Endorsed by: European Association for Cardio-Thoracic Surgery (EACTS) the European Association of Nuclear Medicine (EANM). *Eur Heart J.* 2015;36(44):3075–3123.

Antiemetics and Perioperative Nausea and Vomiting

The anesthesia community has put tremendous effort into addressing the issue of postoperative nausea and vomiting (PONV) and postdischarge nausea and vomiting (PDNV). These undesirable responses to anesthesia unfortunately persist as a clinical problem and make the anesthetic experience unpleasant for the patient and provider, and also greatly reduces patient satisfaction. This complication may result in incisional stress and significant postoperative problems, especially after certain procedures such as oral/facial surgery with a wired jaw, neurosurgical procedures, and upper GI surgery. Bleeding, fluid and electrolyte disturbances, cardiovascular stress, and aspiration may occur. In addition, postanesthesia unit (PACU) discharge may be delayed with PONV, or hospital readmission may be necessary from PDNV. This increases use of resources and personnel with the resulting increases in cost.³¹⁻³³ In a widely reported study on the risk for PDNV, it was noted that the incidence of nausea and vomiting was higher after discharge than in PACU. Apfel et al. conducted a prospective multicenter study of 2170 adults undergoing general anesthesia. In the PACU, 19.9% of patients had nausea and 3.9% had vomiting. The incidence of severe nausea was 3.6% and severe vomiting 0.2%. After discharge, 36.6% had nausea and 11.9% had vomiting. The incidence of severe nausea was 13.3% and 5.0% had severe vomiting.³⁴ Clearly, efforts to prevent this problem must continue.³⁵

Multiple risk factors have been discussed, although few have been identified as significant risk factors (Box 14.4).^{31,34,36} Significant risk factors for PONV and PDNV differ slightly and are given in Box 14.5. Several nonpharmacologic strategies to reduce the risk of PONV include the use of regional rather than general anesthesia when feasible. Other strategies include preferential use of propofol infusions and avoidance of volatile anesthetics and nitrous oxide. Reducing or avoiding the use of intraoperative and postoperative opioids and administering nonopioid analgesics if appropriate can

be helpful. Adequate hydration is also helpful, especially in

Box 14.4^{31,37}

Risk Factors for PONV in Adults

Risk Factors

- Female gender
- History of PONV or motion sickness
- Nonsmoking
- Younger age (< 50 years)
- General vs regional anesthesia
- Use of volatile anesthetics and nitrous oxide
- Postoperative opioids
- Duration of anesthesia

PONV, Postoperative nausea and vomiting.

Multimodal Antiemetic Therapy

Because nausea and vomiting are multifactorial, a multimodal approach using multiple drugs with different mechanisms is the most effective prophylaxis and therapy.^{31,38} Several classes of drugs are used for therapy (Box 14.6).

Current Antiemetic Medications by Drug Classes

Corticosteroids

Dexamethasone, methylprednisolone

Phenothiazines

Chlorpromazine, prochlorperazine

Butyrophenones

Droperidol, haloperidol

Benzamides

Metoclopramide

Anticholinergics

Scopolamine

Antihistamines

Hydroxyzine, dimenhydrinate, meclizine

5-HT₃ Antagonists

Ondansetron, dolasetron, granisetron, tropisetron, palonosetron, ramosetron

NK-1 Antagonists

Aprepitant, vestipitant, fosaprepitant, netupitant, rolapitant, casopitant

Benzodiazepines

Midazolam, lorazepam

5-HT₃, 5-Hydroxytryptamine-3; NK₁ neurokinin-1.

Glucocorticoids

Dexamethasone is a very popular drug for the prevention of PONV. A dose of 4 mg IV is recommended after anesthesia induction rather than at the end of surgery. The efficacy of dexamethasone 4 mg IV is similar to ondansetron 4 mg IV and droperidol 1.25 mg IV. Some clinicians prefer a higher dose of 8 mg IV. The mechanism of action is unclear although several theories have been proposed. Data from animal studies suggest that it exerts its antiemetic effects through central inhibition of the nucleus tractus solitarii.³⁹ A reduction of serotonin in the central nervous system (CNS) via a reduction of tryptophan, decreased release of GI serotonin, a decrease in 5-HT₃ turnover in the CNS, and inhibition of

prostaglandin synthesis have all been proposed.^{39–41} Although corticosteroids are associated with numerous side effects with repeated use, a single dose for an antiemetic effect is generally safe.^{31,32} The effect on wound healing and infection has been reported and a single dose of dexamethasone does not appear to increase wound complications.^{42–44} A significant increase in blood glucose may occur 6 to 12 hours postoperatively in patients with impaired glucose tolerance, type 2 diabetes, or obesity, especially with the higher 8 mg dose. Therefore dexamethasone is relatively contraindicated in diabetics. Methylprednisolone 40 mg IV is also effective for prophylaxis of nausea and vomiting.^{31,32}

5-HT₃ Receptor Antagonists

Ondansetron is the most widely used antiemetic and the gold standard for comparison of other agents. It is generally thought to have a greater antiemetic than antinausea effect, although some data notes a similar efficacy for both.^{31,34} The standard dose is 4 mg administered at the end of the procedure. Its popularity arises in part due to the relative lack of significant side effects. At higher doses, QT interval changes may occur. The single 32 mg IV dose of ondansetron used for prevention of chemotherapy-induced nausea and vomiting (CINV) has been withdrawn from the market because it can prolong the QT interval and could possibly cause a torsades de pointes cardiac arrhythmia. The relatively short duration of 4 to 6 hours makes it unlikely to be effective for PDNV. The efficacy of the 5-HT₃ antagonists increases when combined with dexamethasone.^{31,32,34} Other first generation serotonin antagonists are granisetron (Kytril) and dolasetron (Anzemet). Palonosetron (Aloxi) is a second generation serotonin antagonist with a long half-life of 44 hours, which makes it preferable for PDNV. It is typically administered at the beginning of surgery. It is also marketed as a combination product with a netupitant called *Akynzeo* for prevention of acute and delayed CINV.⁴⁵

All first generation 5-HT₃ antagonists may adversely prolong the QTc interval. Intravenous dolasetron is no longer available for that reason. Some medical conditions that may lead to susceptibility to prolonged QT interval are noted in [Box 14.7](#). Serotonin syndrome

has been reported with concurrent use of 5-HT₃ receptor antagonists and other serotonergic drugs, including selective serotonin reuptake inhibitors (SSRIs) and serotonin and norepinephrine reuptake inhibitors (SNRIs).⁴⁶

Medical Conditions at Risk for Development of Prolonged QT Syndrome

- Congestive heart failure
- Bradycardia
- Hypertension
- Heart block
- Cardiac hypertrophy
- Cardiomyopathy
- Hypomagnesaemia
- Medications
- Diuretics
- Antihypotensives
- Antidepressants
- Antiarrhythmics

Adapted from Kovac AI. Update on the management of postoperative nausea and vomiting. *Drugs*. 2013;73(14):1525–1547.

Neurokinin 1 Receptor Antagonists

Aprepitant (Emend) and its intravenous prodrug fosaprepitant (Emend), netupitant/palonosetron (Akynzeo), and rolapitant

(Varubi) are Substance P/NK-1 receptor antagonists. Neurokinin receptors are found in the nucleus of the solitary tract (NST), where they are involved in the central regulation of visceral function. Neurokinin 1 receptor antagonists are believed to provide antiemetic activity by suppressing activity at the NST, where vagal afferents from the GI tract converge with inputs from the area postrema and other regions of the brain that initiate emesis. Aprepitant has been approved by the Food and Drug Administration (FDA) for PONV, while netupitant/palonosetron and rolapitant have been approved for CINV. Rolapitant is characterized by a long half-life of 180 hours and an active metabolite with a half-life of 158 hours. It is marketed for delayed CINV but may also be effective for prevention of PDNV.^{47,48}

Butyrophenones

Droperidol in small doses of 0.625 mg to 1.25 mg has been used for decades to prevent and treat PONV. It is generally administered at the end of surgery and it acts as a dopamine receptor blocking agent in the CNS. Like any dopamine blocking drug, it may cause extrapyramidal side effects and is contraindicated in patients with Parkinson's disease. In 2001, the FDA issued a black box warning restricting its use due to potential prolongation of the QT interval. The anesthesia community objected that, at the low clinical doses used, this effect was unlikely. The warning suggested an electrocardiogram be performed before droperidol is used. As that is impractical, its use has dropped dramatically in the United States. Haloperidol also has antiemetic properties when used in low doses of 1 to 2 mg. Administration at the beginning or end of surgery is equally efficacious.⁴⁹ Even though it has similar effects to droperidol on the QT interval, it does not contain a black box warning. Some clinicians use it as an alternative to droperidol.^{31,30}

Transdermal Scopolamine

The scopolamine patch is an effective antiemetic when applied the evening before surgery. It has an onset of 2 to 4 hours and a minimum duration of 24 hours. Its effect is to prevent nausea and vomiting by blocking transmission of cholinergic impulses from

vestibular nuclei to higher centers in the CNS and from the reticular formation to the vomiting center. Common side effects are sedation, blurred vision, dizziness, and dry mouth. It appears most effective for prevention of nausea when a patient controlled analgesia device is used for postoperative pain.^{50,51}

Benzodiazepines

Whether or not the benzodiazepines have antiemetic action has been a long standing area of controversy. Lorazepam has been used as an adjunct for CINV; however, newer drugs are currently used. Two recent meta-analyses (2016) suggest that midazolam may have a clinically significant antiemetic effect. They note that administration of preoperative or intraoperative IV midazolam is associated with a significant decrease in overall PONV, nausea, vomiting, and rescue antiemetic use.^{52,53} It appears to decrease dopamine's emetic effect in the chemoreceptor trigger zone and decreases the release of serotonin by binding to the gamma amino butyric acid (GABA) receptor complex.⁵⁰ Concerns that administering a sedative near the end of surgery may prolong recovery limits the dose.⁵⁴

Metoclopramide

Metoclopramide is a weak antiemetic that exerts a mild dopamine receptor blocking effect. No effect is seen unless doses greater than 20 mg are used. It has a short half-life of 30 to 45 minutes, which may explain why many reports note little effect if it is given at the beginning of surgery. Dyskinesia or extrapyramidal effects can be seen with higher doses.^{33,55} Like droperidol it is contraindicated in patients with Parkinson's disease.

Clinical Use of Antiemetics

Clinicians have established guides for the use of antiemetics based on common risk factors. Multimodal PONV and PDNV prophylaxis should be considered for patients at moderate to high risk for PONV. All prophylaxis in children at moderate or high risk for PONV should include combination therapy using a 5-HT₃

antagonist and a second drug. Because the effects of interventions from different drug classes are additive, combining interventions has an additive effect in risk reduction.^{31–33}

When rescue therapy is required, the antiemetic should be chosen from a different therapeutic class than the drugs used for prophylaxis, and potentially one with a different mode of administration. If PONV occurs within 6 hours postoperatively, patients should not receive a repeat dose of the prophylactic antiemetic. An emetic episode more than 6 hours postoperatively can be treated with any of the drugs used for prophylaxis except dexamethasone, transdermal scopolamine, aprepitant, and palonosetron.^{31–33} Doses for select antiemetics are listed in [Table 14.7](#).

TABLE 14.7
Drugs for Postoperative and Postdischarge Nausea and Vomiting

Drug	Usual Adult Dose	Comment
5-HT₃ Antagonists		
Ondansetron (Zofran)	Adult 4–8 mg IV Child 50–100 mcg/kg. (max 4 mg.)	Effective for prevention of both nausea and vomiting; more effective for PONV than PDNV. Administer at the end of the procedure
Granisetron (Kytril)	Adult 1 mg IV Child 40 mcg/kg up to 0.6 mg	Administer at the end of the procedure
Palonosetron (Aloxi)	0.075 mg IV	Long duration may make it effective for PDNV
Dopamine Antagonists		
Droperidol (Inapsine)	0.625–1.25 mg IV	See text for discussion of black box warning
Haloperidol (Haldol)	1–2 mg IV	Sedation, extrapyramidal and QT prolongation may occur
Metoclopramide (Reglan)	10–20 mg IV	Contraindicated in patients with gastric obstruction due to prokinetic effects
Prochlorperazine (Compazine)	10 mg IV	Sedation prominent
Antihistamines		
Hydroxazine (Atarax)	12.5–25 mg IV	Sedation prominent
Promethazine (Phenergan)	12.5–25 mg IV	Sedation prominent
Diphenhydramine (Benadryl)	25 mg IV or IM	Sedation prominent
Glucocorticoid		
Dexamethasone (Decadron)	Adult 4–8 mg IV Child 150 mcg/kg up to 8 mg	May produce hyperglycemia postoperatively in diabetics

Anticholinergic		
Scopolamine Transdermal (Transderm-Scop)	2.5 cm ² patch contains 1.5 mg scopolamine	Long duration may make it effective for PDNV
Neurokinin 1 Antagonist		
Aprepitant (Emend)	40 mg PO	Long duration may make it effective for PDNV
Rolapitant (Varubi)	90 mg PO	Approved for chemotherapy induced nausea and vomiting. Should not be taken more than once every 2 weeks

5-HT₃, Serotonin; *IM*, intramuscular; *IV*, intravenous; *PDNV*, postdischarge nausea and vomiting; *PO*, oral; *PONV*, postoperative nausea and vomiting.

Psychiatric Drugs and Anesthesia

The incidence of psychiatric illness is increasing, with an estimated 9.6 million individual adults (4.1% of adults in the United States) suffering from serious mental illness as defined by the National Survey on Drug Use and Health.⁵⁶ In a 2015 study, as part of the National Surgical Quality Improvement Program, researchers reported that anxiolytic medication (AXM) was used by 16% of patients undergoing a noncardiac operation. Use of AXMs was an independent risk factor for poorer short-term outcome after surgery. Antidepressant medications were used by 21% of patients but it was not an independent risk factor for poor outcome.⁵⁷ The prevalence of depression and anxiety has been shown to be substantially greater among cardiac surgery patients compared to the general population. Depression and anxiety after cardiac surgery are associated with longer durations of stay, greater rates of hospital readmission, reoperation, and short- and long-term mortality.^{58,59}

Most psychiatric drug therapy should be continued into the preoperative period. Maintaining antidepressants, anxiolytics, antipsychotics, and other psychotropic agents will ensure the patient's disease is better controlled during surgery. In the past, discontinuation of the monoamine oxidase inhibitors (MAOIs) was recommended 2 to 3 weeks prior to surgery. This practice is no longer used as it is logistically and medically impractical. Withdrawal requires titration of replacement therapy which is frequently unsuccessful. Modern anesthetic techniques can be successfully adapted to the patient's condition and drug therapy. Important perioperative considerations for patients taking select psychiatric medications are reviewed in the following sections.

Antidepressants

Depression is treated with antidepressive medications, psychotherapy, electroconvulsive therapy (ECT), or a combination of these approaches. Several drug classes are useful for the treatment of depression and they are listed in [Table 14.8](#). The goal

of antidepressant treatment is complete remission of symptoms, because partial response is associated with an increased risk of relapse. Antidepressant treatment is usually given for 6 to 9 months following remission to consolidate recovery. For patients with recurrent depressive episodes, long-term maintenance therapy is indicated.^{60,61}

TABLE 14.8
Antidepressant Drugs

Drug Class	Generic Name	Trade Name	Comment
SSRIs	Fluoxetine	Prozac	First-line treatment for depression. May increase the risk of bleeding due to inhibition of serotonin uptake by platelets. Significant effects on CYP450 isoenzymes may lead to various drug interactions. Abrupt
	Paroxetine	Paxil	
	Sertraline	Zoloft	
	Fluvoxamine	Luvox	
	Citalopram	Celexa	discontinuation may lead to discontinuation syndrome. May lead to serotonin syndrome when combined with other serotonergic drugs.
	Escitalopram	Lexapro	
SNRIs	Desvenlafaxine	Pristiq	May produce dose dependent increase in blood pressure. Can precipitate serotonin syndrome or neuroleptic malignant syndrome. Abrupt withdrawal may lead to severe discontinuation syndrome. Used for analgesic effect in diabetic neuropathy.
	Duloxetine	Cymbala	
	Venlafaxine	Effexor	
TCAs	Amitriptyline	Elavil	Anticholinergic side effects such as urinary retention, dry mouth, blurred vision, and confusion are common. Orthostatic hypotension and cardiac conduction abnormalities may occur. A preoperative EKG should be obtained to rule out conduction changes. Direct acting vasopressors such as phenylephrine are preferred over indirect drugs such as ephedrine.
	Desipramine	Norpramin	
	Imipramine	Tofranil	
	Nortriptyline	Pamelor	
	Protriptyline	Vivactil	
	Doxepin	Sinequan	
MAOIs	Isocarboxazid	Marplan	Enzyme inhibiting effects can persist for up to 2 weeks after discontinuation. Interaction with serotonergic drugs, bupropion and sympathomimetics, can lead to serotonin syndrome. Avoid meperidine due to severe excitatory drug interaction.
	Selegiline	Ensam	
	Phenelzine	Nardil	
	Tranylcypromine	Parnate	
Atypical	Bupropion	Wellbutrin	Bupropion produces dose related seizures. It is prescribed for smoking cessation. Blocks reuptake of both norepinephrine and dopamine.
	Mirtazapine	Remeron	
	Trazodone	Desyrel	
	Nefazodone	Serzone	
	Vilazodone	Vibryd	

MAOIs, Monoamine oxidase inhibitors; SNRIs, selective norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Select Serotonin Reuptake Inhibitors

SSRIs are the first line therapy for major depression and the most widely prescribed class of antidepressants.^{62,63} They are generally

well tolerated and safe. Common side effects include restlessness, insomnia, nausea, diarrhea, headache, dizziness, fatigue, and sexual dysfunction. SSRIs can cause hyponatremia, particularly in elderly patients. They can also increase the risk of bleeding by inhibiting serotonin uptake by platelets. In surgical patients, a small evidence base suggests that SSRI use is associated with bleeding and adverse outcomes in cardiac and orthopedic surgery due to the antiplatelet effects of SSRIs.⁶⁴⁻⁶⁶ When SSRIs are stopped abruptly, discontinuation symptoms including nervousness, anxiety, irritability, electric-shock sensations, bouts of crying, dizziness, insomnia, confusion, nausea, and vomiting can occur. Withdrawal effects are most severe with paroxetine because of its short half-life, and least likely to occur with fluoxetine because of its long half-life. The SSRIs have an inhibiting effect on CYP450 isoenzymes and may interact with many other drugs that rely on hepatic metabolism, including β -blockers, benzodiazepines, and antiarrhythmics. Interactions with other serotonergic drugs may lead to serotonin syndrome.^{60,61} Citalopram and escitalopram may prolong the QT interval, although a recent study (2016) found no increased risk of cardiovascular outcomes in patients treated for depression.^{67,68} Unless a patient-specific concern develops, the SSRI should be continued throughout the perioperative period.⁶⁹

Serotonin Syndrome

Serotonin syndrome is a rare but potentially life-threatening condition associated with increased serotonergic activity in the central and peripheral nervous systems. It can be caused by individual drugs, an overdose, or, most commonly, a drug interaction. The mechanism is thought to be overstimulation of 5-HT_{1A} and possibly also 5-HT₂ receptors through an excess of serotonin precursors or agonists, increased serotonin release, reduced serotonin uptake, and decreased serotonin metabolism. Drugs that are associated with serotonin syndrome are listed in [Table 14.9](#).⁷⁰⁻⁷³ The syndrome is characterized by mental status changes, autonomic instability, neuromuscular hyperactivity, and hyperthermia ([Table 14.10](#)).^{74,75} Symptoms may appear within minutes or up to 24 hours after the initial use of medication, a

change in dose, or the addition of a new serotonergic drug. Mortality may result from rhabdomyolysis with renal failure, hyperkalemia, disseminated intravascular coagulation, and/or acute respiratory distress syndrome.

TABLE 14.9
Drugs Implicated in Serotonin Syndrome

Drug Class	Agents
Monoamine oxidase inhibitors	Phenelzine, moclobemide, isocarboxazid, selegiline, tranylcypromine
SSRIs	Sertraline, fluoxetine, fluvoxamine, paroxetine, citalopram, escitalopram
SNRIs	Duloxetine, venlafaxine, desvenlafaxine
Tricyclic antidepressants	Amitriptyline, doxepin, clomipramine, nortriptyline, imipramine, desipramine
Antibiotics	Linezolid
Opiate analgesics and pain medications	Meperidine, fentanyl, tramadol, pentazocine
OTC cough/cold medications	Dextromethorphan
Antimigraine agents	Almotriptan, sumatriptan
Drugs of abuse	Amphetamine, cocaine, methylenedioxymethamphetamine (MDMA or ecstasy), lysergic acid diethylamide (LSD)
Antiemetics	Metoclopramide, ondansetron
Anticonvulsants	Carbamazepine, valproic acid
Herbal products	Ginseng, nutmeg, St. John's wort
Other	Lithium, methylene blue, buspirone, tryptophan

OTC, Over the counter; SNRIs, selective norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

TABLE 14.10
The Triad of Neuromuscular, Autonomic, and Mental Status Effects Seen in Serotonin Syndrome

Neuromuscular Effects	Autonomic Effects	Mental Status Effects
<ul style="list-style-type: none"> • Hyperreflexia • Tremor • Myoclonus • Ocular clonus • Hypertonia • Rigidity 	<ul style="list-style-type: none"> • Hyperthermia • Tachycardia • Tachypnea • Abdominal pain • Diarrhea • Diaphoresis • Flushing • Mydriasis • Hyper- or hypotension 	<ul style="list-style-type: none"> • Anxiety • Agitation • Confusion • Hallucinations • Delirium • Hyperreactivity • Disorientation

Diagnosis is made using the Hunter Serotonin Toxicity Criteria, which require the presence of one or more of a group of symptoms (Box 14.8). Clonus (spontaneous, inducible and ocular) is the most

important sign in the Hunter Serotonin Toxicity Criteria. This neuromuscular feature has been strongly associated with serotonin

Box 14.8

Hunter Serotonin Toxicity Criteria: Decisions Rules

In the presence of serotonergic agent:

1. IF (spontaneous clonus = yes) THEN serotonin toxicity = YES
2. OR ELSE IF (inducible clonus = yes) AND {(agitation = yes) OR (diaphoresis = yes)} THEN serotonin toxicity = YES
3. OR ELSE IF (ocular clonus = yes) AND {(agitation = yes) OR (diaphoresis = yes)} THEN serotonin toxicity = YES
4. OR ELSE IF (tremor = yes) AND (hyperreflexia = yes) THEN serotonin toxicity = YES
5. OR ELSE IF (hypertonic = yes) AND (temperature > 38°C) AND {(ocular clonus = yes) OR (inducible clonus = yes)} THEN serotonin toxicity = YES
6. OR ELSE serotonin toxicity = NO

From Dunkley EJ, et al. The Hunter serotonin Toxicity Criteria: simple and accurate diagnostic decision rules for serotonin toxicity. *QJM*. 2003;96(9):635–642.

Most cases of serotonin syndrome are mild and may be treated by cessation of the drugs and supportive care. Benzodiazepines may be used to treat agitation and tremor. Patients with moderate or severe cases of serotonin syndrome require hospitalization. Critically ill patients may require neuromuscular paralysis, sedation, and intubation. If serotonin syndrome is recognized and complications are managed appropriately, the prognosis is favorable.⁷⁷

First-line therapy is with cyproheptadine, an H₁-receptor antagonist with antiserotonergic and anticholinergic properties. Cyproheptadine should be started at a dose of 12 mg orally or through a nasogastric tube. An additional 2 mg dose is given every

2 hours until symptoms improve or the maximal dose of 32 mg has been reached. The usual maintenance dose of cyproheptadine is 8 mg three times daily.⁷⁸

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) and MAOIs remain valuable alternatives to the SSRIs and SNRIs for patients with moderate to severe treatment-resistant depression. TCAs are probably the most commonly used adjunct analgesics in the management of both neuropathic and somatic chronic pain. Amitriptyline is the prototype antidepressant used in this context. In general, pain relief may be expected in 7 to 14 days. The TCAs commonly cause anticholinergic effects (urinary retention, constipation, dry mouth, blurred vision, and confusion), orthostatic hypotension, weight gain, sedation, and sexual dysfunction. They can cause cardiac conduction delay, which can lead to arrhythmias. Amitriptyline should be avoided in patients with a history of heart disease (conduction disorders, arrhythmias, or heart failure) and closed-angle glaucoma. Many clinicians routinely get a baseline EKG for patients taking TCAs to screen for long QT syndrome prior to surgery.

Patients treated with TCAs may have altered responses to anesthesia related drugs. An increase in CNS catecholamine levels may increase the minimum alveolar concentration (MAC) of the inhalation anesthetics. Increased peripheral catecholamines may produce exaggerated responses to indirect acting pressors such as ephedrine. This exaggerated response is prevalent upon initial TCA administration and lasts for 4 to 6 weeks. After the initial catecholamine increase, receptor down-regulation and depleted catecholamine stores result in a lesser response. If a vasopressor is administered, a direct acting drug such as phenylephrine is preferred.^{79,80}

Monoamine Oxidase Inhibitors

The MAOIs were widely used as antidepressants prior to the introduction of the much safer SSRIs. They are now used only when other first-line treatments are ineffective due to risk of drug and

food interactions eliciting a hypertensive crisis, the risk of serotonin syndrome, and difficulty with proper dosing. The inhibition of monoamine oxidase leads to central and peripheral increases in norepinephrine, serotonin, and dopamine, producing a sympathomimetic action in nerve terminals. Monoamine oxidase has two subtypes, MAO-A and MAO-B. MAO-A preferentially metabolizes serotonin, norepinephrine, and epinephrine. MAO-B preferentially metabolizes phenylethylamine. Platelets contain exclusively MAO-A and the placenta exclusively MAO-B. Approximately 60% of human brain MAO activity is of the A subtype.⁷⁹

Severe cases of serotonin syndrome have been reported in patients treated with MAOIs who took over-the-counter dextromethorphan, the illegal methylenedioxymethamphetamine (ecstasy), or who started treatment with serotonin reuptake inhibitors, meperidine, or atypical antipsychotics such as aripiprazole.

Because of the risk of serotonin syndrome, serotonergic drugs and MAOIs should not be used together or within 2 weeks of each other. Some drugs with MAOI activity, such as the antimicrobial agent linezolid (Zyvox), and some serotonergic drugs, such as the cough suppressant dextromethorphan, sumatriptan (Imitrex, and generics), tramadol (Ultram, and generics), methadone, and St. John's Wort may not be recognized as serotonergic, but can cause serotonin syndrome when taken concurrently with an SSRI or SNRI.^{60,61}

The use of meperidine in a patient treated with MAOIs may result in a long recognized drug interaction which may produce agitation, headache, skeletal muscle rigidity, hyperpyrexia, and death.⁷¹ An increase in serotonin activity in the brain is presumed to be responsible for excitatory reactions evoked by meperidine. Meperidine and other phenylpiperidines are inhibitors of neuronal serotonin uptake. Slowed breakdown of meperidine due to *N*-demethylase inhibition by MAOIs is the presumed explanation for hypotension and depression of ventilation. There is evidence that meperidine toxicity is increased only when both MAO-A and MAO-B are inhibited. Derivatives of meperidine (fentanyl, sufentanil, alfentanil) have been associated with adverse reactions

in patients treated with MAOIs, although the incidence seems to be less than with meperidine. Morphine does not inhibit uptake of serotonin, but its opioid effects may be potentiated in the presence of MAOIs.^{71,79}

In the past these drugs were discontinued prior to surgery; however, the safest approach is to continue these drugs and adjust the anesthetic plan to make changes such as avoiding meperidine and indirect-acting vasopressors. An exaggerated hypertensive response to administration of an indirect-acting vasopressor such as ephedrine may occur. If needed, the use of a low dose direct-acting agent such as phenylephrine is preferred. Details regarding a patient's MAOI use must be clearly communicated to healthcare providers on the day of the surgical procedure.^{60,61}

Serotonin Norepinephrine Reuptake Inhibitors

The SNRIs are given for major depression, anxiety, and other mood disorders, as well as chronic neuropathic pain, particularly pain associated with diabetic peripheral neuropathy. The effects of SNRIs are mediated via increases in levels of serotonin and norepinephrine in the brain. Side effects are similar to SSRIs but may also include increased sweating, tachycardia, and urinary retention. Severe discontinuation symptoms can occur when these drugs are stopped, especially with venlafaxine and desvenlafaxine, because of their short half-lives. SNRIs can cause a dose-dependent increase in blood pressure. Blood pressure should be under control before starting an SNRI and monitored during treatment.^{60,61}

Lithium

Several drugs are used for the treatment of bipolar disorder, including antipsychotics, anticonvulsants, and lithium. Lithium is generally the drug of choice for maintenance treatment of bipolar disorder. Anticonvulsant drugs such as valproate, carbamazepine, or lamotrigine, or a second-generation antipsychotic such as risperidone are frequently added. Common adverse effects of lithium include tremor, thirst, polyuria, edema, and weight gain. Confusion and ataxia can occur. Toxic renal effects, including tubular lesions, interstitial fibrosis, and decreased creatinine

clearance, have been reported with long-term use of lithium. Nephrogenic diabetes insipidus can occur; it further increases the risk of lithium toxicity, and may be irreversible. Hypothyroidism can occur with long-term lithium treatment and can contribute to exacerbations of bipolar illness. Lithium may cause mild leukocytosis, induce or exacerbate psoriasis, cause severe acne, folliculitis, hair loss, and other skin reactions. Many commonly used drugs, including most nonsteroidal antiinflammatory drugs (but not aspirin), angiotensin converting enzyme inhibitors, and diuretics, can increase serum lithium concentrations and should be avoided if possible. Discontinuation of lithium has also been associated with suicide.⁶¹

Lithium has a narrow therapeutic window and requires careful monitoring. Serum lithium concentrations should be monitored every 3 months (every 6 to 12 months in a stable patient) to maintain serum concentrations within the therapeutic range and avoid toxicity. Concentrations should be measured approximately 12 hours after the last dose. For acute treatment, target serum concentrations are 0.8 to 1.2 mEq/L. For maintenance, serum concentrations should be between 0.6 and 1.0 mEq/L. Thyroid and renal function should be monitored at baseline and every 6 months. Patients taking lithium require evaluation of electrolytes, blood urea nitrogen (BUN), and creatinine. In addition to laboratory monitoring, patients should be monitored for clinical signs of toxicity such as vomiting, diarrhea, tremor, lethargy, slurred speech, and weakness. Liver function and complete blood counts should be monitored in patients taking valproate. Complete blood counts should be monitored in patients taking carbamazepine.^{60,61}

Due to its ability to replace sodium in the propagation of action potentials, lithium prolongs the duration of several nondepolarizing neuromuscular agents. Additionally, due to its blocking of the release of epinephrine and norepinephrine from the brain stem, lithium reduces the MAC of the inhalation agents.^{60,81}

Antipsychotics

Patients with schizophrenia and other serious mental illnesses are at increased risk for perioperative complications. The increased complications are associated with comorbid physical disorders,

hazardous health behaviors, impaired stress response, antipsychotic medications, and potential interactions between antipsychotics and anesthetic drugs. Studies suggest that patients with schizophrenia may have higher pain thresholds, higher rates of death, and postoperative complications such as confusion and ileus. Schizophrenia patients experience more postoperative confusion, delirium, and agitation when psychiatric medications are discontinued preoperatively. They also have increased difficulty reestablishing their proper medication schedule postoperatively. It is suggested that patients with chronic schizophrenia should continue their antipsychotics preoperatively.⁸²⁻⁸⁶

The antipsychotics include two major classes: dopamine receptor antagonists and serotonin-dopamine antagonists. The first generation drugs are also referred to as “typical antipsychotics” and include the phenothiazines, thioxanthenes, and butyrophenones. They block dopamine receptors in the basal ganglia and limbic portions of the forebrain. The dopamine receptor antagonists, haloperidol and fluphenazine, tend to cause extrapyramidal symptoms or Parkinsonian syndrome and induce few autonomic actions such as ileus and hypotension. Chlorpromazine and thioridazine tend to cause confusion and hypotension. All first-generation antipsychotic drugs have been associated with sexual dysfunction, hyperprolactinemia, neuroleptic malignant syndrome, and tardive dyskinesia. Their antidopamine actions make them effective antiemetics.

The second generation of atypical antipsychotics are serotonin-dopamine receptor antagonists or have other mechanisms. Second-generation antipsychotics have a relatively low risk of extrapyramidal effects, and are probably less likely than first-generation antipsychotics to cause tardive dyskinesia and neuroleptic malignant syndrome. Some second-generation drugs, particularly clozapine, olanzapine, and quetiapine cause more weight gain than others. The FDA requires the manufacturers of all second-generation antipsychotics to include product-label warnings about hyperglycemia and diabetes and about an increased risk of death among elderly patients with dementia. Second-generation antipsychotics are now used more commonly than first-generation drugs, even though controlled trials have failed to demonstrate a

clear advantage in efficacy with the newer drugs, except for clozapine and possibly olanzapine. Clozapine is the most effective antipsychotic drug, but it should be reserved for refractory disease because of its potential for serious hematologic toxicity and strict monitoring requirements.

Anesthesia management consists of avoiding hypotension during induction due to additive depression of the anesthetic drugs. A baseline EKG to assess QT interval prolongation may be helpful. Other considerations include a tendency to have a history of seizure disorders, elevated liver enzymes, and abnormal temperature regulation.^{61,82-86}

Summary

Anesthesia providers have to be current on a number of drug classes which are used in the perioperative period. Although they are not anesthetic drugs they are instrumental in providing for a safe and comfortable anesthetic. The numerous antibiotics and antiemetics are essential in daily clinical practice. Patients taking psychiatric medications are encountered daily and knowledge of their potential actions and interactions are important for a safe operative course. This chapter gives an overview of the anesthetic and surgical applications of these drugs.

Chemistry and Physics of Anesthesia

Mark D. Welliver

The dynamics of much of anesthesia practice lie within the framework of chemical and physical science. Chemistry is the study of matter composition, properties, and behavior at the atomic and molecular level. Physics is the study of motion, matter, and energy interaction. Both chemistry and physics are two foundations for nurse anesthetist practice. These foundations explain such actions as pressure, flow, diffusion, expansion, contraction, and other processes that are intimately intertwined with the delivery of anesthetics. From the ancient philosophical beginnings of atomic theory and the proverbial falling apple of Newtonian physics (Sir Isaac Newton, 1642–1727) to current advances in quantum mechanics, discoveries have led to advances and application for anesthesiology. To understand these laws and theories is to understand the how and why of our practice, give us rationale for clinical interventions, and allow us the ability to manipulate dynamic processes to our patients' favor.

The dynamics of anesthesia are herein explained primarily by the atomic and kinetic molecular theories, Newtonian physics, thermodynamics, and the quantum mechanics of electromagnetic radiation. This chapter provides a short, concise resource that focuses on the chemistry and physics of anesthesia.

General Chemistry: Matter and Energy

The universe is composed of two main constituents: matter and energy. Energy is explored more thoroughly in the section on physics. Matter is the tangible composition of the universe that may be solid, liquid, gas, or plasma. Solids are defined as materials that resist changes in shape and volume. Liquids are fluids that exhibit minimal to no compressibility and may change volume with changes in pressure and temperature. Gases are also fluids, but are compressible and easily change volume with changes in pressure and temperature.

Atomic Structure

Atomic theory has its origins in the philosophical musings of the ancient Greek philosopher Democritus, who described indivisible building blocks of matter referred to as “*atomos*.”¹ The orbital theory of atomic structure was later put forth by Ernesto Rutherford (1871–1937) and improved upon by Neils Bohr (1885–1962), who described electron orbits in terms of energy levels and the ability to emit quantized energy by stimulated emission. The atomic theory describes atoms as having a central core, the *nucleus*, with orbiting particles called *electrons* (Fig. 15.1). Electrons are negatively charged. The nucleus contains protons and neutrons. *Protons* have a positive charge and are larger than electrons. *Neutrons* lack a charge and are similar in size to protons. The number of protons in an atom constitutes its *atomic number*.

FIGURE 15.1 Atomic structure showing nucleus containing protons and neutrons with orbiting electrons.

Electron Configuration

Atoms have electrons that orbit in shells around the nucleus. Each shell can contain only a set number of electrons. These shells have been designated K, L, M, N, O, P, and Q. The corresponding maximal number of electrons that may occupy each shell is 2, 8, 18, 32, 32, 18, and 8. Electrons must fill lower shells before occupying higher shells. Quantum physics has refined the electron shell model by designating the K, L, M, N, O, P, and Q shells with n -values 1, 2, 3, 4, 5, 6, and 7, which correspond with increasing energy levels. Electron shells are further divided into subshells with the designations s, p, d, f, and g. These subshells may hold only 2, 6, 10, 14, and 18 electrons, respectively. Subshells are further subdivided into orbitals. Orbitals may only contain two electrons that spin in opposite directions. An s subshell has 1 orbital, a p subshell has 3 orbitals, a d subshell has 5 orbitals, and so forth. Electrons occupy lower energy level orbitals, but may temporarily jump to higher level orbitals when they absorb energy. Electrons that jump to higher levels will emit their excess energy and return to their lower energy state (see section on lasers later in this chapter).

Angular Momentum/Spin

Nuclei and electrons have an angular momentum known as *spin*. Atomic particles possess an intrinsic axis upon which they rotate (spin). Spin is analogous to the axis on which the earth rotates. The

spin of an electron or proton is not directly measurable, but the uneven distribution of charge it produces is measurable. A magnetic moment is created, which is essentially a minute electric current loop (see section on [magnetic resonance imaging later in this chapter](#)).

Ions

Ions are atoms that have gained or lost electrons from their natural composition. An atom that has gained one or more electrons is called an *anion*. Conversely, an atom that has lost one or more electrons is called a *cation*. Ions are important in chemical bonding and aqueous solubility. The mass number (or atomic mass number) is the number of protons and neutrons in an atom. Isotopes of the same element have the same number of protons but different numbers of neutrons, and therefore have different mass numbers.

Molecular Bond Types

Molecules are composed of two or more bonded atoms. Electrons in the outermost shell are called *valence electrons* and are involved in molecular bonding. Molecular bonding may occur by direct sharing of electrons or by thermodynamic interaction due to the distribution of the electron charge. Atoms with unpaired valence electrons are reactive and tend to form bonds that will fill their outer shells. Covalent bonds and electrostatic bonds are two general types of bonds. Atoms may bond to atoms of the same element (e.g., oxygen) or to different element atoms (e.g., water). Compounds are bonded atoms of differing elements.

Covalent Bonds

The physical sharing of electrons between atoms constitutes a *covalent bond*. The sharing of one pair of electrons is called a *single bond*, sharing two pairs of electrons is a *double bond*, and sharing three pairs of electrons is a *triple bond*. Often, covalent bonds are stronger than electrostatic bonds. Covalent bonding may be between same or different atoms that share similar electronegativity.

Electrostatic Bonds

Electrostatic bonds are made by the attraction of electrons between atoms due to electron distribution. Electrostatic bonding may include ion-to-ion interactions, ion-to-dipole interactions, or dipole-to-dipole interactions, and follows the general rule of “opposites attract,” with negative charges attracting positive charges.

Ion-Ion Bonding

Ion-to-ion bonds are the strongest of the electrostatic bonds. These bonds are not directional, and occur anywhere along the outer electron shell of an atom. Molecules with ionic bonds have high melting and boiling points. Sodium chloride (table salt) is an example of ion-to-ion bonding (Fig. 15.2).

FIGURE 15.2 Ion-to-ion bond representation between sodium (Na) and chloride (Cl) ions.

Ion-Dipole Bonding

Ion-to-dipole bonds are weaker than ion-to-ion bonds, with only partial charges involved. Some molecules have structural arrangements that produce an uneven distribution of electrons. This uneven distribution of charges creates a dipole in which there is a more positive or more negative side to the molecule, although the molecule does not have a formal charge. An example of a molecule with an uneven charge distribution is water. The spatial arrangement of water's hydrogens toward one side of an oxygen atom causes that side to have a more positive character and the opposite side to have a more negative character. This water dipole may bond to an ion of opposite charge. Sodium and chlorine ions bond to water through ion-to-dipole interactions (Fig. 15.3).

FIGURE 15.3 Ion-to-dipole bond representation between a water molecule and sodium ion.

Dipole-Dipole Bonding

Water is an example of dipole-to-dipole molecular bonding. The spatial arrangement of water's hydrogens at a 105-degree angle to each other causes this molecule to be dipolar (Fig. 15.4). The dipolar nature of water molecules allows them to form weak bonds with one another (Fig. 15.5). The polar sides of water molecules also enable them to bond to ions and other polar molecules. For this reason, water is a convenient solvent for many substances, such as drugs. The surface tension of water is a physical characteristic that is caused by water's dipole-to-dipole intermolecular attractions.

FIGURE 15.4 Bond angle between two hydrogens and a water molecule.

FIGURE 15.5 Dipole-to-dipole bond representation between two water molecules.

Some molecules may have *induced dipoles* caused by momentary uneven spatial distribution of electrons. Induced dipoles are not permanent. These temporary dipoles may lead to weak bonding between nonpolar molecules. Oils are composed of nonpolar molecules that display induced dipole bonding, often called *London dispersion forces*. London dispersion forces are the weakest of all molecular bonds. Despite this weakness, London dispersion forces at very low temperatures allow oxygen and nitrogen to become liquids.

Molecular Bonding Representations

There are several ways to denote bonding and electron distribution. The Lewis structure (electron dot structure) shows the valence electrons as they bond among atoms. Lewis structures may show dots or lines to represent electrons. Again, only outer shell valence electrons are represented and not lower, fully filled shells. Skeletal diagrams are another frequently used method to represent molecular bonding. In organic chemistry, skeletal diagrams use lines to show atom bonding, often omitting the letter C for carbon (Fig. 15.6).

FIGURE 15.6 Skeletal diagram of diisopropyl phenol molecule.

Valence shell electron pair repulsion diagrams are more descriptive Lewis structures based on the theory of the same name. These diagrams represent electron repulsion, and the resultant approximation of the geometric distribution of atoms in covalently bonded molecules (Fig. 15.7).

FIGURE 15.7 Valence Shell Electron Pair Repulsion (VSEPR) diagram of a tetrahedral-shaped molecule.

Molecular Modeling

Molecular models are detailed representations of molecules. Electrons are in constant “orbit” in an atom, and attempts have been made to graphically represent their possible space-occupying locations (Fig. 15.8). Space-filling models reflect the “electron cloud” of specific atoms in a molecule. These models can appear as spherical, ball and stick, or ribbon-like representations of atoms and molecules that are affixed to one another. Molecular modeling is expanding our understanding, not only of molecular geometries, but also of molecular behavior.²

FIGURE 15.8 Molecular model of sugammadex encapsulating a rocuronium molecule. (From Zhang M-Q, et al. A novel concept of reversing neuromuscular block: chemical encapsulation of rocuronium bromide by a cyclodextrin-based synthetic host. *Angew Chem Int Ed.* 2002;41(2):265. Reproduced with permission.)

Isomers

Isomers are molecules that have the same chemical formula but different structures. The number and type of atoms and bonds are the same in isomers, but the arrangement of the atoms is different. Isomers may be *structural isomers* or *stereoisomers*. Structural isomers have the same molecular formula, but their atoms are located in different places. Enflurane and isoflurane are examples of structural isomers. Structural isomers are truly different molecules with differing physical and chemical properties. Stereoisomers are molecules that have a similar geometric arrangement of atoms but differ in their spatial position. Stereoisomers may be *enantiomers* or *diastereomers*. Enantiomers are mirror images of one another, cannot be superimposed, and possess similar chemical and physical properties. Enantiomers are optically active and can rotate polarized light in a clockwise fashion (denoted by the prefix + or dextro) or counterclockwise fashion (denoted by the prefix – or levo). Racemic chemical compositions contain 50% of the levo form of the isomer and 50% of the dextro form of the isomer. Racemic epinephrine used to treat laryngeal edema is an example of a racemic mixture. Diastereomers are not mirror images, and may have differing physical and chemical properties.

Bond Breaking

Bond energy is the amount of energy needed to make or break a bond. Energy is released when a bond is formed, and energy is consumed when a bond is broken. The energy released when a bond is formed is the same amount of energy needed to break that same chemical bond. Short bonds, such as covalent bonds, tend to possess greater bond energies than longer, electrostatic bonds. When molecular bonds are broken, new molecular bonds are often formed, and energy is released. An example of this is adenosine triphosphate (ATP) conversion to adenosine diphosphate. Energy is actually consumed in the process of breaking an ATP bond. A greater amount of energy is released when the free phosphate forms new bonds with hydrogen.³ Bond energies are measured as an enthalpy change.

Enthalpy

Enthalpy is the total amount of energy possessed by a system. A system can be on the atomic scale or the macroscopic scale. The enthalpy of a system is the total of all kinetic and potential energy. The stored, or potential, energy includes its height in relation to the force of gravity and the energy stored in the bonds of its molecules, atoms, and even subatomic particles. All movement, as well as stored energy, must be accounted for and summated to know the enthalpy of a system. Thus, the total amount of energy contained within a system becomes increasingly difficult to quantify, especially as the complexity of the system increases. Measuring all the energy in a particular system requires a simpler method to evaluate the energy involved in chemical reactions. Therefore, *change of energy* (ΔH) rather than total energy (enthalpy) of a system is measured.

Organic Compounds

Organic chemistry is the study of carbon-containing molecules. Biological life on earth is based on carbon-containing compounds. Carbon is a unique atom that combines with many atoms in multiple arrangements, owing to its four valence electrons available

for bonding. Carbon may make single, double, or triple covalent bonds with other atoms or molecules.

Hydrocarbons

Hydrocarbons are molecules composed entirely of carbon atoms with hydrogen atoms attached. These molecules are often found in straight chains with or without branches. *Saturated hydrocarbons* are single-bonded carbon chains with all available carbon bonds attached to hydrogen. Hydrocarbons containing only single-bonded carbon atoms are called *alkanes*. The six-carbon hydrocarbon shown in Fig. 15.9 is called a *hexane*. The *hex-* prefix denotes six carbons, and the *-ane* suffix denotes an alkane with all single bonds.

FIGURE 15.9 Hexane.

Unsaturated hydrocarbons have one or more double or triple bonds between carbon atoms. Hydrocarbons containing double-bonded carbons are called *alkenes*, and triple-bonded carbons are called *alkynes*. The six-carbon hydrocarbon containing a double bond is called *hexene* (Fig. 15.10).

FIGURE 15.10 Hexene.

Cyclic hydrocarbons are carbon chains in a ring structure. They may contain multiple carbon atoms and may have single, double, or triple bonds. The cyclic hydrocarbons hexane and benzene (1,3,5-cyclohexatriene) are shown in Fig. 15.11.

FIGURE 15.11 Hexane and benzene.

Saturated and unsaturated hydrocarbons that are missing hydrogens are known as *alkyls*, are very reactive, and bond to functional groups. Cyclic hydrocarbons that are missing a hydrogen on any carbon atom are called *aryls*, are reactive, and also bind with functional groups.

Functional Groups

Functional groups impart unique characteristics to molecules. There are many functional groups in organic chemistry, and several have importance in anesthesia.

Amines are derivatives of ammonia (NH_3) and have the general formula NR_3 . Only one or two of the R groups may be hydrogen. All amines have a lone pair of electrons on the nitrogen.

Alcohols have the general formula ROH , where R represents any alkyl group. The hydroxyl group (OH) of alcohols is highly polar and easily forms hydrogen bonds with other polar molecules. The polarity of the hydroxyl group allows alcohols to dissolve many other polar molecules.

Phenols are similar to alcohols in that they both have the general formula ROH . The R in phenols represents an aryl group (benzene). A simple phenol is polar due to the hydroxyl group, but more complex phenols such as propofol (diisopropyl phenol) are not water soluble (Fig. 15.12).

FIGURE 15.12 Phenol and disopropyl phenol molecules.

Ethers have the general formula ROR' , where R and R' are alkyl groups attached by oxygen. Ethers are inert and do not react with oxidizing or reducing agents, but are highly flammable. Both alkyl groups of the outdated anesthetic agent diethyl ether are bonded to oxygen (Fig. 15.13). Halogen substitution on ethers alters anesthetic characteristics (such as blood solubility and potency) while lowering flammability.

FIGURE 15.13 Diethyl ether.

Several functional groups contain a structural arrangement of carbon double bonded to oxygen. This is known as a *carbonyl group*, and is structurally identified as $C=O$. The carbonyl group is polar, with the oxygen being more electrically negative. This polar characteristic is imparted to functional groups that contain a carbonyl group. The carbonyl group, though not a functional group by itself, is a key component of the following functional groups: aldehydes, ketones, carboxylic acids, esters, and amides.

- *Aldehydes* have the general formula $RCHO$.
- *Ketones* have the general formula $RCOR'$.
- *Carboxylic acids* have the general formula $RCOOH$.
- *Esters* have the general formula $RCOOR$.
- *Amides* have the general formula $RCONH_2$, $RCONHR$, or $RCONR_2$.

Solubility

Solubility is the maximum amount of one substance (solute) that is

able to dissolve into another (solvent). Factors that may affect the solubility of solutes in solvents are the intermolecular interactions between the substances, temperature, and pressure.

Solids and Liquids

Solubility is enhanced by intermolecular interactions between substances that have similar electron configurations. “Like dissolves like” is often used to describe solubility. Salt (NaCl) solubility in water is an example. The similar polarity of water and salt's constituent parts promote dissolving. Temperature also affects solubility. Energy is required to break the bonds of dissolving substances. Most often, this is an endothermic reaction, which means it requires more energy than it produces; it consumes heat rather than producing heat. With endothermic reactions, solubility is increased with increased temperature; the additional energy (heat) drives greater dissolving. Most reactions of solids dissolving in liquids are endothermic. Occasionally, the process may be exothermic, meaning energy is released in excess of the energy required to break the bonds of the solute. In this unique scenario, increases in temperature will decrease solubility. Pressure exerts little to no influence on the solubility of solids and liquids.

Gases

Gas solubility in liquids is inversely related to temperature. As temperature increases, less gas is able to dissolve into a liquid. An increased temperature represents greater kinetic energy. Greater kinetic energy allows dissolved gas molecules to escape and prevents further dissolving. Lower temperature slows the kinetic energy of gas molecules, allowing them to dissolve into liquids. A clinical example of temperature affecting solubility is seen with the slower emergence of hypothermic patients receiving volatile agent general anesthetics. The hypothermic patient retains anesthetic gases in the blood because of increased solubility related to temperature.⁴ Gas solubility in a liquid is directly proportional to pressure, and is described by Henry's law.⁵

Henry's Law

Henry's law (William Henry, 1775–1836) states that “at constant temperature, the amount of gas dissolved in a liquid is directly proportional to the partial pressure of that gas at equilibrium above the gas-liquid interface.” The formula is as follows:

$$p = kc$$

where p is the partial pressure of the solute above the solution, k is Henry's constant, and c is the concentration of the solute in solution. Increasing the partial pressure of a gas above a liquid will increase the amount of gas that dissolves in the liquid. Increased delivery of oxygen (FiO_2) to patients to improve arterial oxygenation (PaO_2) and “overpressurizing” (i.e., using high concentrations of) anesthetics reflect the direct relationship of pressure and solubility described by Henry's law. Overpressurizing is the process of significantly increasing the concentration of volatile anesthetic (partial pressure) delivered to a patient to increase the alveolar concentration, thereby increasing the amount dissolved in the blood and speeding uptake.

Diffusion

Diffusion is the net movement of one type of molecule through space as a result of random motion to minimize a concentration gradient (Fig. 15.14). This basic process occurs by Brownian (Robert Brown, 1773–1858) motion, which is driven by the inherent kinetic energy of the molecules.⁶ Temperature is directly proportional to kinetic energy. Kinetic energy allows molecules to move freely in a fluid, and therefore mixtures of fluids tend to evenly distribute. The velocity at which a molecule may distribute is determined by its molecular weight. Every molecule at a given temperature will have the same kinetic energy, independent of its size, but its velocity may differ. From the formula for kinetic energy, $KE = (\frac{1}{2}) mv^2$, we can determine that, if the mass of a molecule is changed, there must be an opposite change in velocity. Greater velocity correlates with faster diffusion. Thus, molecules with smaller mass will diffuse faster.

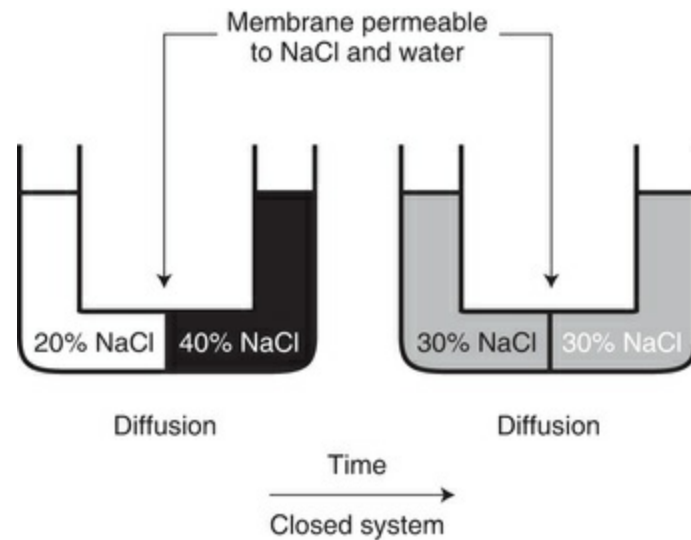

FIGURE 15.14 Diffusion of water and NaCl.

Graham's Law

Thomas Graham (1805–69) determined that the rate of effusion (gas diffusion through an orifice) of a gas is inversely proportional to the square root of its molecular weight. The formula for this relationship is as follows:

$$r = 1/\sqrt{mw}$$

where r is the rate of diffusion and mw is the molecular weight. Graham's law describes the faster diffusion of smaller molecules compared to larger molecules. Graham's law is helpful in understanding the effect of molecular weight on diffusion, but is limited in fully describing all the factors influencing diffusion.

Diffusion Through Permeable and Semipermeable Membranes

Diffusion may occur through open space or through permeable membranes (tissues). Diffusion of a fluid (gas or liquid) through a permeable membrane is dependent on five factors: the concentration gradient, tissue area, and fluid tissue solubility are directly proportional to diffusion; whereas membrane thickness and molecular weight are inversely proportional to diffusion.

Osmosis

Osmosis is the movement of water across a semipermeable membrane to equilibrate a concentration gradient (Fig. 15.15). Semipermeable membranes are permeable to water only and not to solutes. *Osmotic pressure* is the force needed to stop osmosis from occurring. *Oncotic pressure* is the osmotic pressure exerted by plasma proteins and electrolytes in capillaries. Oncotic pressure balances the hydrostatic pressure tendency to push water out of capillaries. Normal oncotic pressure is approximately 28 mm Hg. The vascular system is a semipermeable membrane that responds to intravascular delivery of colloids by sequestering fluid.^{7,8}

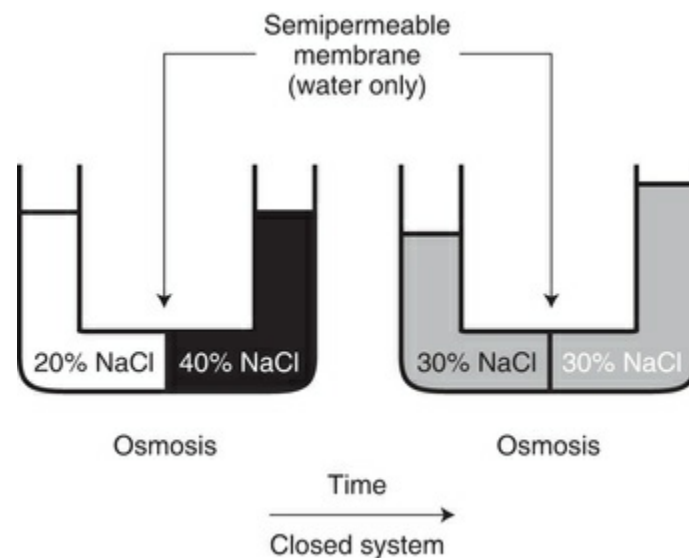

FIGURE 15.15 Osmosis of water through a semipermeable membrane.

Diffusion in Anesthesia

Diffusion is a passive process driven by entropy (discussed later in this chapter). The diffusion of oxygen and nitrous oxide represents both positive and negative consequences of this process. Nitrous oxide diffuses into air-filled cavities; therefore, delivery of nitrous oxide is contraindicated in patients with pneumothorax or where air-filled cavity expansion is undesirable.⁹ Nitrous oxide expansion of endotracheal cuffs may cause tracheal mucosal damage.⁹⁻¹¹ Distention of the bowel during nitrous oxide delivery has also been

documented.^{12,13} Apneic oxygenation is well known, and exemplifies the beneficial process of diffusion.¹⁴ An intubated patient who has previously been ventilated with 100% oxygen and remains connected to the ventilation circuit with 100% oxygen flow will maintain an acceptable PaO₂ if ventilation is ceased. The continual diffusion of oxygen into the blood is driven by a concentration gradient that continually diffuses oxygen into the alveoli via the ventilator circuit. The diffusion of gases across biological tissues is expressed by Fick's law.

Fick's Law

Fick's law for diffusion of a gas across a tissue plane is an encompassing law that accounts for molecular weight, concentration gradient, solubility, and membrane interactions. Fick's law states that diffusion of a gas across a semipermeable membrane is directly proportional to the partial pressure gradient, the membrane solubility of the gas, and the membrane area, and is inversely proportional to the membrane thickness and the molecular weight of the gas. Specific application of the Fick equation for diffusion of respiratory gases is as follows:

$$J = \alpha D / \Delta x (PaO_2 - P_{cap}O_2)$$

where J is diffusion flux, α is the solubility constant for oxygen, D is diffusivity, Δx is the membrane thickness, and $(PaO_2 - P_{cap}O_2)$ is the alveolar-capillary oxygen partial pressure difference. Fick's equation allows determination of pulmonary gas exchange.^{15,16} The diffusion hypoxia that occurs after the delivery of nitrous oxide is discontinued, and low inspired oxygen is administered, as explained by Fick's equation.¹⁷

Newtonian Physics

Gravity

All life on earth is well aware of gravity. From our first steps to our last, gravity affects every facet of our daily lives. It is a unidirectional force that pulls objects down towards earth's center. Gravity appears to pull on heavy objects with greater force than lighter objects, but this is not necessarily true. Aristotle saw gravity this way and felt it was due to an object's desire to return to its natural position at rest on the earth. It took 2000 years to change that perspective. Gravity pulls on all objects with a force of 9.81 m/sec per sec (32 ft/sec per sec). Sir Isaac Newton's law of gravity stated that, "[e]ach particle of matter attracts every other particle with a force which is directly proportional to the product of their masses and inversely proportional to the square of the distance between them." The formula for gravity is:

$$\text{Gravitational force} = (G \times m_1 \times m_2) / (d^2)$$

where G is the gravitational constant ($6.67 \times 10^{-11} \text{Nm}^2/\text{kg}^2$), m_1 and m_2 are the masses of the two objects for which you are calculating the force, and d is the distance between the centers of gravity of the two masses. Remember that mass and weight are not the same. Mass is the total of all matter in an object—the sum of the mass of all the electrons, protons, and neutrons. Weight is the total effect of gravity pulling on all the electrons, protons, and neutrons contained in an object. An example often cited is that you may weigh 70 kg on earth due to the gravitational pull on all your atoms, but you would weigh less on the moon, which has less gravitational pull. Your mass or total amount of matter remains the same on earth or the moon.

$$\text{Mass} \times \text{force of gravity} = \text{weight}$$

The earth attracts all other objects around it with a force of 9.81

m/sec per sec, and those objects in turn attract the earth in relation to their mass and distance from the planet. The formula for gravitational acceleration is:

$$g = GM_e/r_e^2$$

where g is gravitational acceleration, G is the gravitational constant, M_e is the mass of earth, and r_e^2 is the mean radius of earth. Earth's attraction for objects is proportional to mass for all objects at the same distance. One might want to say that objects with greater mass would accelerate or be pulled faster to earth, but objects also resist movement proportional to their mass (third law of motion). Gravity pulls on one atom of carbon with a force of 9.81 m/sec per sec, and the carbon atom resists this pull with a force of x . Gravity pulls on two carbon atoms with a force of 9.81 m/sec per sec on each atom for a total gravitational force of $9.81 \text{ m/sec per sec} \times 2$, or 19.62 m/sec per sec. Two carbon atoms resist movement twice ($2 \times$) as much as one carbon atom; thus, the net gravitational effect (falling) is the same. This is how objects with greater mass are pulled by gravity with the same force and fall at the same acceleration as objects with lesser mass.

This equal attraction on objects is often hidden in everyday life, owing to the effect of air molecules interacting with falling objects. Assuredly, all objects fall due to gravity at the same speed in a vacuum that is devoid of other molecules. Air molecules possess energy, move about, and interact with other matter. This causes friction. Greater friction equals greater force against the pull of gravity and slowing of a fall, but in a vacuum all objects fall equally at equal velocities.

Newton's Laws of Motion

- *Newton's first law* (law of inertia): A body in motion tends to stay in motion unless acted upon by another force.
- *Newton's second law* (law of acceleration): Acceleration of a body is in the direction of and proportional to the force (F), and that acceleration (a) is inversely proportional to the mass (m) of the

body, $F = ma$. If multiple forces exist, the direction and acceleration are proportional to the sum of all the forces. These are called *vectors*.

- *Newton's third law* (law of reciprocal action): For every action, there is an equal and opposite reaction; objects exert equal but opposite forces on one another.¹⁸ Example: An apple on a desk is pulled down by a gravitational force equal to the force with which the table resists the pull of gravity.

Force

Force is the amount of energy required to move an object. From the understanding that the force of gravity pulls equally on all objects proportional to mass, a standardization of force became possible. Because we know that gravity pulls (accelerates) all objects with a force of 9.81 m/sec per sec, this force would also be 9.81 m/sec per sec if applied to any given weight. The force of gravity applied to 1 kg of weight creates a standard by which other forces may be compared, quantified, and measured. Thus the force required to accelerate a 1 kg weight 1 m/sec became known as the *newton*.

The newton is the standard measure of force derived from the force of gravity.

$$\begin{aligned}\text{newton} &= 1 \text{ meter/sec/sec} \\ &= 1/9.81 \text{ kg weight or } 102 \text{ g weight} \\ \text{gravity} &= 9.81 \text{ meter/sec/sec}\end{aligned}$$

One newton is equivalent to 1/9.81 kg weight or 102 g weight. Force is mass multiplied by acceleration. The formula for force is:

$$F = ma$$

where F is force, m is mass, and a is acceleration. Often the newton is too large a unit to be used to express small measures of force; therefore, the *dyne* is used. A dyne is one 1000th of a newton. A dyne is the force required to move a 1 g of weight 1 cm per

second. Dynes are used in calculating systemic and pulmonary vascular resistance (PVR).^{19,20}

PVR is the measure of the pulmonary vascular system's resistance to flow from the right ventricle. Normal PVR is 100 to 200 dyne sec/cm⁵. Systemic vascular resistance (SVR) is the measure of the peripheral vascular system's resistance to flow that must be overcome for flow to occur. The left ventricle must therefore pump blood with a force greater than the resistance of the vascular system. The formula for calculating SVR is $80 \times (\text{MAP} - \text{CVP})/\text{CO} = \text{SVR}$, where MAP is mean arterial pressure, CVP is central venous pressure and CO is cardiac output. Normal SVR is 900 to 1200 dyne sec/cm⁵.

Another application of force measurement used in anesthesia is accelerometry, which is used to measure the degree of neuromuscular blockade.^{21,22} Accelerometry uses a piezoelectric disk to generate an electric current in proportion to acceleration (see the section on [Piezoelectric Effect later in this chapter](#)). An accelerometer measures the acceleration caused by the contraction of the adductor pollicis muscle after ulnar nerve stimulation. A comparison of baseline stimulated muscle twitches (forces) to twitches suppressed by neuromuscular blocking agents allows the quantification of the degree of neuromuscular blockade.²³ Accelerometers provide objective twitch data referenced to the patient's baseline twitch response.²⁴ Visual or tactile assessment of twitch heights is subjective and less reliable than accelerometry.^{24,25}

Force is a basic phenomenon of physics that permeates the universe. Because all matter possesses mass, and all mass has some degree of acceleration, force exists everywhere. All forces possess direction. The study of force direction is explored with vectors.

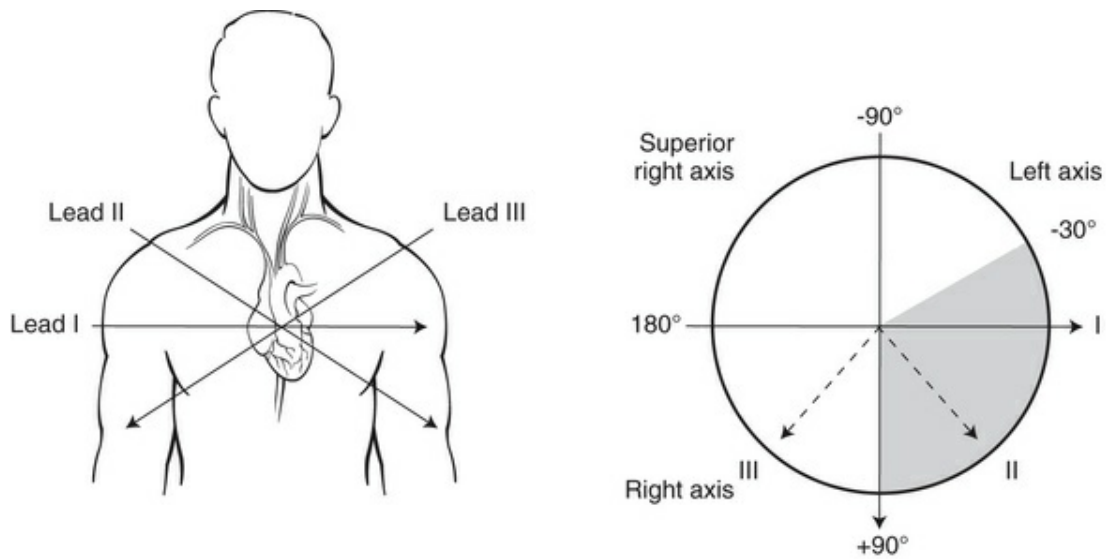

Vectors

Two basic types of values describe our physical world: *scalar values* and *vector values*. Scalar values are fully described by magnitude alone; they possess no motion, and they include mass, energy, and work. Vector values are fully described by magnitude and direction. Vectors express motion and are described by force, speed, velocity, acceleration, distance, and displacement. Vector diagrams are scaled representations of vectors, with an arrow starting at a

given magnitude and pointing in the direction of the force summation.

An electrocardiogram (ECG) is an example of a type of vector diagram that allows us to calculate the predominant direction of electrical force in the myocardium. An ECG records electrical flow as an upward or downward deflection on graph paper. When the flow is toward the positive electrode, an upward deflection will record. When the flow is away from the positive electrode, a downward deflection will record. Twelve-lead ECGs are scaled graphs with multiple points of reference used to measure the force direction of the electrical conductance. As multiple points of reference are recorded, the predominant direction of electrical flow may be determined (vector summation). This is the principle behind determining axis deviation of the heart.

Axis deviation estimates the summation of forces that shift from the normal direction of electrical flow in the heart. ECG vector diagrams are scaled clockwise from 0 degrees in the east position. The normal axis of electrical flow summation in the heart is between -30 degrees and $+90$ degrees. The axis determination steps that follow are based on identifying the positive (upward) deflections of the 12-lead ECG, which represents electrical flow toward the positive electrode. Because the normal axis of electrical flow is between -30 and $+90$ degrees, positive deflections in leads I and II would represent electrical flow in the normal direction. Negative deflections in lead I or lead II would reflect a deviation of normal axis and require determination of the electrical flow vector. Vector deviations are described as *left*, *right*, or *right superior*. Several methods are available for quick determination of myocardial electrical axis deviation. [Fig. 15.16](#), and [Tables 15.1](#) and [15.2](#) offer help in determining axis deviation.

Axis deviation vectors

FIGURE 15.16 Electrocardiogram lead placement with vector direction and location of normal and abnormal axes.

TABLE 15.1
Axis Deviation Determination Methods

Vector Method	Inspection Method	Grant Method
I+, aVF+ = Normal axis	I+, III+ = Normal axis	I+, II+ = Normal axis
I-, aVF- = Superior right	I- = Right axis	I+, II- = Left axis
I-, aVF+ = Right axis	III-, II- = Left axis	I-, II+ = Right axis
I+, aVF- see lead II (if II+ = Normal; if II- = Left axis)		I-, II- = Superior right

TABLE 15.2
Axis Deviations From Normal

Normal Axis	-30 to +90 degrees
Left axis deviation	-30 to -90 degrees
Right axis deviation	+90 to ±180 degrees
Superior right axis deviation	-90 to ±180 degrees

Pressure

Pressure is defined as force over area, where P is pressure, f is force, and a is area:

$$P = f/a$$

Increasing the area in which a given force is applied will result in a lower pressure. The smaller the area to which the set force is applied, the greater the pressure. The standard unit of measurement for pressure is the pascal (Pa). A pascal is the force of 1 newton (N) over 1 square meter.

$$\text{Pa} = 1 \text{ N}/1 \text{ m}^2$$

A pascal equals 102 g acting over an area of 1 square meter. Remember, a newton equals 102 g weight. This is a very small unit of pressure. As the newton was fractionalized to the dyne for the purpose of establishing a more convenient unit of force measurement, the pascal was increased a thousand times to create the kilopascal (kPa) unit. A kilopascal is more convenient to use for measuring pressures. A kilopascal equals 1000 N or 102 kg acting over an area of 1 m².

$$\text{Pa} = 102 \text{ g}/\text{m}^2$$

$$\text{kPa} = 102 \text{ kg}/\text{m}^2$$

Syringes are an example of the pressure generated by a force over a given area. Equal force (20 N) applied to the plungers of different syringes generates different pressures, depending on the area over which the force was applied. The force applied will cause greater pressure on injection with a tuberculin (TB) syringe (plunger area = $8.55 \times 10^{-6} \text{ m}^2$) than with a larger 10-mL syringe (plunger area $3.42 \times 10^{-5} \text{ m}^2$). As you increase the area to which a fixed force (20 N) is applied, the product of the equation, which is pressure (in atmospheres), becomes smaller.

$$P = f/a$$

$$\text{TB syringe : } 20 \text{ N}/8.55 \times 10^{-6} \text{ m}^2 =$$

$$2339.18 \text{ kPa, } 17,543.94 \text{ mm Hg, or } 23.08 \text{ atm}$$

$$10\text{-mL syringe : } 20 \text{ N}/3.42 \times 10^{-5} \text{ m}^2 =$$

$$584.79 \text{ kPa, } 4386.28 \text{ mm Hg, or } 5.77 \text{ atm}$$

$$30\text{-mL syringe : } 20 \text{ N}/5.99 \times 10^{-5} \text{ m}^2 =$$

$$334.16 \text{ kPa, } 2506.40 \text{ mm Hg, or } 3.29 \text{ atm}$$

These calculations show the extremely high pressures that can be generated by exerting a force over a small area. The TB syringe generates more than 20 atmospheres of pressure and can rupture catheters if used to flush or dislodge blockages. Larger syringes are recommended for flushing or unclogging enteral feeding tubes because of the potential for generating high pressures with smaller syringes.²⁶⁻²⁸

Atmospheric Pressure

As previously discussed, gravity pulls on all objects, including atoms and molecules in the atmosphere. Because these atoms and molecules have low mass, they have low gravitational pull, but are nonetheless pulled toward Earth. The cumulative effect of gravity on atmospheric gases gives rise to atmospheric pressure.

Atmospheric gases are less concentrated at altitude and more concentrated at sea level. Atmospheric pressure is the gravitational force on gases in a given area. This can be measured, and is equivalent to 100 kPa (or 14.7 lb/in², 1020 cm of H₂O, or 760 mm Hg —all equivalent to one another) at sea level. *Standard pressure* in the International System of Units (SI) is 100 kPa. Other units of pressure measurement include the following (shown with their equivalents). It is best to memorize these:

$$1 \text{ torr} = 1 \text{ mm Hg}$$

$$1 \text{ kPa} = 10.2 \text{ cm H}_2\text{O} = 7.5 \text{ mm Hg}$$

$$1 \text{ atm (atmosphere)} = 760 \text{ mm Hg} = 760 \text{ torr} = 1 \text{ bar} = 100 \text{ kPa} = 1020$$

$$\text{cm H}_2\text{O} = 14.7 \text{ lb/in}_2$$

Pressure Measurement

The simplest method for determining pressure is by using a manometer. A manometer is a liquid-filled tube that is open to atmospheric pressure on one end and exposed to a pressure for measurement on the other end (Fig. 15.17). A pressure greater than atmospheric pressure (760 mm Hg) will displace the column of liquid proportional to the pressure difference (Δh). Calibrating the column of liquid allows for quantification of the pressure.

FIGURE 15.17 Manometer showing change in liquid column height (Δh) related to pressure applied.

A sphygmomanometer uses an inflatable cuff connected to a mercury-filled manometer to measure blood pressure. As the inflated cuff is slowly deflated, the arterial flow resumes, causing a pressure wave that is transmitted to a mercury column. The mercury column is calibrated to show the measured pressure in millimeters of mercury. An advancement in blood pressure measurement is oscillometry. Oscillometry automates noninvasive

blood pressure measurements by recording the oscillations in pressure caused by arterial pulsation.²⁹ As an inflated cuff is deflated, multiple measurements are made of these oscillations. Oscillations increase at systolic pressure and are maximal at MAP. Algorithmic computation of systolic and diastolic pressures is derived from the MAP. Often these noninvasive automated blood pressure monitors use the piezoelectric principle to record the pressure oscillations and a microprocessor to derive the systolic and diastolic measurements.³⁰ Invasive blood pressure monitors use a piezoelectric transducer that converts pressure waves into electrical signals. Blood pressure measurements are gauge pressures that are zeroed to atmospheric pressure.

Gauge and Absolute Pressure

Different pressure measurements may use different zero reference points. The zero reference point may be a complete vacuum devoid of all molecules and molecular collisions that impart pressure. This is true zero pressure, and is the reference point used when measuring absolute pressure. Absolute pressure is atmospheric pressure plus gauge pressure. Gauge pressure is zero referenced at atmospheric pressure and reads zero at 760 mm Hg at sea level. Gauge pressure is absolute pressure minus atmospheric pressure.

Bourdon gauges are often used in anesthesia to measure high pressures, such as in gas cylinders, and are zero referenced to atmospheric pressure (Fig. 15.18). Bourdon gauges contain a coiled tube that expands as pressure is applied. A linkage connects the coil to a rotating arm that records the pressure. The American Society for Testing Materials (ASTM) International mandates that the zero reading of Bourdon gauges lie between the 6 o'clock and 9 o'clock positions.

FIGURE 15.18 Bourdon gauge showing gauge pressure (*inside pressures*) referenced to absolute pressure (*outside pressures*).

Thermodynamics

The three laws of thermodynamics explain the relationship between heat and energy and their exchange during work processes:

1. *Law of conservation of energy.* Energy cannot be created or destroyed. The increase in the internal energy of a thermodynamic system is equal to the amount of heat energy added to the system minus the work done by the system on the surroundings.
2. *Energy moves toward greater entropy or randomness.* The entropy of an isolated system not in equilibrium will tend to increase over time, approaching a maximum value at equilibrium.
3. *Absolute zero (0°K or -273.15°C) is void of all energy.* Absolute zero is theoretical, because it has been impossible to achieve. As a system approaches absolute zero, all processes cease, and the entropy of a system approaches a minimum value.

Energy

Energy can be defined as the exertion of force (kinetic) or the capacity (potential) to do work. Energy can be expressed as mechanical work, chemical reactions, or heat. The unit of measurement for energy is the joule. A joule is the force of 1 N that moves its point of application 1 m in the direction of that force. Two types of energy are potential energy and kinetic energy. Potential energy is energy waiting to be used; it is energy that is stored and available to be converted into power. Potential energy is defined as mass (m) times gravity (g) times height (h):

$$PE = mgh$$

Kinetic energy is energy of movement. *Kinetic* means movement. *Kinetic energy* is defined as one half the product of mass times the velocity squared:

$$KE = (1/2) mv^2$$

Entropy

Entropy is the universal trend toward equilibration. It is the process that allows everything from ice melting to gas expansion. Sleep and the induction of general anesthesia have been proposed to be entropic processes.³¹⁻³⁴ All of these processes involve the equilibration of energy. Even matter is a form of energy. Entropy is unidirectional; it is the movement of energy from a high concentration to a lower concentration. It moves because of a gradient. The difference in the gradient influences the speed of the flow. Greater difference usually equals greater flow, and always from the higher concentration to the lower concentration. All energy and matter tend to follow this rule. An example of this unidirectional action is adding ice to lemonade. Ice does not make lemonade colder; instead, lemonade makes ice warmer. Entropy ends when all energy is equally distributed. Diffusion is a process driven by entropy. Entropy is the underlying process promoting spontaneous and elicited movement in our everyday lives and the universe in general. Essentially, entropy drives the universe. This process should be kept in mind when learning or reviewing any dynamic concepts of anesthesia.³⁵

Temperature

Matter may change form with the addition of greater heat energy. An example we see every day is the melting of an ice cube into liquid water, and the transformation of liquid water into water vapor with the addition of greater heat energy. Liquid water, with the addition of heat energy, expands. This is due to the water molecules moving apart with greater kinetic energy, which ultimately allows them to escape individually as a vapor. Another liquid, mercury, also expands with the addition of heat energy. When placed in the bottom of a closed glass cylinder, the expansion is limited to one direction in relation to the energy applied. This is a simple application of heat energy (kinetic energy) interacting with matter to allow analysis of the thermal state: a thermometer.

Temperature is the measurement of the thermal state of an object.

Heat is thermal energy; temperature is the quantitative measurement of that energy. Several temperature scales exist: Fahrenheit, Celsius, and Kelvin (Fig. 15.19). Gabriel Daniel Fahrenheit (1686–1736) is credited with inventing the mercury thermometer (1714) and devising the Fahrenheit temperature scale. The Celsius (Anders Celsius, 1701–44) or centigrade scale is the primary scale used for everyday temperature measurements. The Kelvin scale (William Thompson Lord Kelvin, 1824–1907) was developed to better reflect mathematically the temperature/pressure relationship of gases, and is used when calculating their behaviors. Water freezes at 273.15°K and boils at 373.15°K. Conversion among temperature scales is as follows:

FIGURE 15.19 Temperature scales referenced to Kelvin.

Celsius to Kelvin: $^{\circ}\text{K} = ^{\circ}\text{C} + 273$

Celsius to Fahrenheit: $^{\circ}\text{F} = 1.8(^{\circ}\text{C}) + 32$

Fahrenheit to Celsius: $^{\circ}\text{C} = (^{\circ}\text{F} - 32)/1.8$

Standard temperature is 273.15 K (0°C).

Heat Loss

Heat and energy are the same. Heat loss (energy loss) of a system, as discussed previously, is unidirectional from the higher concentration to the lower concentration, from hotter to less hot. Even ice possesses heat (energy). Remember absolute zero, 0°K (-273.15°C or -459.67°F), is the absence of all energy and therefore the absence of all heat. The human body is a system that contains energy. Much of this energy is in the form of heat. Our bodies continually exchange heat with the environment from a high concentration to a lower concentration. On a very hot day or in a very hot room, we could become hyperthermic. Similarly, in a cool room, our bodies could become hypothermic, especially if part of the body surface is exposed. Clothes, hair, skin, and fat insulate us from heat loss, and protective mechanisms exist that further lessen heat loss. Here, we will focus on heat loss in the cool operating room environment.

Vasoconstriction of peripheral vessels slows heat loss from our bodies. An example is the vasoconstriction seen in our limbs when exposed to a cold environment. The reverse thermoregulatory mechanism to promote heat loss is vasodilation when exposed to a hotter environment. Directing blood to or away from our periphery aids in the conservation or removal of our body's heat energy, respectively. This thermoregulatory mechanism is disrupted under anesthesia by vasodilating drugs, specifically volatile anesthetics. Volatile and regional anesthetics vasodilate vessels, including those in the periphery, causing greater blood flow to the surface of our bodies.

Core Temperature Redistribution

Core temperature redistribution is the process of increased heat loss from the body resulting from the vasodilating effects of volatile and regional anesthetics, which cause greater blood flow and therefore

heat flow to the body's surface from the core.³⁶⁻³⁸ A patient's core temperature can drop quickly due to the vasodilating actions of anesthetics, with the greatest decrease occurring in the first hour after anesthetic administration.³⁷ It is imperative that one be cognizant of this heat loss mechanism and take measures to decrease it.³⁹⁻⁴¹ Covering all exposed areas of a patient minus the surgical site, wrapping the head in blankets, and warming the operating room all decrease heat loss. The use of forced warm air devices is effective at decreasing heat loss in the operating room environment.⁴²⁻⁴⁴

Blood flow to our body's surface encourages heat loss by four primary processes. In decreasing order, they are:

1. Radiation
2. Convection
3. Conduction
4. Evaporation

Radiation

Radiation is the most significant mechanism by which our bodies lose heat, especially in patients under anesthesia. Radiation of the infrared electromagnetic wavelength transfers heat energy from our warm bodies to the less warm operating room environment (walls, ceiling, equipment, etc.). Electromagnetic radiation (EMR) is pure energy (see discussion on this later in the chapter). Infrared radiation from our bodies is greatest in areas of highest blood flow. Our heads lose the greatest amount of heat due to the high percentage of blood flow. Blood carries body heat, and the greater amount of blood and heat transported to the head, the greater the heat loss from radiation.

Convection

Convection is the process by which heat creates air currents. Our bodies transfer kinetic energy to air molecules on the surface of our skin. The heated air molecules then move about with greater kinetic energy, rise, and are replaced by colder (less kinetic energy) air

molecules. Our bodies then transfer more kinetic energy to these molecules, which rise and are again replaced by cooler air molecules. When thinking of convection, it helps to think in terms of currents.

Conduction

Conduction is the transfer of heat by physically touching a less warm object. Where two objects are in direct contact, heat exchange occurs from the higher concentration to the lower concentration (entropy). An example would be holding a cold soda can. The sensation of cold is the direct loss of heat from your hand to the can. Cold is not transferred to your hand; heat is transferred to the can. A patient on a cold operating room table will conduct his or her heat to the less warm table by physical contact. This is not a significant process in adult patients, but for pediatric patients who have a large body surface area compared to overall mass, it is quite significant. Use of warming blankets on operating room tables stops or reverses this heat transfer. Warming blankets may add heat energy to a patient, depending on the temperature and establishment of a thermal gradient.

Evaporation

Evaporation is not usually a large contributor to patient heat loss. Heat loss from evaporation includes moisture evaporation from the patient's skin, as well as exhaled water vapor. The process of evaporation, which is the phase change from liquid to gas, requires energy. The source of energy needed for this process comes from the environment surrounding the evaporating substance. *Latent heat of vaporization* is the amount of heat energy per unit mass required to convert a liquid into the vapor phase. The energy withdrawn from the environment to convert one gram of water into vapor is 2500 joules, or approximately 600 calories. An example of this is the cooling off we feel after getting out of a swimming pool. The energy used to change the water into a vapor comes mostly from our bodies. Our body loses heat energy to this process, and we experience a state of lower thermal energy. Patients who have areas of their bodies surgically prepped with liquids (e.g., isopropyl alcohol, povidone-iodine, and chlorhexidine gluconate) experience

heat loss by this method. The process of breathing also causes heat loss through exhaled water vapor. This is not usually a high heat loss method in adult patients, but may become significant in pediatric patients when using high carrier gas flow rates. Lower carrier gas flows, when appropriate, and use of an in-line humidifying apparatus decrease the evaporation of pulmonary water content and limit heat loss by this mode. One should consider these interventions with all intubated general anesthetics to prevent not only heat loss but also the pulmonary drying effects of dehydrated carrier gases.

Heat loss from patients is primarily due to radiation of infrared EMR.⁴⁵ Convection is the second largest method of heat loss in anesthetized patients.^{45,46} Conduction and evaporation cause heat loss to lesser extents, but remain a concern. Prevention of heat loss is extremely important for decreasing the higher morbidity experienced by hypothermic patients.⁴⁷⁻⁴⁹ As Fig. 15.20 illustrates, the use of forced warm air devices, lower gas flow rates, humidification systems, warming the operating room, and covering and insulating patients all are effective methods to decrease patient heat loss.^{43,50}

FIGURE 15.20 Heat loss mechanisms of radiation, convection, conduction, and evaporation in patients under anesthesia.

Vaporization

Vaporization is the process of converting liquids or solids into vapors. Evaporation is the specific process of vaporizing liquids. Vaporization requires energy. As stated previously, the latent heat

of vaporization is the energy needed to transform a given amount of liquid into a gas, and is measured in kilojoules. The temperature at which the bulk of a liquid at a given pressure converts to a vapor is the *boiling point*. The temperature of a liquid will not rise above its boiling point; instead, the additional heat energy transforms the liquid into gas. Heating a liquid to its boiling point increases the kinetic energy of the liquid's molecules. Further addition of heat energy (above the boiling point) is transferred to molecules, which break away from the surface and become a gas. "The rate of vaporization depends only on the temperature, the vapor pressure of the liquid, and the partial pressure of the vapor above the evaporating liquid."⁵¹ As gas molecules escape the liquid, they exert a pressure known as *vapor pressure*, measured in millimeters of mercury. Increasing heat will increase molecular kinetic energy, which will increase the rate of vaporization. In a closed container, equilibrium will be achieved between molecules in the gaseous phase and those in the liquid phase.

All liquids that have high vapor pressures at room temperatures are known as *volatile liquids*. Vapor pressure and boiling points are inversely related. Vapor pressures of the volatile anesthetics at standard temperature and pressure (STP) are as follows:

- *Isoflurane*: 238 mm Hg
- *Sevoflurane*: 160 mm Hg
- *Desflurane*: 660 mm Hg

Vapor pressures are unique characteristics of liquids that depend solely on temperature. Different liquids exert different vapor pressures at a given temperature. Because different volatile anesthetics have different vapor pressures, vaporizers must be calibrated for each specific agent. Placing the wrong agent into a vaporizer will deliver a greater or lower concentration than dialed. If a high vapor pressure volatile anesthetic agent is placed inside a vaporizer calibrated for a lower vapor pressure volatile anesthetic, the output of that vaporizer will be higher than indicated on the control dial. If a volatile anesthetic agent with a lower vapor pressure is placed inside a vaporizer calibrated for a higher vapor pressure anesthetic, the output of that vaporizer will be lower than indicated on the control dial.⁵²

Absolute Zero

The preceding discussion covered the first and second laws of thermodynamics, with examples applied to the practice of anesthesia. With a unidirectional perspective and an understanding that energy can neither be created nor destroyed, the third law becomes self-evident. Absolute zero is the theoretical state devoid of all energy. No matter how much energy is distributed, it will still be present. The lowest possible state of universal entropy would still possess energy, even though it would be very low. There is energy in the universe, and therefore it will always be present in some form and to some degree. The absolute absence of energy is therefore impossible. That does not prevent us from calculating the theoretical temperature that would be devoid of energy. The theoretical temperature of absolute zero is -273°C (0°K , -460°F).

Kinetic Molecular Theory

Thermodynamics set the foundation for explaining the overall action of a system's energy. The kinetic molecular theory builds on Newtonian physics and thermodynamics, and focuses on molecular movement (energy) and forces between these molecules. This theory explains how molecules behave as they follow the previously described laws of thermodynamics. Kinetic molecular theory was created as a conceptual framework to encompass the findings of Charles, Boyle, and Gay-Lussac, including the *universal gas law* that unified their studies. The following is a review of basic matter characteristics.

- *Matter* is composed of small particles called *molecules*, and molecules are composed of atoms. Matter can take the form of a solid, liquid, or gas.
- *Solids*—Molecules in a solid are held together closely by intermolecular forces. They may move about slightly and vibrate.
- *Liquids*—Molecules in a liquid are held together by intermolecular forces and may slide or flow by one another.
- *Gases*—Molecules in a gas move linearly, and the attractive forces between molecules are less than their kinetic energy. They move almost completely free of one another.

The kinetic molecular theory, which best describes the action of gases, makes some generalized assumptions for simplicity:

1. Molecules have no volume.
2. Gas molecules exert no force on each other unless they collide.
3. Collisions of molecules with each other or the walls of the container do not decrease the energy of the system.
4. The molecules of a gas are in constant and random motion.
5. The temperature of a gas depends entirely on its average kinetic energy. The energy of a gas is entirely kinetic.

The kinetic molecular theory was created to explain the ideal gas law. Though the ideal gas law adequately explains the general behavior of gases, it does not take into account the small volume of gas molecules and their intermolecular interactions. These flaws are further addressed in the section covering Van der Waal's equation.

Gas Laws

The kinetic molecular theory was based on the discoveries of three scientists: Jacques Charles (1746–1823), Robert Boyle (1627–91), and Joseph Louis Gay-Lussac (1778–1850). They each studied isolated components of pressure, volume, and temperature to explore the relationship of these components. Charles studied the relationship of volume and temperature at constant pressure. He found that the volume-to-temperature relationship is directly proportional. This means that, at a constant pressure, volume will increase as temperature increases, and vice versa. Boyle studied the relationship of pressure and volume at constant temperature. Boyle found that the pressure-to-volume relationship is indirectly proportional. Thus, at a constant temperature, pressure will increase as volume decreases, and vice versa. Gay-Lussac studied the relationship of pressure and temperature at constant volume. Gay-Lussac found that the pressure-to-temperature relationship is directly proportional. At a constant volume, as pressure increases, temperature will increase, and vice versa. The gas laws allow us to

calculate the behavior of gases when one of the three factors of pressure, volume, or temperature remains unchanged. The clinical significance of these laws is expressed by the ability to calculate the available volume of oxygen from a cylinder of any known pressure. This and other examples are available at the end of the chapter. [Table 15.3](#) summarizes the laws and the interrelationship of pressure, volume, and temperature.

TABLE 15.3
Gas Laws: Gas Properties and Relationships

Property Constant	Studied Properties	Property Relationship	Law
Pressure	Temperature, volume	Directly proportional	Charles
Temperature	Pressure, volume	Inversely proportional	Boyle
Volume	Pressure, temperature	Directly proportional	Gay-Lussac

Universal Gas Law

As the universal gas law unified the findings of Charles, Boyle, and Gay-Lussac, it also became known as the *unified gas law* or *ideal gas law*. The formula is as follows:

$$PV = nrT$$

where P is pressure, V is volume, n is the number of moles, r is a constant (0.0821 liter-atm/K/mole), and T is temperature. A *mole* is the gram molecular weight of a gas. Atomic (or molecular) weight is the additive weight of all of the atomic particles, protons, neutrons, and electrons in an atom or molecule. An example is a mole of helium. Helium has a molecular weight of 4. Placing “gram” after helium's atomic weight gives us a “mole” of helium; therefore, four grams of helium is a mole of helium. This amount of gas establishes a standard reference for calculations.

Using the universal gas law, you can calculate the volume for which 1 mole of a gas will expand at any given temperature or pressure. In the example given, we will calculate the volume in liters that 1 mole of oxygen will expand to at 1 atmosphere pressure at standard temperature (0°C). Celsius is converted to Kelvin.

$$1 \text{ atm}(x) = 1 \text{ mole } (0.0821 \text{ L atm/mol K})(273 \text{ K})$$
$$x = 22.4 \text{ L}$$

One mole of any gas at 0°C will expand to 22.4 liters.

As this is a conceptual text, it is easier to view the universal gas law as $PV = T$ to focus on the relationship between pressure, volume, and temperature. It is easy to see mathematically how increasing or decreasing any value would affect the other values, as described previously. The universal gas law can be rearranged as follows:

$$PV = T \text{ or } T/P = V \text{ or } T/V = P$$

Increasing one value will increase or decrease the other values to maintain balance in the formula. The universal gas law allows understanding and quick determination of such things as: how much oxygen is available to be released from a partially full oxygen cylinder, and at what temperature will a full oxygen cylinder exceed its recommended pressure when heated?

Avogadro's Number

Amedeo Avogadro (1776–1856) was able to show that in a mole of any gas there are 6.023×10^{23} molecules. A mole of gas is equal to the molecular weight of the gas expressed in grams. A mole of helium, which weighs 4 g, contains 6.023×10^{23} atoms. Similarly, a mole of oxygen weighs 32 g and contains 6.023×10^{23} molecules. Oxygen is a molecule composed of two oxygen atoms bonded together, and therefore the molecular weight of the diatomic oxygen molecule is 32, not 16.

Van der Waal's Forces

Unfortunately, the simplicity of the universal gas law is not 100% accurate in fully describing the interaction of gases with their environment. The universal gas law is also called the *ideal gas law* because it explains the behavior of gases if they were “ideal.” An ideal gas would possess molecules that occupy no volume and

never interact with other molecules. Gas molecules do have volume and do occupy space, and therefore the volume they occupy must be taken into account when calculating a gas's expansion or contraction. The universal gas law does not account for gas molecule volume because Charles, Boyle, and Gay-Lussac did not account for this in their studies (remember, the universal gas law unified the work of Charles, Boyle, and Gay-Lussac). An ideal gas also assumes no intermolecular forces. However, molecules do interact with one another, and this behavior alters the net effect of kinetics as calculated by the universal gas law. Van der Waal's (Johannes Diderik van der Waal, 1837–1923) equation corrects the universal gas law and accounts for molecular volume and molecular interaction in a gas. Van der Waal's equation is as follows:

$$(P + n^2a/V^2)(V/n - b) = RT$$

where P is the pressure of the fluid, V is the total volume of the container containing the fluid, a is a measure of the attraction between the particles, b is the volume excluded by a mole of particles, n is the number of moles, R is the gas constant, and T is the absolute temperature.

Because the deviations between the ideal gas law and the van der Waal equation are not clinically significant, the simplicity of the universal gas law and molecular kinetic theory are immensely valuable for describing the behavior of gases used for anesthesia.

Dalton's Law of Partial Pressures

According to the kinetic molecular theory, pressure is purely the result of molecular collisions with the walls of a container. If there are more molecules in a container, there will be more collisions, and thus greater pressure. Dalton's law (John Dalton, 1766–1844) states that the total pressure of a system is the additive pressure of each individual gas in a mixture. Multiple gases in a mixture will each exert a pressure in proportion to its percentage in the mixture. The total pressure is the summation of individual molecular collisions with the walls of a container:

$$P_t = P_1 + P_2 + P_3 + P_4 + P_5 + \dots$$

An example is the mixture of gases that compose medical air at atmospheric pressure:

79% Nitrogen: $0.79 \times 760 \text{ mm Hg} = 600.4 \text{ mm Hg}$ partial pressure of nitrogen

21% Oxygen: $0.21 \times 760 \text{ mm Hg} = 159.6 \text{ mm Hg}$ partial pressure of oxygen = 760 mm Hg total atmospheric pressure

Adiabatic Changes

Reaching a stable state of entropy in any system takes time. Rapid expansion or compression of gases may exceed the speed of energy equilibration with the surrounding environment. Rapid expansion or compression of a gas without equilibration of energy with the surrounding environment is called an *adiabatic* process, and entails no increase or decrease in a system's energy.

Remember that the energy of a gas is almost entirely kinetic. Temperature is the measurement that quantifies the energy distribution among the molecules in a system. One could think of temperature measurement as a quantification of a system's kinetic energy per area. An example would be the experience of placing your hand in sunlight. The surface area of that sunlight measured is equal to the surface area of your hand. It is warm. Now place a magnifying glass with a surface area equal to that of your hand in the sun, and focus that same amount of sunlight energy onto a pinpoint area of your hand. Ouch! The same amount of energy experienced over smaller area is measured as a higher temperature. The temperature measurement is higher, but the system's energy total has not increased or decreased. The total sunlight energy hitting your hand is the same, but is distributed over a different area.

Energy Concentration Effect

Compressing a gas quickly will intensify the kinetic energy (molecular movement) such that the thermal measurement of the gas will be higher. This quick compression of the gas's area does not

allow the system's energy to dissipate into the surrounding environment. Thus, the temperature will quickly rise, proportional to the decreased volume. Although the temperature will be higher, the total energy of the system does not increase. A gas that is compressed quickly has little time to distribute any of its energy, so the thermal measurement becomes higher. This is the mechanism a diesel engine uses to ignite diesel fuel. Quick compression of fuel vapor intensifies the kinetic energy of the gas, with a corresponding increase in temperature, until the ignition temperature is achieved and spontaneous ignition occurs. This effect, though unlikely, could happen with a compressed gas cylinder that is opened quickly. The rapid reexpansion and recompression of gas as it rushes through the outlet channels of a cylinder could increase the temperature significantly. The high temperature generated could cause a burn or ignite any grease placed on the O-ring. Oil or grease is not recommended for use on any cylinder of compressed gas. Usually, rapid recompression in the cylinder stem is not a concern. It is possible and has occurred, but more likely the opposite (rapid expansion of the gas as it leaves the cylinder) will occur.

Energy Dilution, Joule-Thompson Effect

The Joule-Thompson effect, named after James Prescott Joule (1818–89) and William Thompson Lord Kelvin, explains the cooling effect that occurs with adiabatic expansion of a gas. Rapid expansion of a gas causes the temperature measurement to decrease in exactly the opposite of the process explained previously. When we lower the pressure of a gas (i.e., increase its volume) quickly, we lower the energy per area. The temperature measurement will be lower when the volume is rapidly expanded. The total energy of the gas has not changed, but the expression (or thermal measurement) is decreased related to the increased volume. The temperature may be so low that frosting may occur at the cylinder outlet. Potentially, one could suffer a freeze injury. So why does this not always occur? If done slowly, energy from the environment will move into the gas, and ambient temperature will equalize with the lower kinetic energy per area of expanding gas. The second law of thermodynamics (entropy) explains the maintenance of temperature when opening a gas cylinder slowly. Opening a cylinder slowly, therefore, would

not be an adiabatic process. The slow opening of a gas cylinder allows the expanding gas to draw energy from the environment to maintain an equal distribution of energy, and we observe no changes in the temperature of the gas.

Fluid Flow

Basic Principles of Fluid Mechanics

Fluids are defined by their response to stress. Stress is the distribution of force per unit area. The stress, or force distribution, may be tangential (i.e., a shear stress), or it may be perpendicular (i.e., a normal force). Strain is the deformation caused by stress. Fluids continuously change shape (flow) when subjected to shear stress, and respond in one of two ways to perpendicular forces:

1. Resist compression (e.g., liquids)
2. Become compressible and easily expandable (e.g., gases)

Both liquids and gases are fluids. Forces associated with fluids are gravity, pressure, and friction. Friction is resistance to flow from surface interaction, and is proportional to viscosity. Viscosity is the physical property of a fluid that relates shear stress to the rate of strain. Viscosity is the inherent property of a fluid that resists flow. Flow is the result of pressure forces in a fluid established by differences in pressure from one point to another, which creates a pressure gradient. All flow moves from higher pressure or resistance to lower pressure or resistance. The following laws and principles apply to both compressible (gas) and incompressible (liquid) fluids. Flow is defined as the quantity of a fluid passing a point per unit of time, where F is the mean flow, Q is quantity, and t is time.

$$F = \frac{Q}{t}$$

Types of Flow

The three types of flow that occur through tubes and orifices are laminar, turbulent, and transitional. Laminar flow is a type of flow in which all molecules of a fluid travel in a parallel path within the tube. The molecules in the center of the tube encounter the least adhesive force from the walls of the tube, and therefore move at a velocity twice that of the mean flow. Flow decreases near the walls and ceases at the wall. True laminar flow predominates in the smallest airways (terminal bronchioles). Transitional flow is a mixture of laminar flow along the walls of a tube with turbulent flow in the center. Turbulent flow is described as chaotic with irregular eddies throughout. Laminar, transitional, and turbulent airflow are illustrated in [Fig. 15.21](#).

FIGURE 15.21 Three types of flow: laminar, transitional, and turbulent.

Poiseuille's Law

Laminar flow is described mathematically by Poiseuille's law (Jean Louis Marie Poiseuille, 1797–1869). Poiseuille's law is:

$$F = (\pi r^4 \Delta P) / (8 \eta l)$$

where F is flow, π is the constant pi, r^4 is radius to the fourth

power, ΔP is the pressure gradient, n is viscosity of fluid, and l is the length of tube. According to Poiseuille's law, the radius of the tube will have the most dramatic effect on flow. Doubling the radius will result in a 16-fold increase in flow. A tripling of the radius increases flow 81-fold. Therefore, flow through a 16-gauge (1.65 mm) intravenous catheter is much greater than through a 20-gauge (0.89 mm) catheter. If the viscosity of a fluid is increased, flow decreases. Patients with polycythemia have decreased blood flow due to increased blood viscosity. Increasing the length of a tube decreases the flow. If the length of a tube is decreased by 50%, there will be a corresponding doubling of the flow. If the length of a tube is doubled, flow decreases by half.

Clinical application of Poiseuille's law in anesthesia is exemplified as follows. To improve flow when delivering a unit of packed red blood cells, a large-diameter intravenous catheter (18-gauge or larger) is recommended, a pressure bag may be placed on the unit of packed red blood cells to increase the driving pressure (pressure gradient), and the packed red blood cells may be diluted with normal saline to lower the viscosity.⁵³ These interventions are a direct manipulation of the factors associated with Poiseuille's law, and significantly improve flow. Of all the changes that may be made, increasing the diameter of the intravenous catheter will have the most dramatic effect on increasing flow. Large-bore intravenous lines, such as an introducer central line, are best for rapid, large-volume infusion.

Mechanical ventilation of patients also reflects the factors associated with Poiseuille's law. The larger the endotracheal tube, the better flow of gas for ventilation. Delivery of β_2 receptor agonists such as albuterol increase the diameter of the bronchial tubes of the lungs to improve flow. Increasing the peak inspiratory pressure establishes a higher pressure gradient, which improves flow and delivered tidal volumes. Increases in the pressure gradient and flow velocity may initially improve flow, but risk converting that flow to turbulent flow. Turbulent flow may also result when molecules of a fluid encounter rough, irregular walls or angles greater than 25 degrees. Turbulent flow often occurs in the medium to large airways of the lung and predominates during periods of peak flow, coughing, and phonation. Orifice constriction, such as

glottic closure, causes laminar flow to become turbulent. Smaller bronchial tubes of the lung have slower velocities, and laminar flow is maintained. The presence of laminar, turbulent, or transitional flow is determined by the Reynolds number.

Reynolds Number

The Reynolds number (Osborne Reynolds, 1842–1912) is an index that incorporates the factors of Poiseuille's law with the addition of a fluid's density to determine whether a given flow will be laminar or turbulent. The Reynolds number is directly proportional to the density of the fluid, linear velocity of the flow, and tube diameter; flow is inversely proportional to fluid viscosity. The equation is as follows:

$$\text{Reynolds number} = \frac{v\rho d}{\eta}$$

where v is the linear velocity of fluid, ρ is density of fluid, d is diameter of tube, and η is viscosity. A Reynolds number greater than 2000 reflects a predominantly turbulent flow. Conversely, a Reynolds number less than 2000 reflects predominantly laminar flow. Delivery of helium-oxygen mixtures to status asthmaticus patients, who are refractory to standard treatments, is based on the understanding of density's role in reestablishing laminar flow.⁵⁴ Helium, which has a significantly lower density (0.1786 g/L at STP) than nitrogen (1.251 g/L at STP), improves flow by restoring laminar flow through the significantly narrowed airways of a severe asthma attack.

Bernoulli's Principle

Bernoulli's principle (Daniel Bernoulli, 1700–82) describes the effect of fluid flow through a tube containing a constriction. As flow passes through a narrowing in a tube, the velocity of that flow increases, and there is a corresponding decrease in pressure at the area of narrowing (Fig. 15.22A). This drop in pressure is explained by the conservation of energy law. For a steady flow of

incompressible fluids, the sum of pressure, potential energy, and kinetic energy per unit of time must remain constant. The relationship of the pressure gradient to mass flow requires the pressure to decrease when the velocity increases. The Bernoulli equation is as follows:

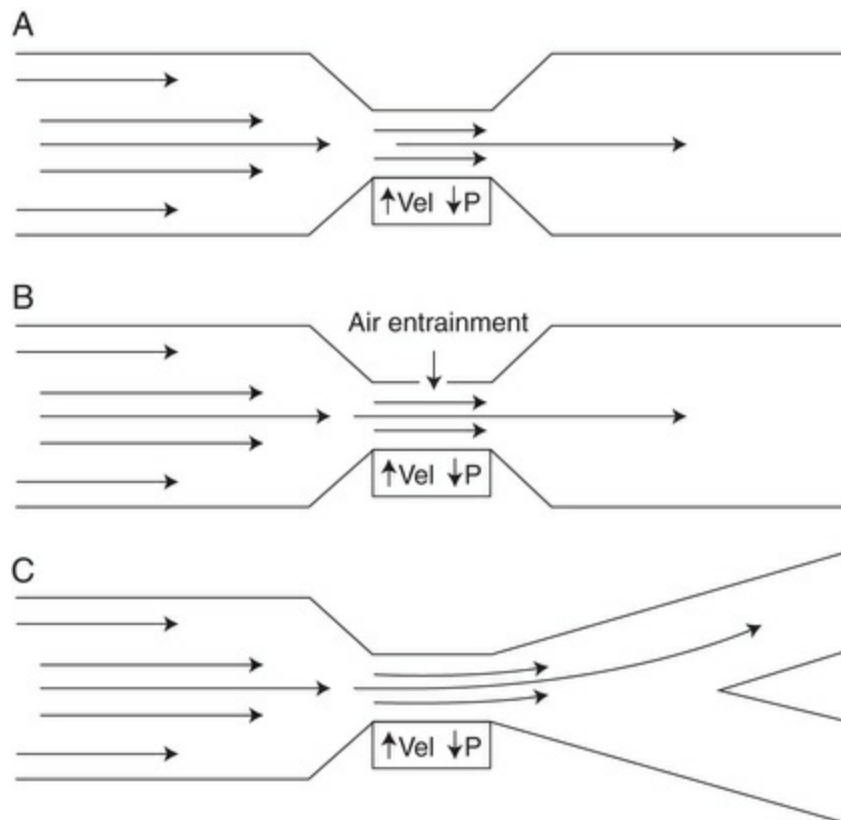

FIGURE 15.22 A, Bernoulli principle; B, Venturi effect; C, Coanda effect. *Vel*, Velocity; *P*, pressure.

$$P + \frac{1}{2} \Delta V^2 + pgh = \text{constant}$$

where P is pressure, Δ is density, V is velocity, g is gravitational acceleration, and h is height. Bernoulli's equation is useful in determining flow through tubes that narrow, but it does not account for friction, and assumes no changes in density or flow rate. This simple equation explains the pressure velocity relationship if fluid flows past a constriction. The velocity of a fluid is equal to the flow rate divided by the area of flow.

$$\text{Velocity} = \frac{\text{Quantity of flow per unit of time}}{\text{area}}$$

If a given quantity of flow is 4 L/min over an area (tube) with a volume of 2 L, the fluid velocity would be 2 L/min. If this flow meets a narrowing in its path that decreases the cross-sectional volume to 1 L, the fluid velocity would increase to 4 L/min.

$$V_1 = \frac{4 \text{ L/min}}{2 \text{ L/min}} = 2 \text{ L/min}$$
$$V_2 = \frac{4 \text{ L/min}}{1 \text{ L/min}} = 4 \text{ L/min}$$

This shows the increase in velocity associated with a narrowing in a tube for a given fluid flow (assuming no changes in density or height). The conservation of energy law dictates there must be a corresponding decrease in pressure. The energy of the flowing system does not change because of a constriction, but rather the expression of that energy has changed. Essentially, more energy is imparted toward velocity as opposed to pushing on the walls of the tube (pressure). Thus, velocity increases and pressure drops to maintain conservation of energy.

Metered-dose inhalers (MDIs) use the Bernoulli principle to create a jet past a constriction that aerosolizes a drug in the expanding flow of gas. The necessity for large and sometimes cumbersome equipment is obviated by MDIs, which are able to consistently deliver aerosolized particles of medication into a fluid stream.⁵⁵ A more applicable example of the Bernoulli principle is taking advantage of the pressure drop across the narrowing in a tube of fluid flow. The Venturi effect relies on the lower pressure at a constriction to entrain air or fluid into a fluid path.

Venturi Effect

The Venturi effect (Giovanni Battista Venturi, 1746–1822) utilizes the pressure drop across a narrowing in a tube. By placing an orifice at the narrowed region of flow, air is allowed to be entrained and enter the flow (see [Fig. 15.22B](#)). Air may be entrained into a

flow of liquid, or a liquid may be entrained into the flow of a gas.⁵⁶ Jet ventilation uses this entrainment of air to augment lung ventilation volumes.^{57–59} Nebulizers use the Venturi effect to deliver both humidification and medications such as albuterol.⁶⁰ Nebulizers effectively deliver medications into fluid paths, such as ventilator circuits, but have been replaced to a large extent by MDIs.

Coanda Effect

The Coanda effect (Henri Coanda, 1885–1972) explains the tendency of fluid flow to follow a curved surface upon emerging from a constriction (see Fig. 15.22C). This may cause preferential flow to one tube at a bifurcation just past a narrowing in a tube.⁶¹ Beyond a narrowing in a tube, there will be an increase in pressure corresponding with a decrease in the velocity of the fluid flow. If, at a widening in a tube, there is a division of flow with different angles, the return to a higher pressure will occur at different points along the bifurcated tube. The bifurcated tube with the delayed reestablishment of higher pressure (and corresponding lower velocity) may preferentially attract a greater percentage of the total flow toward its path. The path with the greater flow will receive a higher volume of fluid or gas at the expense of the path with lesser flow. In situations where this flow is blood in vessels or gas in the lungs, this diversion of flow could be consequential.^{62–64}

Laplace's Law

Laplace's law (Pierre Simon Laplace, 1749–1827) describes the relationship of wall tension (T) to pressure (P) and radius (r) in cylinders and spheres.

- Cylinders: $T = Pr$
- Spheres: $2T = Pr$

Tension is a stress force exerted over a given area. It is measured in newtons per centimeter (N/cm). In cylinders, wall tension increases with an increased radius; similarly, increasing pressure will increase wall tension.⁶⁵ Laplace's law shows why smaller-diameter capillaries do not burst during periods of hypertension, whereas larger vessels or aneurysms may. An abdominal aorta

maintains a mean arterial pressure along its length, including within an aneurysm, if present. Aneurysms, which have a greater radius than the rest of the aorta, have a corresponding greater tension and are more likely to rupture. Laplace's formula, when rearranged, reflects the direct relationship of tension to radius in both the aorta and an aortic aneurysm at a constant pressure:

$$P = \frac{T}{r}$$

Example 1—Cylinders: If the mean aortic pressure is 100 mm Hg with a normal radius of 2 cm and an aneurysm radius of 4 cm, the tension is calculated as follows:

$$Pr = T$$

1. Normal aorta: 100 mm Hg (P) × 2.0 cm (r) = (T)

$$1.33 \text{ N/cm}^2 (100 \text{ mm Hg}) \times 2.0 \text{ cm} = 2.66 \text{ N/cm}$$

2. Aortic aneurysm: 100 mm Hg (P) × 4.0 cm (r) = (T)

$$1.33 \text{ N/cm}^2 (100 \text{ mm Hg}) \times 4.0 \text{ cm} = 5.32 \text{ N/cm}$$

The aortic aneurysm in this example has twice the wall tension of the normal aorta (mm Hg were converted to N in the formula). Any increase in blood pressure will increase the already high wall tensions of an aneurysm, and wall failure may result in dissection or rupture.⁶⁶

In a sphere, wall tension is half that of a cylinder of the same radius. Applying Laplace's law to saccular aneurysms shows the relationship between increasing tension and an increasing radius:

Example 2—Spheres: If the mean pressures of two saccular aneurysms are 100 mm Hg, one with a radius of 0.5 cm and the other with a radius of 1 cm, the tension for each is calculated as follows:

$$Pr = 2T$$

1. Small saccular aneurysm:

$$100 \text{ mm Hg (P)} \times 0.5 \text{ cm (r)} / 2 = T$$

$$1.33 \text{ N/cm}^2 (100 \text{ mm Hg}) \times 0.5 \text{ cm} / 2 = 0.3325 \text{ N/cm}$$

$$100 \text{ mm Hg (P)} \times 0.5 \text{ cm (r)} = (2T)$$

$$1.33 \text{ N/cm}^2 (100 \text{ mm Hg}) \times 0.5 \text{ cm} =$$

$$2 \times 0.665 \text{ N/cm} = 1.33 \text{ N/cm}$$

2. Large saccular aneurysm:

$$100 \text{ mm Hg (P)} \times 1.0 \text{ cm (r)} / 2 = T$$

$$1.33 \text{ N/cm}^2 (100 \text{ mm Hg}) \times 1 \text{ cm} / 2 = 0.665 \text{ N/cm}$$

$$100 \text{ mm Hg (P)} \times 1.0 \text{ cm (r)} = (2T)$$

$$1.33 \text{ N/cm}^2 (100 \text{ mm Hg}) \times 1.0 \text{ cm} =$$

$$2 \times 1.33 \text{ N/cm} = 2.66 \text{ N/cm}$$

Greater wall tension would be present in a large saccular aneurysm (0.665 N/cm) than in a small saccular aneurysm (0.3325 N/cm), and any increases in pressure would risk further increases in wall tension and rupture. Decreasing pressure will decrease wall tension in both cylinders and spheres, and is the rationale for controlling blood pressure in patients with aneurysms.⁶⁷

Laplace's law, as applied to a cardiac ventricle of increasing size, explains the necessary inotropic response but eventual failure of contractility with increasing wall tension and pressure:

$$Pr = 2 T$$

Increased pressure = Increased wall tension

Increased radius = Increased wall tension

Increased wall tension = Increased contractility

(Frank-Starling curve)

Laplace's law is often used to describe the dynamics of alveoli. Laplace's law directly applies to alveoli in the absence of surfactant. Without surfactant, small alveoli would collapse, as they would require higher pressure to open compared to larger alveoli. This is portrayed in [Fig. 15.23](#) by rearranging the formula for pressure.

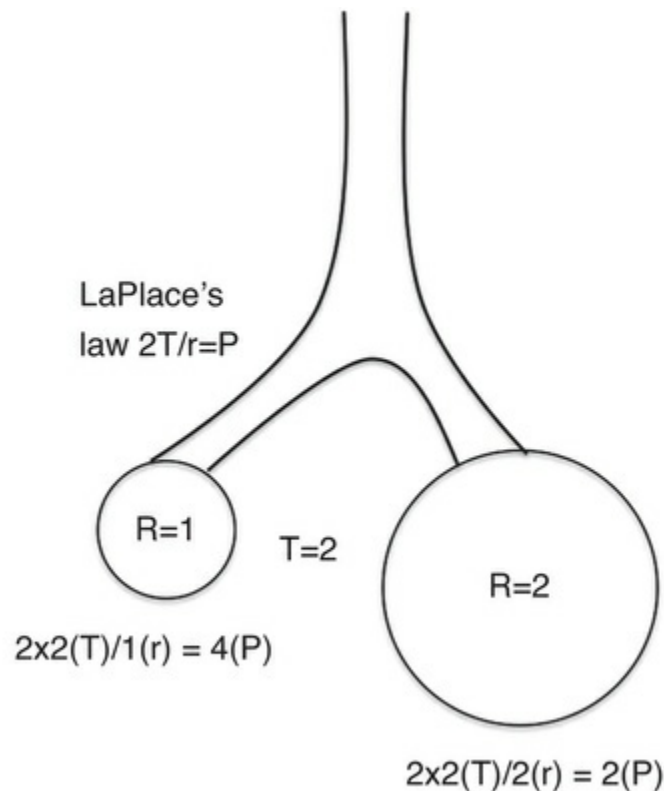

FIGURE 15.23 Alveoli and LaPlace's Law. In the absence of surfactant, the pressure needed to ventilate small alveoli would be greater than the pressure needed to ventilate large alveoli. Small alveoli would collapse (atelectasis).

Surfactant is a substance that lowers surface tension in the alveoli and prevents the effects observed with Laplace's law. By lowering surface tension, the pressure required to open alveoli is lowered.

Surfactant lowers surface tension more in smaller alveoli than in larger alveoli, owing to the concentration effect that occurs when an alveolus contracts.⁶⁸ Greater surfactant concentration has greater surface tension, lowering ability. Surfactant therefore has the ability to equilibrate surface tension among different-sized alveoli and create stabilized alveolar pressures (Fig. 15.24).

FIGURE 15.24 Increased surfactant concentration (dashed line) with decreasing alveolar size.

Waves

Waves are a very important phenomenon in everyday life, as well as in anesthesia. Waves exist macroscopically, such as ocean waves and sound waves. They also exist within atoms and as light energy. Waves surround us and exist within us. Understanding waves and wave action is key to understanding the basic ripple that permeates the universe. That basic ripple is energy. Waves are a periodic disturbance or motion. Waves are essentially the movement of energy. The “disturbance” is energy, and that is what is transported, or moved, along the wave front.

Wave Types

The two basic types of waves are transverse waves and longitudinal waves. *Transverse waves* are composed of up-and-down movement. In a transverse wave, the particles in the medium move perpendicular (up and down) to the wave direction. EMR waves are transverse waves. *Longitudinal waves* are composed of back-and-forth movement along the direction of the wave. In a longitudinal wave, the particles in the medium move forward parallel to the

direction of the wave (propagation). There is no up-and-down motion in longitudinal waves. The wave energy causes only compression and decompression (rarefaction) to occur along its path. These are pressure fluctuations. Sound waves are longitudinal waves.

Wave characteristics:

- *Frequency*—Waves per second; measured in cycles per second, called *hertz* (Hz)
- *Wave length*—Distance from one wave top (crest) to the next
- *Period or phase shift*—How far the wave “slides”
- *Amplitude*—Height of the wave
- *Speed*—Measured in meters per second
- *Wave part*—Crest is the wave top, trough is the wave bottom
- *Pressure waves*—Can be reflected, refracted, diffracted, or absorbed (interfered) by other waves
- *Reflection*—Waves reflect off of a medium at the same but opposite angle; the angle of incidence is the angle at which a wave strikes a medium
- *Refraction*—Redirection due to contact with a new medium
- *Diffraction*—Spreading or scattering; bending around an object
- *Absorption or interference*—Waves may interfere with other waves or be absorbed by matter. When waves interfere, amplitudes are additive. Constructive interference is when the crest of one wave passes through the crest of another wave or the trough of one wave passes through the trough of another wave, and the resultant wave is greater. Addition of two positive amplitudes or two negative amplitudes results in a greater value or wave height. Destructive interference is when the crest of one wave passes through the trough of another wave. Amplitudes from one crest are added to the negative amplitudes from the other wave's trough, and the height of the resultant wave is decreased.

Pressure Waves (Sound Waves)

Sound waves are pressure fluctuations that deviate from ambient pressure and are measured in Pa. Sound pressures are measured on a sound pressure level that uses a logarithmic decibel scale to

narrow the wide range (20 Hz to 20 kHz) of amplitudes audible to the human ear. Sound waves are longitudinal waves that propagate through matter (solid, liquid, gas) at varying speeds determined by the medium's elastic modulus (stiffness), density, and temperature. The speed of sound through air at 0°C is 740 miles per hour. In the absence of matter, there are no sound waves. Sound waves do not exist in a vacuum, and only travel through matter.

Ultrasonography.

Sound waves above the auditory limit of the human ear (20 kHz) are known as *ultrasound*. Ultrasonography uses ultrasound waves to construct a visual image of internal structures by examining the reflection of sound. Ultrasonography is useful for assisting simple procedures such as intravenous catheter insertion or for more invasive diagnostic assessment such as transesophageal echocardiography.⁶⁹⁻⁷³ Ultrasonography uses a signal generator that transmits sound waves through tissues and a transducer to record the time delay for the returning reflected sound waves. The speed of sound waves in tissues is unique and constant to specific tissue compositions, and therefore the time delay of the returning reflected sound waves allows calculation of the location of different internal structures. Not all sound waves are reflected back to the transducer; some sound waves will have been refracted in a new direction, diffracted in multiple directions, or interfered with by tissues that cause attenuation or conversion to heat and resultant dissipation. The fraction of the original signal that is reflected back to the transducer must be amplified and processed into a visual display. The introduction of ultrasonography has been made possible by the development of piezoelectric crystals that act as both signal generators and signal transducers (see [Piezoelectric Effect](#)). A burst of ultrasound pressure waves is produced, followed by measurement of the reflected waves, and this process is repeated many times a second, permitting real-time imaging of internal structures by computational analysis.

Piezoelectric Effect.

Piezoelectric crystals are unique quartz, ceramic, or polymer compositions that contain a matrix of polarized molecules that (1)

respond to electric current by changing shape and (2) respond to mechanical stresses by generating an electric current. Piezoelectric crystals derive their name from the Greek prefix *piezein*, which means “to press tight or squeeze.” The shape change caused by an electric current creates a pressure fluctuation around the crystal; this is a pressure wave. If a piezoelectric crystal is subjected to an alternating electric current, it will vibrate, creating many pressure waves in quick succession. The rate at which the crystal vibrates is called its *resonant frequency*. When not responding to an electric current, piezoelectric crystals are at rest and respond to the mechanical stress of the pressure waves by creating a small electric current.

Doppler Effect.

The Doppler effect (Christian Johann Doppler, 1803–53) describes the change in frequency of a propagated wave from a moving object. The sound of a siren changes to a higher frequency as it approaches a listener and lowers in frequency as it departs. Listener 1 in the Doppler effect figure (Fig. 15.25) will hear a sound emitted from a stationary object with a fixed frequency. Listener 2 will hear a sound emitted from a moving object with increasing frequency as the sound approaches and lessening frequency when it passes. This is due to the “stacking up” of the wave fronts emitted from an approaching object and the stretching of the wave fronts when it recedes.

FIGURE 15.25 Doppler effect.

The Doppler effect, when applied to echocardiography, allows the determination of blood flow direction and speed. As blood cells flow to or away from an ultrasound signal, reflected waves are

either compressed or expanded. This change in frequency allows calculation of blood velocity:

$$V = \frac{\Delta f}{\cos \theta} \times \frac{c}{2f_t}$$

where velocity of blood is V , Δf is the difference in transmitted frequency and received frequency, f_t is the transmitted frequency, c is the speed of sound in blood, and θ is the angle of incidence between the ultrasound beam and blood. Spectral display presents Doppler ultrasound data in a time-velocity graph that allows greater assessment of hemodynamics on a beat-to-beat basis.

Electromagnetic Waves

The term *electromagnetic* succinctly expresses the dual nature of electricity and magnetism. The two are intimately intertwined. Where there is electric current, there are also magnetic waves. Where there are changing magnetic waves, there is also an electric current. EMR is composed of two waves, electric and magnetic, oscillating in unison but perpendicular to one another. The electromagnetic wave is propagated perpendicularly to these oscillating waves. Electromagnetic waves possess both electric and magnetic potential. Electromagnetic waves (also known as *EMR*) are similar to pressure waves in that they both possess frequency and amplitude. Another similarity is that they may be reflected, refracted, diffracted (scattered), or absorbed. The unique wave properties of EMR include its composition, velocity, and independence of transport by matter. EMR differs from pressure waves (sound waves) in its velocity. The speed of EMR in a vacuum is 3×10^8 m/sec (186,000 miles/sec), whereas sound cannot exist in a vacuum. The speed of EMR in air closely approaches 3×10^8 m/sec. The speed of sound in air is only 331 m/sec (740 miles/hr). EMR and sound waves may travel through matter at varying speeds, but only EMR can propagate independently of matter. Sound waves only travel through matter and cannot exist in a vacuum, as shown in [Fig. 15.26](#) and [Table 15.4](#).

FIGURE 15.26 Electromagnetic wave showing electric wave oscillating perpendicular to magnetic wave.

TABLE 15.4

Comparisons of Electromagnetic Radiation and Sound Wave Properties

	EMR	Sound Waves
Speed	300,000,000 m/sec	344 m/sec
Wave type	Transverse	Longitudinal
Energy motion	Perpendicular to propagation	Parallel to propagation

EMR, Electromagnetic radiation.

Inverse Square Law

Waves represent the propagation of energy from a source. As energy moves away from its source, its strength decreases. Newton showed that the strength of the emanating energy is inversely proportional to the square of its distance from its source, as follows:

$$I_1 = \frac{(d_2)^2}{I_2(d_1)^2}$$

where I_1 equals intensity at the original distance, I_2 is the lower intensity at a new distance, d_1 is the distance from original source, and d_2 is the new distance from the source. Newton originally calculated this for the force of gravity; however, it has applications throughout physics.⁷⁴ This relationship is represented by the inverse square law figure (Fig. 15.27), where the y plane is twice the distance from the source than plane x . The energy intensity at I_2 is one-fourth the intensity at I_1 . The inverse square law applies to pressure waves, electricity, light, and radiation, with the intensity of each decreasing with increasing distance from its source.

FIGURE 15.27 Inverse square law representation of decreasing intensity with increasing distance.

Magnetism

Magnets are a unique form of matter in which the charges are aligned in an orderly fashion. There are flows of magnetic currents, or field lines, in all magnets. To observe these invisible fields, place a magnet under a piece of paper and spread iron filings on top. The filings will line up along the magnetic fields. Magnetism is a force between electric currents. Flowing charged particles not only move energy along that current, but also disrupt, or alter, the surrounding environment. This “altering” is not apparent unless one is looking for it. Hold a compass near a wire carrying an electric current. The needle will move and align itself along the flow of magnetism. Turn the wire, and the compass needle will turn. There is a force between the electric current and the compass needle (magnet). Magnetic fields are measured with a gauss meter in units of teslas: 10,000 gauss (G) equal one tesla (T). The earth's magnetic field strength is 0.00005 T (0.5 G). A small magnet's strength is 0.01 T (100 G). The magnet's strength in a magnetic resonance imaging (MRI) machine is 1 to 3 T (10,000 to 30,000 G).

Magnetic Resonance Imaging

MRI uses a strong, continuous magnetic field to uniformly realign the spin of protons within the hydrogen atoms of water. As the proton axes are pulled into one of two possible realigned positions, a radiofrequency pulse is delivered at resonant frequency to

energize the protons. The protons will then reemit this energy. The radiofrequency pulses are delivered in thin “slices” that may be made in the sagittal, coronal, or axial planes. Computer-generated analysis of these data produces very detailed representations of internal tissues. The magnetic field used is very strong, and specific safety considerations need to be addressed when delivering anesthesia care in an MRI suite.

MRI Safety.

Because of the high strength of the magnetic field in and around an MRI scanner, special precautions must be observed. Any ferrous material will interact with the magnetic field, gaining kinetic energy and thermal heat. Movable ferrous objects will also be attracted to the MRI magnet and will be pulled into the magnetic field with great force. Patients and personnel are at potential risk for both thermal injuries from implanted ferrous objects and traumatic injury from ferrous objects violently pulled into the magnetic field. The American College of Radiology has designated four safety zones that surround an MRI scanner, with zone 4 representing the immediate area around the scanner. Zone 4 poses the greatest risk of injury and has the most stringent guidelines.⁷⁵ All ferrous materials such as pagers, phones, jewelry, identification badges, and pens must be removed before entering zone 4. Patient stretchers, oxygen tanks, IV poles, and any other ferrous objects must be kept outside zone 4. Specially designed stretchers and anesthesia machines are designated for zone 4 to prevent attraction to the magnet.

Implanted ferrous materials such as ferrous foreign bodies, prosthetics, stents, and pacemakers have been studied for MRI safety. A review of the current literature regarding the acceptability of various devices for scanning is recommended.⁷⁵⁻⁷⁸ Many implanted devices can be safely scanned in an MRI, and any knowledge of or concerns about potential ferrous interaction should be brought to the attention of the designated MRI personnel.⁷⁵

Electricity

Electricity is the change in potential energy caused by the

movement of electrons from an area of high concentration (high charge density) to an area of low concentration (low charge density). The fundamental unit of charge is e ; it represents one electron's energy and is extremely small. Dealing with the energy of a single electron is difficult, so we use a quantized measurement called a *coulomb* (C): $1 \text{ C} = 1.6022210^{19} e$.

Coulomb's Law

Coulomb's law (Charles-Augustin de Coulomb, 1736–1806) states that like charges repel each other, and opposite charges attract each other inversely to the square of their distance. In short, opposite charges will attract more when closer together, and like charges will repel more when closer together. The electrical potential energy unit is the *volt*. It represents electrical “pressure” or the gradient of charges that could potentially flow. Electric current (I) is the rate of flow of an electric charge through a *conductor*. In operating room electrical equipment, the conductor is usually copper wire. Copper is a good conductor, and therefore the resistance to flow is low. In insulators, also known as *dielectrics*, electrons are not easily moved, and therefore resist the flow of electricity. Current is measured in *amperes* (A), and $1 \text{ A} = 1 \text{ C/sec}$. A volt is the SI unit for 1 J/C .

Ohm's Law

The potential flow of electric charge is proportional to actual current, after accounting for resistance. Resistance is calculated by Ohm's law (Georg Ohm, 1789–1854):

$$E = IR$$

where E represents volts or potential energy, I is current, and R is resistance. Resistance is measured in ohms (Ω). Ohm's law measures resistance to electrical flow ([Fig. 15.28](#)).

FIGURE 15.28 Basic electric circuit showing a live (hot) wire (I = current), a load (R = resistance), and a grounded neutral wire (E = volts).

Electrical Flow

In an electrical current, electrons flow from a surplus of electrons to a deficiency of electrons. Electricity must have a complete circuit for electrical flow to occur. A simple circuit is shown with a positive side (live, hot), a negative side (neutral), and a ground. The ground is a conductor that is connected to the earth (ground) and provides a low, resistive, alternate route for electricity to flow through in the case of an electrical surge. Electricity may be provided by *direct current* (DC) or *alternating current* (AC). In DC circuits, the flow of electrons is always in one direction. In AC circuits, the flow of electrons reverses direction (alternates) at a set frequency, usually 60 Hz (United States) or 50 Hz (Europe) (1 Hz equals 1 cycle per second). Electricity is delivered by the power company as AC because its voltage can easily be maintained while traveling long distances to customers via the power grid. Operating room equipment and most residential and institutional electrical equipment operate on AC. A simple AC circuit is the same as a simple DC circuit, except resistance is more complex with AC circuits, and the positive side alternates between both wires. In AC circuits, resistance is called *impedance* and is the total of all forces that impede electrical flow. In addition to the inherent characteristics of the conductive material, capacitance and inductance contribute to AC impedance. *Capacitance* is the capacity to store charge. A capacitor is composed of two parallel conductive

plates separated by an insulator. When a capacitor is exposed to a voltage source in an open circuit, one plate will store a positive charge, and the other will store a negative charge. Capacitors have useful applications in electronic devices, but can leak *stray capacitance*. There are no absolute insulators, and stray capacitance may create an unintended charge in the casing of electrical equipment. *Electromagnetic inductance* is the transfer of an electric current between circuits without physical contact, using induced magnetic waves. Any conductors carrying an electric current will also carry a magnetic field. In AC circuits, the charge is alternating, and so the magnetic field will change too. This changing magnetic field may induce a small electric current in nearby conductive materials such as equipment metal casings, even in the absence of physical contact between the circuit and the casing.

Electric Shock.

Stray capacitance and inductance may contribute a low risk of shock, because they are low-current flows. Direct contact with exposed electrical wiring constitutes a high risk of electric shock because of higher voltages. Current leakage from wires to equipment casing exposes patients and operating room personnel to the risk of shock by three mechanisms:

1. Direct wire contact with metal casing due to insulation damage or faulty construction
2. Inductance due to the magnetic field of the AC, producing a small electrical flow in the surrounding metal casing despite no direct contact
3. Stray capacitance from the buildup of electrical potentials with an AC circuit despite no closed circuit electrical flow⁷⁹

If a patient or a member of the operating room personnel makes contact with both a live wire and the ground, they may complete an electric circuit and receive a shock. For a shock to occur, a complete circuit must be made. This can happen if a person is standing on the earth and contacts the live wire in a circuit (Fig. 15.29). Shocks may be macroshocks or microshocks. A *macroshock* refers to large

amounts of current conducted through the patient's skin and other tissues. Injuries may be minor or severe, depending on the amount of current and the duration of exposure. Electric current seeks the path of least resistance, and is often dissipated throughout the body tissues. The amount that reaches the heart is often insufficient to cause arrhythmias.

FIGURE 15.29 Electric shock. A is point of contact and B is connection to ground.

However, conductive materials in a patient's body may place that patient at greater risk by providing a low resistive path for electricity to flow to the heart. *Microshock* is the delivery of small amounts of current directly to the heart. The amount of current that may produce ventricular fibrillation has been found to be 50 microamperes or lower.^{80,81} Table 15.5 gives a comparison of how different levels of microshock and macroshock affect the human body.

TABLE 15.5
Effects of Macroshock and Microshock

Macroshock (mA)	Effect
1	Perception
5	Maximal harmless current

10–20	“Let-go” current
50	Loss of consciousness
100–300	Ventricular fibrillation
6000	Complete physiologic damage
Microshock (μA)	Effect
20	Ventricular fibrillation in dogs
100	Ventricular fibrillation in humans ⁵³

Electrical Safety.

To decrease the risk of shock, operating room electrical systems are isolated from the main grounded electrical supply system. A *transformer* is used to isolate the electrical supply systems from one another. A transformer uses the principle of magnetic inductance to transfer electricity from one system to another system without having physical contact. This allows the operating room power supply to be ungrounded, preventing a circuit from being completed when a person contacts one live wire. However, if a person contacts both wires in a circuit, shock may occur as the path of electricity flows through the person from one line to the other. Operating room equipment casing (housing) is grounded to divert electrical flow in case of internal live wire contact with the metal housing.

If there is contact between the live wires and the ground (fault), such as when wiring touches the equipment casing, the system will become a grounded system. A second fault will enable a shock, because the newly grounded system will allow a completed circuit to pass through a person in the operating room that is grounded when a live wire is contacted. To prevent a first fault from being unnoticed, a *line isolation monitor* is placed between the live wires and ground to measure their impedance to flow (Fig. 15.30).⁸² If a live wire has contact or high capacitance to ground, the line isolation monitor will alarm. Line isolation monitors are usually set to alarm at 2 to 5 mA potential leak. If a line isolation monitor alarms, the last piece of equipment plugged in should be disconnected and inspected to verify that it is the offending piece of equipment. Equipment that activates a line isolation monitor may still be operational but increase the potential risk of shock should a second fault occur, because it has converted the isolated power supply system to a grounded system. Line isolation monitor alarms may also be activated because of the cumulative effect of minor

leakages of many pieces of properly functioning electrical equipment. This does not mean a risk is present. Newer systems alarm at 5 mA to account for this normal leakage.

FIGURE 15.30 Ungrounded operating room electric circuit isolated from grounded hospital electrical system. Note that the electrical equipment casing and line isolation monitor are connected to ground, but the electric circuit is not. AC, Alternating current.

Electrocautery

Electrocautery devices use high-frequency electric currents to cauterize, cut, and destroy tissue. These devices may be unipolar or bipolar. Bipolar electrocautery devices have two tips: one to supply the electric current, and the other to return the current. Bipolar devices do not require a return electrode, and are less likely to cause burns or injuries apart from the local area of use. Unipolar devices have only one tip to deliver an electric current, and a large surface area return electrode with good conductive contact must be placed on the patient. The path of current flow from the unipolar device to the return electrode should not cross the patient's heart.

The high current flows used in electrocautery units may cause electromagnetic inductance, which in turn may cause artifact in other electrical equipment such as ECG monitors. Pacemakers may also sense the electromagnetic inductance as inherent electrical activity and not initiate a paced impulse. This would put the patient at risk for asystole if there is no inherent underlying heart rhythm.⁸³ Electrocautery interference has also been documented as initiating

paced tachycardic rhythms.^{84,85} Placing a pacemaker magnet over the patient's pacemaker resets it to a continuous, asynchronous mode. Not all pacemakers are reset to a continuous, asynchronous mode, and interrogation of the pacemaker to understand its settings and functions should be considered prior to surgery using electrocautery.

Quantum Physics

Electromagnetic Radiation

Newtonian physics is helpful in describing the wavelike properties of EMR, but is incomplete in its description. Originally, it was assumed that EMR, like sound waves, was propagated through a medium. A “luminiferous ether” was thought to fill the universe, and was the suspected medium through which EMR traveled. The famous Michelson-Morley^{86,87} experiment successfully disproved the existence of the “ether,” but did not determine how EMR propagates. Max Planck (1858–1947) later theorized that EMR is *quantized*, meaning it is emitted only in discrete quantities of energy, and this revolutionized our perspective of the universe. Planck's constant expresses the quantized nature of EMR, as defined by energy, time, and frequency:

$$E = h\nu$$

where E represents energy, h is Planck's constant (6.626068×10^{-34} m² kg/sec), and ν is frequency.⁸⁸ Albert Einstein introduced the photon concept of Planck's discrete energy quanta, and together with others ushered in the study of quantum mechanics.^{89,90} Quantum mechanics is a branch of physics that explores the subatomic dynamics of pure energy and the quasi-realm of energy/mass transition.

EMR is now thought to travel as photons or packets of energy, and can be observed as both a particle and a wave, depending on how scientists study and measure it. The dual nature of behaving as both a particle and a wave is unique to EMR.⁹¹ EMR is called a *photon* when it exhibits particle-like behaviors. Despite their behavior, photons have no mass. They are pure energy. The energy of EMR is directly related to its frequency. Higher frequencies correspond to higher energies, and lower frequencies correspond to lower energies. The velocity of EMR in a vacuum remains constant and does not change depending on the frequency. The understanding of energy as a quantized event promoted numerous

advances in physics, which ultimately found application in anesthesia. The perspective of EMR as photons allows us to better explain many dynamic interactions of EMR and matter. [Fig. 15.31](#) shows the EMR spectrum.

FIGURE 15.31 Electromagnetic radiation spectrum. Increasing energy associated with decreasing wavelength (increasing frequency) along the electromagnetic radiation spectrum is shown. Example: X-rays possess shorter wavelengths, greater energy, and greater ability to permeate matter than microwaves, which have longer wavelengths and lower energy.

Electromagnetic Radiation/Matter Interaction

EMR exists independently of matter. Sound (pressure) waves do not exist without matter through which their energy is transmitted. Both may be reflected, refracted (scattered), diffracted (redirected), or absorbed (interfered) by matter ([Fig. 15.32](#)). An example of the interaction of EMR with matter is visible light. Visible light is composed of a narrow band of EMR frequencies between 4.3×10^{14} and 7.5×10^{14} Hz (400 to 700 nm wavelengths). These frequencies of EMR are the only frequencies our eye receptors can detect. When we see a color, we actually see the reflected frequencies that correspond to that color. Visible light is composed of the colors red, orange, yellow, green, blue, indigo, and violet, and was first described by Newton. Visualizing the color blue represents the reflected EMR frequencies between 495 and 570 nm. The other visible light frequencies are not seen, because they have been absorbed and scattered by the material that appears blue. Materials that absorb EMR increase their vibration energy (kinetic energy),

owing to their absorption of energy. We experience an example of this when wearing white or black clothing in sunlight. Black clothing absorbs many more frequencies of visible light and gains greater kinetic energy, which causes heat. White clothing appears white because of the high reflection of the visible light spectrum; it gains less kinetic energy, and therefore less heat. The phenomenon of matter reflecting, scattering, and absorbing specific EMR frequencies has many applications in health care, and in anesthesia in particular.

FIGURE 15.32 Electromagnetic radiation interactions with matter.

EMR may also be converted into other forms of energy such as electricity (gas discharge), heat (incandescence), and chemical energy (photoluminescence), but must obey the law of conservation of energy. When matter is exposed to EMR, it too may change form. The analysis of EMR's interaction with matter is the underlying principle of x-ray fluoroscopy, anesthetic gas measurement, pulse oximetry, and lasers.

Radiography

X-Rays

X-rays are able to pass through different organic materials to varying degrees and allow the “photographic” imaging of internal structures. Though x-ray and fluoroscopic imaging offer great medical benefit, they also possess potential for great harm. X-rays are ionizing radiation and lie in the higher-energy frequencies of the EMR spectrum (see [Fig. 15.31](#)). They possess high energy and have the ability to ionize atoms and molecules. X-rays can cause

DNA damage and be mutagenic.⁹² Proper protection is imperative for health care personnel when working near or with x-rays. Safety lies within the three factors of distance from source, barriers, and exposure time. The inverse square law explains how energy intensity significantly decreases with distance from its source.⁹³ X-rays obey this law, and the minimum recommended distance from an x-ray source is 6 feet. The greatest intensity of an x-ray is directly in front of the beam generator. Standing at least 6 feet away and behind or to the side of the beam direction lessens exposure. Although the energy intensity of x-rays decreases significantly with greater distance from the source, proper shielding is also important. Lead barriers are efficient absorbers of x-ray energy, and lead aprons and thyroid shields should be worn. X-ray technicians often wear badges that measure total exposure to x-rays over a period of time. Greater exposure to x-rays is associated with greater risks. Institutional policies establish guidelines for exposure limits. Unless practitioners are exposed to radiographic procedures frequently, the doses received usually fall well below established limits for maximal allowable exposure. Shielding and distance from the x-ray source remain the two most important factors within the control of the practitioner.

Gas Analysis

Gas analysis technologies use several methods to measure organic and inorganic gases. The methods described herein focus on the technologies that are prevalent in the field of anesthesia. The gas analysis technologies shown in [Box 15.1](#) are the most common technologies used to analyze anesthetic gases, oxygen, and carbon

Box 15.1

Organic and Inorganic Anesthetic Gas Analysis Technologies

Organic and Inorganic Anesthetic Gas Analysis

- Infrared absorption analysis
- Raman scattering

- Mass spectrometry
- Piezoelectric analysis
- Interferometric refractometry
- Gas-liquid chromatography

Oxygen Analysis

- Electrogalvanic cell (fuel cell)
- Polarographic electrode (Clark electrode)
- Paramagnetic oxygen sensor
- Fluorescence quenching
- pH optode

Carbon Dioxide Analysis

- Infrared absorption analysis
- Severinghaus PCO₂ electrode
- Fluorescence quenching
- pH optode

Organic and Inorganic Anesthetic Gas Analysis

Infrared Absorption Analysis

Infrared absorption analysis uses each anesthetic gas's ability to absorb specific frequencies of EMR in the infrared spectrum. A sample of a gas or a mixture of gases is subjected to a known range of infrared frequencies. The frequencies lost due to absorption are measured, and the gas or gases may be identified by the specific frequencies each gas absorbs. Anesthetic agents' infrared absorption

spectra are unique but close in frequency. Newer infrared absorption analysis monitors are capable of identifying specific agents without preprogramming the specific agent. Concentration is determined by the amount of infrared absorption (Fig. 15.33).

FIGURE 15.33 Individual anesthetic gas infrared absorption spectra (representation only, not actual). A, B, C, and D indicate four different theoretical anesthetic gases.

Raman Scattering Analysis

The interaction of EMR with matter is the underlying principle used with Raman scattering analysis of gases. Raman scattering passes a monochromatic laser beam through a gas mixture, causing an increased vibration frequency of the excited gas molecules (Fig. 15.34). A laser is a high-intensity beam of a known specific EMR frequency (see laser discussion in this chapter). When this laser beam interacts with an anesthetic gas molecule, it may be absorbed (as previously described with infrared absorption analysis) or scattered. Scattering is a frequency change (energy change) of the initial laser beam after it interacts with gas molecules. The laser frequency interacting with the molecules may be scattered at higher or lower frequencies. Each anesthetic gas scatters laser frequencies uniquely. A gas or gas mixture may be analyzed and identified by comparing the gas sample scattering spectrum to that of known gas scattering spectrums. The scattered frequencies measured in this

spectral analysis are represented as Stokes lines.

FIGURE 15.34 Raman scattering gas analysis technology.

Raman scattering technology requires only that a gas molecule be polyatomic for identification. Raman scattering analysis can identify oxygen, carbon dioxide, nitrogen, nitrous oxide, and all volatile anesthetics, including mixtures of volatile anesthetics.⁹⁴ Helium cannot be analyzed by Raman scattering. Raman scattering analyzers return the sample to the patient circuit, and therefore do not require waste gas scavenging. Raman scattering analyzers are small and portable, but require calibration. They are less accurate with pediatric cases, which use high carrier gas flow rates and small tidal volumes.

Mass Spectrometry

Mass spectrometry historically has been the dominant technology for anesthetic gas analysis, though it has increasingly been replaced by more portable and efficient infrared absorption analysis and Raman scattering analysis technologies. Mass spectrometry ionizes gas molecules and passes them through a magnetic field. The gas molecules with the lowest mass-to-charge ratio are easily deflected

by the magnetic field and collected by an ion detector (Fig. 15.35). Ionized gas molecules with higher mass-to-charge ratios are deflected less by the magnetic field and detected by other ion detectors. Identification of a gas is based on the amount of deflection.

FIGURE 15.35 Mass spectrometry gas analysis technology.

Piezoelectric Gas Analysis

Piezoelectric gas analysis incorporates both the piezoelectric effect and Henry's law.⁹⁵⁻⁹⁷ A piezoelectric crystal will vibrate at a set frequency when an electric current is applied to it. A vibrating piezoelectric crystal coated with a liquid solution will alter its resonant frequency when exposed to a gas. As the gas dissolves into the liquid, in proportion to its concentration above the liquid gas interphase, the resonant frequency of the crystal is altered. The degree of frequency change is proportional to the concentration of gas that dissolves into the liquid. The amount of gas that dissolves into the piezoelectric crystal's liquid coating is directly related to the partial pressure of that gas. This is explained by Henry's law. A drawback of this technology is that it does not identify the specific anesthetic agent.⁹⁸

Photoacoustic Gas Analyzer

The photoacoustic gas analyzer subjects a gas sample to a filtered, pulsating infrared light beam in a closed chamber. The pulsating beam causes the gas molecules to increase then decrease in temperature. The increase and decrease in temperature causes the chamber pressure to increase and decrease according to Gay-Lussac's law. Microphones along the chamber measure the pressure waves. A photoacoustic gas analyzer can measure anesthetic gases, mixtures of these gases, and carbon dioxide.⁹⁹ The units are small, portable, and accurate.

Oxygen Analysis

The primary role of oxygen in biological systems underscores the importance of identification and measurement of this gas when delivering anesthetics. Purposeful redundancy is used in oxygen measurement, and more than one technology is often used at a time. In the practice of anesthesia, oxygen content analysis is accomplished with several technologies. These technologies take advantage of oxygen's unique physicochemical properties and interaction with EMR. The most commonly used technologies pertaining to anesthesia practice are reviewed in the following section.

Electrogalvanic Cell (Fuel Cell) Electrochemical-Oxygen Analyzer

The electrogalvanic cell (Fig. 15.36) is also called a *fuel cell*, because the reaction that takes place creates its own electric current by consuming its "fuel." The electrogalvanic sensor has a membrane that is permeable to gases but not liquids. At the anode of the sensor, electrons are liberated in an oxidative reaction. This is shown with a lead anode:

FIGURE 15.36 Electrogalvanic fuel cell.

The meter measures the current produced by the electrons consumed in the reaction at the cathode (silver or gold):

The electron flow between the anode and cathode is directly proportional to the partial pressure of oxygen in the sample gas. Current flows in proportion to oxygen concentration.

Electrogalvanic cells have a limited life related to the concentration and duration of oxygen exposures. Because of this, some nurse anesthetists remove the oxygen sensor from the circle system if an anesthesia machine is left on and not in use for extended periods of time, such as overnight. Most anesthesia machines have minimal oxygen flow at all times, so removing the electrogalvanic cell from the flow of higher oxygen concentration will extend its duration of usefulness.

Polarographic Electrode (Clark Electrode)

The Clark polarographic oxygen electrode consists of a voltage source and a current meter connected to a platinum cathode and a silver anode (Fig. 15.37). The electrodes are immersed in a potassium chloride electrolyte cell. A membrane permeable to oxygen, but not electrolytes, covers one surface of the cell. A polarizing voltage is applied between the electrodes. At the anode,

electrons are liberated by the oxidative reaction of silver with the chloride electrolyte:

FIGURE 15.37 Polarographic electrode.

The meter measures the current produced by the electrons consumed in the reaction at the cathode:

Current flows in proportion to oxygen concentration. If there is no current applied to these cells, there will be no consumption of the electrodes.¹⁰⁰

Paramagnetic Oxygen Sensors: Magnetomechanical Dumbbell Principle

The paramagnetic oxygen sensor uses oxygen molecules' unique attraction into magnetic fields. Few other gases are attracted by magnetic fields. The paramagnetic oxygen sensor is constructed with two nitrogen-filled bulbs attached together by a stem; this

resembles a dumbbell. This dumbbell-shaped apparatus is suspended parallel to a magnetic field in its “at-rest” state. Nitrogen is not attracted or repelled by magnetic fields. The introduction of oxygen into this sensor causes the dumbbell apparatus to be displaced out of the magnetic field as oxygen is attracted into the field (Fig. 15.38). The amount of displacement of the dumbbell apparatus is directly proportional to the concentration of oxygen. Originally, these sensors measured the physical displacement of the dumbbell apparatus, but were prone to artifact caused by vibration and external movement. These sensors now incorporate a small optical mirror that reflects a projected light beam. The light beam is reflected onto a photocell that generates a small voltage used to counteract the displacement of the dumbbell apparatus. Increased oxygen concentration increases the displacement of the dumbbell apparatus, which in turn directs a greater amount of reflected light onto the photocell. By using a generated electric current to counteract the dumbbell apparatus, displacement proportional to the oxygen concentration, external movement, and artifact are eliminated. These sensors are highly accurate, compact, and durable.

FIGURE 15.38 Paramagnetic oxygen sensor.

Paramagnetic Transducer

The paramagnetic transducer type of oxygen analyzer utilizes the

same unique attraction of oxygen molecules to a magnetic field (Fig. 15.39). Rather than utilizing the displacement of a mechanical apparatus, the transducer measures the pressure difference between a known gas and a sample gas. There are several variations on this principle that measure pressure or flow alterations in relation to the attraction of oxygen concentrations to a magnetic field.

FIGURE 15.39 Paramagnetic oxygen analyzer. (Courtesy Datex-Ohmeda, Madison, Wis.)

Fluorescence Quenching

Fluorescence is caused by a molecule emitting light (photons) in response to being energized. Certain molecules exhibit fluorescence in response to an electric current or exposure to EMR. These molecules are sometimes said to “glow in the dark.” Neon lights are an example of noble gas fluorescence initiated by an electric current. Chemical fluorescence is seen in some sea life and in glow sticks. Both electrically- and chemically-initiated fluorescence are caused by energizing an electron to a higher energy level. The energized (excited) electron then returns to its lower energy level (resting state) by releasing a photon (spontaneous emission). The released photon is observed as light, and its color represents the emitted photon's frequency.¹⁰⁰

Fluorescence quenching is a technology that uses oxygen's ability to suppress, or quench, certain molecules from fluorescing. When a fluorescent molecule is excited to a higher energy state, it will emit

a photon. Oxygen, if present, will absorb this photon and prevent its release. The amount of fluorescence that is quenched is directly proportional to the concentration of oxygen present. The oxygen concentration can be analyzed by measuring the amount of emitted photons (Fig. 15.40).

FIGURE 15.40 Fluorescence-quenching principle. 1, Photon release as fluorescence. 2, Energy absorption by oxygen, which quenches fluorescence.

Carbon Dioxide Analysis

Fluorescence Quenching

Fluorescence quenching technology also may be used to measure carbon dioxide. Carbon dioxide is not the quencher of fluorescence; instead it causes a change in pH, liberating hydrogen ions, which react with a quenching agent or a fluorescent dye in the sensor. Fluorescence is altered by the protonation of these chemical components. The measured change in fluorescence is proportional

to the concentration of carbon dioxide.

Colorimetric Carbon Dioxide Sensor

A dry-state sensor that undergoes a color change in the presence of carbon dioxide is often used to differentiate endotracheal intubation from esophageal intubation. These sensors use the fluorescence principle to indicate carbon dioxide in the gas phase. A paper is impregnated with a fluorescent dye that, in the presence of carbon dioxide, will fluoresce or change color. A phase-transport agent facilitates the reaction to produce an immediate color change (e.g., purple), indicating carbon dioxide. Colorimetric carbon dioxide sensors indicate the presence, but not the amount, of carbon dioxide.

Severinghaus Pco₂ Electrode

The Severinghaus PCO₂ electrode (Fig. 15.41) is frequently used in anesthesia for analyzing carbon dioxide.¹⁰¹ It uses a pH-sensitive electrode immersed in a bicarbonate solution with a gas-permeable membrane. Carbon dioxide diffuses into the sensor and is converted into free hydrogen ions, generating a current of electric charge. The current is proportional to the carbon dioxide concentration.

FIGURE 15.41 Severinghaus partial pressure of carbon dioxide in arterial blood (PCO₂) electrode.

Pulse Oximetry

Pulse oximetry makes use of the fact that different types of matter absorb different EMR frequencies. Oxygenated and deoxygenated hemoglobin are uniquely different molecules, and thus interact differently with EMR. By measuring specific frequencies that are absorbed by a pulsatile blood supply, the percentage of oxygenated and deoxygenated blood in the sample can be determined. The algorithm used to make these calculations is derived from the Beer-Lambert law (August Beer, 1825–63 and Johann Heinrich Lambert, 1728–77). This law is based primarily on the work of Lambert. Lambert's laws state that: (1) the luminance of perpendicular light on a surface is proportional to the inverse square of the distance it travels from its source, (2) the luminance intensity of angled light is proportional to the cosine of the angle with the normal, and (3) luminance intensity decreases exponentially as the light travels through a medium. The Beer-Lambert law is as follows:

$$I_t = I_i \times e^{-DC\alpha}$$

where I_t is the transmitted light, I_i is the incident light, and $e^{-DC\alpha}$ is the distance through the medium, concentration, and absorption coefficient (Fig. 15.42). Pulse oximetry applies the Beer-Lambert law to the absorption of two specific frequencies (infrared and visible red) by hemoglobin. Oxygenated hemoglobin absorbs the infrared frequency that corresponds to a wavelength of 940 nm, and deoxygenated hemoglobin absorbs the visible red wavelength of 660 nm (Fig. 15.43). Analysis of the wavelength that is most absorbed corresponds to that form of hemoglobin. If the wavelength of 940 nm is absorbed, the hemoglobin present is the oxygenated form. Pulse oximeters display a percentage measurement of saturated hemoglobin. Pulse oximeters measure the amount of absorption of these two specific wavelengths many times a second.

FIGURE 15.42 Incident light intensity change when transmitted through a medium.

FIGURE 15.43 Oxygenated hemoglobin and deoxygenated hemoglobin wavelength absorption spectra. The intersection where oxygenated and deoxygenated hemoglobin absorb the same frequency amount is the isobestic point. *Hg*, Hemoglobin.

Pulse oximetry is inexpensive, portable, and allows early detection of hemoglobin desaturation.¹⁰²⁻¹⁰⁴ Probes may be placed on the digits, ears, nose, or even the forehead to detect a pulsatile arterial blood flow. The oxyhemoglobin saturation curve displays the oxygen saturation (SaO_2) relationship to PaO_2 . Important points along this curve include an SaO_2 of 90%, which corresponds to the critically low PaO_2 of 60 mm Hg. An SaO_2 of 70% corresponds to a PaO_2 of 40 mm Hg (Fig. 15.44), and is the saturation at which cyanosis becomes apparent.¹⁰⁵ Pulse oximetry is of great value, and has become a standard of practice. Both a digital display and an

auditory tone alert the nurse anesthetist to the patient's hemoglobin saturation.¹⁰⁶

FIGURE 15.44 Oxyhemoglobin dissociation curve. PaO_2 , partial pressure arterial oxygen; SaO_2 , oxygen saturation as measured by blood analysis.

Disadvantages of pulse oximetry include the susceptibility to artifact from movement and ambient light sources, the risk of burns in poor perfusion states, and the limitation in detecting pulsatile blood flow in hypothermic or vasoconstricted patients. Additionally, some nail polish pigments interfere with accurate estimates of oxygen saturations. During high FiO_2 delivery, ventilation-perfusion abnormalities may be masked. A PaO_2 of 100 mm Hg and a PaO_2 of 500 mm Hg will both give the same pulse oximeter reading of 100%, regardless of the delivered oxygen. Lastly, pulse oximeters do not measure respiratory rate.¹⁰⁷⁻¹¹⁰

Lasers

Lasers derive their name from the acronym **L**ight **A**mplification by **S**timulated **E**mission of **R**adiation. Certain atoms that have been energized by an incident photon may move an electron to a higher orbit, but that electron only stays there momentarily, releases a photon, and quickly returns to its resting energy level (see

Fluorescence Quenching). This is called *spontaneous emission*. When many incident photons raise many electrons to higher energy levels, the *spontaneous emission* that occurs is chaotic, with photons radiating in multiple directions. However, if many atoms of a particular matter are continually energized by incident photons while their electrons are already in a higher energy state, then photons of the same frequency and direction will be emitted as the electrons are forced down to their natural resting state. This is called *stimulated emission*, and is the basis of laser function. Continual energizing of certain atoms forces photons of the same frequency (monochromatic) and direction to be emitted in unison. Population inversion is the condition in which the majority of electrons in an atom are in a higher energy level rather than in their natural resting state; the natural balance of resting electrons to energized electrons has been inverted. Population inversion is required to allow continual production of monochromatic, coherent, and unidirectional photons used in lasers. The intensity of lasers and the ability to direct the beam have many applications in medicine, and present unique considerations for nurse anesthetists (Fig. 15.45 and Table 15.6).

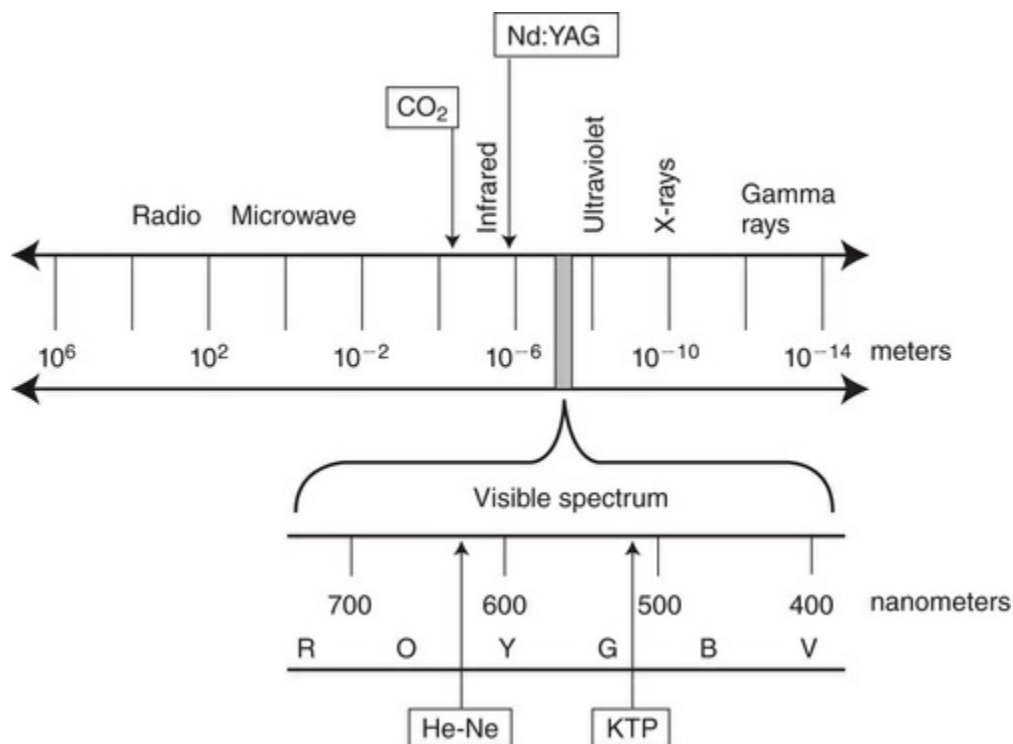

FIGURE 15.45 Common medical laser frequencies. CO_2 ,

TABLE 15.6

Medical Lasers and Uses

Laser	Wavelength	Tissue Penetration	Characteristics/Uses
He-Ne	633 nm	none	Aiming beam for invisible lasers
CO ₂	10,600 nm	less than 0.5 mm	Highly absorbed by water
			Good for superficial lesions
			Used in airway surgeries
Argon	488 nm	0.5–2.0 mm	Selectively absorbed by hemoglobin
	514 nm		Good for hemangiomas, moles
			Also used in eye and ear surgery
KTP	1060 nm	0.5–2.0 mm	Highly absorbed by hemoglobin
			Multiple uses
YAG	1064–2940 nm	2–6 mm	Variable intensities
			Used to ablate and destroy tissues
			Multiple uses

CO₂, Carbon dioxide; *He-Ne*, helium neon; *KTP*, potassium titanyl phosphate; YAG, yttrium aluminum garnet.

Laser Risks

Lasers can cause burns and ignite fires. The patient should have his or her eyes shielded with saline pads and laser goggles. Operating room personnel also should wear appropriate eye protection when lasers are in use.¹¹¹ The risk of fire is ever-present with lasers. Three components are needed to produce a fire: fuel, oxygen, and an ignition source. Lasers are a potent ignition source. The nurse anesthetist should be aware of this risk during laser surgeries, and be prepared to take rapid action. Drapes, dressings, and linens are a few of the combustible materials that may ignite during surgery.¹¹² Lasers should never be kept active when not in use. Lasers are often used for otorhinolaryngologic surgeries. Endotracheal tube fires can occur during these cases. Low inspired oxygen concentrations and nonflammable or shielded endotracheal tubes should be used.¹¹³ Some authors recommend placing saline with methylene dye in the endotracheal tube cuff to dissipate heat and signal cuff rupture.¹¹⁴ A source of saline to extinguish a potential fire should be immediately

available. If an airway fire occurs, stop oxygen flow, stop ventilation, extubate the patient, extinguish the fire, mask ventilate, and reintubate the patient.¹¹⁵ The patient will require airway assessment and medical treatment, including bronchoscopy, lavage, and steroids.

Summary

The historical view of the universe as a machine following fixed specific rules often allowed for unequivocal laws to be discovered. For a time, the actions of the universe seemed destined to be unlocked and forever understood. Unfortunately, or fortunately, this is not the case. The mechanistic view of the universe in Newtonian physics loses its ability to describe certain phenomena, and this underscores a significant limitation. Advances in our knowledge of quantum events may shed light on phenomena that remain elusive.¹¹⁶

Quantum physics has brought us new insight into the subatomic world and uncovered the limitations of classical physics in fully describing the actions and reactions of the universe. What Newtonian physics has done for the physical world, quantum physics promise to do for the nonphysical world: both the world of pure energy and the quasi-world of energy/mass transition. Events in the quantum world are not determined by fixed, describable outcomes; instead, quantum events are described by probabilities. Phenomena that remain only partially understood in anesthesia may be clarified by discoveries in quantum study. Consciousness, awareness, and minimum alveolar concentrations (MACs) all are described in anesthesia as probabilities. Consciousness and awareness are not “on-off” phenomena, but rather fall within a spectrum. Delivery of anesthetics is sometimes measured not in fixed set doses but rather in ranges (or MACs) that provide a guideline for the probability of a desired outcome. Though the concept is controversial, it has been suggested that consciousness is a quantum event that can only be understood by the study of quantum mechanics.¹¹⁷⁻¹²⁰ Newtonian physics and physical chemistry will remain valued sciences that describe many processes in the field of anesthesia well, but quantum study may someday bring new advances and applications to anesthesia. Safer, more

effective anesthesia techniques and technologies may evolve out of quantum understanding, or the mere search itself may stimulate new developments. Regardless, the future is exciting. Chemistry and physics have provided and will continue to provide a conceptual and analytical framework from which we can derive understanding, establish clinical rationales, and direct the practice of safe and effective anesthetic management of patients under our care.

UNIT III

Technology Related to Anesthesia Practice

OUTLINE

16 Anesthesia Equipment

17 Clinical Monitoring I Cardiovascular System

18 Clinical Monitoring II Respiratory and Metabolic Systems

19 Clinical Monitoring III Neurologic System

16

Anesthesia Equipment

Michael P. Dosch, Darin L. Tharp

“To a large extent, anesthesia machines are inherently dangerous. A machine that has the power to induce anesthesia necessarily has the power to cause death and serious injury. An anesthesia department may want to institute periodic training to make sure that everyone in the department is familiar with all of the machines in the hospital.”¹

It would disturb any of us to read in the news about an adult, without driver's training, who attempted to drive a car and caused injury or death as a result. Should it not be equally disturbing to learn that, even after the introduction of electronic self-check routines, some anesthesiologists believe that the gas machine checks itself, or that they feel they were never taught how to properly check the machine?^{2,3} Because anesthesia equipment malfunction is so rare, misuse and human error are much more of a threat to patient safety than outright malfunction.⁴⁻⁸ However, when errors in the use of gas delivery equipment occur, the outcome is often mortality or serious morbidity.⁵ Human error can be most effectively combated by a strong individual, department, and industry commitment “to ensure that no patient is harmed by anesthesia” (the mission of the Anesthesia Patient Safety Foundation).⁹ The means of accomplishing this goal are educational and motivational. We anesthetize patients with many different kinds of problems, for many different kinds of surgical and diagnostic procedures. But there is one thing that is present in every anesthetic: the anesthesia workstation. It is the purpose of this chapter to provide timely, accurate, and safe information about this important and ubiquitous patient-safety technology.

As the previous generation of equipment passes out of use (e.g., Excel, Modulus, Narkomed 3, ADU), they are deemphasized in this edition to allow more focus on current anesthesia equipment

systems. The main additions to this chapter are the new pre-use checklist for the anesthesia gas machine and its impact on patient safety; and new adaptive modes of ventilation (pressure control with volume guarantee, autoflow, pressure support, and continuous positive end-expiratory pressure [CPAP]). Differences between gas machines are presented, if understanding these differences is important to using the machine safely. Brief descriptions of new gas machines are presented (Aisys, Aespire, and Avance [GE Healthcare, Madison, WI]; Fabius GS and Apollo [Dräger Medical, Telford, PA]).

A major objective of this chapter is that readers will gain skill and safety in the use of the anesthesia gas machine. Therefore, throughout the chapter, explicit directions on how to use the machine safely are presented; these directions are based on manufacturers' guidelines and on reports of mishaps from the anesthesia literature. Because of the variety of machines currently in use, no direction in this chapter can be considered universally applicable. The directions given here must be adapted to individual practice settings only after study of the operators' manuals and appropriate local peer review.

Several factors make learning about anesthesia machines difficult. Each model has unique aspects—even those from the same manufacturer. It is not always possible for every anesthetist to be available when department in-service education is conducted. In addition, continuing education content may be too limited, or an opportunity to use new equipment soon after an educational session may not occur. New equipment constantly appears in the anesthesia work area. Although anesthesia equipment is designed to meet all legal and technical requirements, the designers of the equipment are not users. Some design limitations may be recognized only when they are used clinically.¹⁰ Instructional materials accompanying equipment are often inadequate. For example, no matter how well written, supplying one instruction manual per machine is inferior to supplying one instruction manual per user. The potential lack in equipment competency caused by these factors can be a safety problem. Users may be held legally responsible for knowing and following manufacturers' instructions (checklists, operating manuals) and warnings, because these may

contribute to the standard of care. Some courts have defined deviation from manufacturers' instructions as *prima facie* negligence.¹¹

To make learning the content easier, this chapter views the anesthesia workstation from a systems approach, much like the 2008 PreAnesthesia Checklist.¹² For example, all machines have systems to provide (and measure) gas composition, including life-sustaining gases (oxygen), anesthetizing gases, and metabolic by-products (carbon dioxide). When this capability of every gas machine is understood, one need only determine how a particular machine accomplishes this, and how this function is checked before use to operate the machine safely (in this respect). Once all the systems, and their interplay, are understood, learning new equipment is easier. High-fidelity patient simulation is a novel approach that holds promise for both learning anesthesia equipment more efficiently and studying gas machine hazards. Simulation has allowed exploration of questions that could not be studied in the past because of risks to patients.¹³⁻¹⁸

Organization of the Anesthesia Gas Machine

Presenting the anesthesia gas machine as a litany of components does not promote retention, much less aid in the development of a solid concept of the overall organization of the machine. An accurate concept of the overall organization should help one to understand the role of the individual components better, which should in turn promote correct use and thus patient safety. This section presents the supply, processing, delivery, and disposal (SPDD) model.

Supply, Processing, Delivery, and Disposal Model

The SPDD model is depicted in [Fig. 16.1](#) and [Box 16.1](#). This model is comprehensive in that the path of gases can be followed from their arrival in the operating room to their disposal from it. Most system components can be located easily within the overall scheme. Gas flows in the diagram proceed generally from left to right. The vertical bar separates components within the machine and proximal to the common gas outlet (left side), from external components downstream from the common gas outlet (right). The fact that nitrous oxide and air, unlike oxygen, have only one task in the machine is easy to appreciate. The five tasks of oxygen are easy to follow. Understanding the similarities and differences between the fail-safe and hypoxic guard systems is facilitated. The model makes clear that the scavenging system, rather than the patient, is the ultimate destination of gases. Oxygen is central to the figure, because it is the most essential gas delivered. The reader should note that not every component of the SPDD model in [Box 16.1](#) is depicted graphically in [Fig. 16.1](#). The reader should make frequent reference to the model while reading this chapter.

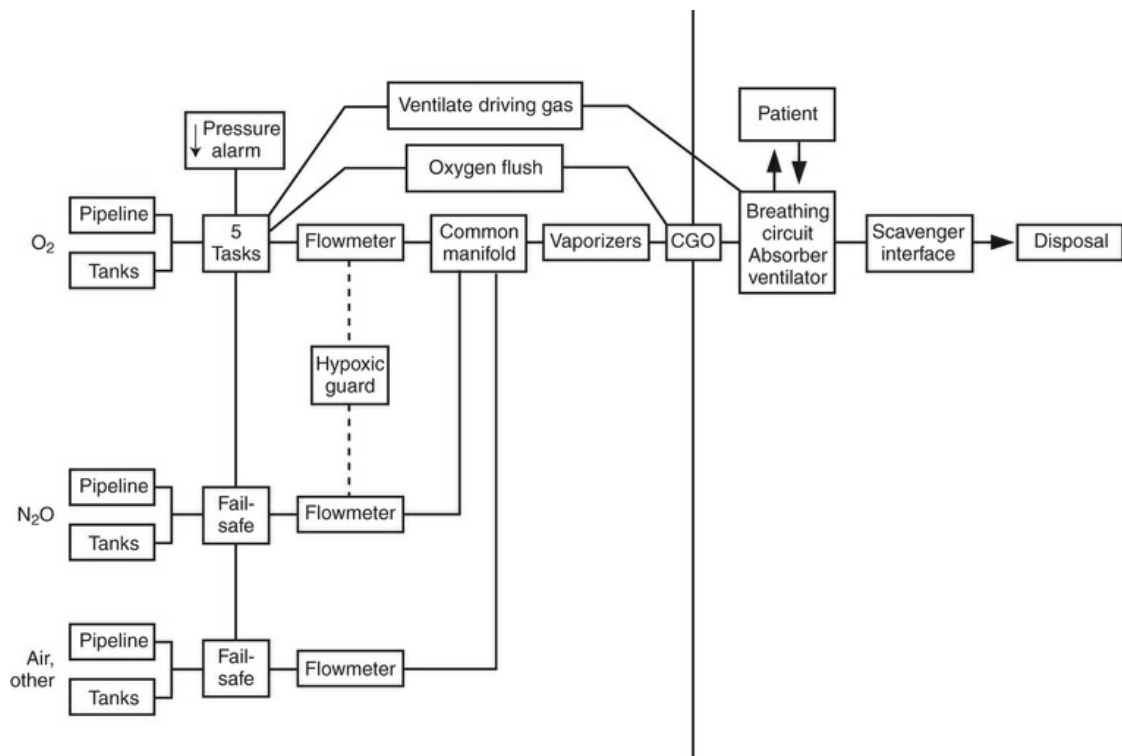

FIGURE 16.1 Supply, processing, delivery, and disposal (SPDD) model. CGO, Common gas outlet. (Courtesy Michael P. Dosch.)

Box 16.1

Components in Supply, Processing, Delivery, and Disposal (SPDD) Model

Supply

How Do Gases Come to the Anesthesia Gas Machine? (Site: Back of the Machine)

- Pipeline
- Wall outlets
- Connecting valves and hoses
- Filters and check valves
- Pressure gauges

- Cylinders
- Hanger yokes (yoke block)
- Filters and check valves
- Pressure gauge
- Pressure regulators

Processing

How Does the Anesthesia Gas Machine Prepare Gases Before Their Delivery to the Patient? (Site: Within the Machine, Proximal to Common Gas Outlet)

- Fail-safe (oxygen pressure-failure devices)
- Flowmeters (main, auxiliary, common gas outlet, scavenging)
- Oxygen flush
- Low oxygen pressure alarms
- Ventilator-driving gas
- Proportioning systems (hypoxic guard)
- Oxygen second-stage regulator (if present)
- Vaporizers
- Check valves distal to vaporizers (if present)
- Common gas outlet

Delivery

How Is the Interaction of Gases With the Patient Controlled and Monitored? (Site: Breathing Circuit)

- Gas delivery hose connecting common gas outlet and breathing circuit
- Breathing circuits
- Nonrebreathing
- Circle
- Carbon dioxide absorption
- Ventilators
- Integral monitors
- Oxygen analysis
- Disconnect
- Spirometry (volumes and flows), capnography, airway pressure
- Ventilator alarms
- Addition of positive end-expiratory pressure
- Means of humidification

Disposal

How Are Gases Disposed of? (Site: Scavenger)

- Scavenger systems
- Interface—closed (active and passive) or open
- Scavenger flowmeter

The model organizes the information on the basis of how components are used, rather than on the pressures to which they are exposed. From the viewpoint of pressure that components are exposed to, components are classified as part of the high-, intermediate-, or low-pressure systems within (proximal to the **Box 16.2** gas outlet) the gas machine ([Box 16.2](#)).

Components in the High-, Intermediate-, and Low-Pressure Pneumatic Systems

High-Pressure System (Exposed to Cylinder Pressure)

- Hanger yoke
- Yoke block with check valves
- Cylinder pressure gauge
- Cylinder pressure regulators

Intermediate-Pressure System (Exposed to Pipeline Pressure—Approximately 50 psi)

- Pipeline inlets, check valves, and pressure gauges
- Ventilator power inlet
- Oxygen pressure-failure devices

- Flowmeter valve
- Oxygen second-stage regulator (if present)
- Flush valve

Low-Pressure System (Distal to Flowmeter Needle Valve)

- Flowmeter tubes
- Vaporizers
- Check valves (if present)
- Common gas outlet

Introduction of new gas machines raises questions about the adequacy and safety of older equipment.^{1,19} One can determine whether current equipment is obsolete by considering how closely it meets current safety standards and practice needs, by the availability of service, and by the presence of essential safety features.^{20,21} Certain systems or components are required by the anesthesia workstation standard, which is a voluntary industry-group consensus standard (Box 16.3).²²

Required Components of an Anesthesia Workstation

The current anesthesia gas machine (workstation) standard is **ASTM F1850** (a standard promulgated by the American Society for Testing and Materials). F1850 specifies what is needed for an anesthesia workstation. The components are typically built into new gas machines, or they may be added to older machines. Required components include the following:

Battery Backup for 30 Minutes

Alarms

- Grouped into high, medium, and low priority
- High-priority alarms may not be silenced for more than 2 minutes
- Certain alarms and monitors must be automatically enabled and functioning prior to use, either through turning the machine on or by following the pre-use checklist: breathing circuit pressure, oxygen concentration, exhaled volume, or carbon dioxide (or both)
- A high-priority pressure alarm must sound if user-adjustable limits are exceeded, if continuing high pressure is sensed, or for negative pressure
- Disconnect alarms may be based on low pressure, exhaled volume, or carbon dioxide

Required Monitors

- Exhaled volume
- Inspired oxygen, with a high-priority alarm within 30 seconds of oxygen falling below 18% (or a user-adjustable limit)
- Oxygen supply failure alarm
- A hypoxic guard system must protect against less than 21% inspired oxygen if nitrous oxide is in use
- Anesthetic vapor concentration must be monitored
- Pulse oximetry, blood pressure monitoring, and electrocardiogram (ECG) are required

Pressure in the breathing circuit is limited to 12.5 kPa (125 cm water).

The electrical supply cord must be nondetachable, or resistant to detachment.

Cylinder Supplies

- The machine must have at least one oxygen cylinder attached.
- The hanger yoke must be pin-indexed, have a clamping device that resists leaks, and contain a filter. It must have a check valve to prevent transfilling and a cylinder pressure gauge.
- There must be cylinder pressure regulators. The machine must use pipeline gas as long as pipeline pressure is greater than 345 kPa (50 psi).

Flowmeters

- Single control for each gas
- Each flow control must be next to a flow indicator
- There must be a uniquely shaped oxygen flow control knob
- Valve stops (or some other mechanism) are required such that excessive rotation will not damage the flowmeter
- Oxygen flow indicator is to the right side of a flowmeter bank
- Oxygen enters the common manifold downstream of other gases
- An auxiliary oxygen flowmeter is strongly recommended

An oxygen flush is present, capable of 35 to 75 L/min flow that does not proceed through any vaporizers.

Vaporizers

- They must be concentration-calibrated
- An interlock must be present
- Liquid level must be indicated and designed to prevent overfilling
- “Should” use keyed-filler devices

- No discharge of liquid anesthetic occurs from the vaporizer, even at maximum fresh gas flow

Only one common gas outlet at 22-mm outer diameter, 15-mm inner diameter, which is designed to prevent accidental disconnection.

Pipeline Gas Supply

- Pipeline pressure gauge
- Inlets for at least oxygen and nitrous oxide
- Diameter index safety system (DISS) protected
- In-line filter
- Check valve

Checklist must be provided (it may be electronic or performed manually by the user).

A digital data interface must be provided.

Supply

The concept of supply is concerned with these questions. How do gases (and electrical power) come to the anesthesia workstation? What are the likely faults and hazards?

Pipeline Supply

Configuration

Oxygen is produced by the fractional distillation of liquid air. It is delivered to facilities, and stored as a liquid at a temperature of -160°C .²³ The liquid oxygen is converted to a gas and supplied to hospital pipelines at a pressure of 50 psi (344 kPa). In the operating suite, main and partial-area shutoff valves are present to isolate sections with leaks, interrupt supply in case of fire, and allow repair work on subsections. Wall outlets, or hoses dropped from the operating room ceiling, are finished with quick-connect couplers. These couplers are used so that the connection of gas machine supply hoses to wall outlets does not require tools. However, the springs and rubber gaskets (O-rings) these couplers contain provide a connection that is less secure than a wrench-tightened connection; thus they are a common source of leaks.²⁴⁻²⁶

Systems processing nitrous oxide are similar. Nitrous oxide is delivered to the hospital in large (size H) cylinders, which are connected to a manifold. Regulators reduce the pressure so that nitrous oxide, like oxygen, is supplied to the pipelines at 50 psi.²³ Consequently, 50 psi is the normal working pressure of the anesthesia gas machine. Shutoff valves and wall outlets with quick-connect couplers are similar for nitrous oxide and oxygen. Delivery piping for both nitrous oxide and oxygen uses the diameter index safety system (DISS) to prevent misconnections. In this system, gas-piping connections are sized and threaded differently so that cross-connection is difficult, though not impossible (Fig. 16.2).^{24,27} In spite of modern equipment which met standards, the connection of a nitrous oxide hose to a carbon dioxide wall outlet resulted in brief hypercarbia without lasting complications.²⁸

FIGURE 16.2 Pipeline connections using the diameter index safety system (DISS) ensure that only the correct gas hose can be connected to each inlet on the back of the anesthesia gas machine, and at the wall outlet. (From *Apollo Operator's Instruction Manual*, Document No. 90 38 237, Rev. 01. Telford, Penn: Dräger Medical Inc; 2005. © Drägerwerk AG & Co. KGaA, Lubeck. All rights reserved.)

Supply hoses connect the pipeline inlets on the back of the machine to the wall outlets. At the pipeline inlet, a filter, check valve, and pressure gauge are present. The check valve ensures unidirectional forward flow, so that a machine running on cylinder supplies, with the hoses disconnected at the wall outlet, does not leak (Fig. 16.3). The filter is required by the current anesthesia workstation standard (ASTM-F1850) because it may help prevent damage to the anesthesia gas machine from particulate matter present in the pipeline gas supply.^{22,29}

FIGURE 16.3 Check valve in the pipeline gas supply inlet at the back of the anesthesia gas machine. Gas enters from the supply hose at “Inlet” and proceeds (*downwards in the illustration*) into the machine (*left*). The right panel shows that gas cannot leak out of the machine if the supply hose is disconnected. (From Bowie, E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI: Ohmeda, a Division of BOC Health Care, Ind; 1985. In Miller RD, et al., eds. *Miller’s Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

Problems With Pipeline Supply

Some of the problems associated with pipeline use can be particularly dangerous because they are occult or infrequent. Pressure loss, excess pressure, cross-connection of gas delivery pipelines, contamination, leaks, and theft of nitrous oxide (for recreational use) have been reported.^{30,31} There were 45 deaths related to pipeline problems in the United States from 1972 to 1993, and this number is probably an underestimate.³² Two patients became hypoxemic during anesthesia due to delivery to a hospital of nitrogen tanks with oxygen fittings in 1996.²⁷ Seven deaths related to piped medical gases were reported from 1997 to 2001.³³ Two patients became hypoxemic due to purging of oxygen lines with nitrogen in 2000.³⁴ A serious failure of the bulk liquid oxygen supply was noted in 2004, but no patients were harmed.³⁵ Complications can arise if oxygen analyzers fail or are misused.^{2,36,37}

Until you can prove it wrong, always trust an oxygen analyzer which is reporting low inspired oxygen.

Pipeline supplies of gas have been reported to contain particulate, gaseous, and bacterial matter, other contaminants, and water.^{29,30,38-40} The Joint Commission allows site visitors to randomly approach and question operating room staff, to ensure they are aware of the location and function of pipeline shutoff valves and alarms related to gas supplies in their area.³⁸

Loss of Oxygen Pipeline Pressure

Loss of oxygen pipeline pressure is indicated by the pipeline pressure gauge. In addition, if pressure loss is profound, the oxygen low-pressure alarm sounds, and the fail-safe valves halt the delivery of all other gases. Some newer machines are designed to switch to air to drive the ventilator bellows when oxygen pipeline pressure is lost. It is important to note that new electronic alarms lack the distinctive and familiar “whistle” of a pneumatic oxygen low-pressure alarm.⁴¹

Two simulation studies point to the need for change in the way we teach and respond to loss of oxygen pipeline pressure.^{15,18} In a simulated loss of pipeline oxygen, most residents recognized the oxygen pressure-loss alarms. But less than half knew how to change an empty oxygen cylinder, attempted to change it (even after prompting), or recognized that bag-valve-mask (Ambu) ventilation would lead to patient awakening.¹⁸ A group of volunteer specialist anesthesiologists (who had completed residency and were in practice) managed a simulated oxygen pipeline failure equally poorly.¹⁵ In their preuse check, 70% failed to identify an empty oxygen cylinder, and only 25% checked for backup ventilation equipment (a bag-valve-mask) before induction. Most failed to conserve cylinder oxygen (by using low fresh gas flows, and turning off the mechanical ventilator), and all used untested pipeline supplies of oxygen when informed that pressure had been restored.¹⁵ These responses could be considered unwise at least, or unsafe at worst. In a third report, more than 700 anesthetics were given over a 3-week period without any checks that the emergency oxygen cylinder was full.⁴²

Management of loss of oxygen pipeline pressure has the

following goals: maintenance of oxygenation, ventilation, and depth of anesthesia; and ensuring the safety of the oxygen supply.¹⁵ **Box 16.4** gives suggestions for management.^{15,18,35,43–46} With complete loss of oxygen pipeline pressure, the anesthetist should fully open the E cylinder of oxygen, disconnect the pipeline, and consider the use of low fresh gas flows and manual ventilation (using the circle system) to conserve the emergency cylinder supply of oxygen. If the E cylinder of oxygen is not opened fully, flow from it may end before the cylinder is empty. Disconnecting the supply hose at the quick-connect fitting at the wall, though not strictly necessary during an oxygen pressure-loss, is recommended for two reasons. First, it must be disconnected in the case of a cross-connection (which is more fully described later), otherwise the contents of the oxygen cylinder will not flow. Remembering one strategy that is effective for two reasonably similar problems is easier than remembering two different strategies. Second, if the loss of pipeline pressure is followed by the flow of contaminated contents from the oxygen pipeline, disconnecting when pipeline pressure is lost **protects the patient from exposure to these contaminants.**

Management of Oxygen Pipeline Supply Failure, or Crossover

Always check for the presence of a full E cylinder and an alternative means of ventilation (bag-valve-mask [Ambu] device) before using an anesthesia machine. If pipeline pressure fails or fraction of inspired oxygen drops, follow these steps:

1. Do not attempt to fix the oxygen analyzer—it must be trusted until it can be proved wrong.
2. Turn on backup oxygen cylinder on machine fully, and disconnect pipeline. Ensure that the measured fraction of inspired oxygen (FiO_2) begins to rise. If the FiO_2 does not increase (with fresh gas flow adequate to wash in the O_2 quickly), ventilate the patient by Ambu bag with room air.
3. Use low flows of oxygen. Maintain anesthesia with a volatile agent. Ensure that FiO_2 and agent concentration are appropriate.

4. Turn off the ventilator and ventilate manually through the circle system.
5. Call for help if needed; calculate the time remaining for the current cylinder; call for additional oxygen cylinders, and install them on the machine if needed.
6. Find out how long the problem is expected to last; participate in the hospital disaster plan, which may require prioritizing oxygen for those patients who need it most.
7. Do not reconnect patient to pipeline gas until the gas supply is tested.
8. If unable to use the circle, ventilate with an oxygen source (freestanding cylinder) or with room air via a bag-valve-mask device, and institute total intravenous anesthesia.

Although excessive pipeline pressure will not trigger alarms in the machine, it should do so in the hospital physical plant or engineering department. Excessive pressure can damage respiratory apparatus or machinery of various types connected to the pipeline, including the anesthesia gas machine.

Cross-Connection of Gases

Cross-connection of gases can occur anywhere from the liquid oxygen supply and piping, to the wall outlets, hoses, and internal circuitry of the anesthesia gas machine. Incidents of cross-connection continue to be reported (as recently as 2009).^{28,47-49} Fatalities (as recently as 2002) have been associated with the shipment in error to the hospital of liquid nitrogen instead of oxygen, liquid carbon dioxide rather than nitrous oxide, the unintentional cross-connection of oxygen and nitrous oxide pipelines during renovation of an operating room, and alteration of an oxygen flowmeter so that it would fit a nitrous oxide outlet in a cardiac catheterization laboratory. A common factor associated with patient injury has been failure to use an oxygen analyzer.

Although not all of the previously mentioned incidents involved

patients connected to anesthesia gas machines, cross-connections also continue to be reported in anesthetized patients. In 1997, a case was described in which the nitrogen hose from the gas machine was discovered to be fitted with a quick-connect coupler for air (at the end that would be plugged into the wall outlet).²⁷ This did not result in patient injury, but would have allowed the delivery of 100% nitrogen had the machine been set to deliver air only. The consequences of this type of error in the oxygen wall-outlet hose could be disastrous. In 1995 it was reported in the United States that two patients became hypoxemic as a result of delivery of liquid nitrogen to the hospital in a tank with oxygen fittings.⁵⁰ In 2009 a wall fitting for carbon dioxide in a lithotripsy area allowed connection of a nitrous oxide hose from the gas machine, resulting in end-tidal carbon dioxide over 105 mm Hg.²⁸ These incidents underscore our susceptibility to the errors of ancillary personnel who install and test gas delivery apparatus. But they also highlight many patient-safety aspects under our control: properly checking oxygen analysis monitors and the anesthesia workstation before use, and proper response to oxygen-analyzer alarms.

In the event of a suspected crossover, one would see declining inspired oxygen concentration. The anesthetist must open the emergency cylinder oxygen supply, disconnect the pipeline, and use low fresh gas flows and manual ventilation (see [Box 16.4](#)). If the pipeline is not disconnected, the pipeline gas will continue to flow, rather than the cylinder oxygen supply. This is because the pressure distal to the cylinder regulator is set at 45 psi (310 kPa), compared with the typical pipeline pressure of 50 psi (344 kPa). Lower pressure is intentionally set on the cylinder regulator so that flow proceeds from the higher-pressure pipeline source if a cylinder is inadvertently left open after the machine has been checked.⁵¹ This is analogous to the situation with an intravenous main line and a piggyback line: whichever is held higher is the one that will flow (greater hydrostatic pressure). In the case of cross-connection between oxygen and nitrous oxide pipelines, the contents of the oxygen pipeline (now nitrous oxide) continue to flow (because the pipeline pressure is 50 psi), whether or not the oxygen cylinder is open. Thus, regardless of the problem with the pipeline supply (lack of pressure, or cross-connection), the cylinder must be opened;

disconnecting the pipeline in any instance of problems with the pipeline is safe. If the pipeline is not disconnected and has pressure within it, the emergency supply of oxygen may not flow from the cylinder.

Cylinder Supply

Cylinders are present on the anesthesia machine as reserves for emergency use. Thus they should be open only when they are checked, or when the pipeline supply is unavailable.⁵² A fresh oxygen cylinder is obtained if the cylinder on the machine has inadequate pressure, depending on the availability of pipeline supplies and additional backup oxygen cylinders (see later under Preanesthesia Checklist). Cylinders are labeled, marked, and color coded (Table 16.1).^{22,53} Anesthetists who practice outside the United States must be aware that the color scheme differs from country to country. Service pressure and cylinder contents are reported slightly differently in various sources.⁵⁴

TABLE 16.1
E Cylinder Characteristics*

Gas	Color, US (International)	Service Pressure psi (kPa × 10 ⁻²)	Capacity (L)	Pin Position
Oxygen	Green (white)	1900 (131)	660	2–5
Nitrous oxide	Blue (blue)	745 (51)	1590	3–5
Air	Yellow (black and white)	1900 (131)	625	1–5

*Note that slightly different values may be found in different sources.

Data from Dorsch JA, Dorsch SE. *A Practical Approach to Anesthesia Equipment*. Philadelphia: Lippincott Williams & Wilkins; 2011; *Standard Specification for Particular Requirements for Anesthesia Workstations and Their Components* [F1850-00]. Philadelphia: American Society for Testing and Materials; 2005; NFPA 99: *Health Care Facilities* [Table 5.1.11]. Quincy, MA: National Fire Protection Association; 2012:49.

Pin position refers to the pin index safety system (PISS) illustrated in Figs. 16.4 and 16.5. In this system, each cylinder valve has a unique arrangement of holes that correspond to its intended contents. The holes mate with pins in the yoke, which is the point where cylinders are attached to the gas machine. The PISS is thus another means of preventing misconnections. The system can be

defeated if the pins are missing, are removed, or if more than one washer is used. Anesthetists should check both pins and washers whenever cylinders are replaced. Furthermore, they should be aware that not all E cylinders are of precisely the right size to fit properly on the machine. Installation of a longer aluminum cylinder has interfered with the casters and prevented an anesthesia gas machine from being moved.⁵⁵

FIGURE 16.4 Pin index safety system, cylinder valve, and yoke. (Modified from Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI: Ohmeda, a Division of BOC Health Care, Ind; 1985.)

FIGURE 16.5 Pin index safety system: pin positions.
 (Modified from Ehrenwerth J, Eisenkraft J, Berry J, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. Philadelphia: Elsevier; 2013.)

The cylinder valve is the most fragile part of the cylinder, so it must be protected during transport. The cylinder valve consists of a body, the port where gas exits, a conical depression (opposite the port) for the securing screw, the holes where the pins on the yoke fit, and safety relief devices. If a fire causes the temperature and pressure within the cylinder to increase, safety relief devices release cylinder contents in a controlled fashion, rather than explosively. Manufacturers use one or more of the following on cylinder valves: a frangible disk that bursts under pressure, a valve that opens at extreme pressure, or a fusible plug made of Wood's metal (which melts at elevated temperatures).

The hanger yoke serves three functions: it orients cylinders, provides a gas-tight seal, and ensures unidirectional flow into the

machine. It also contains a filter that is required by standard.²² A unidirectional valve within the hanger yoke minimizes the likelihood of transfilling, or of leakage to the atmosphere (if a yoke is empty). It also allows cylinders to be replaced during use. If two cylinders of the same gas are open, transfilling occurs when gas flows from the cylinder with higher pressure into the cylinder with lower pressure, rather than proceeding toward the flowmeters. Transfilling is a potential fire hazard because filling a cylinder generates heat. The cylinder pressure gauge is a Bourdon-type gauge (Fig. 16.6).

FIGURE 16.6 Bourdon-type pressure gauges are aneroid gauges used for measuring cylinder (and pipeline) pressure. (Modified from Ehrenwerth J, Eisenkraft J, Berry J, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. Philadelphia: Elsevier; 2013.)

Immediately distal to the hanger yoke for each gas is a regulator (Fig. 16.7). Two diaphragms move together, connected by a rod. The smaller of the two diaphragms opens or closes the high-

pressure inlet (from the cylinder). Gas entering the regulator exerts pressure on the larger diaphragm, whose movement tends to close the inlet. Thus gas can enter the regulator only at a rate controlled by a feedback loop. The outlet pressure is adjustable by a screw and spring that bear on the inlet diaphragm. The high (but variable) cylinder pressure is converted to a constant downstream pressure (45 psi [310 kPa]), set intentionally at slightly less than pipeline pressure, in order to prevent silent depletion of cylinder contents.^{22,38} Pipeline pressure varies, depending on the load that is placed on it throughout the facility. If a cylinder is left open, and pipeline pressure drops below 45 psi, gas will flow from the cylinder. No alarm will sound to warn the user of this condition.³⁰ Furthermore, if the cylinder is left open after checking and the pipeline fails, the operator will not be alerted to the failure at the time it occurs, because gas will simply begin to flow from the cylinder, without alarms. If the mechanical ventilator is in use, a full E cylinder of oxygen may be depleted in as little as 1 hour, because the ventilator-driving gas in a bellows ventilator is usually oxygen.^{43,56} The low oxygen supply failure alarm that rings subsequently announces the end of the emergency supply, instead of its beginning. This is the rationale for keeping cylinders closed after their pressure has been checked.

FIGURE 16.7 A schematic view of a cylinder regulator.

(From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI: Datex-Ohmeda; 1985.)

The US Department of Transportation issues regulations for the manufacture, handling, transport, storage, and disposal of cylinders. These regulations have binding legal force. Industry advisory groups such as the Compressed Gas Association (CGA) and the National Fire Protection Association also have a role in setting cylinder standards. Cylinders are constructed of steel approximately $\frac{3}{4}$ inch in thickness. Only nonferrous (aluminum) cylinders may be used in the magnetic resonance imaging (MRI) environment.⁵⁴ Fatalities have occurred when steel cylinders have impacted patients in the MRI scanner.⁵⁷

Anesthetists must be aware of the rules for the safe handling and use of cylinders.^{30,58} Gas under pressure in cylinders has enormous potential energy, which may be lethal if it is released in a rapid, uncontrolled fashion following damage to the cylinder valve. Selected rules for safe handling of cylinders are presented in [Box](#)

Box 16.5

Rules for Safe Handling of Cylinders

Always

- Protect the cylinder valve when carrying a cylinder; it is the most fragile part.

Never

- Stand a cylinder upright without support; if a rack or stand is not available, lay it on its side.
- Leave empty cylinders on the machine.
- Leave the plastic cover on the port while installing the cylinder.
- Use more than one washer between a cylinder port and the yoke.
- Rely only on a cylinder's color for identification of its contents;

read its labeling.

- Oil valves.
- Remove a cylinder from a yoke without filling the space with a yoke plug if available, which is a backup strategy for guarding against check valve failure.

When installing a cylinder, check the labels, crack the valve, check that both PISS pins are present, check that only one washer is present, place the cylinder in the hanger yoke, observe for the absence of an audible leak, and check for proper gauge pressure. The valve is “cracked” to remove dirt from the port. This is done by opening the valve briefly and carefully before the cylinder is placed on the machine. While cracking the valve, hold the cylinder securely, and do not point the port toward oneself or other personnel.

When relying on cylinder supplies in an emergency, one must be able to calculate how long an oxygen cylinder will last. The following relationship should be used:

$$\frac{\text{Capacity L}}{\text{Service Pressure psi}} = \frac{\text{Contents Remaining L}}{\text{Gauge Pressure psi}}$$

Remember to consider the oxygen flow rate set on the flowmeter when deciding how long the available liters will last. As an example, if the oxygen flow is 2 L/min, and the cylinder's oxygen gauge pressure is 500 psi, how long will the cylinder last? From [Table 16.1](#), we know that the service pressure is 1900 psi and that the capacity is 660 L. Substituting these values into the previous relationship, we obtain the following:

$$\frac{660 \text{ L}}{1900 \text{ psi}} = \frac{x \text{ L}}{500 \text{ psi}}$$

and $x = 174 \text{ L}$

Because 2 L of oxygen flow each minute, the cylinder will last approximately 87 minutes ($174 \text{ L} \div 2 \text{ L/min}$). This type of calculation is not applicable to compressed gases stored as liquids (nitrous oxide or carbon dioxide). It should be remembered that this calculation refers only to requirements at the flowmeters, and assumes manual ventilation. Use of a mechanical ventilator consumes approximately a minute volume of driving gas each minute, and thus should be avoided in situations in which oxygen supply is limited to cylinders only.⁵⁶

Cylinder contents must meet the purity requirements for medical gases established by the United States Pharmacopeia (USP). The contents are also regulated in the United States by the US Food and Drug Administration (FDA). Oxygen is used to power ventilators throughout the hospital because it is dry, readily available, and relatively inexpensive.

Nitrous oxide is stored as a liquid; therefore, the cylinder pressure of 745 psi (5136 kPa) represents the vapor pressure of liquid nitrous oxide at room temperature. The nitrous oxide cylinder pressure gauge remains at 745 psi until the liquid is gone; at this point, the cylinder is more than three quarters empty. After this point, the nitrous oxide cylinder pressure swiftly declines with further use. Thus, nitrous oxide cylinders should be changed if their pressure is less than 745 psi. Rapid removal (more than 4 L/min) from a nitrous oxide cylinder may cause the formation of frost on its wall or freezing of the valve, owing to the loss of the latent heat of vaporization from the liquid nitrous oxide. Nitrous oxide is nonflammable, but it does support combustion.^{30,54} Anesthesia personnel must be alert to the possibility of nitrous oxide abuse.⁵⁹

Atmospheric air is not dry. Hospitals that use compressors to create their own medical air actively dry it because liquid water condensed in the air pipelines can cause serious damage to equipment such as anesthesia machines.^{39,40} Medical air is composed of nitrogen (78%), oxygen (21%), and argon (nearly 1%). Carbon dioxide (0.03%) and other gases are present in trace amounts.

Electrical Power Supply

Electrical power is supplied to the anesthesia workstation through a

single power cord, which can become dislodged. Because of this possibility, as well as the possibility of loss of main electrical power, new gas machines must be equipped with battery backup sufficient for at least 30 minutes of limited operation.²² Which systems remain powered during this period is specific to each model, thus users must read the operator's manuals. Patient monitors (e.g., electrocardiogram, noninvasive blood pressure, gas analysis, pulse oximetry), fresh gas flowmeters, vaporizers, and ventilators may or may not continue to function during the period that battery backup is used. Electrical receptacles are usually found on the back of the machine so that monitors or other equipment can be plugged in. These convenience receptacles are protected by circuit breakers or fuses. It is a mistake to plug devices that convert electrical power into heat into these receptacles (air or water warming blankets, intravenous fluid warmers) for two reasons.⁶⁰ First, these devices draw a lot of amperage (relative to other electrical devices), so they are more likely to cause a circuit breaker to open. Second, the circuit breakers are in nonstandard locations (so check for their location before your first case). If a circuit breaker opens, all devices that receive power there (such as monitors and, in some configurations, the mechanical ventilator) may cease to function. If one is not familiar with the circuit breaker location, valuable time may be lost while a search is conducted.

Loss of Main Electrical Power

Devices that typically require wall-outlet electrical power include mechanical ventilators, physiologic monitors, room and surgical-field illumination, digital flowmeter displays for electronic flowmeters, cardiopulmonary bypass pump/oxygenators, air warming blankets, gas/vapor blenders (Tec 6 [GE Healthcare]), and vaporizers with electronic controls (Aladin cassettes in the Aisys).

Devices (or techniques) that typically do not rely on wall-outlet electrical power include spontaneous or manually assisted ventilation, mechanical flowmeters, scavenging, laryngoscope, flashlights, manual intravenous bolus or gravity-controlled infusions, battery-operated peripheral nerve stimulators or intravenous infusion pumps, monitoring by the anesthetist using the five senses, manual blood pressure cuffs, and variable bypass

vaporizers (e.g. Tec 7 [GE Healthcare]; Vapor 2000 [Dräger Medical]).

Generally, hospitals have emergency generators that will supply operating room electrical outlets in the event power is lost. But these backup generators are not completely reliable. A 90-minute interruption in power during cardiopulmonary bypass, complicated by almost immediate failure of the hospital generators, has been described.⁶¹ Injury to personnel as they hurried in the dark to fetch lights and equipment was an unanticipated hazard.

With power failure in older gas machines, the principal problems were loss of room illumination and failure of mechanical ventilators and electronic patient monitoring. In general, new gas machines have battery backup sufficient for 30 minutes of operation; however, they are typically without patient monitors (e.g., electrocardiogram, pulse oximetry, gas analysis). Mechanical ventilation may or may not be powered by the backup battery (depending on the model). New flowmeters that are entirely electronic (Aisys and Avance [GE Healthcare]) require a backup pneumatic/mechanical (needle-valve and flowtube) flowmeter.^{19,62-64} Mechanical flowmeters with digital display of flows have a backup glass flow tube that indicates total fresh gas flow (ADU⁶⁵ [GE Healthcare]; Fabius GS⁶⁶ and Apollo [Dräger Medical]).

New gas machines with mechanical needle valve flowmeters and variable bypass vaporizers (e.g., Fabius GS, Apollo, Aespire, or Aestiva [GE Healthcare]) have an advantage in that delivery of gases and agent can continue indefinitely during electrical power failure.^{52,66} However, in the event of generator failure, anesthesia would be limited to flashlight illumination and monitoring by the five senses. The Apollo (Dräger Medical) provides gas and vapor delivery, mechanical ventilation, and integrated monitoring (e.g., oxygen, breathing circuit volume and pressure, gas analysis) for 30 minutes or more if main electrical power is lost.^{67,68} Patient monitors will not function on battery power. Pneumatic functions remain even after the battery is exhausted: vaporizers, sensitive oxygen ratio controller (S-ORC) (fail-safe and hypoxic guard), adjustable pressure-limiting (APL) valve, flowmeters, breathing pressure gauge, cylinder and pipeline pressure gauges, and total fresh gas flowmeter.

Because of the differences between models, it remains important to understand and anticipate how each particular anesthesia workstation responds when main electrical power is lost. This information may be reviewed in the operator's manual.

Processing

In this section, the various aspects of the anesthesia gas machine's preparation of gases before their delivery to the patient are discussed.

Manufacturers and Models

Manufacturers of anesthesia gas machines in the United States include Dräger Medical and GE Healthcare. There are some imported models in the market as well. Dräger Medical, Inc. (Telford, PA) is the manufacturer of the Narkomed series (6000 and 6400, GS, MRI, Mobile models), the Apollo, and the Fabius GS. GE Healthcare (Madison, WI) is the manufacturer of the Aestiva, Aestiva MRI, Avance, Aisys, Aespire, and ADU.

Gas machines that are not currently produced remain in widespread use, because the service life is long, often 10 to 15 years, or more. Currently produced models meet or exceed the specifications of the anesthesia workstation standard F1850. The differences among new gas machines are significant; thus what one learns on one model may not transfer very well to a different model. This is particularly true of preanesthesia checkout (see later). The differences are pointed out in this chapter when they are relevant to clinical practice or to demonstrate by comparison how systems function. This section continues with an overview of several current gas machines.

Apollo

The Dräger Apollo ([Fig. 16.8](#)) includes volume, pressure, flow, and inspired oxygen monitoring. It also includes gas monitoring (agent and carbon dioxide). Spirometry is optional.^{19,67,68} The piston ventilator corrects tidal volume for leaks, compliance, and fresh gas flow (by fresh gas decoupling). Mechanical ventilation is activated in two steps (the mode is chosen and then confirmed by a second key press). The ventilator is capable of manual, spontaneous, volume control ventilation (VCV), pressure control ventilation (PCV), pressure support ventilation (PSV), Autoflow (a dual-control

mode), and synchronized intermittent mandatory ventilation (SIMV) modes. SIMV may be used in either volume or pressure modes. VCV is accurate over a wide range of tidal volumes (20 mL to 1400 mL).^{68,69} Mechanical needle valves govern fresh gas flow, which is electronically measured and displayed on screen. A backup total fresh gas flowmeter tube is present. An electronic checklist assists the user in preuse checkout.⁶⁷ The scavenger interface is open.

FIGURE 16.8 Dräger Apollo. (Courtesy Dräger Medical, Inc, Telford, PA.)

Fabius GS

The Dräger Fabius GS (Fig. 16.9) includes volume, pressure, flow, and inspired oxygen monitoring; but not physiologic monitors or gas analysis. The thermal anemometry (*hot wire*) flow sensor in the breathing circuit is available in this machine and only a few others.⁶⁶ The screen displays tidal and minute volume, respiratory rate, and a respiratory pressure waveform.

FIGURE 16.9 Fabius GS. (Courtesy Dräger Medical, Inc, Telford, PA.)

The ventilator is piston driven, corrects tidal volume for compliance and leaks, and features manual, spontaneous, VCV, PCV, PSV, and SIMV with PSV.⁶⁶ Like the Apollo, the mechanical ventilator is activated in two steps (the mode is chosen and then confirmed). The machine uses a manual checklist with several electronic self-tests (e.g., system, leaks and compliance, flow sensor, oxygen sensor). With the Fabius GS (as with all the new models), users must review the operator's manual to check the machine correctly. Sample preanesthesia checkout procedures are available.⁷⁰ The flowmeters are needle valves with electronic capture and display, with a common gas outlet glass flowmeter as backup. Variable-bypass vaporizers are used, and these may be removed without tools.

The Fabius GS breathing circuit is lower volume than older gas machines (2.8 L plus bag, of which 1.2 L is absorbent volume).^{67,71} The absorber head is not warmed. Loose carbon dioxide absorbent granules or prefilled canisters may be used. There is an open scavenger interface. As with the Apollo, fresh gas decoupling causes the manual breathing bag to fluctuate during the mechanical ventilator cycle, which serves as a disconnect alarm.

In case of electrical power failure, there is a 45-minute battery reserve with fresh gas, vaporizers, integrated monitors, and ventilator operational. Because they are not part of the gas machine, patient monitors will not function. Several pneumatic functions

remain after the battery is exhausted: vaporizers, hypoxic guard, APL or “popoff” valve, flowmeters, breathing pressure gauge, cylinder and pipeline pressure gauges, and common gas outlet flowmeter.

Aisys

The Aisys CS2 (GE Healthcare), like Avance, includes physiologic monitors (e.g., electrocardiography, blood pressure, pulse oximetry).^{64,72,73} The Aisys (Fig. 16.10), introduced in 2005, uses the oxygen-driven, standing bellows Smartvent 7900 (like Aestiva) but offers more modes. Modes available include manual, spontaneous, VCV, PCV, pressure control with volume guarantee (PCV-VG), PSV-Pro with apnea backup, CPAP/PSV, and SIMV (in volume, pressure, or PCV-VG mode) with PSV.⁷⁴ PCV-VG, which is only available in Aisys and Avance, is a dual control mode. Autoflow (on the Apollo) is similar. Spirometry is included to help monitor and control ventilation. VCV offers a wide range of tidal volumes (20–1500 mL),^{69,74} so there is no need for nonrebreathing circuits for children. Like most modern ventilators, the low circuit volume, freedom from leaks, and microprocessor control support the use of low-flow anesthesia. The fresh gas inlet enters the circle system proximal to the inspiratory valve (like Aestiva).⁷⁵

FIGURE 16.10 GE Healthcare Aisys. (Courtesy GE Healthcare, Madison, WI.)

Aisys uses Aladin cassette vaporizers, which are electronically controlled. Aisys is similar to Avance, and unique in the North American market, in that it uses electronic control, measurement, and display of fresh gas flow (Fig. 16.11). The user no longer controls the flow of each gas directly, but instead selects the desired carrier gas (nitrous oxide or air), total fresh gas flow, and inspired oxygen concentration. There are no needle valves or glass flowmeter tubes to control individual flows of oxygen, nitrous oxide, or air. In case of electronic failure, there is a backup needle valve and glass flowmeter tube for control and display of total fresh gas flow.^{19,63,72}

FIGURE 16.11 Electronic control of inspired oxygen, carrier gas, and total fresh gas flow, Aisys. (Courtesy GE Healthcare, Madison, WI.)

Aestiva

The Aestiva (GE Healthcare; Fig. 16.12) has many traditional (i.e., mechanical/pneumatic) systems, but with a modern and capable 7900 ventilator. It includes volume, pressure, flow, and inspired oxygen monitoring. Gas analysis and patient physiologic monitors must be added (like Fabius).^{19,76} The 7900 ventilator uses an oxygen-driven standing bellows capable of manual, spontaneous, VCV, PCV, PSV-Pro (which includes apnea backup),⁷⁶ and SIMV.

FIGURE 16.12 GE Healthcare Aestiva. (Courtesy GE Healthcare, Madison, WI.)

The flow sensors compensate tidal volume for compliance losses and leaks in the absorber head and bellows, therefore the ventilator is accurate to very low tidal volume (range 20–1500 mL).⁷⁶ These variable orifice flow sensors have shown some sensitivity to moisture in the breathing circuit in the past.⁷⁷ The “bag/vent”

switch activates the mechanical ventilator in one step. The absorber head design allows for easier disassembly and cleaning than older models. The Aestiva uses a checklist that relies on the user to perform more manual procedures than the checklist for the Apollo, Fabius, or Aisys.⁷⁰

Flowmeters are traditional mechanical needle valves with glass flowmeter tubes. Thus there is no electronic capture of fresh gas flow, as in machines with digital flow display. The oxygen sensor is the galvanic fuel cell type, and the hypoxic guard is mechanical (Link-25).⁷⁶ Variable-bypass vaporizers are used, and these may be removed without tools. The breathing circuit is relatively high volume (5.5 L, including dual canisters of 1.35 kg absorbent each).^{71,78,79} Loose fill granules or prepackaged absorbent may be used. The machine is compatible with circle or nonrebreathing circuits. The scavenger is available as a closed scavenger interface. There is a 30-minute battery reserve with fresh gas, vaporizers, and ventilator operational. The Aestiva is also available in a version compatible with the MRI suite.

Aespire

The Aespire (GE Healthcare; [Fig. 16.13](#)) is like the Aestiva in most of its systems, but is more compact. The standing bellows, oxygen-driven ventilator offers tidal volume compensation. Volume control and pressure control are the two modes of ventilation available.⁸⁰

FIGURE 16.13 GE Healthcare Aespire. (Courtesy GE Healthcare, Madison, WI.)

Avance

The Avance (GE Healthcare; [Fig. 16.14](#)) is similar to the Aisys in most respects: electronic fresh gas flow controls with backup pneumatic control, modern and capable multimode 7900 ventilator, spirometry, and integrated physiologic monitoring. The pneumatic/mechanical Tec 6 and Tec 7 vaporizers included in the Avance are the primary difference between it and the Aisys.

FIGURE 16.14 GE Healthcare Avance. (Courtesy GE Healthcare, Madison, WI.)

ADU

The ADU (GE Healthcare) and other older designs are discussed on a companion web site.⁸¹

Path of Gases Through the Machine

Oxygen, nitrous oxide, and air follow similar paths through the anesthesia gas machine (see Fig. 16.1). Each passes from its supply point to a flowmeter. All gases (except oxygen and, in newer models, air) pass through a fail-safe valve before proceeding to their flowmeters. This valve is held open by pressure in the oxygen circuitry within the anesthesia gas machine. After passing through their respective flowmeters, the gases are joined for the first time in a common manifold. Oxygen is always added to the common

manifold downstream of other gases so that the chance of hypoxic breathing mixtures is lessened (e.g., in the event that a flowmeter tube has cracked).⁸² The combined gases enter any vaporizer that is turned on, and then pass through the common gas outlet. Formerly, a delivery hose with a locking connection conducted gases from the common gas outlet to the breathing circuit. Currently, the connection from flowmeters to the breathing circuit is often internal and thus free of any chance of disconnection or misconnection.

The breathing circuit and ventilator (or manual breathing bag in the circle) transport gases to and from the patient. An amount equal to the fresh gas flow per minute (minus patient uptake, plus gases excreted), leaves the breathing circuit and is conducted to the scavenger interface. From there, it is disposed of in the hospital ventilation or suction systems.

Five Tasks of Oxygen

Oxygen has five tasks in the anesthesia gas machine: (1) it proceeds to the fresh gas flowmeter, (2) powers the oxygen flush, (3) activates fail-safe mechanisms, (4) activates oxygen low-pressure alarms, and (5) compresses the bellows of mechanical ventilators (see Fig. 16.1). The other gases supplied by the machine have only one pathway; they are transported via flowmeter and breathing circuit to anesthetize the patient (nitrous oxide) or sustain life (oxygen and air). Some newer machines can switch to air as a driving gas for the ventilator bellows if oxygen pressure is lost.

Flowmeter

The first task of oxygen is proceeding through the flowmeter and on to the patient as a life-sustaining gas. Flowmeters have several components (Box 16.6). Control knobs are color and touch coded; thus oxygen flow control knobs are distinct, in visual appearance and tactile form, from the control knobs for the other gases (Fig.

Box 16.6

Components of Flowmeters

- Knob

- Needle valve
- Valve stops (not present on all machines)
- Flowtube
- Indicator float

FIGURE 16.15 Flowmeters on the Fabius GS are arranged vertically. The oxygen knob (*at the bottom*) is different visually, and to touch, from control knobs for air and nitrous oxide. To the left of each flow-control knob is a digital display of flow and the common gas outlet flowmeter (glass tube); to the right is the pipeline pressure gauge for each gas. (Copyright Drägerwerk AG & Co. KGaA, Lubeck. All rights reserved.)

It is not necessary to use more than fingertip force to shut off gas flow. The needle valve, which controls gas flow through the flowmeter, can be damaged if excessive force is used. Valve stops ([Fig. 16.16](#)) are usually incorporated to prevent damage, though some workstations lack them (e.g., ADU). Flow increases when the knob is turned counterclockwise. Most current gas machines use mechanical needle valves; Avance and Aisys use electronic controls for flow. On these machines, backup oxygen controls using mechanical/pneumatic needle valves are present in case of

electronic or electrical failure.

FIGURE 16.16 Flowmeter components. (From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI: Datex-Ohmeda; 1985. In Miller RD, et al., eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015.)

Display of Fresh Gas Flow.

An indicator float in a glass tube (Thorpe tube) is the classic way to capture and display fresh gas flow. Oxygen is calibrated to $\pm 5\%$ concentration (or ± 20 mL/min flow) at room temperature and sea level.⁶² Flowmeter tubes are specific for each gas and cannot be interchanged. The flowtube is tapered to be narrower at its bottom.

Thus it may be referred to as a *variable orifice flowmeter* because the annular opening around the float is larger at higher flows. If a gas has two tubes, they are connected in series with a single control valve (Fig. 16.17). It is standard in the United States (but not in the United Kingdom) for the oxygen flowtube to be placed to the right of other flowtubes. Flowmeters on the Fabius GS are unique in that they are arranged vertically, rather than side by side (see Fig. 16.15).^{66,84} Glass flowtubes are the most fragile part of the machine. They are susceptible to breakage, leaks at their seals, and inaccuracy due to the presence of dirt or static electricity.³⁰

FIGURE 16.17 When two flowmeters are present for one gas, they are arranged in series (gas flows first through fine [calibrated in mL] then coarse [calibrated in liters] flow tubes). The figure also depicts the Link-25 proportioning system. (From Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

Rather than using glass flowtubes, many newer gas machines capture flows electronically by means of an anemometer, or by a transducer and chamber of known volume. The chamber fills to a set pressure, and then the gas is allowed to proceed. The number of times this cycle occurs per minute can be converted to gas flow, which can be saved and sent to the automated medical record. These newer machines dispense with glass flowtubes, instead displaying fresh gas flows as colored bar graphs, with numeric data, on a computer screen (e.g., Fabius GS, Aisys, Apollo). At the common gas outlet, some machines with electronic flow displays

have a backup glass flowmeter to measure total fresh gas flow continuously, and in the event of screen or electrical power failure. Setting fresh gas flow on the Aisys or Avance is quite different. The flowmeter controls and display are all electronic. The user sets the inspired oxygen concentration desired, the total fresh gas flow, and what carrier gas is desired (nitrous oxide or air) (see [Fig. 16.11](#)).^{63,73,85}

Care of Flowmeters.

Flowmeters with conventional needle valves and glass flowtubes should be turned off before pipelines are connected, cylinders are opened, or the machine is turned on. If a flowtube is left open, the float will shoot to the top of a glass tube and may damage it. Flowmeters should be included in visual monitoring sweeps. Never adjust a flowmeter without looking at it. Read ball-type indicator floats in their center (Dräger) and plumb bob-type floats at the top (older Datex-Ohmeda). Remember to turn off flowmeters after each case, and particularly at the end of the day. Failure to do so may contribute to premature drying of the carbon dioxide absorbent, which not only hastens its exhaustion, but has been implicated in an increased degradation of volatile agents, the generation of carbon monoxide in canisters, and canister fires.⁸⁶⁻⁸⁸

Other Flowmeters

Auxiliary Oxygen Flowmeters.

Auxiliary oxygen flowmeters are an accessory currently offered on most models of gas machines. They are useful for attaching a nasal cannula or simple face mask. In the past, it was common to attach a nasal cannula to an adapter at the common gas outlet. The auxiliary oxygen flowmeter is advantageous, because the breathing circuit and gas delivery hose (between the common gas outlet and breathing circuit) remain intact while supplemental oxygen is delivered to a spontaneously breathing patient. Thus, if the anesthetist needs to switch from a nasal cannula to the circle breathing system during a case, he or she can accomplish this instantaneously and without the possibility of forgetting to reconfigure the breathing circuit properly. Another advantage is that an oxygen source is readily available for the Ambu bag if the

patient needs to be ventilated manually for any reason during a case (e.g., breathing circuit failure). One disadvantage is that the auxiliary flowmeter is unusable if the pipeline supply has lost pressure or been contaminated; this is because the auxiliary flowmeter is supplied by the same wall outlet and hose connection that supplies the main oxygen flowmeter. If users do not realize this, time could be wasted while they attempt to use this potential oxygen source.^{16,89} Another disadvantage is that the fraction of inspired oxygen (FiO_2) supplied cannot be varied with the auxiliary flowmeter. The chance of fire in sedated patients undergoing head and neck surgery can be lessened with reduced FiO_2 , scavenging the oxygen, and tenting the drapes.⁹⁰⁻⁹²

Common Gas Outlet Flowmeters.

Common gas outlet flowmeters (see [Fig. 16.15](#)) are used as a backup on gas machines that electronically capture and display flows on a computer screen. If offered as an option, they are strongly recommended; they are the only indication of oxygen flow if the computer display fails, or in a power-failure situation after battery backup is exhausted.

Scavenging Flowmeters.

Scavenging flowmeters are used on most new machines, which use open scavenging interfaces. An indication that suction is adequate is mandatory with these systems, in order to avoid exposure to waste anesthesia gases (see [Disposal section](#)). Unfortunately, the suction indicator is usually not visible from the operator's normal position.⁹³ On the Apollo, for example, it is on the left side of the machine, under the breathing circuit.⁶⁸ On the Aisys, the scavenger suction flowmeter (marked "AGSS") is behind the bellows, on the left side of the machine.

Oxygen Flush

The second task of oxygen in the processing area of the machine is to supply the oxygen flush valve. The flush valve is required by standard to deliver 35 to 75 L/min.²² The purpose of the flush valve is to quickly fill the breathing circuit with oxygen. The flush valve is

often protected by a rim that lessens the chance of accidental activation of the flush. Should this occur, barotrauma can result. Users should avoid activating the flush while the mechanical ventilator is in the inspiratory phase; during this phase, the ventilator relief valve closes, preventing gas from exiting to the scavenger.⁹⁴ If flushing is necessary for filling the ventilator bellows, it should be done in short pulses, during the expiratory phase. Alternatively, increasing the fresh gas flow to 8 to 10 L/min for a few breaths will fill the bellows promptly and without the need to flush.

The oxygen flush line proceeds directly from the gas supply source to the common gas outlet (see Fig. 16.1). Activating the flush bypasses the vaporizers, and adds 100% oxygen to the breathing circuit. If partial pressures of nitrous oxide or volatile agent have already been established in the breathing circuit (during maintenance), excessive use of the oxygen flush tends to dilute these inhaled agents and may lessen the depth of anesthesia.

Fail-Safe Systems

If pipeline oxygen pressure fails, and other gases such as nitrous oxide keep flowing, the patient might receive a hypoxic gas mixture (less than 21% oxygen). Therefore, gas machines incorporate devices that halt the supply of all other gases in the event of oxygen supply pressure failure. These are called *fail-safe systems*. It is required by standard that the set concentration of oxygen at the common gas outlet does not decline if the pipeline pressure decreases.²² This requirement is satisfied by the presence of gate like valves in the internal supply line for non-oxygen gases. The “gate” in each is held open by pressure in the oxygen line (Fig. 16.18). Flow of nitrous oxide may be shut off with oxygen pressure below a set limit (e.g., Avance, Aisys, Fabius GS) or proportionally decreased (e.g., Aestiva).^{62,66,72,73,76} It is important to note that fail-safe systems do not analyze oxygen pipeline contents, so they are activated only if oxygen pipeline pressure falls. They do not protect the patient from a crossover, in which oxygen pipeline pressure is intact, but the line does not contain oxygen.

FIGURE 16.18 Fail-safe valve in the nitrous oxide line. **A**, Open. **B**, Closed. (From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI: Datex-Ohmeda; 1985. In Miller RD, et al., eds: *Miller's Anesthesia*, 7th ed, Philadelphia, 2010, Elsevier.)

Fail-safe devices were once placed in air lines as well, with the rationale of leaving oxygen (however briefly) as the last gas flowing, even if oxygen pipeline pressure is lost. However, it is not possible to deliver a hypoxic mixture of air, and leaving air flowing is useful to drive the ventilator bellows in case of oxygen pipeline pressure failure. So the trend in newer equipment is to place fail-safe valves in the nitrous oxide line only, and rely on electronic proportioning systems to prevent hypoxic gas mixtures if oxygen pipeline pressure fails. This is accomplished by shutting off nitrous oxide and leaving agent and air flowing, with air available to drive the ventilator bellows.

Low-Pressure Alarms

The fourth task of oxygen is powering the low-pressure alarms, which signal the operator when pressure is lost in the oxygen circuitry. The older oxygen supply failure alarm was a container with a whistle at its outlet that was pressurized by oxygen when the anesthesia gas machine was turned on. When pipeline pressure decreased to 28 psi, or when the machine was shut off, a characteristic loud whistle was heard as the container released its contents. Newer models lack this distinctive alarm, substituting a variety of visual and auditory alarms.^{24,37,41} The proper response to loss of pipeline pressure is discussed earlier in this chapter (see

Supply section).

Ventilator Driving Gas

The fifth task of oxygen in many anesthesia gas machines is compression of the ventilator bellows. The Aestiva ventilator uses 100% oxygen as its driving gas.⁷⁸ The Aisys may use either air or oxygen, and will switch automatically from oxygen to the secondary drive gas (air) if oxygen pressure is lost.¹⁹

Newer model piston ventilators use electric motors to compress the bellows and deliver tidal volume (e.g., Fabius GS, Apollo).^{66,95} Thus ventilator delivery of tidal volume is unaffected by variation in, or even the absence of, oxygen pipeline pressure. Piston ventilators may operate for prolonged periods with only cylinder supplies of gases because they do not consume oxygen to drive the bellows. This is an advantage in office-based anesthesia, in other settings where pipelines are not available, and in emergency loss of pipeline pressure.⁹⁶

Proportioning Systems (Hypoxic Guard)

All current anesthesia gas machines incorporate nitrous oxide–oxygen proportioning (hypoxic guard) systems designed to prevent the delivery of hypoxic breathing mixtures. All link oxygen and nitrous oxide flows, so that final breathing mixtures at the common gas outlet are at least 23% to 25% oxygen. The ratio of nitrous oxide to oxygen is thus kept at no more than 3 to 1.

An example of a pneumatic-mechanical proportioning system is the Link-25 (used on Aestiva and Aespire). In this system, the flowmeter control knobs for nitrous oxide and oxygen are linked by a chain; oxygen flow is increased automatically when nitrous oxide flow is increased. The Link-25 system (Fig. 16.19) also incorporates secondary regulators, so it has both pneumatic and mechanical components.

FIGURE 16.19 A chain connects oxygen and nitrous oxide flow controls in the Link-25 proportioning system. Either may be adjusted separately, but the chain enforces at most a 3 : 1 ratio of nitrous oxide to oxygen. The chain is not normally visible. (Courtesy Datex-Ohmeda, Madison, WI.)

On contemporary machines, these hypoxic guard system controls are primarily electronic. Dräger Medical calls their system a *sensitive oxygen ratio controller (S-ORC)*, and uses it in the Apollo and Fabius.⁶⁸ This system maintains at least 23% oxygen, but does so by limiting nitrous oxide flow. Electronic alarms are incorporated, and the system includes a nitrous shutoff (so a fail-safe system is also incorporated).

Hypoxic guard systems are not foolproof. With fresh gas flow set to deliver 25% oxygen, the S-ORC hypoxic guard was unable to maintain FiO_2 of at least 21% in almost all patients when fresh gas flow was less than 1.5 L/min.⁹⁷ Box 16.7 lists four situations in which a hypoxic breathing mixture can be delivered despite the use of these systems. Lack of oxygen in the oxygen pipeline may be detected with an oxygen analyzer. A system that is broken or defective should be detected in the preuse checklist, as should leaks downstream of the flowmeters.⁹⁸ The most dangerous of these circumstances is the last, the administration of a third gas, especially that of an inert gas such as helium. It is not widely appreciated that the hypoxic guard systems link only nitrous oxide and oxygen. Perhaps because of the name, the faulty assumption is made that all hypoxic breathing mixtures are prevented. These

systems would not prevent the administration of a hypoxic mixture if a third inert gas (such as helium) is present on the gas machine. The proper use of a calibrated oxygen analyzer in each general anesthetic will always be of vital importance.

Circumstances Under Which Hypoxic Guard Systems Can Permit Formation of a Hypoxic Mixture

- Wrong supply of gas in oxygen pipeline or cylinder
- Defective pneumatics or mechanics
- Leaks downstream of flow control valves
- Inert gas administration (e.g., a third gas such as helium)

Some older machines (Narkomed, ADU) have a switch with two positions: “Nitrous Oxide–Oxygen” and “All Gases.” In the Nitrous Oxide–Oxygen position, the hypoxic guard is active, and only these two gases may flow. In the All Gases position, the hypoxic guard and alarms are inactivated, and all gases (except nitrous oxide) may flow.⁹⁹

Oxygen Analysis

Systems that warn of trouble with oxygen supply (low pressure alarms) or lessen the chances of hypoxemia (hypoxic guard system, fail-safe system) are based on pressure within the oxygen circuitry of the gas machine. They do not sample the oxygen lines to determine that oxygen is present. There is only one system that ensures that oxygen is present in the oxygen pipeline or cylinder (and ultimately in the breathing circuit and the patient): inspired oxygen analysis. Monitoring inspired oxygen is mandatory in every general anesthetic, and the function of the oxygen monitor must be checked before giving any kind of anesthesia care, because general anesthesia may need to be induced as a backup plan in any anesthetic.^{100,101}

Two types of sensors are in current use: the electrochemical, or

galvanic fuel-cell (Aestiva, Aespire), and the paramagnetic analyzer (in most other models). The paramagnetic analyzer is widely used because of its fast response, low cost, and extremely low maintenance requirements.¹⁰² A paramagnetic analyzer is often found in gas analysis monitors (which detect anesthetic agent and carbon dioxide).

Vaporizers

Underlying Physical Principles

A vapor is composed of molecules (in the gaseous phase) of a substance that is a liquid at room temperature and 1 atmosphere of pressure. Vaporization proceeds at a rate that depends on the physical characteristics of the vaporizing liquid and the temperature. Different liquids evaporate at different rates, quantified by their vapor pressure. Elevated temperature increases the rate of evaporation of any liquid, whereas decreased temperature slows the rate. As evaporation proceeds, the remaining liquid and its container cool, because heat energy is carried from the liquid with the energetic, mobile, evaporating molecules. An example would be the cooling effect of stepping out of the shower, or the chilling effect of evaporating gasoline or ether on the hand. In both cases, the evaporating molecules acquire the latent heat of vaporization from their surroundings. Thus, one would expect an anesthetic vaporizer to cool as vaporization proceeds. This cooling slows the rate of further vaporization. To prevent this, materials such as copper are chosen for containing liquid anesthetics in current vaporizers. Copper has high thermal conductivity (transferring environmental heat easily to the liquid anesthetic) and high thermal capacity (acting as a thermal reservoir to help stabilize liquid anesthetic temperature).^{30,103}

The rate of vaporization depends only on the temperature, the vapor pressure of the liquid, and the partial pressure of the vapor above the evaporating liquid—not on the ambient pressure of the remaining gases present. For example, water at a constant temperature evaporates at the same rate into completely dry air, regardless of whether it is at sea level, in a hyperbaric chamber, or at elevations far above sea level.

Classification and Design

Variable-Bypass.

Table 16.2 compares current variable-bypass vaporizers with heated-vapor (Tec 6) types.^{30,104-108} All vaporizers blend the combined flow of fresh gases from the flowmeters with sufficient vapor to form clinically useful concentrations. The problem is ensuring that the vapor concentration is appropriately limited. For example, a fully saturated isoflurane vapor consists of nearly 31% isoflurane (238 mm Hg [31 kPa], the saturated vapor pressure of isoflurane at 20°C divided by the barometric pressure of 760 mm Hg [101 kPa]).⁷⁷ To limit vapor output to a clinically useful concentration, only a small portion of the fresh gas flow is allowed to come into contact with the liquid and pick up anesthetic vapor.

TABLE 16.2
Classification of Vaporizers

Characteristic	Variable Bypass	Injector
Example	Datex-Ohmeda Tec 4, 5, 7 Aisys Aladin Dräger Vapor 19, 2000	Datex-Ohmeda Tec 6 (Desflurane)
Splitting ratio (carrier gas flow)	Variable-bypass (vaporizer determines carrier gas split)	Dual-circuit (carrier gas is not split)
Method of vaporization	Flow-over	Gas/vapor blender (heat produces vapor, which is injected into fresh gas flow)
Temperature compensation	Automatic temperature compensation mechanism	Electrically heated to a constant temperature (39°C, thermostatically controlled)
Calibration	Calibrated, agent specific	Calibrated, agent specific
Position	Out of circuit	Out of circuit
Capacity	Tec 5, 300 mL; Tec 7, 225 mL; Vapor 19, 200 mL; Aladin, 250 mL	390 mL

The splitting ratio (gas entering the vaporizing chamber, divided by total fresh gas flow) is automatically determined in a variable-bypass vaporizer by the resistance to flow in its internal channels; the operator merely has to set the control dial to the desired concentration (Fig. 16.20). Setting the dial to a higher percentage increases the amount of flow sent through the vaporizing chamber. The small portion of the gas flow entering the vaporizing chamber (*carrier gas* or *chamber flow*) flows over the liquid and picks up anesthetic vapor. Full saturation of the carrier gas is ensured by means of a series of wicks and baffles. This fully saturated (and

thus known) concentration of carrier gas at the vaporizing chamber outlet is then diluted with the balance of the fresh gas that bypassed the vaporizing chamber (*bypass flow*) to produce the desired final concentration at the vaporizer outlet.

FIGURE 16.20 The Dräger Vapor 19 vaporizer. (From Miller RD, et al., eds: *Miller's Anesthesia*, 7th ed, Philadelphia: Elsevier; 2010.)

A temperature-compensation device is built into variable-bypass vaporizers, so that more gas is directed into the vaporizing chamber if the vaporizer cools. Variable-bypass vaporizers are calibrated for concentration and are agent specific. Like the Tec 6, variable-bypass vaporizers are out of circuit, meaning out of the breathing circuit. Their capacities for liquid agent are listed in [Table 16.2](#). Variable-bypass vaporizers in the Aisys are electronically controlled, based on inputs from pressure, flow, and temperature sensors at various sites in the vaporizer ([Fig. 16.21](#)).

FIGURE 16.21 The Aladin vaporizer found on the Aisys workstation. A microprocessor controls output by monitoring F_{BC} (bypass chamber flow), F_{VC} (vaporizing chamber flow), P (pressure), and T (temperature) in the vaporizing chamber. (From Miller RD, et al, eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015.)

Measured-Flow (Vernitrol).

Anesthetists who practice in the military, or who use older equipment on mission trips outside of North America, may encounter measured-flow vaporizers. In a measured-flow vaporizer, the operator determines how much gas should be bubbled through the anesthetic liquid by means of a formula; this amount is then set on a second oxygen flowmeter, marked "Oxygen for Vernitrol." If the vaporizer cools, the operator must recalculate and set a new chamber gas flow; this is called *manual temperature compensation*. These devices can be used with multiple agents and are out of the breathing circuit. It is possible to use them safely, but their design is not as inherently safe as that of more modern types.¹⁰⁹ Measured-flow vaporizers are no longer manufactured in the United States, and factory service for them is no longer

available. The military still trains anesthetists on the use of these vaporizers, and they may be seen overseas. They are not addressed in the current anesthesia gas machine standard.²²

Tec 6 Injector.

The Tec 6 vaporizer uses a completely different principle of operation as compared with variable-bypass types (Fig. 16.22); it is a heated, dual-circuit vaporizer.^{106,110,111} Fresh gas flow from the common manifold passes through the vaporizer in one circuit. This fresh gas never flows over, or comes into contact with the liquid agent (as it would in a variable bypass vaporizer). Instead, an appropriate amount of vapor is added to the fresh gas as it flows through the vaporizer. The vapor output has two control points. One is the setting on the concentration control dial, and the other is linked to a transducer that is responsive to the amount of fresh gas flow. Thus more vapor is delivered from the vapor circuit if either the dial setting, or the fresh gas flow, is increased. To maintain a known vapor pressure in the second circuit, the Tec 6 is heated to 39°C; this produces a vapor pressure of approximately 1500 mm Hg (200 kPa). Desflurane is near boiling at room temperature; if it were placed in a conventional variable-bypass vaporizer, it would constitute nearly 100% of the output at first, and a hypoxic breathing mixture would result.¹¹² Modern variable-bypass vaporizers like Aladin are able to deliver desflurane accurately and safely, because they incorporate a variety of sensors and electronic controls.¹⁰⁸

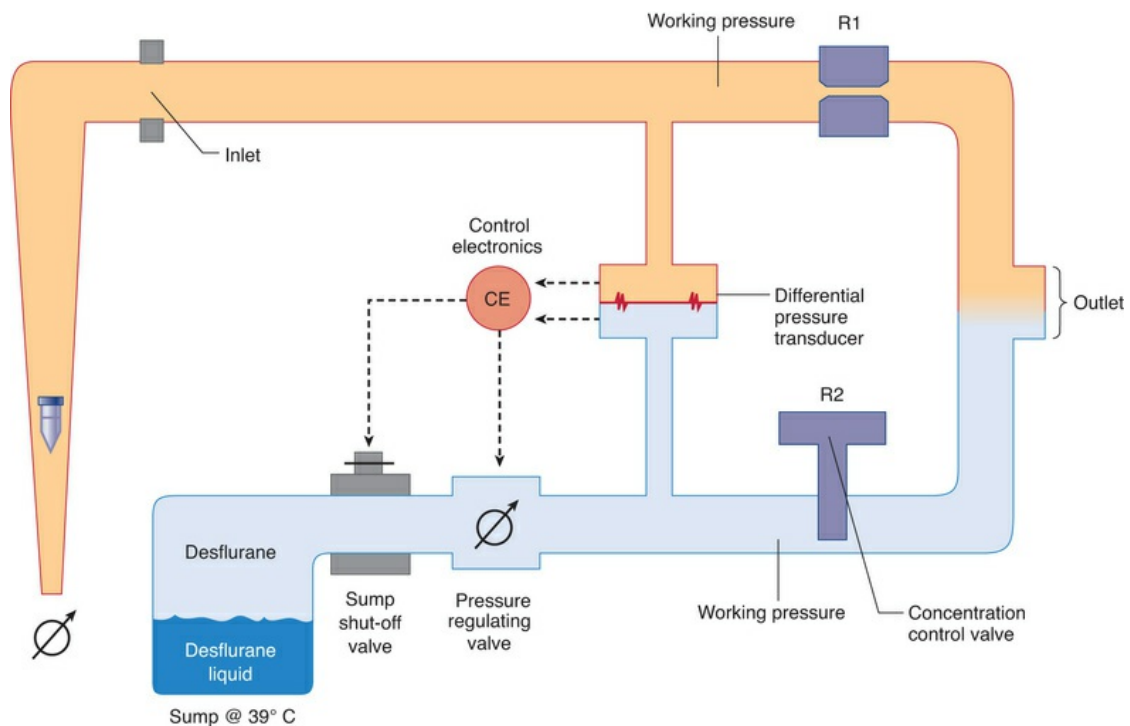

FIGURE 16.22 Principle of operation of the Tec 6 vaporizer. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

The output of any modern vaporizer may be influenced by extremes of fresh gas flow, extremes of temperature, or back pressure from the breathing circuit and ventilator. Current vaporizers function accurately over a wide range of settings, at various ambient temperatures and fresh gas flows (Table 16.3).^{106–108,113} Furthermore, they are more resistant than previous models to the effects of intermittent back pressure (the so-called pumping effect) that increases vaporizer output. This is accomplished by incorporating unidirectional valves at the vaporizing chamber inlet or outlet, or distal to the vaporizer.

TABLE 16.3
Accuracy of Current Vaporizers*

Characteristic	GE Tec 6	GE Tec 7	Dräger Vapor 2000	GE Aladin (Aisys)
Fresh gas flow (L/min)	0.2–10	0.2–15	0.25–15	0.2–8
Temperature (°C)	18–30	18–35	10–40	18–25

*The vaporizers listed function accurately within the ranges specified.

Using Vaporizers

Contemporary vaporizers are secured to the anesthesia machine in manifolds that hold two or three units. The operator is prevented from delivering more than one agent simultaneously by an interlock system. The interlock ensures that only one vaporizer is on, that gas enters only the one that is on, that all vaporizers are locked in so that leaks are decreased, and that trace vapor output is minimal when a vaporizer is off.³⁰

Variable-bypass and Tec 6 vaporizers are all filled in a similar fashion. Funnel-type (Fig. 16.23) and keyed-filler-type (Fig. 16.24) systems are permitted by standard.²² Keyed-filler types are preferred because their use lessens the chance that filling with the wrong agent will occur (although it is still possible).^{112,114-121} The standard requires that overfilling be prevented in the normal operating position, and that liquid level indicators be visible to the operator.²² These indicators usually take the form of a sight glass with two etched lines, corresponding to low and maximum liquid levels within the vaporizer. To fill either the funnel type or keyed-filler vaporizers, the anesthetist should turn the vaporizer off, check the anesthetic liquid (to ensure that the agent and the vaporizer match) and then pour it in. The vaporizer is full when the liquid level reaches the maximum line on the sight glass.^{113,120,122} It is a misconception that while using the keyed-filler vaporizer, one should hold the bottle up until it stops bubbling. If the vaporizer is turned on, is not horizontal, or the keyed-filler device is not perfectly tight on the bottle, overfilling may result.¹¹⁷ Overfilling may result in discharge of liquid anesthetic from the vaporizer outlet, which has caused patient injuries.³⁰ The Tec 6 uses a similar system, but the desflurane bottle has a permanently attached, non-interchangeable spout. The sight glass on the Tec 6 is a liquid crystal display that indicates when the level of liquid is low enough to allow the addition of a full bottle, and it shows when the sump is full. Although the Tec 6 vaporizer is unique in that it can be filled while in operation,¹⁰⁶ it is safer to turn it off momentarily to do so. All variable-bypass vaporizers must be shut off while they are being filled.^{64,113,117}

Models

The Dräger Vapor 19 fits in a manifold with an interlock system. If a vaporizer is removed from the machine, a short-circuit block must be added for leaks to be prevented. The interlock protects against simultaneous inhaled agent administration, regardless of which vaporizer is removed. There is no check valve between the vaporizer outlets and the common gas outlet in Dräger gas machines. The Vapor 19 has a button that must be depressed before the control dial can be turned on. All contemporary vaporizers are designed to increase agent concentration as the dial is turned counterclockwise (as viewed from above).

The Dräger Vapor 2000 (Fig. 16.25) is similar to the Vapor 19,

except that it is removable by hand. It has a unique “T” (transport) setting that allows the vaporizer to be tipped or transported without liquid anesthetic fouling the control mechanisms.

FIGURE 16.25 The Dräger Vapor 2000. Note the “T” (transport) setting to the right of “0.” (© Dräger. Image reprinted with permission.)

The GE Tec 7 is a variable-bypass vaporizer similar to the older Tec 4 and Tec 5 models. It is designed to require less frequent service.

Use of the GE Tec 6 vaporizer is unique, as could be suspected from its unique principle of operation. However, it is not difficult to use. To fill the Tec 6, check the desflurane bottle to ensure that it is the right agent, push it into the vaporizer firmly, and rotate it upward until the display indicates that the vaporizer is full. The

operator then rotates the bottle downward and holds it for an instant (to allow any drops to drain back into it). Finally, he or she supports the bottle while withdrawing it from the vaporizer (Fig. 16.26).¹⁰⁶ If the Tec 6 leaks as it is being filled, check for the lack of an “O” ring on the bottle spout.¹¹⁹

FIGURE 16.26 Filling the Datex-Ohmeda Tec 6 vaporizer.
(From *Tec 6 Vaporizer: Operation and Maintenance Manual*. Madison, WI: Datex-Ohmeda; 1993.)

The operator turns the Tec 6 vaporizer on by turning the concentration control dial to the “On” position while depressing the dial release (on the back of the dial, opposite the zero indicator). The vaporizer requires electric power and a warm-up period of approximately 10 minutes before it can be used from a cold start.¹⁰⁶

The Tec 6 has several visual indicators that are grouped in a status display (Fig. 16.27).¹⁰⁶ These include a light that indicates “Operational” status, a “No Output” indicator light (and audible alarm), a “Low Agent” light (and audible alarm), a “Warm-Up” status light, and an “Alarm Battery Low” light. The No Output alarms are activated if the agent level is less than 20 mL, if the vaporizer is tilted more than 10 degrees from the vertical, if there is a power failure lasting longer than 10 seconds, or if an internal malfunction occurs. The cause of a No Output alarm may be sought if it occurs during a case; however, considering the rapid emergence that is characteristic with desflurane, the operator should ensure continued depth of anesthesia by switching to a different agent without undue delay.

FIGURE 16.27 Display panel of the Datex-Ohmeda Tec 6 vaporizer. (From *Tec 6 Vaporizer: Operation and Maintenance Manual*. Madison, WI: Datex-Ohmeda; 1993.)

Preoperative checkout for variable-bypass vaporizers is relatively straightforward. They are checked to determine whether they are turned off, whether they are full, whether the filling cap is tightly closed, and whether the interlock is functioning. Depending on the machine, they may need to be checked for leaks as well.⁵² The Tec 6 requires a more extensive checkout. After performing the appropriate leak test of the machine low-pressure system, the operator checks the amber Alarm Battery Low indicator and replaces the battery if necessary. Next, he or she turns the Tec 6 on to at least 1%, and disconnects its electrical plug. Within 15 seconds of disconnection, the No Output light and alarm should activate. If they do not, the battery must be replaced and the vaporizer retested before use. If everything is functioning correctly, the operator reconnects the power and turns the dial to the “Off” position; he or she then presses the mute button for 4 seconds to test all alarms and

the display. When the mute button is pressed, all lights and the alarm should activate.¹⁰⁶

The Aladin (Aisys) vaporizer uses one central electronic control mechanism for all agents.^{108,123} Cassettes containing the liquid anesthetic are inserted into a port connected to these control mechanisms, which recognizes the contents of the cassette and dispenses agent into the stream of fresh gas flow (Fig. 16.28). The cassette inserted into the control mechanisms is checked as part of the electronic checklist daily. The Aisys will not deliver volatile agent or nitrous oxide without main power or battery backup and adequate oxygen pressure.

FIGURE 16.28 GE Aladin vaporizer cassettes. The sevoflurane cassette is plugged into the vaporizer port.
(Courtesy Datex-Ohmeda, Tewksbury, MA.)

Hazards of Contemporary Vaporizers

Many of the hazards historically associated with the use of vaporizers have been corrected by advances in design, but a few hazards remain (Box 16.8). Vaporizer contamination with incorrect agents continues to be noted.^{112,114,115} Diligence during filling is not enough to prevent contamination. Departments should strongly consider replacing funnel-type with keyed-filler vaporizers in **Box 16.8** equipment purchases.

Hazards of Modern Vaporizers

- Incorrect (unintended) agent administration
- Tipping
- Overfilling with agent
- Reliance on breath-by-breath gas analysis rather than performing regular preventive maintenance
- Leaks
- Electronic failures

Aladin vaporizers found on Aisys are not sensitive to tipping. If any other vaporizer is tipped by more than 45 degrees from the vertical, the operator's manual or a field service technician must be consulted. Tipping is hazardous, because the entry of liquid agent into the control assembly at the top of the vaporizer can have unpredictable effects on its function, including potential overdose to the patient. The vaporizer sump can be drained and gas run through it for a specified time and at a specified concentration before the vaporizer is returned to use. For the recommended corrective action for a particular make and model, the operator's manual must be consulted.

Overfilling may be prevented by following the manufacturer's guidelines for filling (e.g., fill only to the top etched line on the liquid level indicator glass, fill only when the vaporizer is off).¹²⁰ Managers should not conclude, in this era of cost constraints, that breath-by-breath agent analysis can substitute for regular preventive maintenance of vaporizers. Vaporizers go out of calibration, and may then deliver too-high or too-low concentrations of agent.¹²⁴ Leaks are relatively common, often due to malposition of vaporizers on the back bar, accidental dislodgement, loss of gaskets, or mechanical damage.^{118,125-127} These leaks may not be detected with the standard checklist, unless the negative pressure check is performed. Tec 6 vaporizers can also leak liquid while being filled if the desflurane bottle is missing the

rubber O-ring near its tip.¹¹⁹ This can be mistaken for a defective vaporizer. As vaporizers incorporate electronics, they are susceptible to electronic failure or unanticipated interactions of new designs with each other.^{125,128,129} Case reports detail Aladin vaporizers failing due to fresh gas unit failure, and from copious emesis soaking the machine.^{130,131}

New Agents and Low Flows

Low fresh gas flows should not be instituted too early after induction when desflurane or sevoflurane is used. Induction at low flows would be extremely prolonged, creating the risk of awareness in the time interval between offset of intravenous induction agents, and onset of action of the volatile agent. Overpressure can be combined with low flows, but 18% of 2 L contains far fewer desflurane molecules than 18% of 6 L, and it is the number of molecules presented to the brain per unit time that causes an increase in anesthetic tension within the brain.

Imagine a 1000-mL sink filled with water, with 100 mL/min inflow (of which 1 mL is methylene blue) and 100 mL/min outflow. The goal is turning the initially colorless water in the sink as blue as the inflow solution. Now, imagine the effect of increasing the inflow and outflow to 500 mL/min (of which 5 mL is methylene blue). Would the 1000 mL in the sink turn blue any faster in the second case? Of course, but not because the concentrations are different (both inflows are 1% methylene blue), but rather because the rate of inflow in the second example is a greater proportion of the capacity of the sink.

Wash-in is based on the concept of a time constant. One time constant (equal to capacity divided by flow) brings a system 63% of the way to equilibrium; two time constants to 86%; and three time constants to 95%. Thus the first sink will reach 63% of equilibrium in 10 minutes ($1000 \text{ mL} \div 100\text{-mL flow}$), whereas the second sink reaches this same degree of equilibrium in only 2 minutes ($1000 \text{ mL} \div 500\text{-mL flow}$). In the same way, the volume (capacity) of the functional residual capacity, hoses, and breathing circuit can be brought to equilibrium with the inflow more quickly by using a higher rate of inflow (fresh gas flow). A rational approach for ensuring anesthesia that conserves volatile agents would include a

nonbreathing (semi-open) induction (fresh gas flow, 5 to 8 L/min), followed by low fresh gas flow during maintenance (fresh gas flow, 1 to 2 L/min). This approach helps conserve tracheal heat and humidity, gases, and agent. Emergence, like induction, must occur at higher, nonbreathing flows; otherwise, it will be unacceptably prolonged.

Delivery

This section discusses how the flow of gases to and from the patient is controlled and monitored.

Breathing Circuits

Fundamental Considerations

The purpose of all types of anesthesia breathing circuits is the delivery of oxygen and anesthetic and the elimination of carbon dioxide. Carbon dioxide is eliminated from the breathing circuit by washout with adequate fresh gas flow; or by absorption in carbon dioxide absorbent granules.

Any breathing circuit creates some resistance to gas flow. Resistance in a circuit may be minimized by reducing the circuit's length and increasing its diameter, avoiding the use of sharp bends, eliminating valves, and by maintaining laminar flow. It is important to decrease resistance to flow, because added airway resistance is uncomfortable for the conscious patient. Furthermore, the unconscious or anesthetized patient, challenged by increased work of breathing, may not be able to increase respiratory effort, and hypoventilation may occur. The resistance of the anesthesia breathing circuit is low, typically less than that of an endotracheal tube.

Rebreathing of exhaled gases occurs with the use of anesthesia breathing circuits (as it does in space or submarine environments). Rebreathing does not normally occur in other breathing circuits, such as those in the ventilators used in intensive care units. Rebreathing may be useful. Its advantages include cost reduction, an increase in tracheal warmth and humidity, and a decrease in the potential for exposure of operating room personnel to trace and waste gases (because of decreased rate of release of anesthetic gases into the environment). The degree of rebreathing in an anesthesia breathing circuit is increased as the fresh gas flow is decreased, because there is relatively less fresh gas added to the circuit, and more of the next inhalation will be exhaled gas. Higher fresh gas flow is associated with less rebreathing in both circle and Mapleson

type circuits. The higher the fresh gas flow, the more quickly the composition of gas in the breathing circuit will resemble that at the common gas outlet (the dialed-in concentrations of agent, nitrous oxide, and oxygen).

Patients under anesthesia may rebreathe any component of their exhalations—nitrogen, O_2 , CO_2 , N_2O , and volatile agent. The effects of rebreathing each of these components differ. Rebreathing of exhaled oxygen has no ill effects. Rebreathing of exhaled nitrogen slows induction. Nitrogen that is not eliminated from the breathing circuit delays the establishment of the desired agent concentration; thus high fresh gas flows are appropriate during induction. In contrast, rebreathing of exhaled agent during maintenance is highly desirable for cost and environmental considerations. Rebreathing of CO_2 has the undesirable effect of producing respiratory acidosis, so it is best avoided. Because higher flows reduce the discrepancy between desired concentrations and the concentrations actually inspired, they are appropriate during emergence as well. At the end of an anesthetic, as the flow of volatile agent and N_2O is turned off, it would be undesirable for exhaled agent and N_2O to be rebreathed, because this would delay emergence. So gas that is free of agent (and nitrous oxide) is supplied at high flow during emergence, to create a favorable concentration gradient that speeds elimination of agents from the body.

Dead space is increased to some degree with the use of any respiratory apparatus. The effect of an increase in mechanical (apparatus) dead space is that rebreathing of exhaled CO_2 is more likely. This is one reason that ventilator tidal volumes are set much larger than the volume of a spontaneous breath. To avoid hypercarbia in the face of an acute increase in dead space, a patient must increase minute ventilation (V_E). Conversely, because alveolar ventilation is the minute ventilation minus dead space ventilation ($V_A = V_E - V_D$), if the patient's minute ventilation is fixed (such as by respiratory depression), increasing dead space decreases alveolar ventilation, and increases arterial CO_2 tension.¹³² Dead space ends where the inspiratory and expiratory gas streams diverge. In a circle system, dead space ends at the Y-piece. It is not increased by longer inspiratory and expiratory corrugated plastic hoses

(although, with longer limbs in the breathing circuit, there may be compliance losses that decrease tidal volume). Use of a face mask is associated with greater dead space than is the use of an endotracheal tube.

The anesthesia gas machine uses dry gases so that the problems of internal corrosion and bacterial colonization are minimized. However, provision of completely dry gases to the patient's airway can cause various problems. It is common for anesthesia providers to use various means of passively humidifying and heating inspired gases (with a heat and moisture exchanger, or by using low fresh gas flows). Active humidification has become less common, because it is less effective at preventing hypothermia than heated-air surface warming blankets, and because the added moisture can clog gas-analysis lines and soda lime granules, or obstruct unidirectional valves.⁷⁷

Anesthesia breathing circuits are unique among respiratory equipment in the degree to which they allow manipulation of the inspired concentration of a variety of components for therapeutic benefit. Each component of the breathing mixture follows its own concentration gradient because it is made to wash into the breathing system, and then to wash in from the breathing system into the patient's lungs. In the lungs, gases flow down their concentration gradients, interchanging with pulmonary and blood gases. Understanding the pharmacokinetics of inhaled agent administration involves not only knowledge of respiratory physiology, but also familiarity with the "physiology" of the patient-machine system. For example, the concentration set on the dial differs from the concentrations in the breathing circuit, in the lungs, in the blood, and in the brain. Furthermore, these concentration differences are not constant but vary over time, depending on a number of patient- and machine-related factors. The inspired concentration most closely resembles that delivered from the common gas outlet when rebreathing is minimal or absent (this is typical at high fresh gas flow). Of course, it is desirable that the alveolar concentration differ from the inspired concentration at times. At the start of the emergence phase, the inspired concentration of anesthetic is decreased so that anesthetic gas is washed out while ventilation is continued. Thus emergence is very

different from passively “waking up,” and is as much an active process as induction.

Classification of Breathing Circuits

Table 16.4 gives a classification of breathing circuits that is based on whether a reservoir (breathing bag) is present and on the degree to which rebreathing occurs.¹³³ Patients have access to the atmosphere only in open systems; this is not true in semi-open, semi-closed, or closed systems. A reservoir is present in these three types to provide for the moments during the inspiratory phase when flow in the trachea is greater than fresh gas flow. Both nonrebreathing (Mapleson, Bain) systems and the circle system, at fresh gas flows greater than minute ventilation, are semi-open.¹³⁴ If the fresh gas flow to the circle system is less than minute ventilation, some rebreathing must be occurring. If the APL, or popoff, valve is closed and very low fresh gas flows are used, the supply of O₂, N₂O, and agent just matches the patient's uptake.¹³⁵ In such a closed-circuit system, rebreathing is total.

TABLE 16.4

Classification of Breathing Circuits

Type	Reservoir	Rebreathing	Example
Open	No	No	Open drop Insufflation Nasal cannula or simple face mask
Semi-open	Yes	No	Circle at high fresh gas flow (more than minute ventilation); or a nonrebreathing circuit
Semi-closed	Yes	Yes (partial)	Circle at low fresh gas flow (less than minute ventilation)
Closed	Yes	Yes (complete)	Circle at extremely low fresh gas flow, with adjustable pressure-limiting valve closed

Nonrebreathing Circuits.

Mapleson published a classification of nonrebreathing circuits in 1954; this classification is still used today.¹³⁶ Rebreathing is prevented in systems like the Mapleson D (Fig. 16.29) because during the pause between expiration and the next inspiration, fresh gas fills the corrugated limb, forcing the previously exhaled gas distally (toward the reservoir). If fresh gas flow is sufficient, no

alveolar gas is rebreathed. The common features of nonrebreathing systems are listed in [Box 16.9](#). These circuits offer very low resistance to breathing, and can be used for patients of almost any age, from premature infants to adults. The fresh gas flow required to prevent rebreathing is two to three times minute ventilation.⁸³ This number can be calculated; however, in practice, many use a minimum fresh gas flow of 5 L/min.

FIGURE 16.29 Mapleson D system. Between the end of an expiration and the start of the next inspiration, fresh gas flow (FGF) pushes exhaled gases (containing CO₂) toward the reservoir bag. Thus, the patient's inspired gas will come from the corrugated limb, and be free of CO₂, as long as fresh gas flow is sufficient. (Modified from Ehrenwerth J, Eisenkraft J, Berry J, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. Philadelphia: Elsevier; 2013.)

Box 16.9

Common Features of Nonrebreathing Systems

- All lack unidirectional valves.

- All lack soda lime carbon dioxide absorption.
- Fresh gas flow determines the amount of rebreathing in all.
- Resistance and work of breathing are low in all (no unidirectional valves; no absorbent granules).

The Bain system is often referred to as a *modified Mapleson D circuit*, because the arrangement of its components (entry point of fresh gas, reservoir bag, and APL valve) is similar to that of the Mapleson D. However, in the Bain system, the fresh gas hose is directed coaxially within the corrugated limb, and this configuration gives the inhaled gases greater heat and humidity. Unfortunately, unrecognized kinking or disconnection of this relatively hidden fresh gas hose converts the entire corrugated limb into dead space.¹³⁷⁻¹³⁹ The resulting respiratory acidosis can be severe enough to cause arrhythmias.¹³⁹ Users of Bain systems must test the circuit for these problems before they use the system. Pethick's test and a similar test are available and should be used.⁸³

The use of nonrebreathing circuits has declined for several reasons. Many modern gas machines are not designed to accommodate them (e.g., Fabius GS). It is more common to see a pediatric circle system used, which is characterized by smaller and less compliant corrugated limbs, as compared with the adult circle system. The minimum weight of a child for which a pediatric circle would be suitable has been stated as 10 to 20 kg. However, when infants of mean weight as low as 6 kg were studied, the pediatric circle was equal to a nonrebreathing circuit in preserving blood gas values and end-tidal CO₂, whether assisted or spontaneous breathing was employed.¹⁴⁰ No one guideline applies to all situations, because the decision on whether to use a pediatric circle system in any given child depends on familiarity, clinical judgment, and the anticipated duration of unassisted respiration.

Pediatric circle systems do not place undue burdens (in terms of work of breathing) on spontaneously ventilating patients.¹⁴¹ The pediatric circle system is low compliance, the work of breathing associated with it is reasonable, it requires less reconfiguration to set up, and it allows the use of lower fresh gas flows (the high fresh

gas flow required in nonrebreathing circuits cools children and is more costly).¹⁴² Modern ventilators are accurate to very low tidal volumes (10 to 20 mL), and modern monitoring such as capnography and spirometry allows a high degree of confidence that a child is being ventilated adequately with the pediatric circle.

If a nonrebreathing circuit is used in the middle of a schedule of adult cases using the circle system, some disassembly and reassembly is required, accompanied by the possibility of error or misconnection. The small amount of resistance offered by the soda lime canisters and unidirectional valves of the circle system is deleterious only during spontaneous respiration, which is limited in duration in most general anesthesia for children. The advantages and disadvantages of nonrebreathing circuits are summarized in [Box 16.10](#). Although they are useful, nonrebreathing circuits are associated with loss of heat from the patient and with greater use of volatile agents, owing to their requirement for relatively high fresh

Box 16.10

Nonrebreathing Systems: Advantages and Disadvantages

Advantages

- Lightweight
- Convenient
- Easily sterilized and scavenged
- Exhaled gases in corrugated limb may give heat and humidity to inhaled gas (Bain)

Disadvantages

- Unrecognized disconnection or kinking of fresh gas hose in the Bain circuit (use Pethick's test)
- Pollution and increased costs of agents and gases, owing to need for higher flows

- Loss of heat from patient
- May require disconnection of circle fresh gas supply hose and scavenger connections for assembly; can be reassembled improperly

Circle System.

The circle system is the breathing circuit most commonly used in the United States, because it prevents rebreathing of carbon dioxide, while allowing rebreathing of all other gases. Gas flow during mechanical ventilation is shown in [Fig. 16.30](#). The circle system has separate inspiratory and expiratory limbs. Gas in the inspiratory limb only goes towards the patient; gas in the expiratory limb only proceeds away from the patient. The inspiratory and expiratory unidirectional valves enforce this flow pattern, which ensures that all exhaled gas is directed through the absorbent granules, and is thus cleansed of carbon dioxide. Rebreathing takes place at low fresh gas flows, but, if the valves are functioning, and the granules are unexpired, no rebreathing of carbon dioxide can occur.

FIGURE 16.30 Gas flow in a circle system during mechanical ventilator inspiration. **(A)** Shows inspiration. As driving gas compresses the bellows, it propels gas into the inspiratory limb past the inspiratory unidirectional valve, inflating the lungs. Driving gas pressure also closes the ventilator relief valve, which is the route to the scavenger. **(B)** Shows expiration. Lung deflation propels gas into the expiratory limb past the expiratory unidirectional valve. The exhaled gases fill the bellows to a small pressure first, then excess gas proceeds to the scavenger via the ventilator relief valve. A small weight within the ventilator relief valve makes filling the bellows the path of least resistance, until a small positive end-expiratory pressure (PEEP) builds up, lifting the weight, and opening the valve. NOTE: (1) Fresh gas flows into the circle continuously and (2) Flow in the circle is unidirectional, which forces all exhaled gas

through the carbon dioxide absorbent granules. (From Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

A single-limb, coaxial circle system is also available in which, like the Bain, the inspiratory limb is contained within the expiratory (Fig. 16.31). It is checked and used like any circle system. Like the Bain, the coaxial circle is less bulky, and is thought to provide greater heat and humidity to inhaled gases. Disadvantages include the potential for obstruction or lack of patency of either limb, which may cause respiratory acidosis or even mimic esophageal intubation.^{137,138} This respiratory acidosis does not respond to increased minute ventilation; if exhaled gases are not forced through the absorbent granules, no amount of ventilation will cleanse carbon dioxide from the exhaled gases. The tests for inner tube patency that can be used for a Bain circuit are not readily adaptable to the coaxial circle system.

FIGURE 16.31 In the coaxial circle system (*top*), the inspiratory limb is contained within the expiratory limb, like the Bain (*bottom*).

Gas enters the circle system from the common gas outlet by way of the fresh gas delivery hose, and it exits the circle to the scavenger via the APL valve (or the ventilator relief valve if mechanical ventilation is used). The APL valve creates an adjustable leak during manual ventilation. If it is completely open and the bag is squeezed, all gas exits to the scavenger, because this is the path of least resistance. If the valve is completely closed, all gas ventilates the lungs, and the pressure within the circle increases, because the fresh gas flowing in has no means of escape. The setting of the APL is constantly adjusted during manual ventilation of the lungs so that a resistance sufficient to force gas to inflate the lungs is maintained. If gas cannot exit through the APL or ventilator relief valve, pressure will build within the system.¹⁴³

Unidirectional valves create a pattern of gas flow that forces exhaled gases through the CO₂ absorbent granules (Fig. 16.32). The valve leaflet (disk) is subject to damage, occlusion, foreign body contamination, and sticking with collected moisture or absorbent dust, particularly on the expiratory valve disk.¹⁴⁴⁻¹⁴⁷ Daily performance of a preanesthesia checklist, as well as regular maintenance, should enable the operator to detect or prevent most of these problems. Thus there are only two common reasons for an increase in inspired CO₂: the absorbent granules have been exhausted, or the unidirectional valves are faulty. Fig. 16.33 shows that incompetence of an inspiratory or expiratory valve turns the entire corrugated limb into dead space.^{83,148} This usually results in an increase in inspired and expired CO₂.

FIGURE 16.32 Gas flows in inspiratory (*top*) and expiratory (*bottom*) unidirectional valves during inspiration. (From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI: Datex-Ohmeda; 1985.)

FIGURE 16.33 Incompetence of a unidirectional valve. **A**, Normal function. Incompetence of an inspiratory valve (**B**), an expiratory valve (**C**), or of both unidirectional valves (**D**) creates dead space (*stippled area*) that extends through the entire ipsilateral corrugated breathing hose. (Modified from Gravenstein JS, et al. *Capnography in Clinical Practice*. Boston: Butterworth; 1989.)

If inspired CO_2 of more than 1 to 3 mm Hg is detected on the capnograph (Figs. 16.34 and 16.35), the fresh gas flow should be increased to 5 to 8 L/min; this converts the system to a semi-open configuration, in which rebreathing of exhaled gases is minimized. Similar to the principle in the Mapleson nonrebreathing circuit, a high fresh gas flow in the circle dilutes exhalations and sends them to the scavenger. If substantially increasing the fresh gas flow causes the inspired CO_2 to decrease, the absorbent granules are exhausted and should be replaced at the end of the case. Some gas machines (e.g., Aisys, Apollo) with prepackaged granules or canisters allow granules to be changed during the case, although they are not meant to function for more than very brief periods without a canister attached. Furthermore, it is safest to change between cases, as problems with changing granules leading to hypoventilation continue to be reported.¹⁴⁹⁻¹⁵⁶ If elevated inspired

CO₂ persists in spite of the higher fresh gas flow, the unidirectional valves are likely to be incompetent. The operator should remove the expiratory valve (if possible), inspect and dry it, and then reassemble it (while ventilating the patient with an Ambu bag).³⁰ Note that this may be more difficult in newer absorber heads (e.g., Aisys), and will always be more difficult when the user has never performed it before. This argues for reading the operator's manual and practicing without a patient attached before the maneuver is attempted, because failure to reassemble the valve quickly will result in hypoventilation and interruption in volatile anesthetic delivery. Perhaps the best recommendation is to bring a new gas machine into the room; any valve adjustment can take place outside the pressure of the clinical situation and will not distract the anesthetist from patient care.

FIGURE 16.34 Compared with a normal capnogram (**A**), a capnogram recorded when the inspiratory unidirectional valve is incompetent (**B**) shows increases in inhaled and exhaled carbon dioxide pressure and an abnormally prolonged downstroke. The prolonged downstroke during the inspiratory phase occurs because the patient inspires mixed alveolar and fresh gas from the inspiratory limb rather than fresh gas alone. (Modified from Gravenstein JS, et al. *Capnography in Clinical Practice*. Boston: Butterworth; 1989.)

FIGURE 16.35 Compared with a normal capnogram (**B**), a capnogram recorded with an incompetent expiratory unidirectional valve (**A**) shows increases in inspired and expired carbon dioxide concentration but no changes in morphology. (Modified from Gravenstein JS, et al. *Capnography in Clinical Practice*. Boston: Butterworth; 1989.)

It is mandatory to check unidirectional valves before use. There are a multitude of means proposed to check the unidirectional valves, which vary in ease of performance and complexity.^{30,145,157} One suggested method with applicability to a variety of gas machines follows: A spare breathing bag is placed on the elbow fitting at the patient's end of the Y-piece, and mechanical ventilation of this "artificial lung" is begun. The user carefully observes that the valves lift and fall, and that gas flows back and forth in a tidal fashion between the mechanical ventilator bellows and the artificial lung expected during inspiration and expiration.⁶⁵ The test should be repeated using the manual/spontaneous limb of the circuit, simulating assisted ventilation of the artificial lung. Breathing through the elbow or mask of a clean circuit (with a paper mask on) is an alternative method, but presents problems of cross-contamination. Dräger suggests a similar test, but also breathing through each limb individually as follows⁶⁶: If the inspiratory limb is detached and occluded with one's palm, the operator should be able to exhale, but not inhale, through the expiratory limb. Similarly, if the inspiratory limb is replaced and the expiratory limb detached and occluded, the operator should be able to inspire, but not expire, through the inspiratory limb. This test may be more sensitive than the first test mentioned. If a preanesthesia check is performed daily, the capnograph is used properly, and the operator is aware of the steps that should be taken in the event of an increase in inspired CO₂, perhaps this more rigorous test need be performed only if unidirectional valve function is in doubt, particularly because it is problematic to perform this more rigorous test in a

hygienic fashion.³⁰

Simulating manual or ventilator breathing checks not only for unidirectional valve function, but also checks for obstruction to expiration secondary to mold flash or plastic wrap emboli, problems that have resulted in mortality.^{5,146,158-164} Checking for breathing circuit obstruction is critical, because an obstructed circuit can prevent positive pressure ventilation, simulating bronchospasm at induction.⁵ Newer machines have electronic routines to check for leaks and compliance. This helps the ventilator accurately deliver the set tidal volume. These checks must be repeated when the type of circuit is changed, for example, from adult to pediatric. With any newer gas machine, the corrugated plastic breathing circuit hoses should be expanded before the electronic leak and compliance test is initiated.

The advantages and disadvantages of the circle system are listed in [Box 16.11](#). One advantage of at least partial rebreathing is relative constancy of inspired concentrations. In a completely nonrebreathing circuit, each breath is fresh gas, so depth can vary much more quickly. The use of lower flows also reduces the rate of release of anesthetic agents into the environment. The circle conserves respiratory tract humidity. Misconnections, although a potential disadvantage, occur much less frequently now than in the past, because the diameter of breathing hoses (22 mm) has been standardized to be different from the diameter of scavenger hoses (19 or 30 mm).²² Nevertheless, misconnections continue to be reported.¹⁶⁵⁻¹⁶⁷ Maintenance of the circle system is detailed in the operator's manuals, and these must be consulted before one

[disassembles](#) and cleans the absorber head.

Circle System: Advantages and Disadvantages

Advantages

- Constant inspired concentrations
- Conservation of respiratory tract heat and humidity
- Minimal operating room and environmental pollution

- Useful for closed-system, low-flow, and semi-open configurations
- Low resistance (less than the endotracheal tube; not as low as in nonrebreathing circuits)

Disadvantages

- Relatively complex
- Opportunities for misconnection or disconnection
- Malfunctioning unidirectional valves cause serious problems
- *Open*: Rebreathing
- *Closed*: Occlusion
- Less portable than nonrebreathing circuits
- Increased dead space (true of all respiratory apparatus; extends to the point where inspired and expired gas streams diverge [i.e., at Y-piece])

Several design changes in newer circle systems facilitate low-flow anesthesia. Low fresh gas flow is desirable to reduce pollution and the cost of using volatile agents and nitrous oxide, preserve tracheal heat and moisture, delay the drying of carbon dioxide–absorbent granules, and preserve patient body temperature. Factors that enhance the safety and efficiency of low flows in modern circle

Box 16.12 Breathing systems and ventilators are shown in [Box 16.12](#).

Breathing System and Ventilator Design Features That Support Low-Flow Anesthesia

- Compliance and leak testing, automatic leak detection
- Fresh gas compensation or decoupling

- Warmed absorber heads (in some models)
- Low-volume and less-leaky absorber heads (allow faster equilibration of dialed and delivered agent concentration)
- Fabius GS 1500-mL canister (Fabius GS volume is 2800 mL, including bag for entire breathing system)
- Aestiva 2700 mL (canisters alone)
- Aisys 2.7 L (vent mode), 1.2 L (bag mode)
- No mandatory minimum oxygen flows (there are exceptions; Aespire and Aestiva, at 50 mL/min)

A traditional-sized absorber head like the Aestiva is larger than the volume of many of the newer designs.^{71,74,76} Circles with smaller volume will have shorter time constants. The time constant equals capacity divided by flow, and measures how quickly a breathing system reaches equilibrium with a change in the inflow. In a circle system with lower volume, changes in dialed concentration of agent will be reflected more quickly in the inspired concentration, at any flow rate, as compared to a higher volume circle system. In a nonrebreathing circuit, or a circle system at flows substantially higher than minute ventilation, each breath reflects the dialed concentration of agent, because there is no rebreathing of exhaled gases in either. Thus a circle system with higher flows is suitable when rapid changes are desired, such as at induction and emergence.

There are, however, circumstances in which to avoid low flows (fresh gas flow 1 L/min). Absolute contraindications include patients with smoke inhalation injury, malignant hyperthermia, or other conditions in which washout of potentially dangerous gases or a high oxygen uptake is expected. If equipment breakdown occurs mid-case that would affect the safety of low flows (i.e.,

failure of inspired oxygen or anesthetic agent monitors, or failure of soda lime granules), higher flows should be used. Relative contraindications to low fresh gas flows include when using older equipment that is less leak-proof, face mask anesthesia, during rigid bronchoscopy, and with the use of uncuffed endotracheal tubes.¹⁶⁸

Humidification and prevention of nosocomial infection are desirable with the use of any respiratory apparatus. Both of these goals may be addressed with breathing circuit filters that incorporate heat and moisture exchange with filtration (HMEF).¹⁶⁹ The use of low flows during maintenance results in an increase in circuit humidity and a lower rate of use of volatile agents. Heat- and moisture-exchanging filters precipitate exhaled water vapor on their filter media. The next inhalation returns this moisture to the patient. HMEF filters may slow the rate of heat loss from the patient, because they decrease the rate of evaporation of water from the tracheal mucosa. They may also confer the benefit of bacterial and viral filtration. Even if HMEF are used, cleaning the bellows is necessary after anesthesia has been provided to a patient with a disease transmitted by airborne particles or oral secretions. To limit contamination of the machine, consider avoiding the mechanical ventilator, using bacterial/viral filters on the Y-piece or on each limb, and changing the soda lime after the case.

The American Association of Nurse Anesthetists (AANA) Standards for Nurse Anesthesia Practice and infection control guidelines call on anesthetists to use safety precautions to minimize the risk of infection for the patient, the anesthetist, and other staff.^{170,171} It is certain that anesthesia equipment, as well as providers, are contaminated with potential pathogens.¹⁷² Furthermore, many of the surfaces of the anesthesia gas machine and monitors have been shown to be contaminated with blood, both visible and occult.¹⁷³ It is therefore mandatory for patient safety to ensure that departmental cleaning and sterilization programs are adequate, that good housekeeping during administration of anesthesia is practiced, and that universal precautions are observed. For equipment, the AANA advocates a classification system and specific equipment recommendations that are published in their *Infection Control Guide*.¹⁷⁴ In addition, manufacturers include directions for cleaning and sterilizing

equipment in their operation and maintenance manuals.

Carbon Dioxide Absorption

Carbon dioxide absorption makes rebreathing of exhalations possible. Thus it conserves agent, oxygen, nitrous oxide, and tracheal humidity, while preventing the respiratory acidosis that would result from the rebreathing of CO₂.

Fresh gas flow determines the amount of rebreathing in the circle system. A circle system with fresh gas flows of 0.3 to 0.5 L/min (closed-circuit) provides near-total rebreathing, and full reliance on absorbent for prevention of rebreathing of CO₂. At the other extreme, use of a circle system with fresh gas flows above minute ventilation (greater than 5 to 8 L/min for a traditional large, dual-canister absorber head) is associated with little if any reliance on absorbent granules, because exhaled carbon dioxide is rapidly diluted and sent to the scavenger with such high fresh gas inflows.^{83,168} This relationship can be confusing. When faced with exhausted granules, which cause an increase in expired (and inspired) CO₂, one may be tempted to increase minute ventilation (V_E) by increasing tidal volume, respiratory rate, or both. This approach is ineffective with exhausted absorbent (even though it is the obvious response for controlling hypercarbia from other causes), because the patient simply inspires more of a gas mixture from which CO₂ has been inadequately absorbed. The correct response to hypercarbia associated with exhausted absorbent is increasing fresh gas flow (and then changing the absorbent at the end of the case). Whereas this can be accomplished mid-case with the newer absorbent canister designs, it is safest to wait until the case is over, controlling CO₂ with high fresh gas flow in the interim.

Chemistry

The chemistry of soda lime CO₂ absorption is shown in [Box 16.13](#). The ionic reactions take place on the surface of the granules in an aqueous medium. An appropriate water content (10% to 20% depending on formulation) is important for the speed and efficiency of the reactions. Dry granules become exhausted much

more quickly than moist granules. Activators (NaOH, KOH) are added to increase the speed of the reaction. Potassium hydroxide is used much less frequently, because it has been implicated in reactions that produce carbon monoxide and compound A from degradation of inhaled anesthetic agents.^{175,176} The activator combines with carbonate ions in a reversible reaction that produces water and energy. The absorption of 1 mole of CO₂ produces 13,000 kcal of heat energy.¹³² Absorbents contain ethyl violet as an indicator of absorbent pH. Fresh CO₂ absorbent has a caustic alkaline pH because of the sodium hydroxide. As the reactions proceed, the pH becomes less alkaline. At a critical pH of 10.3, the ethyl violet changes from colorless to blue-purple.

Carbon Dioxide Absorption in Soda Lime

1. $\text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{CO}_3$
2. $\text{H}_2\text{CO}_3 + \text{NaOH} \leftrightarrow \text{Na}_2\text{CO}_3 + \text{H}_2\text{O} + \text{energy}$
3. $\text{Na}_2\text{CO}_3 + \text{Ca}(\text{OH})_2 \rightarrow \text{CaCO}_3\downarrow + \text{NaOH}$

For soda lime, reaction 1 is also called the first neutralization reaction; reaction 3 is also called the second neutralization reaction. Note that activator is regenerated in step 3. KOH may take the place of NaOH, and K₂CO₃ may take the place of Na₂CO₃ in steps 2 and 3.

Soda lime does not regenerate to any extent; in other words, it does not regain capacity to absorb CO₂ during periods when it is not in use. Its capacity is similar whether it is used continuously or intermittently. However, it does exhibit some color reversion (a change in appearance from blue-purple back to white) during a rest period. The color of the absorbent at the beginning of the day may not reflect its remaining capacity because of this color reversion.¹³² When a subsequent anesthetic is begun, the color of absorbent that had not seemed exhausted initially may quickly change to blue-purple. Therefore, it is recommended that the user judge the degree of color change at the end of each case, and change the canister

before the next case if necessary.

Soda Lime

The characteristics of soda lime and other selected absorbents are listed in Table 16.5.^{87,177–180} The main constituent of most absorbents is calcium hydroxide. Hardeners (silica and kieselguhr) may be added to soda lime. Soda lime is manufactured to have a water content between 13% and 20% by weight. The size of all granular absorbent is 4 to 8 mesh, meaning they will pass through screens with 4 to 8 holes per inch. The selection of granule size involves a compromise between resistance to flow and absorption efficiency. Larger granules have less resistance to gas flow; however, they are also less efficient because their surface area is relatively small with respect to their mass. Fine granules or soda lime dust would have a great deal of resistance to gas flow, but their efficiency would be high because of their increased surface area.

TABLE 16.5
Characteristics of Absorbents

Component	Sodasorb (WR Grace)	Medisorb (GE)	Drägersorb 800 Plus (Dräger)	Amsorb Plus (Armstrong Medical)*	Litholyme (Allied Health Care)	Spiralith (Medipore)
Ca(OH) ₂ %	50–100	70–80	75–83	> 80	> 75	—

Soda lime degrades most current volatile agents, with sevoflurane degraded most, and desflurane least. Degradation may produce compound A (sevoflurane), carbon monoxide (the ethyl methyl ethers isoflurane and desflurane), and other compounds. Degradation is favored by dry absorbent, and the presence and quantity of strong bases (potassium hydroxide more than sodium hydroxide).^{175,181–183}

Sevoflurane is unstable in soda lime, producing compound A. Compound A is lethal in rats at 130 to 340 ppm, and may cause renal injury at 25 to 50 ppm. Compound A concentrations of 25 to 50 ppm are achievable in normal clinical practice if extremely low fresh gas flows are used. The incidence of toxic (hepatic or renal) or lethal effects from sevoflurane, used in millions of humans, is comparable to desflurane.¹⁸⁴ The product insert does not recommend sevoflurane at total fresh gas flows less than 1 to 2 L/min for more than 2 minimum alveolar concentration (MAC)-hours.¹⁸⁵ The production of compound A may be affected by the particular gas machine used. At a constant fresh gas flow, it was produced least in the gas machine with the lowest circuit and absorbent volume.¹⁷⁹

Carbon monoxide is produced by desflurane, much more than isoflurane, when these agents are in contact with absorbent granules. Sevoflurane produces little, if any, carbon monoxide. Production of carbon monoxide is greatest in dry absorbent. It is recommended that oxygen be turned off at the end of each case, absorbents changed regularly (particularly if fresh gas flow is left on over the weekend or overnight), and low flows used (this will tend to keep granules moist). Current recommendations for avoiding problems with carbon monoxide are summarized in [Box](#)

Box 16.14

Recommendations on the Safe Use of Carbon Dioxide Absorbents

1. Use carbon dioxide absorbents with lower (or no) amounts of strong bases (particularly potassium hydroxide [KOH]).
2. Create institutional, hospital, and/or departmental policies regarding steps to prevent desiccation of the carbon dioxide absorbent.
3. Turn off all gas flow when the machine is not in use.
4. Change the absorbent regularly, on Monday morning, for instance.
5. Change absorbent whenever the color change indicates exhaustion.
6. Change all absorbent, not just one canister in a two-canister system.
7. Change absorbent when uncertain of the state of hydration, such as when the fresh gas flow has been left on for an extensive or indeterminate time period.
8. If compact canisters are used, consider changing them more frequently.
9. Low flows also have a role in preserving humidity in absorbent granules. Use relatively low fresh gas flows for the majority of procedures, changing flows from high to low as soon as practical in any given case (after the patient has attained maintenance levels of volatile anesthetic).

Absorbents Lacking Strong Bases

The strongly basic activators (NaOH, and particularly KOH) have been convincingly implicated in the carbon monoxide problem with the methyl ethyl ethers (especially desflurane) and the generation of compound A by sevoflurane. Many absorbents available in North America lack KOH, and may have reduced amounts of NaOH (see [Table 16.5](#)). Because of the controversial efficiency of absorbents that lack all strong bases, most soda lime-based absorbents have

been modified to include less NaOH, and no KOH (see [Table 16.5](#)). The goal is to maintain efficiency, while lessening the production of byproducts. Dräger Medical makes an absorbent with decreased amounts of NaOH and no KOH: Drägersorb 800 Plus. GE Medical supplies Medisorb, which lacks KOH, in the prefilled canisters for all of their gas machines (i.e., Aestiva, Aisys). Eliminating both activators entirely produces an absorbent that has similar physical characteristics and carbon dioxide absorption efficiency (the second being controversial) as compared with soda lime, while avoiding the problems of Compound A or carbon monoxide generation (Amsorb Plus [Armstrong Medical Ltd., Coleraine, Northern Ireland]).^{87,180,186,187}

Lithium may also be used as a catalyst for soda lime absorbents. Litholyme (Allied Healthcare Products Inc, St Louis, MO) is a soda lime-based absorbent whose main constituent is $\text{Ca}(\text{OH})_2$ and which contains lithium chloride, presumably as a catalyst, though the formulation is proprietary (see [Table 16.5](#)).^{188,189} Litholyme does not degrade inhaled agents to carbon monoxide or Compound A even if dessicated, does not undergo color reversion, and is efficient in absorbing carbon dioxide.¹⁸⁹

Lithium hydroxide (rather than $\text{Ca}(\text{OH})_2$) is the main constituent of Spirolith, a unique absorbent which is efficient, and does not degrade volatile agents. It does not desiccate since its water content is chemically bound.^{190,191} Spirolith is a powder enclosed in a polymer sheet, making the absorbent recyclable, and also limiting the danger to eyes and skin posed by dust in traditional absorbents. Because it lacks a color indicator, it may only be used with fractional concentration of inspired CO_2 (FiCO_2) monitoring.¹⁹²

Using Carbon Dioxide Absorbents

Certain similarities are apparent with all absorbents. The resistance of filled canisters in a circle system is low (less than 1.5 cm H_2O at a flow rate of 100 L/min). Resistance of other breathing circuit components, particularly the endotracheal tube, is greater. Inhaled absorbent dust is caustic and a respiratory irritant (it may lead to laryngospasm, bronchospasm, and pneumonia).¹³² A trap for water, which also prevents the passage of dust toward the patient, may be

incorporated distal to the granules in circle systems; if present, it must be emptied periodically. In addition, when the breathing circuit is pressurized for checkout, the pressure should be released through the APL valve, rather than through the elbow at the patient's end. This technique not only prevents the propulsion of dust toward the patient, but is also useful for checking APL valve function.

Absorbent efficiency is decreased by channeling and the wall effect.^{187,193} The amount of CO₂ absorbed varies throughout the canister. The inside edge of the canister wall is a low-resistance pathway. Exhaled gas follows this pathway, or other low-resistance pathways, through the canister, forming channels whose capacity to absorb CO₂ is exhausted before the capacity of the bulk of the absorbent is used. Thus the wall effect and channeling produce exhaustion of absorbent before its theoretic capacity has been reached. To help prevent these two effects, shake the canister before installation in the circle system, to promote uniform packing throughout.¹³² Finally, ensure that the canister is without cracks and, if loose-fill granules are used, the lid is in the locked position after refilling. Cracks, even in new canisters, are not an uncommon source of circuit leaks. There is at least one case report of a canister exploding open, spreading granules on the floor, when the circuit pressure went above 30 cm H₂O while bag-masking a patient after induction. This caused a rather large leak, and upon further testing, it was shown that the soda lime canister was not properly locked after it was refilled.¹⁹⁴

Exhaustion and Replacement of Canisters

The clinical signs of absorbent exhaustion are shown in [Box 16.15](#). Some of these signs (e.g., hyperventilation) may be masked in the anesthetized patient. In practice, increased FiCO₂ and indicator color change are primary indications of exhaustion. It is unwise to rely on color change or canister temperature alone as a measure of exhaustion.¹⁹⁵ The process of canister replacement for Aestiva-style dual-canister absorbers is illustrated in [Fig. 16.36](#), and the steps for replacement are shown in [Box 16.16](#). Canister replacement for the [Box 16.15](#) is shown in [Fig. 16.37](#).

Clinical Signs of Carbon Dioxide–Absorbent Exhaustion

Early

- Increase in partial pressure of end-tidal carbon dioxide; may be accompanied by an increase in inspired carbon dioxide
- Respiratory acidosis
- Hyperventilation
- Signs of sympathetic nervous system activation (flushed appearance, cardiac irregularities, sweating)
- Increased bleeding at surgical site
- Color of indicator

Late

- Increase (and later a decrease) in heart rate and blood pressure
- Dysrhythmia

FIGURE 16.36 Changing dual-canister carbon dioxide absorbers. (From Schreiber P. *Safety Guidelines for Anesthesia Systems*. Telford, 1985, Drägerwerk AG & Co. KGaA, Lubeck.)

Box 16.16

General Steps for Changing Carbon Dioxide–Absorbent Canisters

1. Protect eyes and skin with goggles and gloves. Wear a mask if pouring loose absorbent.
2. Note purple color, date last changed, or both.
3. Loosen clamp or screw.
4. Remove and discard top canister.
5. Remove plastic wrap and seals from new canister.
6. Insert new canister on bottom, and the old bottom canister on top.
7. Retighten screw.
8. Check breathing circuit for leaks.

NOTE: Be hesitant to change any canister in mid-case, as they do not always go back together smoothly. Do not change a dual canister in the middle of a case; convert to a semi-open breathing circuit by using 5 to 8 L/min fresh gas flow.

FIGURE 16.37 Changing carbon dioxide granules in the

Aisys, viewed from the left side of the workstation. First release the latch (*at thumb in left panel*), and the canister will pivot downwards on its hinge (*right*). Pull the old canister out, slide the new canister in on the bracket rails, then rotate upwards until the latch clicks. (From Datex-Ohmeda, Inc. *Aisys User's Reference Manual - Part 2 of 2, Document No. M1122365* 10 07 01 04 23. Tewksbury, MA: Datex-Ohmeda, Inc.; 2008.)

Do not change Aestiva-style dual canisters or loose fill in the middle of a case, and be hesitant to change absorbent mid-case on any machine. If the new canister is placed in its clear plastic holder upside down, or if for any other reason the circuit cannot be reassembled promptly, resumption of ventilation might be delayed.¹⁴⁹⁻¹⁵² If granules do become exhausted, a safer alternative strategy is to change fresh gas flow to 1 to 2 times the minute ventilation; this approach should ensure that expired CO₂ is reduced to acceptable levels. The granules can then be replaced after the case.

Each canister (top or bottom) in an Aestiva-style dual absorber contains 1.1 kg of granules in a volume of 1400 to 1500 mL.^{76,78,196} This compares to 0.8 kg per canister in the Aisys. Each 100 g of granules has a theoretical capacity to absorb as much as 15 L of CO₂ before the outlet concentration is 1% (7.6 mm Hg), assuming that no channeling occurs. The average to maximum production of CO₂ by the anesthetized adult is 12 to 18 L/hr.¹³² Therefore, when total rebreathing is occurring during closed circuit anesthesia, the top canister in an Aestiva might be expected to last for 8 to 10 hours of continuous use. A much longer life is observed clinically for these large canisters, principally because higher flows are used (typically in many clinical settings, 2 to 4 L/min of fresh gas flow). These higher flows cause increases in both the dilution of exhaled CO₂, and the rate of washout of exhalations from the breathing circuit to the scavenger. In one study in which fresh gas flows of 4 L/min were used, two canisters were used for 67 and 79 hours (anesthesia time) over 2.5 weeks without exhaustion, with a final minimum water content in some segments of 4% to 8.5%.¹⁹⁷ As lower flows become more common for economic and environmental reasons, and canisters become smaller, anesthetists will need to remain vigilant for the signs of absorbent exhaustion, and realize that

absorbent must be changed more frequently.¹⁹⁸

The manufacturer of Sodasorb recommends that the absorbent be changed if it is left in the machine for longer than 48 hours.¹³² Dräger recommends that absorbent in the Fabius be changed if the machine has been idle for 48 hours, or at least each week on Monday.⁶⁶ These extremely cautious guidelines are based on recognition of two problems that arise with extended use. First, the ethyl violet indicator present along the wall of the canister may be inactivated by drying, or intense light. Second, dehydration of the granules occurs over time, particularly if higher gas flows or an excessive amount of oxygen flush is used. It is not uncommon for gases to be left flowing accidentally overnight or over the weekend. The resultant dehydration of the granules reduces their efficiency, and makes production of carbon monoxide and compound A more likely.⁸⁷

Ventilators

Classification and Theory of Operation—Gas-Driven Bellows Ventilators

Modern ventilators using compressible bellows are multimode, double-circuit, electronically controlled, volume- or pressure-limited ventilators. Because they are electronically controlled, these ventilators cannot operate without main electrical power or a backup battery. Ventilators in current use may be classified with respect to a number of parameters (Box 16.17). Fig. 16.30 shows gas flow in the breathing circuit with mechanical ventilation. The bellows is similar to the anesthetist's hand squeezing a breathing bag, in that both force gas into the patient's lungs. The mechanical ventilator is a "bag in a bottle"; it uses the force of compressed gas (O₂ or air) as the driving mechanism to compress the bellows.

Within the bellows is the gas inspired and expired by the patient. Thus the bellows contains what the patient breathes, and separates it from the surrounding driving gas. Leaks in the bellows may cause dilution of gas within the bellows by driving gas, or loss of

Box 16.17 agent and oxygen from within it.¹⁹⁹

Classification of Modern Ventilators

Power Source

- Gas-driven bellows—compressed gas and electricity
- Piston ventilator—electricity only

Drive Mechanism

- Double-circuit—bellows compressed by driving gas, which surrounds and compresses the patient circuit gas within. The driving gas is 100% oxygen or compressed air.
- Piston ventilators (compression of patient gas is by an electrically driven piston)

Cycling Mechanism

- Electronically time-cycled. Flow can also terminate when a volume or pressure target is achieved.

Modes

- Manual/spontaneous
- Volume-controlled ventilation (VCV)
- Pressure-controlled ventilation (PCV)
- Synchronized intermittent mandatory ventilation (SIMV) in either volume or pressure mode, with or without pressure support of the patient's spontaneous breaths
- Pressure-support ventilation (PSV)
- Pressure-controlled ventilation with volume guarantee (PCV-VG)
- Continuous positive airway pressure (CPAP)

Bellows Classification

- Gas-driven bellows
- Most have ascending (standing) bellows.
- Descending (hanging) bellows are seen less commonly.
- Piston ventilators are driven by electric motors.

Data from Dosch M. *The Anesthesia Gas Machine: Ventilators*, 2011. Accessed 2016 at: <http://www.udmercy.edu/crna/agm/08.htm>; Dorsch JA, Dorsch SE. *Understanding Anesthesia Equipment*. 5th ed. Philadelphia: Lippincott, Williams & Wilkins; 2008; Dorsch JA, Dorsch SE. *A Practical Approach to Anesthesia Equipment*. Philadelphia: Lippincott, Williams & Wilkins; 2011.

Without a means of escape, the continual addition of fresh gas flow into the breathing circuit would cause increased volume and pressure within it (and in the patient's lungs). A ventilator relief valve (also known as the *bellows pop-off valve*, *spill valve*, or *overflow valve*) maintains circuit volume and pressure by releasing gas to the scavenger, in an amount equal to the fresh gas flow per minute. The ventilator relief valve opens only during the expiratory phase (see [Fig. 16.30](#)). During inspiration, driving gas closes this relief valve, inflating the lungs by preventing gas within the bellows from exiting to the scavenger as the bellows are compressed. During early expiration, a weight within the ventilator relief valve holds the pathway to the scavenger closed until the bellows have filled. This creates 2 to 3 cm H₂O of positive end-expiratory pressure (PEEP) within the breathing circuit. This small amount of PEEP is inherent to the design when standing-bellows mechanical ventilation is used.^{52,200} Note that the “Bag/Vent” switch set to “Vent” or “Auto” removes the reservoir bag and APL valve from the breathing circuit (not true for ventilators with fresh gas decoupling), so, in a standing bellows ventilator, the APL valve can be open during mechanical ventilation without causing a leak.

Hanging Bellows.

A few ventilators with gas-driven bellows have “hanging” bellows.

To distinguish between ascending (standing) and descending (hanging) bellows, use the mnemonic, “Ascend and descend contain *e*'s, so look at the bellows during *exp*iration to distinguish them.” Both standing and hanging bellows are safe; both are capable of alerting the user to a disconnection, as long as appropriate monitoring is used.²⁰¹ Standing bellows have an advantage in that they will not fill in the event of a disconnect, whereas hanging bellows may fill with room air even when completely disconnected from the patient. Water may gather in the bellows (lessening tidal volume and creating an infection risk), but this should be lessened if the absorber head is heated.

Theory of Operation—Piston-Driven Ventilators

Piston ventilators use an electric motor to compress the gas in a rigid piston during inspiration. They use no driving gas and may be used without depleting the oxygen cylinder in case of oxygen pipeline failure.²⁰² Piston ventilators, like gas-driven bellows, are safe and effective.

In the Apollo ventilator, the piston is out of view, and its motion is not normally visible during mechanical ventilation. The anesthetist relies on pressure and capnography waveforms, plus the movement of the manual breathing bag, to guard against disconnects or other problems. The Fabius GS also has a piston ventilator, but the bellows travel vertically, and their movement is continuously visible through a window to the left of the flowmeter bank.

The piston ventilator has positive and negative pressure relief valves built in. If the pressure within the piston reaches 75 ± 5 cm H₂O, the positive pressure relief valve opens. If the pressure within the piston declines to -8 cm H₂O, the negative pressure relief valve opens, and room air is drawn into the piston, protecting the patient from negative end-expiratory pressure (NEEP).^{66,68}

There are several advantages to a piston ventilator.²⁰² It is quiet. There is no PEEP (2 to 3 cm H₂O is mandatory on standing bellows ventilators because of the design of the ventilator spill valve). There is great precision in delivered tidal volume, owing to compliance and leak compensation, fresh gas decoupling, and the rigid piston

design. There are fewer compliance losses with a piston, as compared with a flexible standing bellows compressed by driving gas. Electricity is the driving force for the piston, so if oxygen pipeline pressure fails, or pipeline supplies are unavailable (as in office-based settings), mechanical ventilation may continue without exhausting the cylinder oxygen simply to drive the bellows. Piston ventilators (like gas-driven bellows) are capable of all modern ventilation modes.

The piston design also has some disadvantages.³⁰ They do not display the characteristic motions of a standing bellows during disconnects, or when the patient is breathing over and above the ventilator settings. But disconnects can be seen in a piston ventilator with fresh gas decoupling (see later), because the manual breathing bag remains in the breathing circuit during mechanical ventilation with a piston. The piston is quiet, so that it may be harder to hear its regular cycling. The piston ventilator design cannot easily accommodate nonrebreathing circuits, although this is also true of newer ascending bellows ventilators like the Aisys. The piston has the potential for NEEP and dilution of the patient's inspired gas with room air.

Typical Ventilator Alarms

Modern ventilators have safety alarms to protect the patient from a number of conditions (Box 16.18). One important safety feature of modern equipment is that apnea (disconnect) alarms are enabled with the first breath sensed. Alarm fatigue has received attention recently, with missed alarms being called a top-ten health technology hazard for 2016.²⁰³ Audible alarms should not be **Box 16.18** rendered permanently in routine circumstances.

Causes of Critical Incidents

Underlying Causes of All Critical Incidents

- Improper or infrequent maintenance
- Inadequate in-service education
- Substandard equipment monitoring

- Failure to check equipment before use
- Lack of familiarity with equipment standards

Mechanisms of Critical Incidents

Failure to Ventilate

- Disconnection
- Failure to initiate ventilation or resume it after an interruption
- Misconnections of breathing circuit
- Occlusion or obstruction of breathing circuit
- Kinking or plugging of endotracheal tube
- Kinking of fresh gas delivery hose
- Mold flash or plastic emboli from wrapping material
- Leaks
- Failure or improper reassembly of bellows after cleaning
- Damage to or disconnection of pressure monitoring or other hoses
- Failure of pipeline and tank oxygen supply
- Driving a vent with cylinders (when pipeline is unavailable) causes rapid tank depletion
- Inadvertent application of suction to the breathing circuit
- Failure of scavenger interface negative-pressure relief valve

- Intubation of trachea with nasogastric tube, which is then connected to suction

Barotrauma

- Excess inflow to breathing circuit (flushing during ventilator inspiration)
- Ventilator relief valve may stick closed
- Control assembly problems

Ventilator Modes and Settings

Besides increased tidal volume accuracy (because of compliance and leak compensation), the most notable advance in current ventilators is their expanded modes of ventilation, most of which are pressure control. PCV allows more efficient and safe ventilation for certain types of patients. PCV with volume guarantee (PCV-VG or Autoflow) helps to maintain tidal volume in the face of changing lung compliance; for example, when pneumoperitoneum is applied or released. PSV and CPAP are important recent additions for patients who are spontaneously breathing, which is seen with much greater frequency since the adoption of the laryngeal mask airway. The improvement in accuracy afforded by modern ventilators at small tidal volumes means that switching of circuits (e.g., to a nonrebreather for small children) are not used as often. This helps avoid potential misconnects. Finally, the proliferation of ventilation modes and monitors (spirometry, flow-time waveforms) has been matched by additional controls available to the anesthetist (e.g. inspiratory flow and time, trigger window and sensitivity, Pmax, Tpause, etc.). Whereas the additional controls allow ventilation to be optimized for a wide variety of patients and situations, they add complexity and learning burdens for the workstation operator. The reader should consult discussions of individual controls and how the various controls interact.^{83,200}

Volume-Controlled Ventilation.

All ventilators offer VCV. In this mode, the desired tidal volume

(V_T) is delivered at a constant flow. The ventilator is volume limited, time cycled, and constant flow in VCV. Inspiration is terminated when the desired V_T is delivered or if an excessive pressure is reached (60 to 100 cm H₂O).^{66,68,72} Patients under general anesthesia often have decreased functional residual capacity and compliance.²⁰⁴ Because volume is controlled, alveolar ventilation and arterial carbon dioxide can be maintained despite changes in pulmonary function.²⁰⁵ However, with VCV, the peak inspiratory pressure is uncontrolled, and rises as the patient's compliance decreases or airway resistance increases.

V_T is adjusted to prevent atelectasis, and respiratory rate (RR) is adjusted to keep end-tidal carbon dioxide at the desired value. Tidal volumes in the range of 5 to 7 mL/kg ideal (predicted) body weight, with PEEP and alveolar recruitment maneuvers, are currently advocated to avoid the dangers of atelectasis and ventilator-induced lung injury.^{206,207} Peak inspiratory pressure (PIP) is monitored but not controlled. Typical initial settings for VCV in an adult are V_T 5 to 7 mL/kg ideal body weight, RR 6 to 12 breaths per minute titrated to end-tidal CO₂, and inspiratory:expiratory (I:E) ratio 1:2. PEEP of 5 to 10 cm H₂O may be added to prevent atelectasis.²⁰⁵ In any mode, if the flow-time waveform shows that expiratory flow is incomplete before the next inspiration (resulting in auto-PEEP), RR should be decreased, or the I:E ratio prolonged (e.g. 1 : 3 instead of 1 : 2).^{200,205}

Pressure-Controlled Ventilation.

In PCV mode, PIP (Pmax) is limited, and the cycle is controlled by time, with a decelerating flow pattern. In a decelerating flow pattern, inspiratory flow is strongest early in inspiration (in order to reach the set pressure quickly), and declines to flow just sufficient to maintain the set pressure later in inspiration. This flow pattern increases lung inflation and oxygenation, at the lowest PIP.

However, the increase in mean airway pressure may decrease venous return and cardiac output.²⁰⁸ Inspiratory pressure is controlled rather than volume (as with VCV).^{205,209} Tidal volume is uncontrolled, and increases if compliance increases, or airway resistance falls. If the desired tidal volume is not obtained, either

P_{max} or inspiratory rise (the rate of inspiratory flow) can be increased. Target pressure is adjusted for the desired V_T ; RR is adjusted to maintain a reasonable end-tidal carbon dioxide. In patients with low compliance (e.g., morbidly obese), PCV may result in an increased tidal volume at a lower PIP compared to VCV, especially if PIP had been high when employing VCV (e.g., in laparoscopic abdominal or pelvic surgery). V_T must be monitored closely in PCV. During PCV, if pulmonary compliance drops (e.g., application of pneumoperitoneum) or airway resistance increases (e.g., bronchospasm, kinked endotracheal tube), delivered V_T may drop substantially. Conversely, if pulmonary compliance improves (e.g., release of pneumoperitoneum, return to supine from steep Trendelenburg position) or airway resistance decreases, V_T may increase substantially.

There are several indications for PCV. Patients for whom high inspiratory pressure is particularly dangerous may benefit (e.g., laryngeal mask airway, emphysema, neonates).²¹⁰ In patients with low compliance, PCV can often produce higher tidal volumes than VCV (e.g., pregnancy, laparoscopic surgery, morbid obesity, or adult respiratory distress syndrome). PCV can compensate for leaks (e.g., infants with uncuffed endotracheal tubes, laryngeal mask airway). PCV may provide effective ventilation and lower airway pressure during one-lung ventilation.^{209,211}

Typical initial settings for PCV in an adult include pressure limit 12 to 20 cm H₂O, RR 6 to 12 breaths per minute, I:E ratio 1:2. PEEP 5 to 10 cm H₂O may be added to help prevent atelectasis.²⁰⁰ Pressure control is the basis of other modes, such as PCV-VG (which adjusts inspiratory pressure to lessen variation in delivered V_T ; see hereafter) and as SIMV with pressure control breaths.

Synchronized Intermittent Mandatory Ventilation.

With the advent of the laryngeal mask airway (LMA) and the prevalence of short, ambulatory, or office-based surgical procedures, spontaneous unassisted breathing has become much more common during general anesthesia. But it may be difficult to maintain a light enough plane of anesthesia to permit spontaneous ventilation, while still retaining sufficient depth for surgery to

proceed. If the spontaneously breathing patient is maintained in a plane of anesthesia that is too deep, respiratory acidosis will occur. Indeed, it is difficult to see how anesthetized patients breathing without assist could ever have normal blood gas tensions, given the influence of respiratory depressant volatile agents and intravenous drugs, as well as the effects of positioning. Yet if the patient is kept too light, bucking and awareness are risks. The traditional solution was to assist ventilation manually, because unsynchronized volume control ventilation was all the mechanical ventilator could provide. Ventilation modes that could support a spontaneously breathing patient (i.e., provide normocapnia without bucking) include SIMV, PSV, CPAP, and airway pressure release ventilation (APRV).^{200,205,212,213} On newer gas machines, SIMV may be selected based on either pressure or volume controlled breaths. SIMV can be used for anything from full to partial support of ventilation. Typical settings for SIMV mirror those used for VCV (or PCV if a pressure-controlled mode is chosen).

In SIMV the intermittent mandatory breaths are delivered in synchrony with the patient's spontaneous efforts. Trigger window (percent) and sensitivity may need to be adjusted (Fig. 16.38). Any spontaneous breaths occurring outside the trigger window for the next large mandatory breath may also be pressure supported (SIMV-PS).^{66,73}

FIGURE 16.38 Trigger window and sensitivity may be set when choosing synchronized intermittent mandatory ventilation (SIMV). (From *S/5 Anesthesia Delivery Unit User's Reference Manual*, Catalog No. 8502304. Madison, WI: Datex-Ohmeda;

Trigger window controls the percent of time during expiration that the ventilator is sensitive to spontaneous breaths (the negative pressure generated by the patient's diaphragm). Sensitivity controls how much negative pressure the patient needs to generate before a breath is triggered. If spontaneous breaths are triggered too often (e.g., by motion in the surgical field), the trigger window should be reduced, or the sensitivity made more negative.

Pressure-Controlled Ventilation With Volume Guarantee.

Pressure-controlled ventilation with volume guarantee (PCV-VG on GE machines; Autoflow on Dräger models) was created to address the problem that V_T in pressure control mode varies, sometimes strikingly, when the patient's compliance changes. Like PCV, the basic controls are maximum pressure and rate, but in PCV-VG, a target V_T is also set. Like PCV, the ventilator delivers breaths using a decelerating flow pattern at a pressure which is less than P_{max} . But in PCV-VG, the inspiratory pressure is adjusted to deliver the target V_T , using the lowest possible pressure, and staying within the maximum pressure limit. PCV-VG begins by delivering a volume breath at the set V_T . The patient's compliance is determined from this volume breath, and the inspiratory pressure level is then adjusted for the next breath. PCV-VG combines the advantages of pressure-controlled ventilation, yet dynamically compensates for changes in the patient's lung characteristics (Fig. 16.39).^{73,200}

FIGURE 16.39 Pressure-controlled ventilation with volume guarantee. The pressure waveform at top shows that peak inspiratory pressure is adjusted up and down (4) to deliver the set tidal volume. The bottom is a flow-time waveform. 1, Paw waveform; 2, T_{insp} ; 3, T_{exp} ; 4, Variable pressure to deliver desired TV; 5, PEEP; 6, Flow waveform; 7, TV. *Paw*, Airway pressure; *T_{insp}*, time for inspiration; *T_{exp}*, time for expiration; *TV*, tidal volume; *PEEP*, positive end-expiratory pressure. (From *Aisys User's Reference Manual*, part 2 of 2, Document No. M1122365 10 07 01 04 23. Tewksbury, MA: Datex-Ohmeda, Inc; 2008.)

Pressure-Support Ventilation.

PSV is like PCV in that it is a pressure-controlled ventilation mode, but with an RR of zero. It is like SIMV in that it is responsive to the patient's efforts, delivering pressure to the airway (which causes inspiratory flow), provided the effort occurs within a trigger window and enough negative inspiratory pressure is generated. Thus it is only useful for patients who are breathing spontaneously. There is no minimum minute ventilation, although some ventilators allow setting an apnea backup rate or delay (PSVPro on Aisys).^{200,205}

PSV is useful to augment the V_T of a spontaneously ventilating patient during maintenance or emergence. It may also be useful during denitrogenation, in part because PEEP may be added in patients at high risk for atelectasis.²⁰⁷ The primary setting is the pressure-support level, which, for adults, may be started at 10 cm H_2O , and adjusted based on tidal volume and end-tidal carbon

dioxide. Trigger window, sensitivity, maximum inspiratory flow, and apnea backup rate may also be set, depending on the particular ventilator (Fig. 16.40).

FIGURE 16.40 Trigger window and sensitivity settings interact with the patient's spontaneous breaths in pressure-support ventilation. The two breaths at the left are triggered by patient efforts; the breath at the right comes only after a period of apnea. (Modified from Ehrenwerth J, Eisenkraft J, Berry J, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. Philadelphia: Elsevier; 2013.)

Continuous Positive Airway Pressure (CPAP), Bilevel Positive Airway Pressure (BiPAP) and PEEP.

CPAP may be available as a mode on some newer machines. If not, manipulating PSV mode settings can serve as a conduit to two other useful ventilation modalities: CPAP and Bilevel Positive Airway Pressure (BiPAP). Whether using an endotracheal tube, LMA, or face mask, one can employ these modes if there is a proper seal and connection to the ventilator. CPAP may be useful during

denitrogenation, and immediately postanesthesia, as well as in patients at risk for postoperative atelectasis.²⁰⁷ One may engage CPAP by selecting PSV mode, adjusting the pressure support to zero, and adding PEEP to the desired CPAP level. For instance, setting the pressure support to 0 cm H₂O and PEEP to 5 cm H₂O, will maintain a continuous airway pressure of 5 cm H₂O. CPAP increases intrathoracic pressure, prevents airway and alveolar collapse, prevents atelectasis, and maintains functional residual capacity. However, CPAP does not assist the bellows function of the chest, and thus cannot ensure alveolar ventilation. Also, as CPAP delivery pressure (PEEP) is increased, conscious patients may find the resistance to exhalation troublesome.²¹⁴

BiPAP is PSV with P_{max} greater than PEEP, and PEEP greater than zero.²¹⁴ It can (unlike CPAP alone) maintain adequate minute ventilation (as long as there are spontaneous breaths), as well as provide the benefits of CPAP mentioned earlier. Typical BiPAP settings on an anesthesia ventilator are: PSV mode, P_{max} 10 cm H₂O, and PEEP 5 cm H₂O.^{200,205,214}

Safety Features of Modern Ventilators

Flexibility.

The availability of pressure control modes is a major advantage, allowing more challenging patients to be ventilated efficiently, such as patients with acute respiratory distress syndrome or morbid obesity who are difficult with VCV mode. PCV also increases safety for patients in whom excessive pressure must be strictly avoided, such as neonates and infants, and patients with emphysema. PSV and SIMV are quite valuable in supporting the patient with spontaneous respirations. Perhaps the biggest hurdle in implementation for all new modes is the education of generations of providers who are only familiar with “plain vanilla” volume control mode.

Accuracy at Lower Tidal Volumes.

Factors contributing to a discrepancy between set and delivered tidal volumes are especially acute in pediatrics, and include the

large compression volume of the circle system relative to the infant's lung volume, leaks around uncuffed endotracheal tubes, the augmentation of delivered V_T produced by fresh gas flow, and the difficulty of setting a small V_T using an adult bellows assembly.¹⁹

Modern ventilators have an unprecedented V_T range for two reasons; greatly increased accuracy in V_T delivery achieved through electronic compliance and leak testing, and V_T that is compensated for these factors and for changes in fresh gas flow. They are able to ventilate smaller patients much more accurately than any previous anesthesia ventilator could. This has significantly lessened the need for nonrebreathing (Mapleson) circuits and made care safer, because anesthesiologists no longer have to disassemble and reconfigure a nonrebreathing circuit for a child in the middle of several adult cases. However, it is mandatory to substitute pediatric circle disposable hoses for small tidal volumes (less than 200 mL with the Fabius).²¹⁵ The lower limit of accuracy for V_T in VCV mode is 20 mL (for Fabius,⁶⁶ Aestiva, Apollo,⁶⁸ Avance,⁶² and Aisys⁷⁴). When sensors or disposable breathing circuit types are changed for a pediatric case, users must repeat the leak and compliance tests of the preanesthesia check, so that maximum V_T accuracy is ensured. Likewise, these must be repeated when returning to the adult configuration.

Compliance and Leak Testing.

Accuracy in delivered V_T comes with a price. An electronic leak and compliance test is part of the morning checklist, and it must be repeated every time the circuit is changed to a circuit with a different configuration (adult circle to pediatric circle, or adult to long circuit). Users must familiarize themselves with whether vaporizers and other components are included in the leak and compliance test, because what is actually checked varies between different models.

The placement of the sensor used to compensate tidal volumes for compliance losses and leaks has some interesting consequences. The Aestiva flow sensors are placed between the disposable corrugated breathing circuit limbs and the absorber head. Here they

are able to compensate tidal volumes for fresh gas flow, compliance losses, and leaks internal to the machine and absorber head, but not for any of these that occur distally (in the breathing hoses). The D-Lite sensor (ADU) is placed at the Y-piece. In this position, it can compensate for all leaks and compliance losses out to the Y-piece (thus including the breathing circuit hoses). However, at this point, it adds appreciable bulk and weight close to the patient's face. This may make mask ventilation more cumbersome. Furthermore, a sensor closer to the patient is exposed to more exhaled moisture, but the impact on monitoring integrity can be lessened with a heat and moisture exchanger between patient and sensor. Unfortunately, this adds further bulk and weight. The Apollo, Aisys, and Fabius test compliance and leaks of all components to the Y-piece via a pressure transducer within the internal circuitry near the bellows. Here the sensor is relatively protected from moisture.

Fresh Gas Decoupling Versus Tidal Volume Compensation.

Another factor adding to modern ventilator accuracy is that they compensate delivered tidal volume for changes in fresh gas flow. In older ventilators, the delivered V_T is the sum of the volume delivered from the ventilator and the fresh gas flowing during the inspiratory phase, so the actual delivered V_T changes as fresh gas flow is changed. For example, consider a patient with a fresh gas flow of 4 L/min, an RR of 10, an I:E ratio of 1 : 2, and a V_T of 700 mL. During each minute, the ventilator spends a total of 20 seconds in inspiratory time and 40 seconds in expiratory time (as a result of the 1 : 2 ratio). During these 20 seconds, the fresh gas flow is 1320 mL (one third of 4000 mL/min fresh gas flow). So each of the 10 breaths of 700 mL is augmented by 132 mL of fresh gas flowing while the breath is being delivered, and the actual delivered V_T is 832 mL/breath (a 19% increase).

What happens when we decrease the fresh gas flow to 1000 mL/min? During each minute, the ventilator spends 20 seconds in inspiratory time and 40 seconds in expiratory time (1 : 2 ratio). During 20 seconds, the fresh gas flow is 330 mL (one third of 1000 mL/min fresh gas flow). So each of the 10 breaths of 700 mL is augmented by 33 mL of fresh gas flowing while the breath is being delivered, making the total delivered tidal volume 733 mL/breath.

This means that changing fresh gas flow from 4000 mL/min to 1000 mL/min, without changing ventilator settings, has resulted in a 12% decrease in delivered V_T (832 to 733 mL). It would not be surprising if the end-tidal carbon dioxide rose slightly as a result.

The situation is more acute with a child ventilated without fresh gas flow compensation. Assume a 10-kg patient with a fresh gas flow of 4 L/min, an RR of 20, I:E ratio of 1 : 2, and a V_T of 60 mL. During each minute, the ventilator spends 20 seconds in inspiratory time and 40 seconds in expiratory time (1 : 2 ratio). During these 20 seconds, the fresh gas flow is 1320 mL (one third of 4000 mL/min fresh gas flow). So each of the 20 breaths of 60 mL is augmented by 66 mL of fresh gas flowing while the breath is being delivered, making the total delivered V_T 126 mL/breath. This is a 110% increase above what is set on the ventilator. Decreasing fresh gas flow from 4 to 1 L/min, again without changing ventilator settings, decreases tidal volume (by the same calculation) from 126 to 76 mL (a 40% reduction).

There are two approaches to dealing with the problem. The Apollo and Fabius use fresh gas decoupling ([Fig. 16.41](#)). Fresh gas flow during inspiration is not added to the delivered V_T , because it is diverted (by the closed decoupling valve) to the manual breathing bag, which remains in circuit during mechanical ventilation. The same fresh-gas decoupled circuit is shown during expiration in the bottom panel of [Fig. 16.41](#). The piston refills with the patient's exhaled gas, and also fresh gas contained in the manual breathing bag (through the open decoupling valve). The ventilator relief valve is now open, allowing excess gas to exit to the scavenger.

FIGURE 16.41 Circle breathing system with fresh gas decoupling. (See text for explanation.) *NPR*, Negative pressure relief valve. (From Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

Fresh gas decoupling helps ensure that the set and delivered tidal volumes are equal in spite of changes in fresh gas flow. The visual appearance of the circuit during mechanical ventilation is unusual in that the manual breathing bag (normally quiescent in bellows ventilators) moves with each breath. Further, this manual breathing bag movement is opposite to the movement seen in a mechanical ventilator bellows, which empties during inspiration, and fills during expiration. With fresh gas decoupling, the manual breathing

bag inflates during inspiration (due to fresh gas flow) and deflates during expiration as the contents empty into the piston. With fresh gas decoupling, if there is a disconnect, the manual breathing bag rapidly deflates because the piston retraction draws gas from it.

The second approach to preventing augmentation of delivered V_T by fresh gas flow is called tidal volume compensation, which is used in the Aestiva and Aisys (among others). The volume and flow sensors provide feedback that allows the ventilator to adjust the delivered V_T so that it matches the set $V_{T'}$ in spite of changes in fresh gas flow.

Suitability for Low Flows.

Low fresh gas flow during maintenance is desirable to reduce pollution, reduce the cost of volatile agents and nitrous oxide, preserve tracheal heat and moisture, prevent soda lime granules from drying, and help preserve patient body temperature. Factors that enhance the safety and efficiency of low-flow anesthesia in modern ventilators are shown in [Box 16.12](#). As can be seen, a traditional-sized absorber head like the Aestiva is roughly twice the volume of some of the newer designs. All newer, nondisposable portions of the breathing circuit are designed to be more leak-proof than earlier designs.

Electronic Selection of Positive End-Expiratory Pressure.

Electronic selection of PEEP is safer than previous approaches, which involved adding adapters to the expiratory limb of the breathing circuit. Add-on adapters came in different varieties, depending on how much PEEP was desired (e.g., 5 or 10 cm H₂O). They were intended to be placed between the expiratory limb of the breathing hoses and the expiratory unidirectional valve. They have been placed accidentally in the inspiratory limb, where they cause complete obstruction to flow in the breathing circuit.²¹⁶ Although it would seem easy to find this fault immediately, in the heat of the moment with a patient who is already hypoxemic, the clinician may become distracted and unable to focus effectively on the problem. This is an example of a clinical pearl. When a change in the patient's condition is noticed, think back to the last alteration made to the equipment (or to the last drug thought to be given), and determine

whether it might have contributed to the change.

Current Ventilator Designs

GE Healthcare 7900 “SmartVent”.

The 7900 was designed to provide consistent delivered V_T in spite of changes in fresh gas flow, small leaks, and absorber or bellows compliance losses. It uses variable-orifice flow sensors (proximal to the inspiratory and expiratory limbs) and pressure sensors to accomplish this.^{200,217} The ventilator can use either oxygen or air as a driving gas, and will switch automatically to air if oxygen pipeline pressure is lost. Available modes include manual/spontaneous, VCV, PCV, and SIMV (in either volume or pressure mode with pressure support). PSV is available as PSV-Pro, the “pro” indicating protection against apnea, because the vent will revert to backup settings (PCV) if no spontaneous breaths are detected. PCV-VG is available on the Aisys and Avance. PEEP is integrated and electronically controlled. Spirometry loops are available. It is found on a variety of machines, including Aestiva, Aisys, and Avance.

GE Healthcare 7100.

The 7100 is similar to the 7900, except that the selection of modes is not as extensive. The 7100, like the 7900, features tidal volume compensation. It is found on the Aespire.

Fabius GS Ventilator.

The Fabius GS ventilator is a piston ventilator.^{66,202} It offers pressure control, volume control, pressure support, SIMV-volume with PSV, and manual/spontaneous modes. There is no mechanical Bag/Vent switch. Switching between modes is accomplished by electronic keypad. It corrects delivered V_T for compliance losses by measuring circuit compliance, and for fresh gas flow changes by fresh gas decoupling. Electronic PEEP is integrated. One can view measured respiratory parameters or ventilator settings (but not both simultaneously) on the monitor screen. VCV and SIMV-volume are accurate to very low tidal volumes (range 20 to 1400 mL). Pediatric circle system (low compliance) hoses are used for tidal volumes less

than 200 mL, and the ventilator self-test should be repeated when changing circuits.

The piston movement is visible in a window to the left of the flowmeter bank. Like the Apollo, it provides a visible indication of lung inflation and potential disconnects in that fresh gas is diverted to the manual breathing bag, which inflates during mechanical ventilator inspiration and deflates during expiration. The piston design avoids NEEP by entraining room air if pressure within the bellows is less than atmospheric pressure. The “fresh gas low” error message warns of this condition.

Apollo Ventilator.

The Apollo ventilator is a piston similar to the Fabius, except that spirometry is displayed. The absorber head is heated. Modes are manual/spontaneous, volume and pressure control, pressure support, and SIMV in either volume or pressure mode. Autoflow is available as an option.^{68,200}

Traditional Anesthesia Ventilators

The Datex-Ohmeda 7000, 7800, and ADU, and the Dräger AV-2, AV-E, and Narkomed 6000 Divan ventilators were covered in previous editions of this text. Departments who still retain or use older ventilators should ensure that all personnel are familiar with them and can use them safely in an emergency.¹

Critical Incidents Related to Ventilation

Disconnects and Other Causes of Low Pressure in the Breathing Circuit.

Clinical experience with anesthesia ventilators and breathing circuits has identified several situations that have led to critical incidents. Vigilance directed toward situations that have the potential to cause patient injury may contribute to the prevention of future occurrences (see [Box 16.18](#)). Failure to ventilate caused by disconnection has been called the most common preventable equipment-related cause of mishaps.³⁰ The most common site for disconnection is between the breathing circuit and the endotracheal

tube (at the Y-piece).²⁰¹ Disconnects can be partial or complete. Recent reported causes of low pressure (leak) conditions are many: absorbent granules changed between cases by ancillary personnel but improperly reassembled or even left open^{194,218,219}; defective absorber canister^{155,220}; failure of the Bag/Vent switch^{221,222}; leaks in corrugated hoses²²³; incompetent ventilator relief valve²²⁴; leaks from a hot wire anemometer sensor²²⁵; the gas sampling line preventing manual ventilation by preventing closure of an APL^{226–230}; and ventilator failure due to moisture in flow sensors.⁷⁷ The variety of faults leading to low pressure accidents emphasizes proper performance of preanesthesia equipment checklists (though not all of these faults were detected, most were detectable). It also emphasizes being prepared to manage low pressure in the breathing circuit regardless of its cause.

Protocols for managing leaks and other causes of low pressure in the breathing circuit have been published.^{45,231} Prevention of disconnects involves a thorough preanesthesia check of equipment, including a high pressure leak check of the breathing circuit before use on every patient. A primary monitor for disconnection is continuous auscultation of breath sounds with a precordial or esophageal stethoscope, as well as direct visual observation of chest movement (both are recommended by standards).^{100,171} Electronic monitors for disconnection include capnography, and pressure- and volume-based alarms (Box 16.19).^{45,201} Because electronic monitors may have alarms disabled, either inadvertently or intentionally (because of artifacts, monitor failure, or alarm fatigue), there is no substitute for the anesthetist's vigilance through remaining in touch with the patient with the five senses.

Typical Ventilator Alarms

Pressure Alarms

- High (isolated or continuing)
- Subatmospheric
- Volume—low tidal or minute volume

- Rate — high respiratory rate
- Reverse flow (may indicate incompetence of expiratory unidirectional valve in the breathing circuit)

Apnea/Disconnect Alarms*

These may be based on the following:

- Chemical monitoring (lack of end-tidal carbon dioxide)
- Mechanical monitoring:
 - Failure to reach normal inspiratory peak pressure, or failure to sense return of tidal volume
 - Spirometry
 - Failure of standing bellows to fill during exhalation
 - Failure of manual breathing bag to move and fill during mechanical ventilation (machines with fresh gas decoupling — Apollo, Fabius, Narkomed 6000)
 - Other — lack of breath sounds or visible chest movement.

*Note that low readings on the pulse oximeter is less valuable, because it is a late sign of hypoventilation.

To manage inability to ventilate due to low pressure in the breathing circuit, first ensure ventilation is occurring by checking breath sounds. If not, and the circuit has obviously lost volume (emptied bellows), check for disconnects quickly, then try to ventilate manually using the anesthesia breathing circuit. Using the breathing circuit, if possible, is superior to immediately using a bag-valve-mask, because, with the circuit, one can still administer volatile agents. If no volume loss is apparent, check settings of fresh gas flow, scavenger, and ventilator, as well as monitor artifact.⁴⁵ Do not interrupt ventilation for diagnosis of machine problems; proceed to manual ventilation with backup ventilation equipment (Ambu bag) without undue delay.²³¹

Failure to Initiate or Resume Ventilation.

Failure to initiate or resume ventilation may be less likely in the future because of the incorporation of modern monitoring in current gas machines, all of which possess common features that add to patient safety. They have a centralized data and alarm display, as well as alarms prioritized to warnings, cautions, and advisories. They provide electronic preuse checklists.²³² Furthermore, the apnea and disconnect alarms are typically enabled once a breath is sensed. Therefore, the anesthesia gas machine should alert the operator to a failure to turn on a mechanical ventilator after intubation, or to a failure to resume ventilation after the ventilator is shut off either temporarily (in the middle of a case for radiography) or permanently (during emergence). If turning off a mechanical ventilator temporarily mid-case, it is safest to leave one's finger on the switch until it is time to resume ventilation.

The number of different alarm conditions programmed into a modern anesthesia gas machine with integrated monitoring is staggering, consisting of a six-page list in the Aisys operator's manual.⁶⁴ It is absolutely necessary to read the manuals and participate in training for machines of such complexity.^{73,233} Although equipment has improved dramatically, some of the underlying causes of failure to ventilate and of barotrauma will likely remain problems for the foreseeable future (e.g., lack of knowledge or training, and failure to use checklists).

Barotrauma and High Pressure in the Breathing Circuit.

Although such problems as misconnections are less likely now than in the past because of improvements in design, other possible causes of failure to ventilate, or barotrauma, are still hazards: occlusion, bellows leaks, failure of gas supply, failure of the ventilator relief valve, and inadvertent application of suction or positive pressure to the airway.^{138,143,148,234,235}

Unlike disconnects and other low-pressure breathing circuit problems, high pressure in the breathing circuit can evolve quickly and produce devastating consequences, allowing little time for diagnosis or correction. Sustained high intrathoracic pressure rapidly and severely impedes venous return and cardiac output. The causes of sustained high pressure in the breathing circuit are diverse. Obstruction to exhalation (but not inhalation) has been caused in recent times by direct connection of wall oxygen to a tracheal tube,²³⁴ improper manufacture of a scavenger assembly,²³⁶ failure to remove plastic wrap around a soda lime canister before installing it in the machine,^{150,237} malfunctioning ventilator relief valve,¹⁴³ occlusion of the lumen of a breathing circuit extender adaptor by mold flash or other plastic debris,^{158-161,163,238} insertion of an occluded disposable PEEP valve into the breathing circuit,¹⁵⁸ and an occluded expiratory unidirectional valve.¹⁴⁷ Most of these obstructions would have been easily detected by a preinduction high-pressure check of the breathing circuit, with release of pressure through the APL valve, and by checking for obstructions in the breathing circuit (a “flow test”; using a second breathing bag as an artificial lung during checkout to ensure gas flows properly in the breathing circuit, or simply by breathing through the circuit). Consequences of obstructed breathing circuits included high PEEP, decreased venous return, cardiovascular collapse, pneumothorax, massive subcutaneous emphysema, or death.

The algorithm for responding to sustained high pressure in the breathing circuit is as follows⁴⁵: Assess patient-related causes such as bronchospasm. Try manually ventilating the patient with the breathing circuit (in “Bag” mode). If the high pressure is relieved, it is likely that the ventilator relief valve is at fault. The ventilator is unusable until this valve is serviced. If circuit pressure is sustained during manual ventilation with the circuit, it is likely that the

scavenger is obstructed or that its relief valves have failed. In either case, disconnect the patient from the breathing circuit and continue ventilation by bag-valve-mask (Ambu bag).

The Anesthesia Workstation and Malignant Hyperthermia.

When an unexpected malignant hyperthermia (MH) crisis arises during a case, one follows a protocol including (as far as equipment is concerned) withdrawal of triggering agents. This would include stopping the administration of volatile agents (and succinylcholine), hyperventilating with oxygen 100%, increasing fresh gas flow, and (if time and help are available and can be spared from other more important tasks such as mixing dantrolene) changing the disposable breathing circuit components and granules.^{239,240} Activated charcoal filters are easily applied between the inspiratory and expiratory ports and the corrugated limbs of the breathing circuit. They quickly and reliably reduce the concentration of volatile agent in the breathing circuit, and are recommended by the Malignant Hyperthermia Association of the US (MHAUS).^{240,241}

When preparing the gas machine for a patient who is known to be susceptible, change the breathing circuit and carbon dioxide absorbent granules, disable or remove the vaporizers, and flush all traces of volatile agent from its internal circuitry. The old guideline was flushing with a fresh gas flow rate of 10 L/min for 20 minutes. New evidence indicates that this may be very inadequate for some machines, with the Fabius requiring as much as 104 minutes.^{79,239,242–248} MHAUS recommends charcoal filters, and high fresh gas flow (10 L/min) throughout maintenance, in addition to other recommendations.²⁴⁹

Disposal

The final “D” of the SPDD model is concerned with a simple but vital question: How are gases disposed of?

Scavenging Systems and Disposal of Waste Anesthesia Gases

Scavenging is the collection of waste anesthetic gases from the breathing circuit and ventilator and their removal from the operating room. An amount equal to the fresh gas flow must be scavenged each minute.^{250,251} Otherwise, the breathing circuit and the patient's lungs will either gain or lose pressure, resulting in barotrauma or failure to ventilate. The components of the scavenger are listed in Box 16.20 and shown in Fig. 16.42.

Components of the Scavenger System

Gas collection assembly— at adjustable pressure-limiting (APL) valve and ventilator relief valve

Transfer tubing— 19 or 30 mm, sometimes color-coded yellow

Scavenging interface (most important part)

- Closed interface (all older models)
- Communicates to atmosphere only through valves
- If used with passive disposal system, must have positive pressure relief
- Used with active (suction) disposal system; must have positive *and* negative pressure relief

- Open interface (most new models)
- No valves; open to atmosphere (both negative and positive pressure relief “built in”)
- Must be used *only* with active systems
- Reservoir required
Safety:
- Safer than closed interface for the patient; no barotrauma
- Less safe than closed interface for the caregiver (if used improperly)

Gas disposal tubing

Gas disposal assembly – active disposal (common) or passive disposal

FIGURE 16.42 Components of the scavenging system. APL, Adjustable pressure limiting valve. (From Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

Advisory recommendations for exposure to waste anesthetic gases are published by the Occupational Safety and Health Administration (OSHA).²⁵¹ OSHA advises that no worker should be exposed to more than 2 ppm halogenated agents (0.5 ppm if used with nitrous oxide), and no more than 25 ppm nitrous oxide, based on a time-weighted 8-hour average concentration. Levels in unscavenged anesthetizing locations may be as high as 7000 ppm (0.7%) N₂O and 85 ppm (0.008%) halothane.²⁵ The highest levels are found in the anesthetist's workstation, and between the anesthesia gas machine and the wall.²⁴ Operating-room personnel working in ear, nose, and throat operating rooms had measurable levels of exhaled sevoflurane higher than controls up to 18 hours after being on duty, although this study did not report what type of scavenging, if any, was employed.²⁵² The health effects of chronic exposure to volatile agents are unproved, though it is clear that occupational exposure to nitrous oxide should be avoided.¹⁸⁴

Several variables determine the attainable reduction in waste anesthetic gases in the operating room, including the degree of room ventilation, the condition of anesthesia equipment, the effectiveness of the scavenger, and the anesthetic techniques of the

user. However, with appropriate attention to these areas, trace gas levels within the operating room can meet OSHA requirements.^{25,253}

The most important component of the scavenger system is the interface (between the breathing circuit and wall suction), because it protects the patient's airway from excessive buildup of positive pressure, and from exposure to suction. There are two types of interfaces: closed and open. The closed interface is found on older machines.^{254,255} A closed interface is useful where passive scavenging is used (no dedicated suction line for the scavenger). Note that hospital accreditors currently require active scavenging in the United States.²⁵³ A closed interface communicates with the atmosphere only through valves (Fig. 16.43). A means for relief of positive pressure is mandatory for all closed interfaces. If the suction attached to the scavenger fails or if a hose distal to it becomes kinked, positive pressure relief valves operate before the pressure buildup within the scavenger is transmitted to the breathing circuit and the lungs. In this case, the positive pressure relief valve opens and releases waste gases into the operating-room air. If the closed interface is attached to suction, a negative pressure relief valve is also mandatory. The negative-pressure relief valve on the closed interface opens to draw in room air when suction is excessive, preventing the emptying of gas from the patient and breathing circuit. Suction should be adjusted in a closed interface as fresh gas flows change, so that the scavenger reservoir bag is neither flat nor overdistended.²⁵⁵

FIGURE 16.43 Closed scavenger interface attached to suction. Note the reservoir, the positive and negative pressure relief valves, and the capped extra port. (Modified from Ehrenwerth J, Eisenkraft J, Berry J, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. Philadelphia: Elsevier; 2013.)

Because the closed-interface relief valves can fail,²⁵⁶ an open scavenger interface is supplied by the manufacturer on all new workstations (Fig. 16.44). The open interface is open to the atmosphere. There are no valves, such as those found in closed-interface systems, to impede the flow of gases into, or out of, the reservoir. Each patient exhalation is led to the bottom of the open-interface reservoir, where a second tube withdraws it by suction before the next exhalation arrives. Use of the device with appropriate suction is critical to its proper function.²⁵⁴ If scavenger suction is inadequate, all patient exhalations and waste gases will be released into the operating room.²⁵⁶ The open interface affords

patient safety advantages. Though rare failures of open-interface scavenging have been reported, at least there is no chance of relief valve failure (as with the closed interface), which can cause barotrauma or the application of suction to the breathing circuit.^{257,258} The device is perhaps less safe for the operator who is unfamiliar with its use; however, the only danger of this ignorance is increased occupational exposure to waste anesthetic gases. The smell of volatile agents during a case is abnormal, and its cause must be sought. The threshold for smelling volatile agents is variously stated as 5 to 300 ppm.^{25,250} Thus if any agent is smelled, the concentration is excessive (i.e., well above that described in the OSHA advisory).²⁵³

FIGURE 16.44 The open scavenger interface. A and B, Two open scavenging interfaces. Each requires an active disposal system. The open interface shown in A differs somewhat from the one shown in B. The operator can regulate the vacuum by adjusting the vacuum control valve

shown in B. *APL*, Adjustable pressure limiting valve; *Vent*, ventilator relief valve. (From Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

Many factors, in addition to the scavenger, affect exposure to waste anesthetic gases. Alterations in technique can greatly lessen occupational exposure. Guidelines for limiting exposure are listed [Box 16.21](#).^{25,250,259-261}

Means of Limiting Exposure to Waste Anesthetic Gases

- Check the scavenger (for correct level of suction) before use.
- Perform regular preventive maintenance of room ventilation systems.
- Perform regular preventive maintenance of all anesthesia equipment.
- Conduct personnel monitoring and ambient trace gas monitoring.
- Seek the source of the smell of anesthetics noted during a case.
- Keep a good mask fit.
- Avoid unscavengeable techniques (open drop, insufflation).
- Prevent flow from breathing system into room air, e.g., pause fresh gas flow during intubation of the trachea.
- Turn on anesthetic gases only after the mask is on the patient.
- Turn off anesthetic gases before suctioning.
- Wash out anesthetics into the scavenger at the end of the case.
- Do not spill liquid agent.
- Use cuffed endotracheal tubes.

- Use low fresh gas flows.
- Check the machine regularly for leaks.
- Disconnect nitrous oxide at the wall outlet at the end of the day.
- Use total intravenous anesthesia.
- Avoid use of nitrous oxide.

Risk Management

Department-Level Aspects

Risk management is defined as a detection system designed to predict failures and ensure that precautions to prevent patient harm are taken.¹³⁴ Typical anesthesia risk management activities include preoperative and postoperative rounds, avoiding indifferent treatment of patients, maintaining vigilance and high standards of care, peer review, continuing education, and the commitment to delivery of high-quality and humane patient care. In terms of equipment, risk management includes cleanliness, daily performance of equipment checklists, familiarity with equipment manuals, and appropriate equipment maintenance.^{134,262}

The Safe Medical Device Act of 1990 requires hospitals to report instances in which medical devices cause or contribute to death, serious illness, or serious injury.²⁶³ All health care personnel who become aware of a problem with a device must remove the equipment from contact with patients and report the problem to their supervisors. The hospital risk manager then conducts an investigation and reports the results to the FDA within 10 working days. The most common barrier to investigation of a critical incident, and the degree to which anesthesia equipment may have contributed to it, is alteration of the equipment (i.e., it has been cleaned, disassembled, or tested).²⁶⁴ In the case of patient injury in which equipment may be at fault, it is most helpful if equipment (including wastebaskets and syringes in the anesthesia work area) is sequestered “as is,” pending a forensic evaluation conducted by the representatives of the hospital, the manufacturer, and perhaps the patient. Equipment logs should be kept for each anesthesia machine and include reports of maintenance, critical incidents, additions or alterations, pollution control, and vaporizer calibration. Preventive maintenance should be done at intervals specified by the manufacturer (usually two to four times per year) by qualified, factory-trained technicians.¹³⁴

Individual Risk Management

The department-level risk management plan requires the active involvement of all department members. In addition to participation in the department-level activities noted earlier, individuals play a vital role in three further aspects of risk management for equipment: performance of the machine checklist before use, limiting equipment-related disease transmission, and reducing trace and waste gas exposure through alteration of work practices (the latter two were discussed earlier in this chapter).

Anesthesia Gas Machine Checklist

Reports of equipment problems surfacing in the 1980s prompted the professional societies to develop a recommended anesthesia checklist.²⁶⁵⁻²⁶⁸ Although equipment failures are rare, they are often the result of human error in the use of the equipment.^{4,5,265,268} Failure to check anesthesia equipment adequately has been reported as a factor in up to 30% of critical incidents.^{269,270} Users reported that they often did not perform the preanesthesia checklist, and many did not feel competent in their ability to perform it correctly.³ When a checklist was performed, 30% of the gas machines in one study had serious faults discovered.² Checklists have been the focus of several studies of fault-detection ability and much comment.^{232,268,271-277} It is possible that proper and consistent use of checklists will not only prevent critical incidents, but also help teach users to learn anesthesia gas machine function.¹⁴ Performance of the preanesthesia checklist is required by various standards.^{12,277} Performing and documenting the equipment check has been associated with decreased mortality.²⁷⁸ One-third of recent closed claims (and six out of eight breathing circuit claims) were judged to be preventable if an adequate preanesthesia checklist had been performed.⁵

Because of these problems, a new PreAnesthesia Checkout (PAC) was published in 2008 ([Boxes 16.22](#) and [16.23](#)).¹² It became necessary to abandon the 1990s FDA checklist because it recommended procedures that no longer worked for different model workstations. Considering the significant differences between models, and variations in their self-test routines, no one set of procedures can cover all gas machines. This new checklist is a statement of principles of what should be checked, how often, and

who should check it, rather than a procedures list. For example, the availability of backup ventilation equipment and backup oxygen supplies, and the calibration of the oxygen analyzer must be checked, regardless of which machine is used. But how these actions are performed varies from machine to machine. If they have not done so already, anesthesia departments need to develop specific procedures and training for the machines they use, in consultation with manufacturers and the operator's instruction manuals. User training is also vital, and departments should ensure that all department members are trained on all workstation types in

Box 16.22

Summary of Preanesthesia Checkout Recommendations

To Be Completed Daily	To Be Repeated Before Each Case
1. Verify that auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.	
2. Verify that patient suction is adequate to clear the airway.	*
3. Turn on anesthesia delivery system and confirm that AC power is available.	
4. Verify availability of required monitors, including alarms.	*
5. Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine.	
6. Verify that the piped gas pressures are 50 or greater psi.	
7. Verify that vaporizers are adequately filled, and if applicable, that the filler ports are tightly closed.	*
8. Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet.	
9. Test scavenging system function.	
10. Calibrate, or verify calibration of, the oxygen monitor and check the low oxygen alarm.	
11. Verify that carbon dioxide absorbent is not exhausted.	*
12. Conduct breathing system pressure and leak testing.	*
13. Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.	*
14. Document completion of checkout procedures.	*
15. Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)	*

psi, Pounds per square inch.

From Sub-Committee of the American Society of Anesthesiologists (ASA) Committee on Equipment and Facilities: Recommendations for PreAnesthesia Checkout Procedures, 2008. Available at <http://www.asahq.org/resources/clinical-information/2008-asa-recommendations-for-pre-anesthesia-checkout>.

Box 16.23

Recommendations for Preanesthesia Checkout Procedures

General Considerations

The following document is intended to serve not as a preanesthesia checkout (PAC) itself, but rather as a template for developing checkout procedures that are appropriate for each individual anesthesia machine design and practice setting. When using this template to develop a checkout procedure for systems that incorporate automated checkout features, items that are not evaluated by the automated checkout need to be identified, and supplemental manual checkout procedures included as needed.

Simply because an automated checkout procedure exists does not mean it can completely replace a manual checkout procedure or that it can be performed safely without adequate training and a thorough understanding of what the automated checkout accomplishes. An automated checkout procedure can be incomplete and/or misleading. For example, the leak test performed by some current automated checkouts does not test for leaks at the vaporizers. As a result, a loose vaporizer filler cap, or a leak at the vaporizer mount, could easily be missed.

Ideally an automated checkout procedure should clearly reveal to the user the functions that are being checked, any deficient function that is found, and recommendations for correcting the problem. Documentation of the automated checkout process should preferably be done in a manner that can be recorded on the anesthesia record.

Operator's manuals, which accompany anesthesia delivery systems, include extensive recommendations for equipment checkout. Although these recommendations are quite extensive and typically not used by anesthesia providers, they are nevertheless important references for developing machine-specific and institution-specific checkout procedures.

Personnel Performing the PAC

The previously accepted *Anesthesia Apparatus Checkout Recommendation* placed all of the responsibility for pre-use checkout

on the anesthesia provider. This guideline identifies those aspects of the PAC that could be completed by a qualified anesthesia and/or biomedical technician. Critical checkout steps (e.g., availability of backup ventilation equipment) will benefit from intentional redundancy (i.e., having more than one individual responsible for checking the equipment). *Regardless of the level of training and support by technicians, the anesthesia care provider is ultimately responsible for proper function of all equipment used to provide anesthesia care.*

Adaptation of the PAC to local needs, assignment of responsibility for the checkout procedures, and training are the responsibilities of the individual anesthesia department. Training procedures should be documented. Proper documentation should include records of completed coursework (e.g., a manufacturer course) or for in-house training, a listing of the competency items taught and records of successful completion by trainees.

Objectives for a New PAC

1. Outline the essential items that need to be available and functioning properly prior to delivering every anesthetic.
2. Identify the frequency with which each of the items needs to be checked.
3. Suggest which items may be checked by a qualified anesthesia technician, biomedical technician, or a manufacturer-certified service technician.

Basic Principles

The anesthesia care provider is ultimately responsible for ensuring that the anesthesia equipment is safe and ready for use. This responsibility includes adequate familiarity with the equipment, following relevant local policies for performing and documenting the PAC, and being knowledgeable about those procedures.

Depending on the staffing resources in a particular institution, anesthesia technicians and/or biomedical technicians can participate in the PAC. Each department should decide whether or

not the available technicians can or should be trained to assist with checkout procedures.

- Critical items will benefit from redundant checks to avoid errors and omissions.
- When more than one person is responsible for checking an item, all parties should perform the check if intentional redundancy is deemed important, or either party may be acceptable, depending on the available resources.
- Whoever conducts the PAC should provide documentation of successful performance. The anesthesia provider should include this documentation on the patient chart.
- Whenever an anesthesia machine is moved to a new location, a complete beginning-of-the-day checkout should be performed.
- Automated checks should clearly distinguish the components of the delivery system that are checked automatically from those that require manual checkout.
- Ideally, the date, time, and outcome of the most recent check(s) should be recorded and the information made accessible to the user.
- Specific procedures for preuse checkout cannot be prescribed in this document because they vary with the delivery systems. Clinicians must learn how to effectively perform the necessary preuse check for each piece of equipment they use.
- Each department or health care facility should work with the manufacturer(s) of their equipment to develop preuse checkout procedures that satisfy both the following guidelines and the needs of the local department.
- Default settings for ventilators, monitors, and alarms should be checked to determine whether they are appropriate.
- These checkout recommendations are intended to replace the pre-

existing FDA-approved *Anesthesia Apparatus Checkout Recommendations*. They are not intended to be a replacement for required preventive maintenance.

- The PAC is essential to safe care but should not delay initiating care if the patient needs are so urgent that time taken to complete the PAC could worsen the patient's outcome.

Guidelines for Developing Institution-Specific Checkout Procedures Prior to Anesthesia Delivery

These guidelines describe a basic approach to checkout procedures and rationale that will ensure that these priorities are satisfied. They should be used to develop institution-specific checkout procedures designed for the equipment and resources available. (Examples of institution-specific procedures for current anesthesia delivery systems are published on the same website as this document.)

Requirements for Safe Delivery of Anesthesia Care

- Reliable delivery of oxygen at any appropriate concentration up to 100%
- Reliable means of positive pressure ventilation
- Backup ventilation equipment available and functioning
- Controlled release of positive pressure from the breathing circuit
- Anesthesia vapor delivery (if intended as part of the anesthetic plan)
- Adequate suction
- Means to conform to standards for patient monitoring

Specific Items

The following fifteen items need to be checked as part of a

complete PAC. The intent is to identify what to check, the recommended frequency of checking and the individual(s) who could be responsible for the item. For these guidelines, the responsible party would fall into one of four categories: Provider, Technician, Technician or Provider, or Technician and Provider. The designation “Technician and Provider” means that the provider must perform the check whether or not it has been completed by a technician. It is not intended to make the use of technician checks mandatory. The intent is not to specify how an item needs to be checked, because the specific checkout procedure will depend upon the equipment being used.

1. Verify auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.

Frequency: Daily.

Responsible Parties: Provider and Technician.

Rationale: Failure to be able to ventilate is a major cause of morbidity and mortality related to anesthesia care. Because equipment failure with resulting inability to ventilate the patient can occur at any time, a self-inflating manual ventilation device (e.g., ambu bag) should be present at every anesthetizing location for every case and should be checked for proper function. In addition, a source of oxygen separate from the anesthesia machine and pipeline supply, specifically an oxygen cylinder with regulator and a means to open the cylinder valve, should be immediately available and checked. After checking the cylinder pressure, it is recommended that the main cylinder valve be closed to avoid inadvertent emptying of the

cylinder through a leaky or open regulator.

2. Verify that patient suction is adequate to clear the airway.

Frequency: Prior to each use.

Responsible Parties: Provider and technician.

Rationale: Safe anesthetic care requires the immediate availability of suction to clear the airway if needed.

3. Turn on anesthesia delivery system and confirm that AC power is available.

Frequency: Daily.

Responsible Parties: Provider or technician.

Rationale: Anesthesia delivery systems typically function with backup battery power if AC power fails. Unless the presence of AC power is confirmed, the first obvious sign of power failure can be a complete system shutdown when the batteries can no longer power the system. Many anesthesia delivery systems have visual indicators of the power source showing the presence of both AC and battery power. These indicators should be checked, and connection of the power cord to a functional AC power source should be confirmed.

Desflurane vaporizers require electrical power and recommendations for checking power to these vaporizers should also be followed.

4. Verify availability of required monitors, including alarms.

Frequency: Prior to each use.

Responsible Parties: Provider or technician.

Rationale: Standards for patient monitoring during anesthesia are clearly defined. The ability to conform to these standards should be confirmed for every anesthetic. The first step is to visually verify that the appropriate monitoring supplies (blood pressure cuffs, oximetry probes, etc.) are available. All monitors should be turned on and proper completion of power-up self-tests confirmed. Given the importance of pulse oximetry and capnography to patient safety, verifying proper function of these devices before anesthetizing the patient is essential. Capnometer function can be verified by exhaling through the breathing circuit or gas sensor to generate a capnogram, or verifying that the patient's breathing efforts generate a capnogram before the patient is anesthetized. Visual and audible alarm signals should be generated when this is discontinued. Pulse oximeter function, including an audible alarm, can be verified by placing the sensor on a finger and observing for a proper recording. The pulse oximeter alarm can be tested by introducing motion artifact or removing the sensor.

Audible alarms have also been reconfirmed as

essential to patient safety by American Society of Anesthesiologists (ASA), American Association of Nurse Anesthetists (AANA), Anesthesia Patient Safety Foundation (APSF), and The Joint Commission. Proper monitor functioning includes visual and audible alarm signals that function as designed.

5. Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine.

Frequency: Daily.

Responsible Parties: Provider and technician.

Rationale: Anesthesia delivery systems rely on a supply of oxygen for various machine functions. At a minimum, the oxygen supply is used to provide oxygen to the patient. Pneumatically powered ventilators also rely on a gas supply. Oxygen cylinder(s) should be mounted on the anesthesia delivery system and determined to have an acceptable minimum pressure. The acceptable pressure depends on the intended use, the design of the anesthesia delivery system, and the availability of piped oxygen.

Typically, an oxygen cylinder will be used if the central oxygen supply fails.

If the cylinder is intended to be the primary source of oxygen (e.g., remote site anesthesia), then a cylinder supply sufficient to last for the entire

anesthetic is required. If a pneumatically powered ventilator that uses oxygen as its driving gas will be used, a full “E” oxygen cylinder may provide only 30 minutes of oxygen. In that case, the maximum duration of oxygen supply can be obtained from an oxygen cylinder if it is used only to provide fresh gas to the patient in conjunction with manual or spontaneous ventilation. Mechanical ventilators will consume the oxygen supply if pneumatically powered ventilators that require oxygen to power the ventilator are used. Electrically powered ventilators do not consume oxygen, so the duration of a cylinder supply will depend only on total fresh gas flow. The oxygen cylinder valve should be closed after it has been verified that adequate pressure is present, unless the cylinder is to be the primary source of oxygen (i.e., piped oxygen is not available). If the valve remains open and the pipeline supply should fail, the oxygen cylinder can become depleted while the anesthesia provider is unaware of the oxygen supply problem.

Other gas supply cylinders (e.g., Heliox, CO₂, Air, N₂O) need to be checked only if that gas is required to provide anesthetic care.

6. Verify that piped gas pressures are 50 or greater psi/g.
Frequency: Daily.

Responsible Parties: Provider and technician.

Rationale: A minimum gas supply pressure is required for proper function of the anesthesia delivery system. Gas supplied from a central source can fail for a variety of reasons. Therefore, the pressure in the piped gas supply should be checked at least once daily.

7. Verify that vaporizers are adequately filled, and if applicable, that the filler ports are tightly closed.

Frequency: Prior to each use.

Responsible Parties: Provider. Technician if redundancy desired.

Rationale: If anesthetic vapor delivery is planned, an adequate supply is essential to reduce the risk of light anesthesia or recall. This is especially true if an anesthetic agent monitor with a low agent alarm is not being used. Partially open filler ports are a common cause of leaks that may not be detected if the vaporizer control dial is not open when a leak test is performed. This leak source can be minimized by tightly closing filler ports. Newer vaporizer designs have filling systems that automatically close the filler port when filling is completed.

High and low anesthetic agent alarms are useful to help prevent over- or under-dosage of anesthetic vapor. Use of these alarms is encouraged, and they should be set to the appropriate limits and

enabled.

8. Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet.

Frequency: Daily and whenever a vaporizer is changed.

Responsible Parties: Provider or technician.

Rationale: The gas supply in this part of the anesthesia delivery system passes through the anesthetic vaporizer(s) on most anesthesia delivery systems. In order to perform a thorough leak test, each vaporizer must be turned on individually to check for leaks at the vaporizer mount(s) or inside the vaporizer. Furthermore, some machines have a check valve between the flowmeters and the common gas outlet, requiring a negative pressure test to adequately check for leaks. Automated checkout procedures typically include a leak test but may not evaluate leaks at the vaporizer especially if the vaporizer is not turned on during the leak test. When relying upon automated testing to evaluate the system for leaks, the automated leak test would need to be repeated for each vaporizer in place. This test should also be completed whenever a vaporizer is changed. The risk of a leak at the vaporizer depends upon the vaporizer design. Vaporizer designs where the filler port closes automatically after filling can reduce the risk of leaks. Technicians can provide useful assistance with this aspect of the machine checkout because it can

be time consuming.

9. Test scavenging system function.

Frequency: Daily.

Responsible Parties: Provider or technician.

Rationale: A properly functioning scavenging system prevents room contamination by anesthetic gases. Proper function depends upon correct connections between the scavenging system and the anesthesia delivery system. These connections should be checked daily by a provider or technician. Depending upon the scavenging system design, proper function may also require that the vacuum level is adequate, which should also be confirmed daily. Some scavenging systems have mechanical positive and negative pressure relief valves. Positive and negative pressure relief is important to protect the patient circuit from pressure fluctuations related to the scavenging system. Proper checkout of the scavenging system should ensure that positive and negative pressure relief is functioning properly. Due to the complexity of checking for effective positive and negative pressure relief, and the variations in scavenging system design, a properly trained technician can facilitate this aspect of the checkout process.

. Calibrate, or verify calibration of, the oxygen monitor and check the low oxygen alarm.

Frequency: Daily.

Responsible Parties: Provider or technician.

Rationale: Continuous monitoring of the inspired oxygen concentration is the last line of defense against delivering hypoxic gas concentrations to the patient. The oxygen monitor is essential for detecting adulteration of the oxygen supply. Most oxygen monitors require calibration once daily, although some are self-calibrating. For self-calibrating oxygen monitors, they should be verified to read 21% when sampling room air. This is a step that is easily completed by a trained technician. When more than one oxygen monitor is present, the primary sensor that will be relied upon for oxygen monitoring should be checked.

The low oxygen concentration alarm should also be checked at this time by setting the alarm above the measured oxygen concentration and confirming that an audible alarm signal is generated.

. Verify that carbon dioxide absorbent is not exhausted.

Frequency: Prior to each use.

Responsible Parties: Provider or technician.

Rationale: Proper function of a circle anesthesia system relies on the absorbent to remove carbon

dioxide from rebreathed gas. Exhausted absorbent as indicated by the characteristic color change should be replaced. It is possible for absorbent material to lose the ability to absorb CO₂, yet the characteristic color change may be absent or difficult to see. Some newer absorbents do change color when desiccated. Capnography should be used for every anesthetic, and when using a circle anesthesia system, rebreathing carbon dioxide as indicated by an inspired CO₂ concentration greater than 0 can also indicate exhausted absorbent.

. Conduct breathing system pressure and leak testing.

Frequency: Prior to each use.

Responsible Parties: Provider and technician.

Rationale: The breathing system pressure and leak test should be performed with the circuit configuration to be used during anesthetic delivery. If any components of the circuit are changed after this test is completed, the test should be performed again. Although the anesthesia provider should perform this test before each use, anesthesia technicians who replace and assemble circuits can also perform this check and add redundancy to this important checkout procedure. Proper testing will

demonstrate that pressure can be developed in the breathing system during both manual and mechanical ventilation and that pressure can be relieved during manual ventilation by opening the adjustable pressure-limiting (APL) valve.

Automated testing is often implemented in the newer anesthesia delivery systems to evaluate the system for leaks and also to determine the compliance of the breathing system. The compliance value determined during this testing will be used to automatically adjust the volume delivered by the ventilator to maintain a constant volume delivery to the patient. It is important that the circuit configuration that is to be used be in place during the test.

. Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.

Frequency: Prior to each use.

Responsible Parties: Provider and technician.

Rationale: Pressure and leak testing does not identify all obstructions in the breathing circuit or confirm proper function of the inspiratory and expiratory unidirectional valves. A test lung or second reservoir bag can be used to confirm that flow through the circuit is unimpeded. Complete testing includes both manual and mechanical

ventilation. The presence of the unidirectional valves can be assessed visually during the PAC. Proper function of these valves cannot be visually assessed because subtle valve incompetence may not be detected. Checkout procedures to identify valve incompetence that may not be visually obvious can be implemented but are typically too complex for daily testing. A trained technician can perform regular valve competence tests. Capnography should be used during every anesthetic and the presence of carbon dioxide in the inspired gases can help to detect an incompetent valve.

. Document completion of checkout procedures.

Frequency: Prior to each use.

Responsible Parties: Provider and technician.

Rationale: Each individual responsible for checkout procedures should document completion of these procedures. Documentation gives credit for completing the job and can be helpful if an adverse event should occur. Some automated checkout systems maintain an audit trail of completed checkout procedures that are dated and timed.

. Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)

Frequency: Immediately prior to initiating the anesthetic.

Responsible Parties: Provider.

Rationale: This step is intended to avoid errors due to production pressure or other sources of haste. The goal is to confirm that appropriate checks have been completed and that essential equipment is indeed available. The concept is analogous to the “time out” used to confirm patient identity and surgical site prior to incision. Improper ventilator settings can be harmful, especially if a small patient is following a much larger patient or vice versa. Pressure limit settings (when available) should be used to prevent excessive volume delivery from improper ventilator settings.

Items to Check

- Monitors functional?
- Capnogram present?
- Oxygen saturation by pulse oximetry measured?
- Flowmeter and ventilator settings proper?
- Manual/ventilator switch set to manual?
- Vaporizer(s) adequately filled?

From Sub-Committee of the American Society of Anesthesiologists (ASA) Committee on Equipment and Facilities: Recommendations for Pre-Anesthesia Checkout Procedures, 2008. Available at <http://www.asahq.org/resources/clinical-information/2008-asa->

The Aestiva is a system that must be manually checked; there are no electronic aspects to the checklist.⁵² At the other extreme, some gas machines checkout procedures rely primarily on electronic checklists. These electronic self-check routines (like that in the Aisys, Fabius, and Apollo) may help prevent errors and omissions in the preanesthesia checklist.²⁸⁰ Electronic checklists of this type are not all identical, but they do cover most essential functions, can detect leaks, and can measure breathing circuit compliance. All of these new workstations require that the circuit be occluded for the electronic self-tests, then reconfigured to be ready for use. The Aisys and Apollo warn if leaks greater than 150 to 250 mL/min are detected.^{64,68} If leaks are detected, users should check that all breathing circuit connections are tight, as well as the bellows and ventilator relief valve if these are accessible. Ensure that the Y-piece is properly occluded, gas flows are closed, and the gas sampling lines are not connected to the circuit (in the Apollo, these must be connected).

The user performs a few manual tests at the end (e.g., suction, cylinder pressure, high-pressure leak check of the reassembled breathing circuit, unidirectional valves, and oxygen analysis). The great advantage of electronic self-tests is that, unlike checks performed by humans, the workstation cannot forget steps or perform steps incorrectly. There are significant disadvantages however. It is very difficult to know what is being checked in the self tests, even after consulting the operator's manual. For example, the negative-pressure leak test has been found to be most sensitive in detecting low pressure system leaks.²⁸⁰ However, it is impossible to determine from the operators' manuals for Apollo or Aisys whether their electronic self-test uses this method. Furthermore, some steps over and above the electronic self-test must always be performed by the user. Models differ in their clarity in prompting users to perform these checks, and users may make the assumption that the electronic self-test "does it all," and no further checks on their part are required.³ For example, there are many recent reports of obstructions in the breathing circuit which prevented ventilation, yet the machines were most often reported to have passed some

attempt at a preuse checklist.^{164,238,257,258,281–284} One current model's self-test allows users to accept an intentionally created and complete obstruction of the expiratory limb and initiate patient care, whereas two other workstations failed the self-test and prevented the user from proceeding.¹⁰ A vaporizer with a leak significant enough to prevent positive pressure ventilation was reported to have passed the self-test.²⁸⁵ A workstation whose CO₂ absorbent granules were missing was reported to pass the self-test.²⁸⁶ A misconfigured workstation passed all self-tests and yet, after induction, could not deliver a single positive pressure breath. Delay in establishing effective ventilation resulted in asystole, requiring atropine and chest compressions.¹⁶⁷ These recent and numerous reports of breathing circuit problems leading to inability to ventilate, not caught by attempts at daily checkout, are particularly ominous considering that one of the most frequently missed steps in the checkout is failure to check for a bag-valve-mask (Ambu bag).^{5,15,18,287}

What can be done? It is critical that the anesthetist can answer several questions in the affirmative at the end of a properly performed checkout. Is there oxygen in the oxygen line? Can the patient breathe unobstructed through the circuit? Can the patient be given a positive pressure breath? Are there leaks in the breathing circuit once reassembled? Is backup ventilation equipment present in the room? Users can and should incorporate simple checks that are easy to perform at the end of any model workstation self-test, that ensure these basic safety requirements are met: (1) checking the oxygen analyzer; (2) checking that the circuit is unobstructed and that the unidirectional valves are functioning properly; (3) checking the reassembled breathing circuit for leaks with high pressure, and (4) checking for the presence of a bag-valve-mask (Ambu).^{10,12,268,284} Adding these four steps at the end of any workstation self-test will increase safety. Check that the oxygen analyzer reads 21% when exposed to room air, and the reading increases when the sensor is exposed to gas from the oxygen pipeline (step 10 of the 2008 PAC). Check for a bag-valve-mask (step 1). While checking for backup ventilation equipment (e.g., Ambu bag), walk around the machine, checking for cylinder oxygen pressure, suction, and an extra circuit; the location of circuit breakers; the presence of a cylinder wrench

and head strap; and whether gas analysis monitors are scavenged.

Two user-performed breathing circuit checks are vital, and are not done by any model's electronic self-test. Step 12 of the PAC is a breathing circuit leak check, and step 13 (flow test) checks that the breathing circuit is unobstructed. To ensure that all breathing circuit connections are gas-tight, always perform a high-pressure check of the reassembled breathing circuit after the checklist is complete. Gas should be released from the pressurized circuit by opening the APL valve. This checks its function, as well as propelling any absorbent dust toward the scavenger, and not the elbow. Perform a flow test to ensure that the unidirectional valves are working properly, and that the circuit is not obstructed by mold flash, foreign objects, or plastic wrapping.^{10,12,30,158,161} The flow test uses a second breathing bag as a test lung, observing for to-and-fro movement between bellows (or manual breathing bag) and test lung. Alternatively, one may breathe through the circuit.³⁰

There is no “minimum” test other than that suggested by the operator's instruction manuals and the PAC. In administering an anesthetic for an emergency surgical procedure, the PAC guideline recognizes that patient needs can be so urgent that harm might come to the patient with even a few minutes delay to check the machine thoroughly. There are, however, a few steps that can be taken to increase safety even when time is limited. One should always check the suction, check for a backup means of ventilation (e.g., Ambu bag), and perform a high-pressure leak test of the breathing circuit before the mask is placed on the patient's face. During preoxygenation, (whether in emergencies, or as a matter of routine in every case), take a brief moment to check the breathing bag for fluctuations. Respiratory effort that is visible in the breathing bag before induction ensures that the patient is breathing, the mask fit is good, and oxygen is flowing. A situation in which any of these conditions is absent requires immediate attention.

Summary

Compared with its forebears, today's anesthesia workstation is a system of tremendous capability, power, safety, and complexity. Although the computer interface and design of modern workstations no doubt adds to safety, it should not bewitch us into abandoning tried and true methods of staying in touch with the patient. No electronic monitor currently available can clearly warn of early wheezes or mild upper airway obstruction (and thus give time for early corrective action) as quickly or efficiently as a precordial or esophageal stethoscope.^{288,289}

The anesthesia workstation is a result of both improvements in design and of the integration of electronic controls, physiologic monitors, and machine function monitors. Use of an anesthesia gas machine was more straightforward in the past because all types of anesthesia machines contained simpler, similar elements. With the introduction of new designs, this is no longer the case. The days when a few “wizards” in an anesthesia department could specialize in equipment operation and maintenance and could instruct and troubleshoot for all of their coworkers have likewise passed. Equipment competency must be a part of everyone's toolkit of patient-care skills. It is hoped that through study of this chapter, current equipment will be more widely understood. In this manner, our future patients may “sleep” in safety, afforded the level of care that we all wish for ourselves and our loved ones.

Clinical Monitoring I

Cardiovascular System

Mark A. Kossick

Monitoring of anatomic and physiologic variables during an anesthetic procedure enables anesthesiologists to enhance patient safety and meet established standards of care.¹ Many different monitors are commonly used to assist in the delivery of an anesthetic, and it is the responsibility of the anesthesiologist to assimilate data provided by monitors to make appropriate clinical judgments. Consequently, the application of critical thinking skills, thorough physical assessment, vigilance, and the appropriate selection and application of monitors are key requirements in the process of monitoring.

Fundamental monitoring/assessment techniques include inspection (visual examination), auscultation, and palpation. They provide essential objective and subjective data not available from advanced monitoring modalities and can alert the anesthesiologist to occult problems in select patients. *Inspection* of the patient can provide information regarding the adequacy of oxygen delivery and carbon dioxide elimination, fluid requirements, as well as positioning and alignment of body structures. *Auscultation* is used to verify correct placement of airway devices such as the endotracheal tube and laryngeal mask airway, to assess arterial blood pressure (BP), and to continually monitor heart sounds and air exchange through the pulmonary system. *Palpation* can aid the anesthesiologist in assessing the quality of the pulse and degree of skeletal muscle relaxation, as well as locating major vascular structures when placing central venous lines or performing regional anesthesia techniques.

Critical thinking skills are cardinal prerequisites for successful monitoring of a patient's anesthetic. In addition, it is well known

that errors in anesthesia care are minimized when anesthesiologists remain alert and vigilant. This chapter reviews the more commonly used noninvasive and invasive cardiovascular monitors in anesthesia practice.

Electrocardiogram Monitoring

Continuous monitoring of cardiovascular status via electrocardiogram (ECG) is a requirement for any patient receiving an anesthetic. This includes assessment of heart rate, rhythm, and, for some patients, ST segments and T waves. Computerized real-time ST segment analysis continues to be incorporated in many operating rooms (ORs), intensive care units, and postanesthesia care units across the country. Many factors support this trend, including the development of practice guidelines by professional societies that advocate such monitoring techniques in select patient populations^{2,3} and the demographics of the general surgical population. Approximately one-third of patients scheduled for noncardiac surgery have risk factors for coronary artery disease (CAD), and postoperative myocardial infarction (MI) is three times as frequent in patients with ischemia compared to patients without ischemia.⁴ Research has shown prolonged stress-induced ischemia (i.e., ST segment depression) to be the major cause for cardiac morbidity (MI) after significant vascular surgery⁵; there is also a direct relationship between recurrent ischemia detected by computer-assisted ST segment analysis in patients with unstable and myocardial morbidity (e.g., MI) and mortality.⁶ The overall incidence of perioperative ischemia in patients with CAD scheduled for cardiac or noncardiac surgery ranges from 20% to 80%.^{7,8}

As a result of its low cost, noninvasiveness, widespread availability, and designation as a standard of care for monitoring of all anesthetized patients,⁹ the ECG remains the most common and required diagnostic tool in the OR. ST segment trending monitors have an average sensitivity of 74% and an average specificity of 73% in detecting myocardial ischemia.¹⁰ When used to guide treatment in patients with silent ischemic episodes or patients considered high-risk, ST segment trending monitors may reduce morbidity.^{5,6,11}

Current recommendations for ST segment deviation thresholds account for the influence of gender, ECG lead, age, and race on the position of the ST segment.¹²⁻¹⁵ In particular, two chest leads (V₂ and

V_3) have been shown to exhibit the greatest shift of the ST junction (i.e., J point), and as such must be accounted for in applying diagnostic criteria for myocardial injury; otherwise, the proportion of false positives would increase.

The degree of elevation (or depression) is relative to an isoelectric line which is commonly referenced as the PR segment. The PR segment extends from the end of the P wave to the start of ventricular depolarization (e.g., appearance of a Q wave [Fig. 17.1]). The ST junction is defined as where the QRS complex ends and the ST segment begins. It is also synonymous with the J point. In the clinical setting, some biomedical engineers have eliminated the J point in their computerized ST segment analysis software algorithms (Fig. 17.2). Recommended threshold values for ST segment elevation are listed in Table 17.1.¹² For ST segment depression, the threshold values are -0.5 mm (-0.05 mV) for males and females of all ages in ECG leads V_2 and V_3 , and -1.0 mm (-0.1 mV) in all other ECG leads.¹² When these threshold values are met, an imbalance between oxygen supply and demand (e.g., myocardial ischemia/injury) may exist.

FIGURE 17.1 A single cardiac cycle (ST snippet) and enlarged section of the snippet providing greater details. The PR segment is measured from the end of the P wave to the beginning of the QRS complex. **(A)** A depressed ST

segment that is upsloping. The junction between the S wave and ST segment defines the ST point. **(B)** The PR segment is extended out via a horizontal line. This serves as an isoelectric reference (no deviation of the electrocardiogram stylus upward or downward) to determine the degree of ST segment shift. The distance from the extended PR segment to the ST point demonstrates that the ST segment is depressed by 3.7 mm (i.e., J point depression of 3.7 mm). (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing.)

FIGURE 17.2 Two ST snippets illustrating two different techniques to calculate ST segment depression values. The ST snippet shown in **(A)** measures ST segment deviation 80 ms (2 mm) from the J point. The ST snippet shown in **(B)** measures ST segment depression at the J point. The most recent American Heart Association/American College of Cardiology Foundation/Heart Rhythm Society recommendations for standardizing and interpreting the electrocardiogram advocate measuring ST segment changes at the J point (i.e., **B**). (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing.)

TABLE 17.1

Threshold Values for ST Segment Elevation

Gender & Age	ECG Leads	J-Point Elevation
Males ≥ 40 years of age	I, II, III, aVR, aVL, aVF V ₁ , V ₄ , V ₅ , V ₆	1 mm (0.1 mV)
	V ₂ , V ₃	2 mm (0.2 mV)
Males < 40 years of age	V ₂ , V ₃	2.5 mm (0.25 mV)
Females	I, II, III, aVR, aVL, aVF V ₁ , V ₄ , V ₅ , V ₆	> 1 mm (0.1 mV)
	V ₂ , V ₃	1.5 mm (0.15 mV)
Males & Females	*V _{3R} , V _{4R}	0.5 mm (0.05 mV)
Males < 30 years of age	*V _{3R} , V _{4R}	1 mm (0.1 mV)
Males & Females	†V ₇ , V ₈ , V ₉	0.5 mm (0.05 mV)

*Right ventricular ECG leads;

†posterior chest leads; mV, millivolt.

Data from Galen SW, et al. AHA/ACCF/HRS Expert Consensus Document: AHA/ACCF/HRS Recommendations for the Standardization and Interpretation of the Electrocardiogram. Part VI: Acute Ischemia/Infarction: A Scientific Statement from the American Heart Association Electrocardiography and Arrhythmias Committee, Council on Clinical Cardiology; the American College of Cardiology Foundation; and the Heart Rhythm Society Endorsed by the International Society for Computerized Electrocardiology. *JACC*. 2009;53:1003–1011.

It should be appreciated when critiquing the literature that researchers may use the J point in combination with the ST point as a means to determine the degree of ST segment deviation. Examples would include assessing the extent of ST segment shift by measuring 60 ms (1.5 mm) or 80 ms (2 mm) from the J-point. [Fig. 17.2](#) contrasts these two means of calculating ST segment deviation. The most current guidelines from the American College of Cardiology, the American Heart Association, and the Heart Rhythm Society recommend measuring the degree of ST segment depression or elevation at the J point to accurately determine the extent of ST segment deviation.^{12,16}

For anesthesia providers who use ST segment analysis software that incorporates a J point in combination with an ST point, caution should be exercised in blindly accepting numerical ST segment deviation values. Shortened ST segments are predictably associated with tachyarrhythmias, which can result in T waves encroaching on ST segments. Should this occur, the use of older software to determine ST segment deviation values (e.g., J + 80 ms or even J + 60

ms) could lead to an ST point intersecting a T wave instead of the ST segment. In this circumstance, the computer-derived ST segment deviation value would reflect either (1) a falsely elevated ST segment, suggesting myocardial injury (false positive) or (2) the masking of a significant ST segment depression (false negative [Fig. 17.3]). Thus, it is apparent that critical assessment of computer-generated ST segment deviation values is vital to avoid errors in patient management.

FIGURE 17.3 Two cardiac cycles from lead III and V₄ illustrating a shortened ST segment. Use of a J + 80 ms value to measure ST segment deviation in each lead results in the ST point intersecting the T wave, thus producing inaccurate ST segment deviation values. For lead III, the misplaced ST point produces a false positive, and for lead V₄, a false negative. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing.)

Regarding the significance of the various forms of ST segment depression, it is important to recall that a horizontal or downsloping depressed ST segment has greater specificity (fewer false positives) than an upsloping depressed ST segment. Adding upsloping ST segment changes to myocardial injury diagnostic criteria does improve overall sensitivity, but at a cost to the specificity and positive predictive value.^{17,18} Also, it is important to remember that it is more challenging to identify the affected regions of the myocardium based on an ST segment depression versus an elevation.¹²

Setting the ST Segment Parameters

Most manufacturers of computerized ST segment analysis monitors use sophisticated algorithms that allow fairly consistent and accurate placement of ST measurement points. Nevertheless, anesthesiologists should periodically assess these parameters and change them as needed; responding to false trends secondary to incorrectly placed ST measurement points could lead to iatrogenic injury. In fact, manufacturers have incorporated software that permits health care providers to override the monitor's placement of ST measurement points. A common technique for setting ST measurement points involves adjustment of two (Iso point and ST point) or three (Iso point, J point, and ST point) variables. Manipulation of a keypad or touchscreen device on the ECG monitor permits the operator to scroll each of these "points" along a horizontal axis. The points are depicted as vertical lines that intersect various components of a single cardiac cycle (see [Fig. 17.2](#)). [Fig. 17.4](#) illustrates the consequences when real-time ST segment analysis software incorrectly places the Iso point on the apex of the P wave. The application of an ST segment deviation algorithm can reduce the occurrence of such mishaps and improve overall management of patients at risk for ischemic changes ([Fig. 17.5](#)).

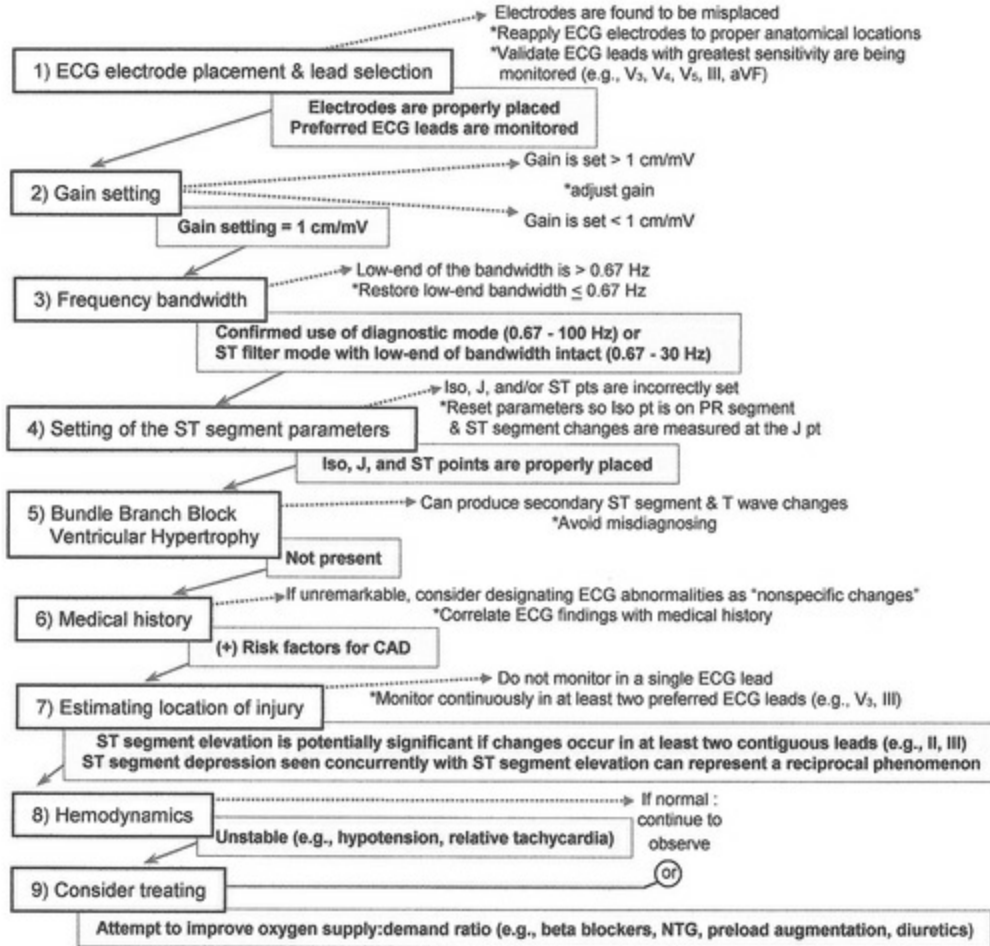

FIGURE 17.4 Iso point incorrectly placed on top of the P wave by an electrocardiogram monitor, producing an exaggerated ST segment deviation value. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing.)

ST Segment Deviation Algorithm

*Potential significant changes include ST-segment deviation threshold values of 0.5 – 2.5 mm depending on ECG lead, gender, age, & medical history

CHECK THE FOLLOWING NINE VARIABLES TO IMPROVE DIAGNOSTIC ACCURACY :

* Each of the above variables could produce a false positive or false negative

FIGURE 17.5 An ST segment deviation assessment and treatment algorithm. CAD, Coronary artery disease; ECG, electrocardiogram; NTG, nitroglycerin. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing.)

Other significant variables to account for when monitoring patients at risk for ischemic events include ECG electrode placement, ECG lead selection, gain setting, and frequency bandwidth. Each of these is briefly reviewed here.

Electrocardiograph Electrode Placement

It is fairly common to see ECG electrodes placed incorrectly on a

patient in an attempt to “move an OR schedule along.” Many times with an American Society of Anesthesiologists (ASA) I or II patient, accurate ECG electrode placement is not a significant issue.

However, in patients with risk factors for CAD, such inattentiveness can lead to iatrogenic injury by producing deviated ST segments, inverted T waves, or pathological Q waves that can be viewed as “real” problems. Proper placement of the limb lead and chest lead electrodes is described in [Table 17.2](#). For emphasis, the precordial leads should be placed via palpation of the costae, not by gross visual estimation of an intercostal space ([Fig. 17.6](#)).

Understandably, some surgical procedures do not permit the use of optimal ECG lead selection and placement, as ECG electrodes can interfere with skin preparation and surgical incisions. Under these circumstances, it may be necessary to settle for a less than optimal ECG lead placement by sacrificing a preferred chest lead and/or limb lead. When this occurs, the reason for not monitoring in the desired ECG lead should be documented on the anesthetic record to provide evidence of still meeting established American Association of Nurse Anesthetists (AANA) practice standards (e.g., Standard V and VI).¹

TABLE 17.2

Proper Placement of Electrocardiographic Electrodes for Monitoring Chest Leads and Limb Leads

RA	*Over the outer right clavicle
LA	*Over the outer left clavicle
LL	*Near the left iliac crest or midway between the costal margin and left iliac crest, anterior axillary line
RL	At any convenient location on the body (e.g., upper right shoulder)
V ₁	Fourth intercostal space right of the sternal border
V ₂	Fourth intercostal space left of the sternal border
V ₃	Equal distance between V ₂ and V ₄
V ₄	Midclavicular line at the fifth intercostal space
V ₅	Horizontal to V ₄ on the anterior axillary line; or, if the anterior axillary line is difficult to identify, then midway between V ₄ and V ₆
V ₆	Horizontal to V ₅ on the midaxillary line
V ₇	Horizontal to V ₆ on the posterior axillary line
V ₈	Horizontal to V ₇ below the left scapula
V ₉	Horizontal to V ₈ at the left paravertebral border
V _{3R}	Right side of chest wall in mirror image to chest lead V ₃
V _{4R}	Right side of chest wall in mirror image to chest lead V ₄

*Mason-Likar electrocardiographic electrode placement; *LA*, Left arm electrocardiographic electrode; *LL*, left leg electrocardiographic electrode; *RA*, right arm electrocardiographic electrode; *RL*, right leg electrocardiographic electrode.

Electrocardiographic Lead Selection

The decision regarding which ECG leads to monitor during the

course of an anesthetic can be extremely important relative to the medical history of the patient. Improper selection can result in unrecognized myocardial ischemia, injury, or infarction. Research has validated that use of a single ECG lead for ischemic monitoring in patients with documented CAD is inadequate; monitoring with multiple leads enhances patient safety. In patients at risk for ischemic events, this author recommends that the maximum number of ECG leads be displayed (e.g., 3, 7, or 12 [derived 12-lead]) during the perioperative period to enhance continuous and comprehensive assessment of ST segment and T wave changes (Figs. 17.7 and 17.8). Which lead(s) is/are optimal to use for detecting significant ST segment changes should be based upon the preanesthetic assessment. First and foremost, if a preoperative 12-lead ECG has been done, “fingerprinting” of this tracing should serve as the primary guide for lead selection during the perioperative period. For example, if the baseline 12-lead shows significant primary ST segment changes in limb leads III and aVF, then this lead set should be prioritized for continuous display in the OR. The ECG monitoring system software will dictate what lead display options can be configured. For example, with Philips software and a five-cable ECG lead system, a derived 12-lead (EASI) can be continuously displayed (see Fig. 17.8). With other manufacturers and a five-cable ECG lead system, a true V lead (e.g., V₃), a modified V₅ chest lead (e.g., central subclavicular 5 [CS₅]), and a bipolar limb lead (e.g., lead II) can be configured for ECG monitoring (Fig. 17.9). The potential value of a preoperative 12-lead ECG depends on it being correctly recorded by the ECG technician (e.g., each ECG electrode was properly placed, the patient was in a supine position while it was recorded,¹⁹ and the low-frequency cutoff was set with a lower limit not exceeding 0.67 Hz^{19,20}).

FIGURE 17.7 Monitoring in three electrocardiogram leads during anesthetic administration captured significant ST segment elevation. The greatest change in ST segments occurred in limb lead III, followed by limb lead II. Noteworthy was the failure of lead V₅ to demonstrate any appreciable change in the ST segment. Postoperatively, a cardiology consultation resulted in a diagnosis of Prinzmetal angina.

FIGURE 17.8 Derived 12-lead electrocardiogram (ECG [EASI]) recorded just prior to anesthetic induction in the operating room. The ECG monitor can be configured to continuously display all 12 leads for comprehensive assessment of ST segments and rhythm changes.

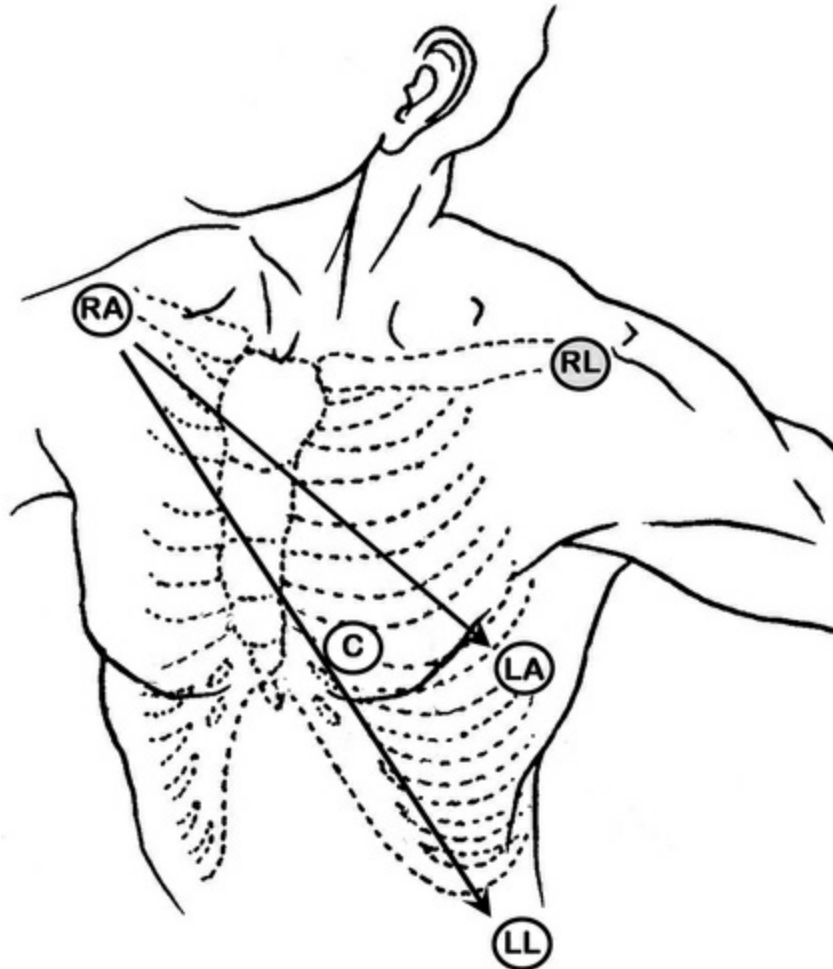

FIGURE 17.9 Preoperative electrocardiogram (ECG) configured with a five-cable ECG system to continuously display limb lead II (right arm [RA] negative and left leg [LL] positive), true V_3 chest lead (C), and modified chest lead 5 (MCL₅, i.e., central subclavicular 5 [CS₅]). V_3 electrode placement (C): equal distance between V_2 and V_4 . Lead selector switch set to display lead I causes the RA electrode to become negative and the left arm (LA) electrode (placed in the V_5 position) to become positive (CS₅). RL, Right leg. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing.)

In patients without a preoperative 12-lead or who have a baseline 12-lead that is unremarkable (unknown ST fingerprint), the literature suggests that leads V_3 , V_4 , V_5 , limb lead III, and aVF (in this order of preference) be selected for continuous monitoring for ST segment elevation or depression.²¹⁻²⁶ Limb lead II is recommended for assessment of narrow QRS complex rhythms,

particularly if the P wave is significant for diagnostic criteria (e.g., atrial flutter, atrial fibrillation, junctional rhythms).

The 1988 recommendation for V₅ and limb lead II as the preferred ECG leads²⁷ in patients where ST segment monitoring is desired has been challenged by other researchers, critical care task forces, and major publications.^{2,22,24,28,29} In 2002, Landesberg et al. studied 185 consecutive patients undergoing vascular surgery who were monitored by continuous 12-lead ST-trend analysis during the perioperative period and up to 72 hours postoperatively. Chest lead V₃ was found to detect ischemia earliest and most frequently (86.8%). Lead V₄ was the second most diagnostic lead (78.9%), and V₅ came third (65.8%). In patients sustaining an MI, V₄ was the most sensitive lead (83.3%), with V₃ and V₅ being the second most sensitive (75%).²⁴ In this study, MI was diagnosed if cardiac troponin I levels were greater than 3.1 ng/mL and were accompanied by symptoms of ischemia or the presence of ECG criteria (i.e., ST segment elevation, ST segment depression, or large Q waves). Of interest is the observation that 97% of ischemic events were expressed as ST segment depressions—not elevations—and ST shifts were considered significant if their duration of change exceeded 10 minutes. As reported elsewhere in the literature, monitoring in multiple leads was advocated as a means to improve sensitivity for detecting ST segment changes.^{5,24,25,27}

Given this information, it is prudent for anesthesia providers to monitor and assess multiple ECG leads in the OR. In the absence of an ST segment fingerprint, this author advocates the following ECG lead combinations (for ST segment elevation or depression) in patients with documented or identified significant risk factors for ischemic heart disease:

1. For a five-cable ECG recording system, the 3-lead set of V₃, MCL₅, and aVF (the use of MCL₅ precludes the use of limb lead III), or V₃ combined with limb lead III and aVF.
2. For a three-cable ECG recording system, a 2-lead set comprising MCL₅ combined with limb lead aVF.

Extended monitoring capabilities help to optimize detection of

regionalized myocardial ischemia. Many times, this entails nothing more than changing the lead selector switch to another ECG lead (e.g., changing III to aVF) or displaying a multilead ECG when indicated or continuously during an anesthetic (Fig. 17.10). The latter produces an ECG recording of all six limb leads and a single chest lead, permitting the anesthetist to more comprehensively assess ECG data, including arrhythmias, the mean QRS axis (i.e., limb leads I and aVF), T wave morphology, ST segment changes, QT intervals, and the presence of right or left bundle branch block.

FIGURE 17.10 Multilead electrocardiogram (ECG) displayed in the operating room. ECG leads displayed include limb leads I, II, III, aVR, aVL, aVF, and true chest lead V₃. This configuration permits a more comprehensive view of cardiac anatomy. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing.)

With the introduction into clinical practice of the EASI system, nurses and physicians have a convenient method to globally assess the overall wellbeing of the myocardium (see Fig. 17.8). The 12-lead is derived from modified vectorcardiographic leads and requires

the use of a five-cable ECG lead system.³⁰ To monitor with this system, the five ECG electrodes are placed in the following locations: LA electrode over the manubrium; chest (V) electrode over the lower body of the sternum; LL electrode left midaxillary, horizontal to the chest electrode; RA electrode right midaxillary, also horizontal to the chest electrode; and the RL electrode in any convenient location. Current and past research suggests the derived 12-lead is comparable (but not equivalent)¹⁹ to the standard 12-lead for multiple cardiac diagnosis in adults and children (e.g., ST segment changes, MI, wide QRS complex tachycardia, or QT interval measurements).³¹⁻³⁵ It is possible that patients at substantial risk for CAD would benefit from global ischemic monitoring via a derived 12-lead. This software option also eliminates any need to consider “preferred” ECG leads, because all six limb leads and six chest leads can be viewed during an anesthetic.

In contrast to a derived 12-lead or five-cable ECG electrode system, a three-cable system offers challenges to anesthesia providers due to potential errors with ECG lead configuration. The literature documents that health care providers consistently struggle with modified chest lead configuration—even those who routinely monitor the ECG.³⁶ Modified chest leads offer an alternative to true chest leads when only a three-cable ECG recording system is available. The modified chest lead $MAC_{1(L)}$ (modified augmented chest lead V_1) was introduced into clinical practice in 2003. This modified chest lead is configured using augmented limb lead aVL and has been shown to have a diagnostic accuracy similar to true chest lead V_1 . The internal validity of this finding was based on His-bundle recordings, which are the gold standard for distinguishing between premature ventricular ectopy and premature aberrantly conducted beats.³⁷ The simplicity of this unique ECG lead has the potential to reduce modified chest lead configuration errors. Research would need to be done to substantiate this theoretical advantage (e.g., ease of configuration of $MAC_{1(L)}$ vs modified chest lead V_1 [MCL_1]). [Fig. 17.11](#) illustrates the ECG configuration of $MAC_{1(L)}$, as well as the similarities in morphologic characteristics of single cardiac cycles recorded in V_1 and $MAC_{1(L)}$.

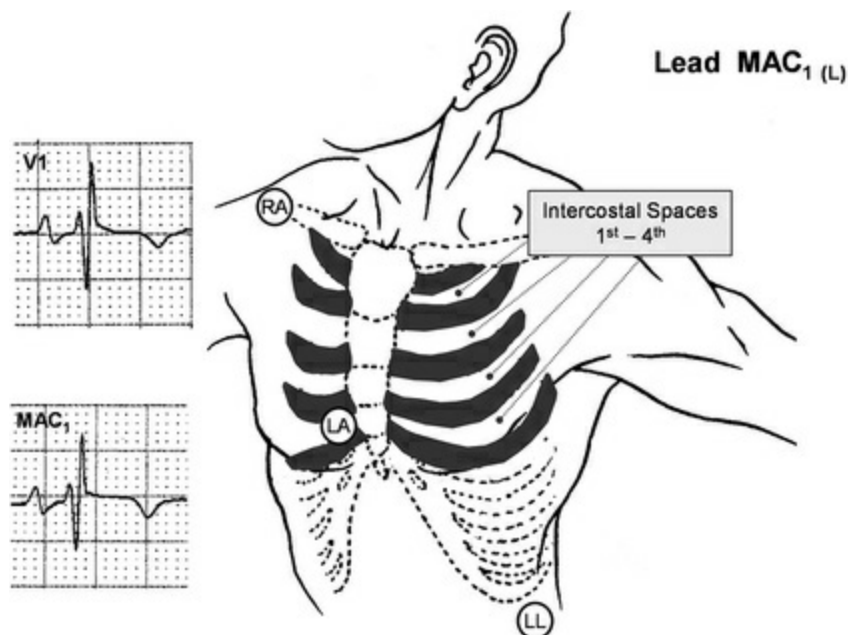

FIGURE 17.11 Modified augmented chest lead V_1 ($MAC_{1(L)}$). It is configured by (1) using limb lead aVL, which causes the left arm (LA) electrode to become positive, and (2) placing the LA electrode in the V_1 position. The remaining ECG electrodes are placed in their normal positions. These two single cardiac cycles illustrate great similarity in cardiac cycle morphology between V_1 and $MAC_{1(L)}$. LL, Left leg; RA, right arm. (Modified and reprinted with permission from Kossick MA. *Evaluation of a new modified chest lead in diagnosing wide complex beats of unknown origin*. Dissertation. Memphis, Tenn: The University of Tennessee Health Science Center; 2003:2,9.)

In summary, practitioners who limit ECG monitoring and assessment to a single lead or pair of leads in patients with documented or recognized risk factors for ischemic heart disease are potentially compromising patient safety by not using multilead display configuration options (when available).² In such patients, the continuous display of three ECG leads, a multilead ECG (six limb leads and one true chest lead), or a derived 12-lead could be of clinical benefit. The literature substantiates that myocardial ischemia (T wave and/or ST segment changes) can be regionalized and completely missed when viewing two or fewer ECG leads. Similar concerns exist when three-cable ECG lead systems are used in place of available five-cable ECG lead systems. The latter permits the viewing of a true chest lead, which is always preferred over a modified chest. Unarguably, critical assessment of all available

patient data will help anesthesiologists exercise better judgment during an anesthetic and potentially improve anesthetic outcome.

Gain Setting and Frequency Bandwidth

Two other potential problems with continuous ST segment monitoring relate to the amplitude at which the ECG monitor has been set and whether filtering of the electrical signal is excessive. When accurate visual assessment of ST segments is a priority during an anesthetic, the gain of the ECG monitor should be set at standard levels (i.e., a 1 mV signal delivered by the ECG monitor produces a 10-mm calibration pulse). This gain setting fixes the ratio of the ST segment and QRS complex size so that a 1-mm ST segment change (indicating potential myocardial injury) is accurately assessed. Failure to recognize the use of other gain settings can lead to overdiagnosis or underdiagnosis of myocardial injuries (ST segment changes). [Fig. 17.12](#) illustrates how changes in gain settings and incorrect ECG electrode and/or lead wire placement can confound ST segment assessment. ^{19,38,39}

FIGURE 17.12 Series of electrocardiographic (ECG) recordings illustrating how the gain setting and incorrect ECG electrode placement can lead to misinterpretation of ST segment changes. In strip **A**, the gain setting (*arrow*) on

the ECG monitor has been set at half standardization (1 mV = 5 mm); it grossly gives the appearance of a minor ST segment change. When concurrent strip **B** is compared with strip **A**, it becomes apparent that use of smaller gain settings can mask ST segment deviation. Therefore, if a 0.5-mm ST segment deviation in ECG strip **A** were to occur, it would equate with a 1-mm change. A similar error in assessment of ST segment changes can occur secondary to misplaced ECG electrodes. ECG strip recording **C** has all limb lead electrodes properly placed and displays an ST segment elevation of approximately 0.75 mm. In contrast, ECG rhythm strip **D** mistakenly has the left leg electrode placed in the second intercostal space, midclavicular line, and therefore is not representative of a lead II. The end result is an ST segment that is falsely elevated (approximately 1.5 mm), suggesting inferior transmural myocardial injury. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 2nd ed. Park Ridge, Ill: AANA Publishing; 1999:26–27.)

The filtering capacity of the ECG monitor is yet another potential source of artifact. Research has demonstrated that filtering out the low end of the frequency bandwidth (e.g., 0.05 to 0.5 Hz, to produce a new bandwidth range of 0.5 to 40 Hz) of the monitor's electrical signal can lead to distortion of the ST segment (elevation or depression) and the T wave (inversion).^{40,41} For this reason, the diagnostic mode of an ECG monitor should be used in many (but not all) cases when ST segment analysis is a priority during an anesthetic. However, as noted previously, the low-frequency cutoff has been amended by the American National Standards Institute and the Association for the Advancement of Medical Instrumentation to a value not to exceed 0.67 mV for routine filters.²⁰ This recommendation has also been endorsed by the International Society for Computerized Electrocardiology.¹⁹

Clearly, the sensitivity and specificity of computerized real-time ST segment analysis software is dependent on the ability of the anesthetist to critically analyze the large number of factors that influence displayed ST segment values. Attentiveness to such variables as the patient's physical status, the ECG lead placement and selection, verification of proper placement of the Iso point and the ST point, the type of electronic filtering used by the ECG

monitor, and the gain setting may affect anesthetic outcome in patients at risk for myocardial ischemia or injury. In essence, overreading of ECG data is not optional, but is an essential part of anesthesia care.

Central Venous and Arterial Hemodynamic Measurements

Central venous catheters and pulmonary artery catheters (PAC) are not commonly used in the general surgical population. In fact, since the introduction of the PAC in 1970, the frequency of its use as a monitoring tool for significant surgical procedures has significantly diminished. Even during cardiac or large invasive vascular surgical procedures, many surgeons and anesthesia providers have opted for less invasive means to assess hemodynamic measurements (e.g., the Flo Trac sensor). Part of the rationale for this change in practice relates to insufficient evidence demonstrating decreased mortality due to use of the PAC.⁴² The literature is clear in regards to the numerous challenges health care providers face in accurately interpreting data derived from PACs and central venous lines.⁴³ Cardinal concepts that relate to critical assessment of hemodynamic data will be reviewed in this section.

Practice guidelines for PAC use have been recommended and established by various professional societies.⁴⁴ It is also recognized that the competency of health care providers to manage central venous and arterial hemodynamic parameters can vary significantly. In one study, attending physicians from the departments of medicine, surgery, and anesthesia were unable to correctly determine the pulmonary artery occlusive pressure (PAOP) from a clear tracing and apply PAC data for proper patient treatment.⁴⁵ A study of anesthesiologists who specialize in cardiovascular anesthesia care also demonstrated cognitive deficits with the use of the PAC (e.g., 39% of cardiovascular anesthesiologists could not correctly interpret a PAOP waveform).⁴⁶ Results from these two studies suggest that the understanding of PAC data among health care providers is extremely variable, and misinterpretation of PAC data may result in increased morbidity and mortality. It is likely that similar deficiencies in the application and interpretation of PAC data exists for advanced practice nurses (including Certified Registered Nurse Anesthetists [CRNAs]), especially given that failing scores were noted on competency tests

used to assess other areas of critical care.³⁶ Such research findings have caused several groups to develop guidelines for the indications of a PAC, along with competency requirements for interpretation of data.^{44,47}

Physiology and Morphology of Hemodynamic Waveforms

Essential to accurate interpretation of hemodynamic data derived from central venous lines is a solid foundation in what constitutes “normal” distances, pressures, and waveform morphology for central venous pressure (CVP) and right ventricular (RV), PA, and PAOP recordings. Table 17.3 illustrates the approximate distances for reaching the junction of the *venae cavae* and the right atrium (RA) from various distal anatomic sites. Table 17.4 lists the anticipated distances for reaching various cardiac and pulmonary structures from the right internal jugular vein. Advancement of a catheter 10 cm beyond these distances without the production of a characteristic waveform could indicate coiling of the central line. If this problem arises with a PAC, the balloon should be deflated and the catheter withdrawn. If any resistance is met during withdrawal, a chest radiograph should be taken to rule out knotting or entanglement with the *chordae tendineae*.

TABLE 17.3

Distance to the Junction of the Venae Cavae and Right Atrium From Various Distal Anatomic Sites

Location	Distance (cm)
Subclavian	10
Right internal jugular vein	15
Left internal jugular vein	20
Femoral vein	40
Right median basilic vein	40
Left median basilic vein	50

TABLE 17.4

Distance From the Right Internal Jugular Vein to Distal Cardiac and Pulmonary Structures

Location or Structure	Distance (cm)
Junction of the venae cavae and right atrium	15
Right atrium	15–25
Right ventricle	25–35
Pulmonary artery	35–45
Pulmonary artery wedge position	40–50

Right Atrial Pressure Waveform

Familiarity with the anticipated distances of relevant hemodynamic anatomy, as well as normal intracardiac pressures, pulmonary pressures (Table 17.5), and waveform morphology, facilitates accurate interpretation of PAC data and placement of central lines. For example, under normal circumstances, a CVP tracing will generate mean RA pressures in the range of 1 to 10 mm Hg. The fidelity of the transducing system determines whether discernible *a*, *c*, and *v* waves will be displayed once the distal tip of a central line lies just above the junction of the *venae cavae* and the RA (Fig. 17.13). The *a* wave is produced by contraction of the RA, the *c* wave by closure of the tricuspid valve, and the *v* wave by passive filling of the RA (which encompasses a portion of RV systole). The reason the *a* wave is commonly larger than the *c* wave is based on the position of the catheter relative to the physiologic event responsible for the pressure change. In essence, RA systole and the subsequent increase in atrial pressure is detected by a catheter positioned just above (or inappropriately within) the RA, whereas RV systole (a more distal physiologic event relative to the position of a CVP catheter) indirectly increases RA pressure by closure of the tricuspid valve.

TABLE 17.5

Normal Intracardiac and Pulmonary Pressures

Location	Absolute Value (mm Hg)	Range (mm Hg)
MRAP	5	1–10
RV	25/5*	15–30/0–8
PA S/D	25/10*	15–30/5–15
MPAP	15	10–20
PAOP	10	5–15
MLAP	8	4–12
LVEDP	8	4–12

*Values indicate systolic pressure/diastolic pressure.

LVEDP, Left ventricular end-diastolic pressure; *MLAP*, mean left atrial pressure; *MPAP*, mean pulmonary artery pressure; *MRAP*, mean right atrial pressure; *PA*, pulmonary artery; *PAOP*, pulmonary artery occlusive pressure; *RV*, right ventricular; *S/D*, systolic/diastolic.

FIGURE 17.13 Positive and negative waveforms of a central venous pressure tracing. The third cardiac cycle in this figure does not produce a c wave.

Right Ventricular Pressure Waveform

Further advancement of a PAC (by approximately 10 cm) produces dramatic changes in the morphology of the hemodynamic waveform. As shown in Fig. 17.14, a rapid upstroke (isovolumetric contraction and rapid ejection [RV systole]) and steep downslope (reduced ejection and isovolumetric relaxation [RV systole and diastole]) are viewed on an oscilloscope when a PAC is advanced through the right intraventricular cavity. A PAC with the distal balloon inflated should remain in the RV for as short a time as possible to reduce the incidence of ventricular ectopy, or the development of a conduction defect such as right bundle branch block. Because it is undesirable to leave the tip of a central line in the RV, pressures generated during RV systole and RV diastole are assessed indirectly via the CVP port of a PAC and the distal tip of the PAC. The former is used to estimate RV end-diastolic pressure (RVEDP), and the latter is used to estimate RV systolic pressure via the PA systolic recording. Thus, RVEDP is used to estimate RV end-diastolic volume (RVEDV), which approximates RV preload (and, less accurately, left ventricular [LV] preload).

FIGURE 17.14 Pressure waveforms during positioning of a pulmonary artery catheter (PAC). *EDP*, End-diastolic pressure; *PAOP*, pulmonary artery occlusive pressure; *PAP*, pulmonary artery pressure; *RAP*, right atrial pressure; *RVP*, right ventricular pressure. 1, Isovolumetric contraction (ascent of pressure waveform); 2, rapid ejection; 3, isovolumetric relaxation (mid-descent of pressure waveform); 4, atrial systole (slight increase in pressure).

Pulmonary Artery Pressure Waveform

When a catheter enters the PA, the diastolic pressure is acutely increased, with little change in the systolic pressure. The upstroke of the PA tracing is produced by opening of the pulmonic valve, followed by RV ejection. The downstroke contains the dicrotic notch, which is produced by sudden closure of the pulmonic valve leaflets (the beginning of diastole).

Pulmonary Artery Occlusive Pressure Waveform

Final advancement of a PAC by 5 to 10 cm should produce a PAOP tracing. This waveform is similar to a CVP (the *a* wave is produced by left atrial [LA] systole, the *c* wave by closure of the mitral valve, and the *v* wave by filling of the LA, as well as upward displacement of the mitral valve during LV systole), except that the pressure values are somewhat greater. In addition, it is less common to detect a *c* wave on a PAOP tracing, because retrograde transmission of LA pressure (produced by closure of the mitral valve) is significantly attenuated within the pulmonary circulation. The characteristic waveform morphologies of a PAOP tracing are shown in [Fig. 17.14](#).

Negative Waveforms

The descents that follow the *a*, *c*, and *v* waves of a CVP or PAOP tracing are labeled as *x*, *x*¹, and *y* (see Fig. 17.13). The *x* descent corresponds to the start of atrial diastole; more specifically, its terminal component (just before the upstroke of the *c wave* [or, in its absence, the *v wave*]) with RVEDP and LVEDP. The *x*¹ descent is produced by downward pulling of the septum during ventricular systole, and the *y* descent corresponds to opening of the tricuspid valve.

Correlation of Pressure Waveforms and the Electrocardiogram

The interpretation of hemodynamic waveforms can be facilitated by correlating their morphology and timeline with the ECG. The *a* wave of a CVP tracing, which is produced by atrial contraction, will follow depolarization of the atria (i.e., the P wave on the ECG). The *c* and *v* waves occur after the beginning of ventricular depolarization (QRS complex); alternatively, the *v* wave may not appear until shortly after the T wave (Figs. 17.15 and 17.16). When compared with the CVP tracing, the PAOP recording shows greater hysteresis between the waveforms of the ECG and the display of *a*, *c*, and *v* waves, meaning there is a greater distance between ECG activity and the subsequent pressure waveform. Identification of abnormal waveforms is greatly facilitated by the use of the ECG; for example, without an ECG recording, large positive waveforms on a PAOP tracing can be diagnosed as either cannon *a* waves or large *v* waves.

FIGURE 17.15 Temporal relationship between the electrocardiogram and hemodynamic waveforms.

FIGURE 17.16 Electrocardiographic recording with a concurrent central venous pressure tracing that demonstrates hysteresis between atrial depolarization (P wave) and the production of an *a* wave, as well as the QRS complex and the associated *c* and *v* waves.

Distortion of Pressure Waveforms

Arrhythmias can produce significant alterations in hemodynamic waveforms. Atrial fibrillation, junctional rhythms, and premature ventricular contractions) can alter the shape of *a* waves. With atrial fibrillation, no synchronized atrial contraction occurs. In the CVP or PAOP tracing, this can lead to the loss of *a* waves or the appearance of small fibrillatory *a* waves. Complete atrioventricular block and some forms of junctional arrhythmias cause the atria to contract against a closed tricuspid valve, which can produce large cannon *a*

waves (Fig. 17.17). Ventricular pacing can be associated with both the presence of cannon *a* waves and the loss of *a* waves. The former occurs if a patient does not have an atrioventricular sequential pacemaker; the latter when ventricular pacing is used in the setting of asystole (neither atrial or ventricular depolarization is occurring). Valvular defects can also produce dramatic changes in the CVP and PAOP tracings, causing an increase in the amplitude of the *v* wave secondary to regurgitation (with mitral regurgitation (MR), a portion of the stroke volume is ejected retrograde into the pulmonary circuit, owing to an incompetent mitral valve). Recognition of such abnormalities is critical for accurate recording of pressure measurements and proper placement of central lines. Significant tricuspid regurgitation can cause a CVP recording to mimic an RV tracing, and MR can cause a PAOP recording to appear as a PA tracing. Specifically, large *v* waves become superimposed on *a* waves. For the indistinguishable PA and PAOP recording, analysis of a mixed venous oxygen saturation (SVO₂) blood sample can assist in making a differential diagnosis. The saturation will be elevated (greater than 77%) if the catheter is in a wedged position, assuming the distal tip is not in a region of the lung that is atelectatic; which, in contrast, would produce a false-negative result (normal or low SVO₂). As a precautionary measure, a catheter suspected of being in a wedged position should not be flushed with the fluid contained in the pressurized transducing system. Although the overall incidence of PA rupture is low (0.064%),⁴⁸ flushing of a wedged catheter (as well as balloon overinflation) can result in vascular damage ranging from minor endobronchial hemorrhage to massive hemoptysis.

FIGURE 17.17 Electrocardiographic recording of a junctional rhythm (*top*) in which there is simultaneous retrograde atrial and antegrade ventricular depolarization

(as evidenced by the lack of a P wave in each cardiac cycle). This results in the right atrium contracting against a closed tricuspid valve. As a consequence, the central venous pressure tracing (*bottom*) has cannon *a* waves.

Significant tricuspid regurgitation and MR may also be associated with normal CVP and PAOP tracings.⁴⁹ These occur in patients with a low volume status and compliant atria. In addition, a poor correlation has been found between the size of the *v* wave and the degree of regurgitation. Also of interest is the finding that large *v* waves can be observed in the absence of significant regurgitation. This phenomenon can occur whenever an acute increase in preload occurs, which dynamically reduces atrial and pulmonary vascular compliance.⁴⁹

Whenever large *v* waves are detected on a CVP or PAOP tracing, estimates of preload should be measured just before the upstroke of the *v* wave (or *c* wave, when present). This point on the pressure recording equates with the EDP, the moment just before ventricular systole that ultimately produces the large *v* waves. [Box 17.1](#) indicates how various rhythm disturbances, pacing, and valvular defects can distort the CVP tracing.

Factors That Can Distort Central Venous Pressure and Pulmonary Artery Occlusive Pressure Tracings

Loss of *a* Waves or Only *v* Waves

- Atrial fibrillation
- Ventricular pacing in the setting of asystole

Giant *a* Waves or “Cannon” *a* Waves

- Junctional rhythms
- Complete AV block
- PVCs (simultaneous atrial and ventricular contraction)

- Ventricular pacing (asynchronous)
- Tricuspid or mitral stenosis
- Diastolic dysfunction
- Myocardial ischemia
- Ventricular hypertrophy

Large *v* Waves

- Tricuspid or mitral regurgitation
- Acute ↑ in intravascular volume

↑, Increase; *AV*, atrioventricular; *PVCs*, premature ventricular contractions.

Implications of Abnormal Hemodynamic Values

The CVP serves as an estimate of RV preload. [Table 17.6](#) lists the causes of an elevated CVP. A low CVP correlates with hypovolemia of any cause. As stated previously, RV pressures can be assessed indirectly from the CVP and PA pressure (PAP) recordings. RV values can be elevated secondary to pulmonary hypertension, ventricular septal defect, pulmonary stenosis, RV failure, constrictive pericarditis, or cardiac tamponade.

TABLE 17.6

Potential Causes of Elevated Central Venous Pressure, Pulmonary Artery Pressure, and Pulmonary Artery Occlusive Pressure

CVP	PAP	PAOP
• RV failure	• LV failure	• LV failure
• Tricuspid stenosis or regurgitation	• Mitral stenosis or regurgitation	• Mitral stenosis or regurgitation
• Cardiac tamponade	• L-to-R shunt	• Cardiac tamponade
• Constrictive pericarditis	• ASD or VSD	• Constrictive pericarditis
• Volume overload	• Volume overload	• Volume overload
• Pulmonary HTN	• Pulmonary HTN	• Ischemia

ASD, Atrial septal defect; CVP, central venous pressure; HTN, hypertension; L, left; LV, left ventricular; PAOP, pulmonary artery occlusive pressure; PAP, pulmonary artery pressure; R, right; RV, right ventricular; VSD, ventricular septal defect.

Like the RV waveform, the PA tracing occurs within the QT interval of the ECG. LVEDP can be estimated by measuring the pressure value that exists just prior to the upstroke of the PA waveform (see [Fig. 17.14](#)). See [Table 17.6](#) for a list of causes of an increase in the PAP. A false high value can also be produced by a phenomenon called *catheter whip*, which is exaggerated oscillation of the PA tracing. This can occur with excessive catheter coiling if the tip of the PA catheter is near the pulmonic valve; it also occurs in patients with dilated pulmonary arteries, which may occur if pulmonary hypertension exists.

When properly used, the PAOP recording has the potential to improve the clinician's ability to make a differential diagnosis in critically ill patients. Like the CVP, it indirectly assesses ventricular function and therefore has distinct limitations. To ensure that accurate pressure recordings are documented, the mean or diastolic pressure should always be determined at end-expiration (whether the patient is spontaneously breathing or receiving positive pressure ventilation). This is the time when pleural pressures are approximately equal to atmospheric pressures (except when positive end-expiratory pressure [PEEP] is being used). The rationale for this timing relates to the fact that vascular pressure recordings are calibrated relative to atmospheric pressure. As stated previously, the correct area on the pressure recording to determine preload (e.g., LVEDP) is just before the upstroke of the *v* wave (or *c* wave, if present). Causes of an elevated PAOP are listed in [Table 17.6](#).

Variables That Influence Hemodynamic Measurements

Recognizing how numerous variables can skew displayed pressure values is essential for proper management of hemodynamic parameters. The foundation for understanding PAC data begins

with the recognition that absolute numbers are generally not as important as trends. In addition, most of the data obtained from a PAC allows only for indirect assessment of cardiovascular function and pulmonary indices. For example, PA diastolic pressure (PADP) approximates PAOP, which approximates LA pressure, which approximates LVEDP, which provides an estimate of left ventricular end-diastolic volume (LVEDV). [Table 17.7](#) lists clinical factors that can skew these pressure and volume relationships. Obviously, reliance on indirect pressure measurements mandates that the anesthetist understand how to interpret these data in light of such limitations. For most patients who require a PAC or CVP, it should be assumed that several, if not numerous, pathophysiologic states exist (e.g., cardiovascular disease, pulmonary dysfunction) that will skew the pressure-to-pressure and pressure-to-volume relationships.

TABLE 17.7

Factors That Alter the Relationships Among Central Cardiovascular Pressures and Volumes

CVP ≠ PADP	<ul style="list-style-type: none"> • Change in RV compliance (e.g., PS) • Tricuspid valve disease
PADP ≠ PAOP	<ul style="list-style-type: none"> • Pulmonary HTN • MR or AR • Lung zone I or II • Tachycardia • ARDS • RBBB
PAOP ≠ MLAP	<ul style="list-style-type: none"> • Juxtacardiac pressure (e.g., PEEP) • Lung zone I or II • Mediastinal fibrosis • RBBB
MLAP ≠ LVEDP	<ul style="list-style-type: none"> • Juxtacardiac pressure (e.g., PEEP) • Mitral valve disease • Change in LV compliance (e.g., AS)
LVEDP ≠ LVEDV	<ul style="list-style-type: none"> • Juxtacardiac pressure (PEEP) • Ventricular interdependence • Change in LV compliance (e.g., ischemia)

AR, Aortic regurgitation; ARDS, acute respiratory distress syndrome; AS, aortic stenosis; CVP, central venous pressure; HTN, hypertension; LV, left ventricular; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume; MLAP, mean left atrial pressure; MR, mitral regurgitation; PADP, pulmonary artery diastolic pressure; PAOP, pulmonary artery occlusive pressure; PEEP, positive end-expiratory pressure; PS, pulmonic stenosis; PVR, pulmonary artery vascular resistance; RBBB, right bundle branch block; RV,

right ventricular.

Of the variables listed in [Table 17.7](#), several require further discussion. Many of the factors listed can be viewed as disruptions or obstructions of the continuous column of blood that exists between the RA and LV. This is the case for valvular defects and pulmonary factors.

The goal for placement of a PAC is to have it reside in a West zone III⁵⁰ of the lung; this usually does occur, because the bulk of pulmonary blood flow lies within this physiologically defined region of the lung. In this position, the PAP is greater than the pulmonary venous pressure, which is greater than the alveolar pressure. This zone corresponds to a complete circuit or conduit that allows for direct communication between right-sided heart and pulmonary pressures with left-sided intraventricular pressures ([Fig. 17.18](#)). It is important to recall that each of the lung zones is physiologically – not anatomically – defined; thus, a zone III can change into a zone II ($PAP > \text{alveolar pressure} > \text{pulmonary venous pressure}$) or a zone I ($\text{alveolar pressure} > PAP > \text{pulmonary venous pressure}$), which is also known as a *no-flow zone*.

FIGURE 17.18 Pulmonary artery catheter with balloon inflated (wedging) in a West lung zone III. In this zone, pulmonary pressures equilibrate during diastole, because both arterial and venous pulmonary pressures are greater than alveolar pressures. The addition of positive end-expiratory pressure (*dashed line [alveolus]*) or hypovolemia can convert a zone III to a zone I or II and lead to

distended alveoli and inaccurate estimates of pressures distal to the invagination. P_a , Arterial pressure; P_A , alveolar pressure; P_v , venous pressure; PA , pulmonary artery.

Factors that contribute to the dynamic state of zone III include the application of PEEP (see Fig. 17.18), significant diuresis, hemorrhage, and a change in patient position (e.g., supine to sitting). The influence of PEEP is contingent on the quantity applied, the intravascular volume status, and the pulmonary compliance. Normally, less than 50% of PEEP is transmitted to the microvasculature—even less if pulmonary compliance is poor (e.g., patients with adult respiratory distress syndrome).⁵¹ In contrast, patients with decreased volume status (e.g., left atrial pressure less than 5 mm Hg) who receive PEEP as low as 7.5 cm H₂O can have collapse of the pulmonary capillaries, which distorts the PAOP.⁵² A PAC located in zone I or II will produce marked variations in the PAOP waveform recording during the ventilatory cycle. In addition, *a* and *v* waves (cardiac influences) are lost, and the PAOP exceeds the PADP. This is in contrast to a PAOP recording produced by a catheter located in a true wedge position in a zone III. The distinguishing criteria include the development of a characteristic waveform with balloon inflation and a PAOP reading less than or equal to the PADP. The latter criterion assumes that no valvular defect is present, which could also cause the mean PAOP to exceed the PADP.

A rapid heart rate (HR) can also skew the relationship between PADP and the PAOP. Research has demonstrated that left-atrial-paced induced tachycardia (increased HR from 74 to 124 beats per minute) can produce an 11-mm Hg gradient between the PADP and LVEDP.⁵³ The increase in PADP and decrease in LVEDP result from the shortening of diastole, which reduces the amount of blood being transported from the pulmonary circulation to the LV.⁵³ Also, as HR increases, the left atrium begins to contract against a partially closed mitral valve.⁵⁴

Another variable that significantly influences PAC data is a change in ventricular compliance. To illustrate this point, consider the fact that a high PAOP (or LVEDP) can exist in patients with an elevated preload with normal ventricular compliance, as well as in patients with a low preload with poor ventricular compliance. A

patient with reduced ventricular compliance (e.g., myocardial ischemia, left ventricular hypertrophy, cardiac tamponade, or ventricular interdependence) has a high PAOP or PADP that results in overestimation of LVEDV (Fig. 17.19) and underestimation of LVEDP. In the setting of poor compliance, PAOP is not a reliable index for LVEDV.⁵⁵ In fact, it has been shown that during myocardial revascularization procedures, high PAOP values exist more than 50% of the time in conjunction with a low volume status (as determined by echocardiography), with patients responding favorably (despite a high PAOP) to an increase in intravascular volume.⁵⁶

FIGURE 17.19 Effect of changes in ventricular compliance on CVP (which estimates RVEDP) and PAOP (which estimates LVEDP). The curve with decreased compliance distorts the relationship between pressure values and estimated ventricular volume. A preload of 80 cm³ in a compliant versus a noncompliant ventricle generates a pressure difference of ≈ 6 mm Hg (*flat portion of each curve*). On the steeper portion of both curves, the relationship between volume and pressure is skewed even more dramatically. A preload of 120 cm³ generates a pressure difference of ≈ 13 mm Hg, which can ultimately lead to a gross overestimation of ventricular preload. Δ , Change; CVP, central venous pressure; LVEDV, left ventricular end-diastolic volume; PAOP, pulmonary artery occlusive pressure; RVEDV, right ventricular end-diastolic volume.

To summarize, the PADP correlates poorly (by 5 mm Hg or more) with the PAOP under the following circumstances: when pulmonary vascular resistance (PVR) is elevated (e.g., chronic obstructive pulmonary disease, human papillomavirus, pulmonary embolus, adult respiratory distress syndrome, hypercarbia), when HRs exceed 130 beats per minute, when severe mitral or aortic regurgitation is present, or when a lung zone III has changed to a zone II or I (e.g., in the presence of hypovolemia, PEEP). Increases in PVR and HR cause the PADP to exceed PAOP. Severe regurgitation and lung zone changes produce the opposite effect, with PADP being less than the PAOP; this may also hold true for right bundle branch block, as one research group found that this conduction defect caused the PADP (in the setting of normal PVR) to be up to 7 mm Hg less than the mean left atrial pressure.⁵⁷ A review of the gross interpretation of CVP and PAOP values is presented in [Table 17.8](#).

TABLE 17.8

Potential Clinical Diagnosis via the Use of Hemodynamic Values: Interpretation of Pulmonary Artery Catheter Data

CVP	PADP	PAOP	Interpretation
Low	Low	Low	Hypovolemia, transducer not at phlebostatic axis*
Normal			
or high	High	High	LV failure
High	Normal or low	Normal or low	RV failure, TR, or TS
High	High	Normal or low	Pulmonary embolism
High	High	Normal	Pulmonary HTN
High	High	High	Cardiac tamponade, ventricular interdependence, transducer not at phlebostatic axis*
Normal	Normal or high	High	LV myocardial ischemia or MR
Low	High	Normal	ARDS†

*The phlebostatic axis is the fourth intercostal space, midanteroposterior level (not midaxillary line); for the right lateral decubitus position, fourth intercostal space midsternum; for the left lateral decubitus position, fourth intercostal space at the left parasternal border.

†ARDS patients commonly require initial fluid administration for hemodynamic stability.

ARDS, Acute respiratory distress syndrome; CVP, central venous pressure; HTN, hypertension; LV, left ventricular; MR, mitral regurgitation; PADP,

pulmonary artery diastolic pressure; *PAOP*, pulmonary artery occlusive pressure; *RV*, right ventricular; *TR*, tricuspid regurgitation; *TS*, tricuspid stenosis.

Other Hemodynamic Indexes

Some authors encourage the use of calculated indexes to optimize the care of critical care patients. These indexes include the pulmonary vascular resistance index (PVRI), systemic vascular resistance (SVR) index (SVRI), and cardiac index (CI). The potential advantages and limitations of each index will be reviewed.

The PVRI (PVR calculated with the CI instead of the cardiac output [CO]) is equal to the difference in pressure across the pulmonary circuit (mean PAP – PAOP) divided by flow (CI) times 80. This formula is taken from Ohm's law (with the variables mathematically manipulated) for electric currents (R [Resistance] = V [Voltage] = I [Current]). A normal value is considered to be 45 to 225 dynes • sec/cm⁵ • m². Two limitations of extrapolating physiologic resistance from Ohm's law are (1) blood flow is pulsatile and not flowing continuously through a set of rigid pipes, and (2) resistance is not uniform throughout the pulmonary circuit. The electrical counterpart describes resistance not in alternating currents, but in direct currents.⁵⁸

When PVR is used clinically, it should be viewed as a gross estimate of RV afterload; similarly, SVR is associated with LV afterload. In the intact heart, *afterload* is defined as systolic wall stress or the impedance the ventricle must overcome to eject its stroke volume. It is important to understand that vascular resistance is not synonymous with afterload, but is used as an extension of the concept. PVR, like SVR, can affect afterload, but neither formula accounts for changes in ventricular wall thickness or radius, which are components of afterload.

SVRI is calculated as the difference between systemic input pressure (mean arterial pressure) minus the output pressure (right atrial pressure or CVP), divided by the CI times 80. The normal range is 1760 to 2600 dynes • sec/cm⁵ • m². SVR is commonly used to offer some guidance in the use of vasoconstrictors (e.g., phenylephrine infusion) or afterload reduction (e.g., intravenous nitroglycerin or sodium nitroprusside). The limitations described
