System Review and Examination

The two body systems that are of primary interest in a preanesthetic system review are the respiratory and cardiovascular systems.

However, there are other important metabolic and structural problems that can have a significant impact on the anesthesia plan.

When performing a physical assessment, the anesthetist should assess for the presence of congenital anomalies. These problems can

Box 52.6 occur most often in SGA and LGA neonates ([Box 52.6](#)).

Common Metabolic and Structural Problems in SGA and LGA Infants

Small for Gestational Age (SGA)

- Congenital anomalies
- Chromosomal abnormalities
- Chronic intrauterine infection
- Heat loss
- Asphyxia
- Metabolic abnormalities (hypoglycemia, hypocalcemia)
- Polycythemia/hyperbilirubinemia

Large for Gestational Age (LGA)

- Birth injury (brachial, phrenic nerve, fractured clavicle)
- Asphyxia
- Meconium aspiration
- Metabolic abnormalities (hypoglycemia, hypocalcemia)
- Polycythemia/hyperbilirubinemia

Head and Neck Abnormalities

Any abnormality of the head and/or neck should raise concerns regarding airway management. The shape and size of the head, with or without the presence of pathology, can make airway management difficult. The small mouth and large tongue can obstruct the airway during mask ventilation. Neonates have very small nares, and when obstructed by an anesthesia facemask, airway obstruction can occur particularly if the mouth is being held closed. A nasogastric tube can obstruct half of the neonate's airway and should be placed orally. A small and/or receding chin, as seen in Pierre Robin and Treacher Collins syndromes, may make direct

laryngoscopy and visualization of the glottis impossible, requiring airway adjunctive equipment. Cleft lip, with or without cleft palate, may complicate intubation. Anomalies such as cystic hygroma or hemangioma of the neck can produce upper airway obstruction. In the case of a preterm neonate, it should also be determined whether the patient has ROP, cataracts, or glaucoma. Atropine administration could result in significant increases in intraocular pressure and further damage to the eye.

Respiratory System Abnormalities

The incidence of respiratory distress syndrome (RDS) and bronchopulmonary dysplasia (BPD) is inversely related to gestational age at birth. The onset of RDS can be as early as 6 hours after birth. The symptoms include; tachypnea, retractions, grunting, and oxygen desaturation. BPD manifests as a need for supplemental oxygen, lower airway obstruction and air trapping, carbon dioxide retention, atelectasis, bronchiolitis, and bronchopneumonia. Oxygen toxicity, barotrauma of positive-pressure ventilation on immature lungs, and endotracheal intubation have been reported as causative factors. Careful monitoring of the acid-base status, the use of increased peak inspiratory pressure, and positive end-expiratory pressure may be needed to maintain oxygenation during surgery.

Cardiovascular System Abnormalities

During the evaluation of the neonate's cardiovascular system, several variables should be examined: heart rate, blood pressure patterns, skin color, intensity of peripheral pulses, and capillary filling time. Presence of a murmur or abnormal heart sound, low urine output, metabolic acidosis, dysrhythmias, or cardiomegaly, alone or in combination, raises the concern of some type of congenital heart defect. These patients should be further evaluated by chest x-ray, ECG, echocardiogram, and other indicated cardiac tests. The results of these diagnostic tests will allow for effective planning of the anesthetic, decreasing the possibility of complications ([Table 52.14](#)).

TABLE 52.14**Pathophysiology and Clinical Picture of Congenital Heart Defects**

Lesion Type	Pathophysiology	Clinical Signs and Symptoms
Shunt Lesion Without Outflow Tract Obstruction		
Atrial septal defects Ventricular septal defects Atrioventricular canal defects Patent ductus arteriosus Aortopulmonary window	Intracardiac L-R shunt Increased pulmonary blood flow	CHF (systemic and pulmonary vascular congestion); No cyanosis (unless high pulmonary blood flow leads to increased left atrial pressure, pulmonary edema, and intrapulmonary V/Q mismatch and shunt)
Shunt Lesions With Right Ventricular Outflow Tract Obstruction		
Tetralogy of Fallot Ebstein anomaly Pulmonary stenosis with atrial or ventricular septal defects Eisenmenger syndrome	Intracardiac R-L shunt Decreased pulmonary blood flow	Cyanosis
Transposition Physiology (Intercirculatory Mixing)		
Dextro-transposition of the great arteries	Intracardiac L-R and R-L shunts are equal	Cyanosis
Single-Ventricle Physiology		
One-Ventricle Lesions		
Hypoplastic left heart syndrome Tricuspid atresia Double-inlet left ventricle	Mixing of systemic and pulmonary venous blood Parallel distribution of pulmonary and systemic blood flow determined by relative circuit resistances	CHF (systemic and pulmonary vascular congestion); Cyanosis
Two-Ventricle Lesions		
Truncus arteriosus Tetralogy of Fallot with pulmonary atresia Severe neonatal aortic stenosis		
Left Ventricular Outflow Tract Obstructive Lesions		
Mitral Stenosis		
Valvular Cor triatriatum		
Aortic Stenosis		
Valvular Subvalvular (subaortic membrane) Supravalvular (Williams-Beuren syndrome)	Left ventricular pressure overload from aortic lesions Increased left atrial pressure from left ventricular systolic and diastolic dysfunction; OR obstruction to left atrial emptying	CHF (if high left atrial pressure leads to pulmonary vascular congestion); No cyanosis (unless high left atrial pressure leads to pulmonary edema and intrapulmonary V/Q mismatch and shunt)
Coarctation		
Shone syndrome (mitral stenosis, aortic stenosis, coarctation)		

Mixing of Systemic and Pulmonary Venous Blood With Series Circulation		
Partial anomalous pulmonary venous return (PAPVR); Total anomalous pulmonary venous return (TAPVR)	Mixing of systemic and pulmonary venous blood Increased pulmonary blood flow	<i>CHF</i> : Systemic and pulmonary vascular congestion; pulmonary vascular congestion is severe if pulmonary venous obstruction No cyanosis; <i>PAPVR</i> : Cyanosis; <i>TAPVR</i> : Exacerbated if pulmonary venous obstruction leads to pulmonary edema and intrapulmonary V/Q mismatch and shunt

CHF, Congestive heart failure; *L-R*, left to right; *R-L*, right to left; *V/Q*, ventilation/perfusion ratio.

From Davis PJ, Cladis FP. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia: Elsevier; 2017:634.

It is beyond the scope of this chapter to discuss all anesthetic implications associated with congenital heart disease in the neonate; however, important information includes¹⁰⁰

- direction and flow through any shunt;
- baseline oxygenation;
- dependence of the systemic or pulmonary circulation on flow through the ductus arteriosus;
- the presence and size of any obstruction to blood flow;
- heart failure (high output, low output, or hypoxic);
- drug therapy; and
- antibiotic prophylaxis (e.g., bacterial endocarditis).

Central Nervous System Abnormalities

An assessment of the CNS should include the status of the infant's ICP and intracranial compliance. Intraventricular hemorrhage (IVH) is almost exclusively seen in preterm neonates. There can be spontaneous bleeding into and around the lateral ventricles of the brain. The hemorrhage is usually the result of RDS, hypoxic-ischemic injury, and/or episodes of acute blood pressure fluctuation that rapidly increase or decrease cerebral blood flow. Laryngoscopy and intubation in the presence of inadequate anesthesia can precipitate IVH.¹⁰¹ The symptoms of IVH include hypotonia, apnea, seizures, loss of sucking reflex, and a bulging anterior fontanelle. Particular evaluation of the neonate with myelomeningocele (spina bifida) is discussed subsequently.

Preoperative Laboratory Values

Neonates who are premature (younger than 60 weeks' postgestational age), those with concurrent cardiopulmonary disease, and in whom major blood loss is anticipated during the surgical procedure should have a complete blood count, electrolytes, blood gases, and serum osmolality measured. The test values will assist in the fluid, electrolyte, and blood replacement during the surgical procedure. Other testing will be dictated in accordance with the history and physical findings.

Preoperative Treatment of Significance for Anesthesia

Many of the preexisting conditions in the neonate will require medical treatment. [Table 52.15](#) illustrates some of the preoperative drugs and their anesthetic implications. Parental preparation with psychosocial support is important. It is imperative that the parents be prepared and the informed consent for anesthesia be obtained. The anxiety of the parents of a newborn with a serious illness requiring surgical intervention is frequently high. The anesthesiologist should foster trust and confidence through being understanding and explaining the anesthetic experience.

TABLE 52.15

Preoperative Treatment of Significance for Anesthesia

Drug	Implication
Diuretics for heart failure bronchopulmonary dysplasia (BPD)	Hypokalemia
Digoxin for heart failure	ECG abnormalities
Steroids for BPD	Hyperglycemia
Immunocompromised	
Anticonvulsants	Cardiac arrhythmia Potent inducer of hepatic enzymes
Indomethacin	Increases risk of bleeding Displaces bilirubin from protein-binding sites Transient hyponatremia
Renal Impairment	
Theophylline or caffeine	Significant toxic side effects; convulsions, tachycardia, tremor
Prostaglandins E ₁ or E ₂	Ventilatory depression and apnea Hypotension, cerebral irritability, seizures, tachycardia, pyrexia, cardiac irritability, transient oliguria, increased gastric acid
Prostacyclin	Hypotension

PPHN, Persistent pulmonary hypertension of the newborn.

Regional Anesthesia in the Neonate

Regional anesthesia in the neonate can be a useful option when the risks of complications from general anesthesia and endotracheal intubation are very high. These techniques have allowed surgical procedures to be done on critically ill neonates under minimal general anesthesia, with considerable reduction in the need for CNS depressant drugs. The use of regional techniques must be associated with sufficient knowledge about the various techniques, as well as adherence to adequate dosage guidelines and other safety precautions. Regional anesthesia may offer advantages in these patients, although opinions differ on which techniques are appropriate.^{102,103} An additional benefit to the use of regional anesthesia in this age group is postoperative pain control. The two most common techniques used in the neonate are the spinal and caudal epidural blocks.

Anatomic differences in the neonate must be considered, particularly the location of the terminal end of the spinal cord, the dural sac, and the volume of cerebrospinal fluid (CSF). The spinal cord extends as far as L3 in the newborn and does not reach the adult position of L1 until 1 year of age. The dural sac extends from S3 to S4 in these babies and does not reach the adult position of S1 until approximately 1 year of age (see [Fig. 52.5](#)). The volume of CSF is twice that of the adult (4 mL/kg vs 2 mL/kg). This dilutes the local anesthetics injected and could explain the higher dose requirements and shorter duration of analgesia.

Patients in this age group have been reported to have fairly stable cardiovascular responses to regional anesthesia. It is thought that this could be due to the immature sympathetic nervous system or the proportionately small blood volume in the lower limbs, decreasing the amount of venous pooling.^{104,105} The ventilatory response to the regional anesthetic is related to the level of the block. With a level as high as T2 to T4, there could be intercostal muscle weakness that requires the dependence on diaphragmatic movement for tidal breathing, but tidal volume and respiratory rate

may not be affected.¹⁰⁶

There are pharmacologic considerations when regional anesthesia is used in neonates. The extracellular fluid volume is greater as compared with in an adult, and the initial dose of local anesthetic will be diluted into a larger volume of distribution, resulting in a lower initial plasma peak concentration. Local anesthetics, particularly amides, are metabolized more slowly in neonates due to immature hepatic degradation. The major elimination pathway for ester local anesthetics is hydrolysis via plasma cholinesterase which is decreased in a neonate.

Most neonates will have a regional technique performed after the induction of general anesthesia because of the age of the patient and the possibility of agitation and continuous movement affecting the placement and success of the block.¹⁰⁷ The use of ultrasound-guided blocks has decreased the risk of complications associated with the placement of spinal and epidural needles and catheters, as well as enabled monitoring of the spread of local anesthetics.¹⁰⁸ It is difficult to assess a dermatome level, because these patients are nonverbal.

Spinal Anesthesia

The use of spinal anesthesia in neonates and infants was common in the early part of the 20th century, but its use declined with the advent of safer general anesthesia in this young age group. There has been a renewed interest in various regional techniques in select patients such as those at risk for apnea of prematurity. It is useful in neonates and infants undergoing surgical procedures of the lower abdomen. Caudal blocks are common in neonatal anesthesia because of their simplicity and ability to provide excellent analgesia, which helps avoid large amounts of opioid analgesia with potential side effects that can impair recovery. Spinal anesthesia via catheters in the younger infant, neonate, and even preterm neonate remains controversial.¹⁰⁹

Spinal anesthesia can be performed in the sitting or lateral position; however, the neck should be extended to prevent airway obstruction (Fig. 52.7). The lumbar puncture is performed at the L3 to L4 or L4 to L5 interspace because the spinal cord ends at L3 in

the neonate. A $\frac{1}{2}$ -inch, 22-gauge needle is inserted, and even with this small needle, resistance can be felt when the needle enters the ligamentum flavum, and the characteristic “pop” occurs when the needle enters the subarachnoid space. The distance is approximately 1 cm.¹¹⁰ Large amounts of local anesthetics are necessary to produce an adequate block (0.14 mL/kg of bupivacaine 0.5%). When the local anesthetic is injected, the neonate should be immediately placed in the supine position, and the legs should be secured with tape to prevent them from being raised.

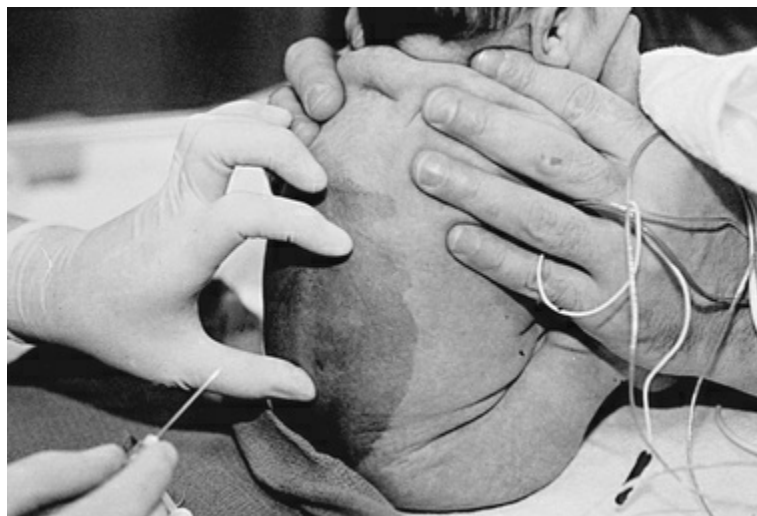

FIGURE 52.7 Spinal block performed in sitting position. Note that the head is in neutral position to prevent airway obstruction. (From Suresh S, et al. Regional anesthesia. In Cote CJ, et al, eds. *A Practice of Anesthesia for Infants and Children*. 5th ed. Philadelphia: Elsevier; 2013.)

Caudal Anesthesia

Caudal anesthesia is the most commonly used regional block in pediatric anesthesia. It can be used for any procedure involving innervation from the sacral, lumbar, or lower-thoracic dermatomes.¹⁰⁵ In the youngest patients, the caudal block can be used as an adjunct to general anesthesia or solely for postoperative analgesia. In the neonate, it is most often placed after induction of general anesthesia prior to the beginning of the surgical procedure.

With ultrasound, it is now possible to visualize the injection of

local anesthetics in the caudal space, as well as monitor the cranial spread. The use of ultrasound is highly recommended in neonates who receive concomitant general anesthesia.^{103,105} The patient is placed in the lateral position with the upper knee flexed (Fig. 52.8). The landmarks are identified: the tip of the coccyx to fix the midline, and the sacral cornu on either side of the sacral hiatus. These landmarks form the points of an equilateral triangle with the tip resting over the sacral hiatus. A 22-gauge needle is placed bevel-up at a 45-degree angle to the skin. When the sacrococcygeal membrane is punctured, a distinctive loss of resistance is felt, and the angle of the needle is reduced and advanced cephalad. Saline should be used with the loss of resistance technique because the use of air has been reported to cause both intravascular air embolism, as well as permanent spinal cord injury. With aspiration, if there is no CSF or blood, the local anesthetic can be administered. Any local anesthetic can be used. The volume of the local anesthetic determines the height of the block. Volumes of 1.2 to 1.5 mL/kg provide analgesia and anesthesia to the T-4 to T-6 dermatome. The choice of local anesthetic is determined by the practitioner's preference; however, the concentration is adjusted to deliver no more than 2.5 mg/kg. The addition of epinephrine (1 : 200,000) or clonidine (1–2 mcg/kg) will prolong the block significantly. Clonidine 1 mcg/kg can be used; however, side effects including hypotension, bradycardia and sedation can occur.¹¹¹

Anesthetic Considerations for Selected Cases

Gastrointestinal

The acuity of intraabdominal procedures is variable and can range from a hernia repair to a complex abdominal/thoracic procedure. Implications such as increased intraabdominal pressure causing ventilation perfusion mismatch, initiation of the celiac reflex, heat loss and hemorrhage are always a concern. With the advent of laparoscopic surgery, complications such as CO₂ gas embolism, intraabdominal organ damage and ventilation strategies must also be considered.

Pyloric Stenosis

Pyloric stenosis is an obstructive lesion characterized by an “olive-shaped” enlargement of the pylorus muscle. It is a common GI anomaly, particularly in males. It is usually diagnosed between 2 and 12 weeks of life, and clinical symptoms include nonbilious postprandial emesis that becomes more projectile with time, a palpable pylorus, and visible peristaltic waves. A pyloromyotomy is performed to relieve the gastric outlet obstruction.

Pyloric stenosis is considered a medical emergency and initial management is focused on correcting hypovolemia, acid base disorders and electrolyte abnormalities. The use of laparoscopy has become standard and has greatly facilitated the surgical course.¹¹¹ Due to difficulty with feeding and regurgitation, optimization of fluid and electrolyte imbalance is essential in the preoperative period. Fluid, electrolyte, and acid-base balance should be corrected prior to anesthesia. The metabolic disorder that is most commonly associated with pyloric stenosis is hypochloremic, hypokalemic, metabolic alkalosis.

Prior to induction, the neonate's stomach is suctioned via orogastric tube. Some anesthesiologists will irrigate the stomach via the orogastric tube with warm normal saline until the aspirate is clear and minimal. Infants having a pyloroplasty are considered to be at

increased risk of gastric aspiration due to their disease process.

After preoxygenation, a rapid-sequence induction with cricoid pressure and gentle positive-pressure ventilation via mask is indicated. An awake oral intubation can also be performed. Oral endotracheal intubation is mandated to protect the airway from any gastric contents that may be residual. Maintenance can be accomplished using inhalation anesthetics or in combination with intravenous anesthetic agents. Extubation should occur when the infant's airway reflexes are intact.

Postoperatively, these patients, particularly a preterm or SGA neonate, could exhibit drowsiness, lethargy, or apnea. This could be attributed to electrolyte abnormalities, postgestational age, or residual anesthetics.

Inguinal Hernia

The presence of an inguinal hernia is prevalent in the preterm infant. The surgical problem presents the possibility of incarceration of the small bowel in the hernia defect, possibly resulting in colon ischemia and tissue death. Also of concern is the potential injury to the ipsilateral testicle. The surgical approach can be accomplished with an open procedure via standard abdominal incision or by laparoscopic technique. In most situations, the contralateral side is explored to rule out the presence of another defect because of the high incidence of bilateral involvement.

The choice of anesthetic is based on practitioner preference. The most frequent indication for placing a caudal block while the neonate is awake is for inguinal hernia repair.¹⁰³ Inhalation or intravenous induction is acceptable, as well as airway management with a mask, laryngeal mask airway, or endotracheal tube. The use of the laparoscopic approach will necessitate the use of the endotracheal tube. Maintenance can be accomplished with inhalation anesthetics or in combination with intravenous drugs. Small neonates who are at risk for postoperative apnea may benefit from spinal anesthesia.¹¹²

Congenital Diaphragmatic Hernia

A congenital diaphragmatic hernia (CDH) is a defect of the

diaphragm that allows extrusion of the abdominal contents into the thoracic cavity. This disorder has an incidence of 1 in 2500 live births.^{113,114} The herniated abdominal contents act as a space-occupying lesion and prevent normal lung growth and development. The diagnosis of CDH should be made prenatally in virtually all cases where routine maternal ultrasonography is available. The prognosis can be predicted based on whether the diaphragmatic hernia is isolated and the degree of pulmonary and or intraabdominal organ involvement. Prenatal intrauterine surgical intervention may be offered in fetuses that have a predicted poor outcome. The aim of this procedure is to reverse the key determinant of survival, pulmonary hypoplasia. Percutaneous fetal endoscopic tracheal occlusion by a balloon is a minimally invasive procedure that has been shown to be safe and yields a 50% survival rate in severe cases. The outcome can be predicted by the gestational age at birth, the lung size before and after balloon placement, and whether the balloon has been removed prenatally.¹¹⁵ Nearly 80% of CDH patients experience herniation of the abdominal contents through the left side of the diaphragm. The lung affected to the greatest extent is on the ipsilateral side, but the contralateral lung can be affected as well. The lungs have reduced-sized bronchi, less bronchial branching, decreased alveolar surface area, and abnormal pulmonary vasculature. There is a thickening of the arteriolar smooth muscle extending to the capillary level of the alveoli. This results in increased pulmonary artery pressure and causes right-to-left shunting.¹¹⁶

Neonates with CDH present immediately after birth with dyspnea, tachypnea, cyanosis, absence of breath sounds on the affected side, and severe retractions. Their physical appearance includes a scaphoid abdomen and a barrel chest. It is estimated that between 44% and 66% of neonates with CDH have other anomalies, particularly heart lesions.

The emergent nature of the repair has been reexamined in the past decade, and more emphasis is now placed on stabilizing pulmonary hypertension and other medical issues. A review of these cases noted that the median age at operation was 4 days and the median weight was 3800 g. Laparotomy, thoracoscopic repair, and a laparoscopic approach may be used.¹¹⁷

Studies published by Azarow et al.¹¹⁸ and Jona¹¹⁹ in the late 1990s demonstrated that the ventilation parameters were a major factor in survival of these babies. Permissive hypercarbia with high-frequency, oscillatory ventilation was most successful in improving outcomes. A thorough assessment of the baby, including laboratory values, radiographic findings, and physical symptoms, is mandatory. Listening to breath sounds will assist in evaluating the degree of ventilation on each side of the chest after intubation. Due to the increased incidence of respiratory complications, most of the patients will already be intubated and have intravenous access and an arterial line in place when they arrive in the operating room. If they are not intubated, an endotracheal tube should be placed after a rapid-sequence induction. If a difficult airway is suspected, an awake intubation should be accomplished.

It is important in these patients to administer an anticholinergic (atropine 0.02 mg/kg) intravenously just prior to induction to prevent bradycardia during induction. If an awake intubation is planned, some type of analgesia should be used to decrease the stress response of airway instrumentation. Ventilation should be delivered gently to avoid inflating the stomach with air, which would increase the potential for passive gastric regurgitation and further decreasing pulmonary compliance.

The patient's hemodynamic stability should determine the anesthetic drugs that are administered. The use of inhalation agents and narcotics are guided by the cardiovascular stability. Nitrous oxide should be avoided because it will increase the volume of GI tissue and further impair ventilation.

Monitoring must include blood pressure, ECG, pulse oximetry, capnography, temperature, and heart rate. To monitor for right-to-left shunting, oximeter probes should be placed preductal (right upper extremity) and postductal (lower extremity). The use of arterial blood pressure monitoring will not only allow beat-to-beat assessment of blood pressure but also provide an outlet for easier blood sampling. All conditions that can increase pulmonary vascular resistance such as hypoxia, hypothermia, and/or acidosis must be avoided. Carbon dioxide should be kept at normal or slightly elevated levels and oxygen saturation maintained above 80 mm Hg. Electrolyte abnormalities must be corrected quickly and

any significant blood loss replaced.

In the event that cardiorespiratory instability prevents the neonate from being transported to the operating room, the anesthetist might be required to administer anesthesia in the NICU while the baby is still on extracorporeal membrane oxygenation. Under these circumstances, the recommended anesthetic choice is to administer an opioid and nondepolarizing muscle-relaxant instead of an inhalation agent. Postoperative ventilation is required, with the goal of keeping the arterial oxygenation greater than 150 mm Hg and slowing weaning to lower oxygen concentrations over a 48- to 72-hour period.¹¹⁶

Omphalocele and Gastroschisis

Omphalocele and gastroschisis anomalies are both defects in the abdominal wall that occur during gestation when the visceral organs fail to move from the yolk sac back into the abdominal cavity. It is more common to encounter omphalocele in term newborns and gastroschisis in preterm newborns. There are several differences between the two defects that are noted in [Table 52.16](#). The defects occur at the insertion of the umbilicus. They are often associated with other anomalies. Some of those anomalies might be cardiac, genitourinary (bladder exstrophy), metabolic (e.g., Beckwith-Wiedemann syndrome with macroglossia, hypoglycemia, organomegaly, gigantism), malrotation, Meckel diverticulum, and intestinal atresia. When the omphalocele is in the epigastric region, cardiac and thoracic pathology is more prevalent. If the omphalocele is located in the hypogastric area, cloacal anomalies and exstrophy of the bladder are seen more often.¹¹³ These abdominal wall defects have very different surgical management techniques and outcomes. Gastroschisis outcomes have improved dramatically over the past 4 decades but still comprise the largest group of patients needing bowel transplant. Omphalocele outcomes remain poor overall despite many advances in care. Large omphaloceles are one of the most difficult things to manage in pediatric surgery, and there is no standardized closure technique.¹²⁰ Both GI anomalies, although different in presentation, are similar as far as the anesthetic management that is required.

TABLE 52.16**Differences Between Gastroschisis and Omphalocele**

	Gastroschisis	Omphalocele
Covering membrane	No	Yes
Location of defect	Right of umbilicus	Midline including umbilicus
Umbilical cord insertion	Body wall at normal location	Omphalocele membrane
Herniated abdominal organs	Bowel	Bowel and sometimes liver
Associated anomalies	Uncommon	Very common
Prognostic factors	Condition of bowel	Associated anomalies

From Ledbetter DJ. Congenital abdominal wall defects and reconstruction in pediatric surgery: gastroschisis and omphalocele. *Surg Clin North Am.* 2012;92(3):714.

A newborn with an omphalocele or gastroschisis is brought to the operating room soon after birth to minimize the possibility of infection, the loss of fluid and heat, and the possible death of bowel tissue. A thorough preoperative evaluation must be done to identify the presence of any of the previously mentioned associated anomalies. Historically, the surgical approach was to immediately attempt primary closure of the defect. This entailed placing a large amount of abdominal contents into a cavity that was not usually large enough, and the result was a significant increase in intraabdominal pressure, which impeded ventilation and caused profound hypotension secondary to aortocaval compression. Over the past decade, surgeons have opted for a staged closure, using a Silastic silo as a temporary housing for the bowel. This silo is sutured to the defect, and over the next 3 to 7 days, the silo is reduced to allow for accommodation of the gastric contents and abdominal-wall stretching. The neonate is usually then brought to surgery for complete closure of the defect.¹²⁰⁻¹²²

The choice of anesthetic agent and technique is determined by several guiding principles: severe dehydration and massive fluid loss from exposed viscera and internal third-spacing of fluid due to bowel obstruction, hypothermia, the potential for sepsis, associated anomalies, and postoperative ventilation requirements. It is not uncommon for the anesthetist's choice to be an opioid and NDMR technique; however, even with the use of muscle relaxants, the abdominal wall may not allow primary closure. Ventilatory compromise and decreased organ perfusion are major problems as intraabdominal pressure increases. It is imperative to have

adequate intravenous access to infuse large amounts of fluid quickly and invasive monitoring to guide the replacement. A pulse oximeter probe placed on a lower extremity will indicate whether there is compromise in the perfusion to the lower extremities due to obstruction of venous return.

Postoperative ventilation is mandatory on all of these babies, requiring the continued use of paralytics and sedation with an opioid until their clinical status stabilizes.

Tracheoesophageal Fistula and Esophageal Atresia

The development of the upper respiratory and GI tracts take place between the 21st day and the 5th week of gestation. Esophageal atresia (EA), with or without tracheoesophageal fistula (TEF) can be suspected prenatally by the presence of polyhydramnios and finding a stomach bubble on ultrasound. It is normally diagnosed immediately after birth when an orogastric tube cannot pass into the stomach, when there is coughing and choking after the first feeding, or after recurrent pneumonia associated with feedings.¹¹³ In the past, this condition was often lethal. Today, there is an expectation of almost 100% survival.¹²³

There is a significant association between TEF and other serious congenital anomalies. Some sources report that as high as 30% to 50% of newborns with EA and TEF have other anomalies. The acronym VACTERL can be used to recall the most common developmental pathologic conditions:

- Vertebral anomalies
- Anal atresia (imperforate anus)
- Cardiac anomalies
- Tracheoesophageal fistula and esophageal atresia
- Renal anomalies
- Limb malformation

Preoperative echocardiography is necessary to exclude both associated cardiac defects and a right-sided aortic arch which occurs in 2.5% of cases. An identified congenital heart defect may need to be managed preoperatively after consultation with a

pediatric cardiologist, although surgical correction is almost always performed after the TEF/EA surgery. In the case of a right-sided aortic arch, surgical access to the esophagus and the TEF via the typical right thoracotomy is associated with the potential for massive rapid hemorrhage, so left thoracotomy may be performed.¹²³

Esophageal atresia with a distal fistula is the most common presentation of TEF in approximately 80% to 90% of patients.¹¹³ The esophagus ends in a blind pouch, and the distal esophagus forms a fistula with the trachea, usually above the carina. There are other configurations of this anomaly, varied by the location of the fistula and the presence or absence of EA (Fig. 52.9). The morbidity and mortality of TEF are directly related to the resulting pulmonary complications caused by gastric aspiration.¹²⁴ The focus of the preoperative preparation should be to minimize the pulmonary complications by discontinuing oral feedings, placing a balloon tipped catheter to suction nasopharyngeal secretions that accumulate in the blind esophageal pouch and prevent further aspiration, maintaining the infant in a semirecumbent position to minimize aspiration of secretions, and placing of a gastrostomy tube to prevent excess gastric distention from impairing ventilation. The surgical procedure is performed via a right-sided thoracotomy. The sequence of the repair is the ligation of the fistula and then anastomosis of the two ends of the esophagus if possible. Complete surgical correction may also be accomplished in several stages.

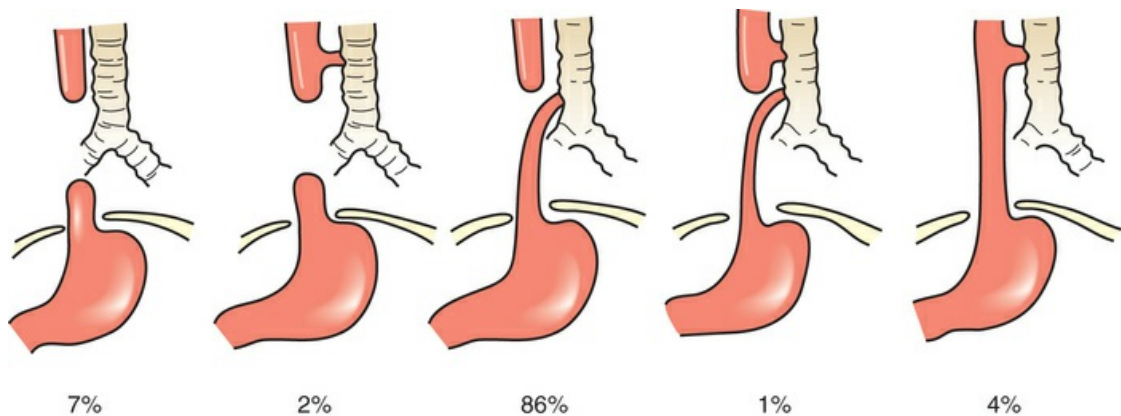

FIGURE 52.9 Anatomic variants and incidence of esophageal atresia with tracheoesophageal fistula. (From Townsend CM, et al. *Sabiston Textbook of Surgery: The Biologic Basis of*

Standard monitors should be used. The cardiorespiratory condition of the neonate should dictate the use of more invasive monitoring techniques such as an arterial line commonly placed either in the umbilical or the radial artery. Preductal and postductal oximeter probes should be used.²¹ In view of the unknown features and potential problems with airway management in TEF, some clinicians advocate performing bronchoscopy intraoperatively before intubation and thoracotomy. Bronchoscopy has been used effectively to assess the presence, type, number, size, and location of fistula, as well as to determine or exclude additional fistulas that may otherwise be unidentified and leave the patient with a potentially continued source of aspiration.

The induction technique should be based on the clinician's evaluation of the airway. Some clinicians feel that inhalation induction with spontaneous respiration avoids overventilation and reduces the physiologic stress associated with airway manipulation. This technique minimizes gastric distention from anesthetic gases passing through the fistula and allows proper placement of the endotracheal tube without positive-pressure ventilation. If this technique is used, care must be taken to avoid hypoxemia that will result from the respiratory depression produced by high concentrations of inhalation agents. With any of the described techniques, once the endotracheal tube is placed, proper position must be verified. A common method of verifying the correct position is to actually intubate the right mainstem bronchus and then withdraw the endotracheal tube until breath sounds are heard on the left side of the chest. The tip of the tube is likely between the fistula and the carina ([Fig. 52.10](#)). If a gastrostomy is in place, an alternative method is to submerge the gastrostomy tube in water and, if there are bubbles on ventilation, the fistula is being ventilated and the tube must be repositioned. The bevel of the endotracheal tube should be turned anteriorly to allow the posterior surface of the endotracheal tube to occlude the fistula. In one configuration of TEF, the fistula is located very close to the carina. In this case, the endotracheal tube may need to be placed in the bronchus of the nonoperative lung until the fistula can be ligated.

After ligation, the tube can be withdrawn to above the carina.

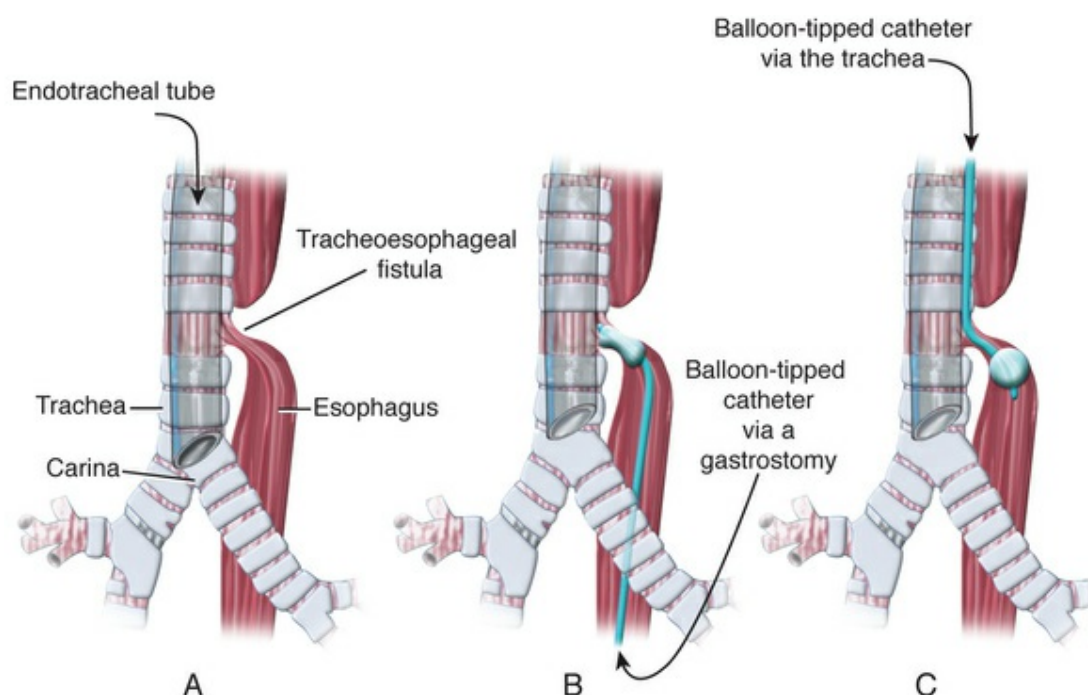

FIGURE 52.10 Methods for minimizing gastric insufflation in infants with a tracheoesophageal fistula. (From Cote CJ, et al: *A Practice of Anesthesia for Infants and Children*, ed 5, St. Louis, 2013, Elsevier.)

During the procedure, it is essential to monitor ventilation to ensure adequate oxygenation and to minimize peak inspiratory pressures. Airway obstruction can occur if the trachea is compressed or if secretions or blood block the openings of the endotracheal tube.

The neonate who does not have significant preoperative pulmonary pathology and who meets extubation criteria may be extubated in the operating room. If there is any concern about airway obstruction or impaired ventilation, mechanical ventilation should be continued. It is thought that should bag-and-mask ventilation or reintubation be required, undue stress could be placed on the suture lines of the repair with laryngoscopy and neck extension, resulting in damage to the esophagus, necessitating further surgical procedures. Another problem that can occur with early extubation in smaller neonates is an inability to maintain the work of breathing due to preoperative lung disease. If

postoperative mechanical ventilation is needed, the endotracheal tube should be positioned 1 cm away from the fistula repair to allow for healing of the suture line. A suction catheter should be clearly marked with a distance for insertion that approximates the distance just above the anastomotic repair.¹²⁵ Postoperative pain can be managed with opioids and/or a caudal epidural, placed intraoperatively.

Complications may occur later that could influence anesthetic management. Neonates who have had EA/TEF repair early in life can develop a diverticulum at the site of the old tracheal fistula. This could present problems in the future if inadvertent intubation of the diverticulum occurs. Esophageal stricture could develop at the site of esophageal anastomosis requiring repeated dilation or possible resection.¹²⁶

Malrotation and Midgut Volvulus

Intestinal malrotation in the newborn is usually diagnosed after signs of intestinal obstruction occur, such as bilious emesis, and can be corrected via the Ladd procedure.¹²⁷ As the intestine is developing and migrating into the abdominal cavity during the first trimester of gestation, it can become twisted, compromising superior mesenteric artery and intestinal blood flow. The ensuing ischemia can cause bowel strangulation, bloody stools, peritonitis, and hypovolemic shock. When this occurs, it is termed *volvulus*.¹¹⁶

Many of these neonates are diagnosed in the first week of life when the neonate presents with bilious vomiting, a tender and distended abdomen, and increasing hemodynamic instability. The surgical procedure relieves the obstruction by reducing the volvulus, dividing the fixation bands between the cecum and the duodenum or jejunum, and widening the base of the mesentery.

The major concerns include airway management, fluid and electrolyte replacement, treatment of sepsis, and postoperative pain management. Any neonate or infant with intestinal obstruction will likely have abdominal distention (which could impede diaphragmatic movement) and is at higher risk for aspiration of gastric or intestinal contents. This necessitates the use of a rapid-sequence induction with the proper application of cricoid pressure. If there is concern for difficult airway, awake intubation should be

considered. Altered fluid status resulting in hypovolemia can be caused by inadequate feeding, regurgitation, peritonitis, ileus, bowel manipulation, and sepsis. It is absolutely necessary to have adequate intravenous access, and it is desirable to have a central line and an arterial line.

The choice of anesthetic agents should be dependent on the neonate's condition. Nitrous oxide should be avoided due to the potential for bowel inflation. As with other emergent abdominal procedures, postoperative mechanical ventilation, paralysis and sedation may be required. The maintenance of an adequate circulating volume and red blood cell volume is vital to ensure perfusion of vital organs.

Necrotizing Enterocolitis

Necrotizing enterocolitis is an intestinal inflammatory condition that is a life-threatening emergency. It occurs primarily in preterm babies with a gestational age of less than 32 weeks and a weight of less than 1500 g. The etiology associated with NEC is reported to be secondary to bowel ischemia and immaturity, probable bacterial invasion, and premature oral feeding.^{113,116} The origin of infection may be the umbilical cord stump, infection due to circumcision, and similar lesions.¹²⁸ [Box 52.7](#) lists the common symptoms of NEC. Diagnosis is confirmed by imaging studies that commonly show fixed dilated intestinal loops, pneumatosis intestinalis, portal vein air, ascites, and pneumoperitoneum. Accompanying laboratory values may show hyperkalemia, hyponatremia, metabolic acidosis, hyperglycemia, hypoglycemia, and, in the most serious cases, signs of disseminated intravascular coagulation.

Common Symptoms of Necrotizing Enterocolitis

- Increased gastric residuals with feeding
- Abdominal distention
- Bilious vomiting

- Lethargy
- Occult or gross rectal bleeding
- Fever
- Hypothermia
- Abdominal mass
- Oliguria
- Jaundice
- Apnea and bradycardia
- Fever

The primary initial intervention is medical management that is focused on ensuring oxygenation and resolving hypovolemia and acidosis. When medical management is unsuccessful, surgical intervention consists of an exploratory laparotomy or laparoscopy with resection of dead bowel, usually a colostomy, and peritoneal lavage.

Neonates with NEC may be septic and frequently come to the operating room already intubated and on ventilator support. The anesthetic drugs chosen should depend on the patient's condition, but a common choice is a narcotic and relaxant technique. These are thought to be the safest choice in the presence of cardiovascular instability because the inhalation agents may further depress the myocardium and lower the blood pressure to unacceptable levels. Nitrous oxide is due to the potential for bowel extension. If cardiac output is low and renal perfusion is below normal, inotropes may be indicated. The amount of third-space loss in these patients is very large and may require multiple blood volumes of crystalloid and colloid combinations to replace intravascular volume. Red blood cells, fresh frozen plasma, and platelets may also be required to increase oxygen-carrying capacity or to treat factor deficiency.^{113,116} Postoperative care should focus on continuation of

the fluid resuscitation and cardiorespiratory support and mechanical ventilation until the baby stabilizes.

Imperforate Anus

During the first few days after birth, when there is no passage of meconium, the diagnosis of imperforate anus is considered. The degree of this anomaly can range from a mild stenosis to complete anal atresia that is associated with other anomalies. The VACTERL syndrome contains all the previously mentioned anomalies.¹²⁹ In male newborns, the operative procedure may be urgent to allow the passage of meconium via a colostomy. In female newborns, owing to the usual presence of a rectovaginal fistula, the procedure can be delayed for a few weeks. The anesthetic considerations for this neonate are based on the existence of associated anomalies and fluid and electrolyte balance.

Other Intestinal Obstructive Lesions

Duodenal obstruction, jejunoileal atresia, and meconium ileus can all result in a complete intestinal obstruction. Although each of these pathologies are different in etiology and presentation, the anesthetic management is similar to that previously mentioned for malrotation of the intestines.

Neurosurgical

Neonatal Hydrocephalus

Hydrocephalus is most often the result of an existing pathologic process. It is usually due to obstructed CSF flow within the brain. As a result, ICP increases. The standard treatment includes the placement of a catheter into a ventricle of the brain to decrease ICP. Most often, the shunt is placed from the ventricle to the peritoneal cavity. Occasionally the catheter is placed in the right atrium or pleural cavity. In the newborn and neonate, if the hydrocephalus develops slowly, the cranial vault will expand to accommodate the increase in brain bulk. When intracranial volume is at capacity, ICP begins to increase which can result in cerebral ischemia and cerebral herniation. The signs and symptoms associated with

increasing ICP are bulging anterior fontanelle, irritability, somnolence, and/or vomiting, loss of consciousness and cardiovascular collapse.

Anesthetic management is directed at controlling the ICP and relieving the obstruction. The urgency of the procedure is determined by the preanesthetic assessment of the ICP. The major risk associated with delay is the possible herniation of the brain due to increasing pressure in the cranial vault. Comorbidities such as prematurity and all associated problems must be addressed.

Intubation in the presence of increased ICP is frequently accomplished by rapid-sequence induction. A variety of anesthetic agents are acceptable for maintenance, with the goal being to extubate the patient at the end of the procedure. Inhalation agents which cause cerebral vascular dilation and MAC of greater than 1 vol % can result in greater increases in ICP. The preoperative neurologic status and intraoperative surgical and anesthetic course will guide the decision to extubate following surgery or if mechanical ventilation and sedation should continue.

Myelomeningocele

Myelomeningocele is the most common CNS defect that occurs during the first month of gestation. Another common name for this defect is *spina bifida*. It is failure of the neural tube to close, resulting in herniation of the spinal cord and meninges through a defect in the spinal column and back. If the herniation only contains meninges, it is a meningocele. If the herniation contains meninges and neural elements, a myelomeningocele is confirmed. These lesions most often occur within the lumbosacral region, but it can occur at any level of the neuroaxis. The repair of the defect is considered urgent, and it is usually undertaken with the first 24 hours of life to avoid the increasing risk of bacterial contamination of the spinal cord and further deterioration of neural and motor function (Fig. 52.11). Most newborns with a myelomeningocele do not have other associated anomalies or congenital heart disease. These neonates, however, may have Arnold-Chiari malformation which is the result of the hindbrain being displaced downward into the foramen magnum, resulting in hydrocephalus. This will necessitate the placement of a ventriculoperitoneal shunt, usually

during the myelomeningocele repair. There are usually significant neurologic deficits below the level of the lesion, and evaluation of the degree of deficit is important to anesthetic decision making. Preoperative assessment should include a thorough review of all other organ systems to rule out additional congenital anomalies. Laboratory testing should at minimum include a blood count and a type of screen for blood.

FIGURE 52.11 A lumbar myelomeningocele is covered by a thin layer of skin. (From Kliegman RM, et al. *Nelson Textbook of Pediatrics*. 19th ed. Philadelphia: Elsevier; 2011:2001.)

Routine neonatal monitoring is necessary, and the use of invasive monitoring techniques should be based on the particular newborns status. Positioning and airway management is one of the biggest challenges for the anesthetist. Most of these infants and children can be induced and intubated in the supine position with the lumbosacral defect supported in a “donut” shaped ring or with strategically placed towels to avoid direct pressure on the dural sac. If the defect is very large or if there is accompanying severe hydrocephalus, it may be necessary to place the neonate in the lateral position for induction and intubation. If there is a suspicion of a difficult airway, the endotracheal tube may be placed with the patient awake. Adequate intravenous access is essential because of the possibility of significant blood loss during the procedure. If the defect is large, the surgeon may be required to undermine a large amount of tissue for closure, resulting in a large blood loss.

Anesthesia can be induced with an inhalation or intravenous

technique. After the endotracheal tube is placed, the procedure is performed in the prone position with appropriate protection of all body parts. In some institutions, the use of muscle relaxants is discouraged to allow for stimulation and identification of neural tissue. Anesthesia can be maintained with a variety of drugs, keeping in mind the goal of extubation at the end of the procedure and the possibility of postoperative apnea.

These patients are prone to developing hypothermia, and conservation of body heat should include warming the operating room to at least 27°C before the procedure and until the patient is draped. Radiant heat lamps should be used during the preparation and positioning of the patient. A forced-air warmer also should be placed underneath the neonate to maintain body temperature. Anesthetic gases should be humidified to prevent heat loss and minimize pulmonary complications. An increased sensitivity to latex in these babies has been reported. As a precaution, they should be treated as latex allergic, avoiding all products that contain latex.^{130,131}

Summary

Despite the advances in neonatal medicine, surgery, and particularly anesthesia, the anesthetic management of critically ill neonates continues to be a challenge. A thorough knowledge of developmental physiology and knowledge of neonatal disease states and their treatment is imperative to providing safe anesthesia. Many conditions that were once thought to be a death sentence for neonates are now surgically treated with increasingly good outcomes. Providing neonatal anesthesia requires the anesthetist to have astute clinical observation skills and to be intensely vigilant to ensure perioperative safety.

Pediatric Anesthesia

Sass Elisha, Paula Belson

Pediatric subspecialty practice requires mastery of the foundations associated with pediatric growth and development, the anatomic and physiologic differences during various stages of maturation, and the influence of anesthetic medications on immature organ systems. Anesthetic management for the pediatric patient requires integration and application of this specialized knowledge and refinement of the acquired technical skills of adult anesthetic management.

This chapter provides an extensive discussion of the essentials for pediatric practice. The foundation of anesthetic management is developed through an understanding of pediatric anesthetic morbidity and mortality; the pharmacologic and physiologic differences among adults, infants, and children; and a clinical strategy for anesthetic management.

Pediatric Anatomy and Physiology

A thorough understanding of the anatomic and physiologic differences between pediatric and adult patients is of paramount importance when providing safe anesthesia care. Due to the immaturity of children's organ systems—which is most significant until 2 years of age—the psychological and physical stress of surgery, the effects of anesthetic medications, and related pathology all play an integral role in patient outcomes. A thorough discussion of anatomy and physiology for the pediatric patient is presented in [Chapter 52](#).

Pediatric patients are commonly subdivided by age. Categorical groupings include: neonates (up to 30 days old), infants (30 days to 1 year old), toddlers (1–3 years old), preschool (4–6 years old), school age (6–13 years old), and adolescents (13–18 years old).

Pediatric Pharmacologic Considerations

A complete discussion regarding the recent concern over possible cognitive changes associated with anesthetic medications in developing children is included in [Chapter 52](#).

Immature organ systems are responsible for the pharmacologic differences that exist between the infants and children. Physiologic characteristics that modify pharmacokinetic and pharmacodynamic activity include differences in total body water (TBW) composition, immaturity of metabolic degradation pathways, reduced protein binding, immaturity of the blood-brain barrier, a greater proportion of blood flow to the vessel-rich organs (i.e., brain, heart, liver, and lungs), reductions in glomerular filtration, a smaller functional residual capacity, increased minute ventilation, and immature receptor responses.

Water freely diffuses across cell membranes, and it is essential for the transport of cellular nutrients and substrates that support metabolic reactions. TBW, expressed in liters, represents a percentage of total body weight (1 L of water weighs 1 kg), steadily decreases with increasing age, and varies according to sex and body habitus. TBW is distributed into the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. With maturation, there is an accompanying decrease in the relative volumes of TBW and ECF during the first year of life, followed by additional decreases in ECF later in childhood. [Table 53.1](#) illustrates the changes in TBW, ICF, and ECF during maturation.

TABLE 53.1
Body Composition During Growth

	Preterm Newborn (1.5 kg)	Full-Term Newborn (3.5 kg)	Adult (70 kg)
Muscle mass, as % of BW	15	20	50
Fat as % of BW	3	12	18
Total body water	90%	80%	60%
Extracellular fluid	50%	40%	20%
Intracellular fluid	40%	40%	40%

BW, Body weight.

Volume of Distribution

Drug distribution is best described by determining the volume of distribution, which is calculated by dividing the dose of the administered drug by the resulting plasma concentration.

Accordingly, body water composition influences the volume of drug distribution. Infants have a larger ECF compartment and a greater TBW content. Due to a dilutional effect, lower plasma drug concentrations occur rapidly after administration of water-soluble drugs. Accordingly, a larger drug loading dose is required to achieve the desired plasma concentration. The fat, muscle, and fluid volume compartments are compared in [Table 53.1](#). Higher plasma concentrations occur for lipid-soluble drugs when administered according to weight due to the decreased fat and muscle volume of infants as compared with an adult.¹

Protein Binding

Alterations in protein binding theoretically affect the availability of the free fraction of highly protein-bound drugs. Reductions in plasma proteins such as albumin and α_1 -acid glycoprotein (AAG) increase the free-drug fraction, which may increase the availability of active drug. Total plasma protein levels are lower in infants, reaching equivalent adult concentrations by 5 to 6 months of age. Albumin, the predominant plasma protein, is responsible for the binding of primarily acidic pharmacologic compounds and AAG, and other proteins are responsible for the binding of basic drugs. Both albumin and AAG concentrations are diminished at birth but reach adult equivalency by 5 to 6 months, and the albumin binding capacity approaches fully functional adult levels at approximately 1 year old. Albumin concentrations may fluctuate, decreasing in chronic disease states with parallel increases in inducible AAG concentrations. Protein binding of many anesthetic drugs is lower in young children relative to adults, but there is little clinical consequence. The major factor affecting drug action is the reduced clearance. A highly protein-bound drug with a high extraction ratio and a narrow therapeutic index, such as lidocaine, requires reduced doses.² Drug metabolism takes place in the liver, gastrointestinal

tract, gastric mucosa, and lungs. In most instances, metabolism reduces drug activity; however, metabolism may activate the metabolite, as with a prodrug. The ultimate goal of drug metabolism is the production of a water-soluble compound that can be more easily excreted.

Drug metabolism occurs in two phases. Phase I metabolism consists of three enzymatic reactions (oxidation, reduction, and hydrolysis) catalyzed by the cytochrome P-450 (CYP450) enzyme system. Enzyme systems within the red blood cells, plasma, and other extrahepatic tissues are capable of hydrolyzing a variety of pharmacologic agents, including local anesthetics, the depolarizing relaxant succinylcholine, and the nondepolarizing relaxants atracurium and cisatracurium. Esmolol is hydrolyzed by esterases in red blood cells. Phase I reactions introduce polar hydroxyl, amino, sulfhydryl, or carboxyl groups to produce a water-soluble metabolic product for excretion in the bile or urine. Phase II reactions, which are immature at birth, consist of conjugation or synthesis. Conjugation couples the drug with an endogenous substrate (i.e., via glucuronization, methylation, acetylation, and sulfation) to facilitate excretion. The newborn lacks the capacity to efficiently conjugate bilirubin due to decreased glucuronyl transferase activity.

Although the necessary enzyme systems are present at birth, enzyme activity is reduced, thereby increasing drug elimination half-lives. Many medications have a prolonged effect in newborns and young infants. Some medications that have a prolonged plasma half-life in the pediatric patient include bupivacaine (25 hours),³ mepivacaine (8.5 hours),⁴ diazepam (up to 100 hours),⁵ indomethacin (15 to 20 hours),⁶ meperidine (22 hours), and phenytoin (21 hours).⁷

Drug Administration

Absorption

Most drugs used in anesthesia are given by the inhalation or intravenous (IV) routes. Routine medications are also administered orally and rectally. Drugs are usually formulated as liquids for oral administration in children. Midazolam may be administered orally

for premedication, and the rectal route may be selected for the administration of acetaminophen, opioids, and benzodiazepines.⁸ Both routes rely on passive diffusion for drug absorption, although the pharmacologic effect of drugs administered by the rectal route can be highly variable. The resulting plasma drug concentration is dependent on the molecular weight, degree of drug ionization, and lipid solubility.

The degree of ionization of orally administered drugs is dependent on gastric and intestinal pH levels. Acidic drugs are nonionized and are favorably absorbed in an acidic environment such as the stomach. Basic drugs are more favorably absorbed in the alkaline medium of the intestine. Most oral medications are absorbed in the intestine. The rate of absorption of many orally administered drugs is slower in neonates and young children because of a delayed gastric emptying time, which prolongs the time it takes for the medication to reach the intestines. Gastric emptying time reaches the adult range by 6 months of age.⁹⁻¹¹

Rectal drug absorption is directly affected by drug formulation and rectal blood flow. The superior (upper third of the rectum), middle, and inferior rectal veins carry blood away from the rectal mucosa. The superior rectal vein empties into the portal system, whereas the middle and inferior rectal veins empty into the systemic circulation by way of the inferior vena cava. For example, the administration of acetaminophen to the upper third of the rectum results in a lower plasma concentration because of first-pass metabolism with drug transport to the liver. Opioids and midazolam undergo first-pass metabolism, and their administration to the upper third of the rectum should be avoided.

Acetaminophen is a commonly prescribed antipyretic and analgesic administered to children during the perioperative period. It is capable of inducing dose-dependent hepatocyte injury, which is directly related to the dose and the duration of administration. Acetaminophen is metabolized by the hepatic microsomal enzyme system, and approximately 80% of the parent drug is conjugated with glucuronic acid and sulfate (phase II metabolism). Animal data suggest that a small amount of the parent drug is metabolized by the CYP450 enzyme system (phase I metabolism), producing an intermediate metabolite that undergoes conjugation with

glutathione and is excreted in the urine. High doses of acetaminophen may deplete glutathione, increasing the accumulation of this intermediate metabolite, which is thought to be responsible for acetaminophen-induced liver necrosis. Glutathione depletion may develop with continued administration of high doses of acetaminophen.¹² Doses used in anesthesia rarely approach toxic levels.

IV acetaminophen (Ofirmev) is prescribed for mild to moderate pain to reduce fever in adults and children. When given in conjunction with an opioid for moderate to severe pain, it has an opioid-sparing effect. The recommended dose of Ofirmev for patients older than 13 who weigh more than 50 kg is 1000 mg every 6 hours or 650 mg every 4 hours IV; the maximum daily dose of acetaminophen by any route is 4000 mg. For patients aged 2 or older weighing less than 50 kg, the recommended dose is 15 mg/kg every 6 hours or 12.5 mg/kg every 4 hours IV, not to exceed 75 mg/kg per day.¹³

Types of Agents

Inhalation Agents

The rapid increase in the alveolar concentration of an inspired anesthetic is quantified by the ratio of the alveolar concentration divided by the inspired concentration (F_A/F_I). Factors that affect the F_A/F_I ratio include the delivered inspired anesthetic concentration, the blood-gas partition coefficient of the inhalation agent, alveolar ventilation (V_A), cardiac output (Q_t), and the distribution of Q to the vessel-rich organs (i.e., heart, brain, kidneys, and liver). Although tidal volume is similar between children and adults (5 to 7 mL/kg), children have significantly greater minute ventilation and a higher ratio of tidal volume to functional residual capacity (5 : 1) compared to adults (1.5 : 1). The greater minute ventilation and higher Q_t in infants and children are responsible for rapid inhalation anesthetic uptake and rapidly increasing alveolar anesthetic concentrations. In addition, their decreased distribution of adipose tissue and decreased muscle mass affect the rate of equilibration among the alveoli, blood, and brain. The percentage of blood flow to the

vessel-rich organs is greater than in the adult, and the blood-gas partition coefficients are lower in infants and children.^{14,15}

The minimum alveolar concentration (MAC) of inhalation anesthetics is an indicator of dose and anesthetic requirements that change with age. The MAC is lower throughout the neonatal period (Fig. 53.1). The MAC is higher in infants from age 1 to 6 months as compared to adults. Thereafter, MAC values are known to decrease with increasing age.^{16,17} These requirements for increased amounts of the inhalation agent administered to infants and children are a reflection of the increased basal metabolic rate and a decreased metabolic rate throughout the aging process.

FIGURE 53.1 Effects of age on maximum alveolar concentration. (Data from Lerman J, et al. The pharmacology of sevoflurane in infants and children. *Anesthesiology*. 1994;80:814–824.)

Myocardial depression may be exaggerated when inhalation anesthetics are administered to pediatric patients.^{18,19} A more rapid rise in the F_A/F_I ratio, the greater percentage of blood flow to the vessel-rich organs, and higher administered anesthetic concentrations are central to the cause of myocardial depression. To summarize, inhalation induction is more rapid in pediatric patients because of increased minute ventilation; however, the incidence of hemodynamically compromising myocardial depression in this population is greater than in an adult because of the structural and functional immaturity of the pediatric heart.

Sevoflurane.

The MAC of sevoflurane in oxygen is 3% for infants up to 6 months of age, decreasing to 2.5%–2.8% up to 1 year of age.^{20,21} It produces a rapid induction and emergence due to its low blood-gas partition coefficient.²² Sevoflurane is not a potent airway irritant and as a result, this inhaled agent is preferred during inhalation induction. Sevoflurane depresses minute ventilation and, at higher cerebral concentrations, the respiratory rate. At high inspired concentrations, apnea will occur.^{23,24}

Sevoflurane metabolism may produce concentration-dependent elevations in serum fluoride levels that decline when it is discontinued.²⁵ Concerns regarding fluoride-induced renal damage have not been a clinically significant. Sevoflurane does not sensitize the myocardium to the effects of endogenous and exogenous catecholamines. As with any inhalation agent, the degree of myocardial depression is dependent on the concentration—higher concentrations cause a greater degree of inhibition of myocardial contractility and peripheral vascular dilation.

Isoflurane.

The MAC of isoflurane in oxygen is 1.6% in infants and children. Inhalation induction with isoflurane produces more adverse respiratory events (i.e., breath holding, coughing, and laryngospasm with copious secretions) than sevoflurane. Administration of isoflurane to adults produces dose-dependent decreases in peripheral vascular resistance, whereas an increased heart rate maintains blood pressure. This compensatory advantage (i.e., the maintenance of blood pressure by the increased heart rate) does not occur in infants. Anesthetic induction in infants with isoflurane produces significant dose-dependent decreases in heart rate, blood pressure, and mean arterial pressure.²⁶

Desflurane.

The MAC of desflurane in oxygen is 9% for infants and 6% to 10% for children. Desflurane has the lowest blood-gas partition coefficient of all the inhalation anesthetics (0.42), which facilitates a rapid induction, rapid alterations in anesthetic depth, and rapid emergence. Like isoflurane, desflurane is pungent, and it is

associated with more adverse respiratory events during inhalation induction including breath holding, laryngospasm, coughing, and increased secretions with accompanying hypoxia. After inhalation induction with sevoflurane, desflurane is appropriate for the maintenance of general anesthesia with facemask, endotracheal tube (ETT), or a laryngeal mask airway (LMA). As in the adult population, rapid increases in inhaled concentrations of desflurane may induce sympathetic stimulation, as evidenced by tachycardia and hypertension.^{27,28}

Emergence Delirium.

A variety of terms are used interchangeably when referring to postoperative agitation. These include *emergence delirium*, *emergence agitation*, and *postanesthetic agitation*. These terms describe altered behavior in the immediate postoperative period that manifest as restlessness, crying, moaning, incoherence, and disorientation.^{29,30} These episodes can be very upsetting to the parents and caregivers. Emergence delirium, fortunately, is self-limiting but may manifest for as long as 45 minutes. The incidence of emergence delirium ranges from 10% to 80% in the pediatric population. It occurs during the early stage of emergence during initial waking. No single factor has been identified as the cause of emergence agitation; it appears to be a composite of biologic, pharmacologic, psychological, and social components.³¹ A hypothesis as to why this phenomenon occurs is that the rapid emergence associated with the newer low-solubility anesthetic agents such as sevoflurane and desflurane may create a dissociative state in which children awaken with altered cognitive perception. However, others dispute the speed of emergence as a factor. There is conflicting research as to the incidence of emergence agitation with the slower emergence that occurs with the use of isoflurane.^{32,33} Proposed causes also include rapid awakening in unfamiliar settings, pain, stress during induction, hypoxia, airway obstruction, a noisy environment, anesthesia duration, the child's personality, premedication, and the type of anesthesia used. It has been determined that propofol, fentanyl, dexmedetomidine, and preoperative analgesia have a prophylactic effect in preventing agitation and treating acute episodes. Midazolam and serotonin (5-HT₃) antagonists do not

appear to significantly decrease the incidence of emergence delirium.³⁴

Intravenous Anesthetics

As discussed previously, a higher proportion of cardiac output is delivered to vascular-rich tissues (i.e., heart, brain, kidneys, and liver) in infants and children. Intravenously administered drugs are rapidly delivered and absorbed by these tissues, and they are subsequently redistributed to muscle and fat, tissues that are less well perfused. Intravenously administered drugs may have a prolonged duration of action in infants because of decreased hepatic degradation and renal excretion. The central nervous system (CNS) effects of opioids may also be prolonged because of the immaturity of the blood-brain barrier.^{35,36} Increased doses of propofol and ketamine are required, presumably because of a greater volume of distribution and a greater metabolic rate.³⁷

Propofol.

Propofol has a rapid onset and a short duration of action, and it is the most popular agent for induction and maintenance of general anesthesia and unconscious sedation. It may also be combined with an opioid to provide total IV anesthesia. Propofol may be delivered as a continuous infusion for short diagnostic and radiologic procedures, and is used as a primary sedative in chronically ventilated intensive care patients. The drug's antiemetic properties may reduce the incidence of postoperative nausea and vomiting (PONV) in children undergoing strabismus correction.³⁸ Infants require larger induction doses (2.5–3.0 mg/kg) than children (2.0–2.5 mg/kg).^{39,40} These induction doses produce decreased systolic blood pressure due to direct myocardial depression and vasodilation.^{41,42} The pain that accompanies IV administration may be reduced with the addition of lidocaine. Additional strategies used to decrease the pain during injection include a slower injection of propofol into a rapid-running IV line or injection into larger IV catheters placed in the antecubital space.⁴³

In 1992, Parke et al. reported the deaths of five children who received long-term, high-dose propofol infusions.⁴⁴ The large doses

were administered by continuous infusion in critical care units with long-term sedation over several days; however, this phenomenon was not associated with short-term anesthesia use. Additional case reports followed, further characterizing this serious reaction, which is referred to as *propofol infusion syndrome*. Propofol infusion syndrome causes severe lactic acidosis, hypertriglyceridemia, fever, hepatomegaly, dysrhythmias, rhabdomyolysis, and heart failure. It frequently results in cardiovascular collapse and death. The likely mechanism involves propofol inhibiting mitochondrial function and uncoupling oxidative phosphorylation. Children with mitochondrial defects may have an increased risk of developing this syndrome.^{45,46} Propofol infusions at doses of greater than 4 mg/kg per hr for greater than 48 hr increase the risk of this syndrome. However, propofol infusion syndrome can also develop with infusions less than 4 mg/kg per hr. When prolonged administration is planned, algorithms have been proposed to help prevent this adverse drug effect.⁴⁷

Neuromuscular Blocking Agents

Neuromuscular blocking drugs are highly ionized and have a low lipophilicity, restricting their distribution to the ECF compartment. The ECF compartment is larger in neonates and infants than in children and adults, causing a dilutional effect and thereby increasing the volume of distribution. Increases in ECF volume and the ongoing maturation of neonatal skeletal muscle and acetylcholine receptors affect the pharmacokinetics and pharmacodynamics of neuromuscular relaxants. [Table 52.8](#) references the effective doses of neuromuscular blocking drugs for various age groups.

The neuromuscular junction is incompletely developed at birth, maturing after 2 months of age.⁴⁸ Skeletal muscle, acetylcholine receptors, and the accompanying biochemical processes essential in neuromuscular transmission mature during infancy and throughout childhood.

The presynaptic release of acetylcholine is slow in children compared with adults, which explains the decreased margin of safety for neuromuscular transmission in the neonate. The acetylcholine receptors of the newborn are anatomically different

from the adult receptors, which may explain the sensitivity of the neonate to the nondepolarizing class of neuromuscular relaxants.⁴⁹ This neuromuscular immaturity may be demonstrated with the appearance of fade after tetanic stimulation in the absence of neuromuscular blocking drugs.^{48,50}

Succinylcholine.

In the early 1990s, a series of unexpected cardiac arrests were reported after the routine administration of succinylcholine to apparently healthy children, and less than 40% of the patients were successfully resuscitated. It was determined that the patients had undiagnosed Duchenne muscular dystrophy. Succinylcholine administration produces massive hyperkalemia and subsequent cardiac arrest in these children.⁵¹ The U.S. Food and Drug Administration (FDA) relabeled succinylcholine, restricting its use to emergency airway management in children.^{52,53} It is now used only as a rescue drug in children younger than 8 years of age. Most clinicians avoid using this medication for patients through the early teen years and in patients with muscle disorders. Its use is contraindicated in patients with malignant hyperthermia (MH).^{54,55}

Nondepolarizing Neuromuscular Blocking Agents.

Infants and children are more sensitive than adults to the effects of nondepolarizing neuromuscular blocking drugs (see [Table 52.8](#)). A lower plasma concentration of the selected neuromuscular relaxant is required to achieve the desired clinical level of neuromuscular blockade. This does not imply that the selected dosage should be decreased because infants have a greater volume of distribution. The larger volume of distribution and slower drug clearance result in longer elimination half-life, decreasing the need for repeated drug dosing (longer dosing intervals). Neuromuscular function must be monitored to guide repeated administration of these drugs in all pediatric patients. The degree of neuromuscular blockade should be assessed using physical signs (e.g., strength of movement, spontaneous respirations with adequate tidal volume) and neuromuscular monitoring (i.e., train of four and sustained tetanus). Neuromuscular function should be checked by assessing the adductor pollicis muscle on the forearm because function in this

region is more reflective of diaphragmatic activity as compared with the orbicularis oculi (temporal region). The selection of a nondepolarizing neuromuscular relaxant should take into consideration the desired degree and duration of skeletal muscle paralysis, the immaturity of the organ systems, and the associated side effects of the selected relaxant.^{56,57}

Antagonism of Neuromuscular Blockade.

Residual neuromuscular blockade places the infant and child at risk of hypoventilation and the inability to independently and continuously maintain a patent airway. Due to the increased basal oxygen consumption, impaired respiratory function will lead to arterial oxygen desaturation and CO₂ retention. The detection of residual neuromuscular blockade requires the integration of clinical criteria and the assessment of neuromuscular blockade via a peripheral nerve stimulator. Conventional doses of the anticholinesterase inhibitors (50 to 60 mcg/kg of neostigmine; 500 to 1000 mcg/kg of edrophonium) combined with appropriate doses of atropine (0.02 mg/kg) or glycopyrrolate (0.2 mg for each 1 mg of neostigmine) are acceptable for antagonism of nondepolarizing neuromuscular blockade. Because bradycardia is a consequence of administering an anticholinesterase drug, some anesthesia providers will administer the anticholinergic drug prior to the anticholinesterase drug to avoid this complication. Presently, sugammadex is not FDA-approved for the antagonism of neuromuscular blockage in patients who are younger than 18 years of age.

Voluntary clinical tests are not able to be obtained from the infant and young child. Useful clinical signs of successful antagonism of neuromuscular blockade include the ability to flex the arms, lift the legs, and flex the thighs upon the abdomen, providing evidence of the return of abdominal muscle tone in addition to the return of a normal responses to nerve stimulation.⁵⁸ Neonates are capable of generating a negative inspiratory force (NIF) of -70 cm H₂O with the first few breaths after birth.⁵⁹ A NIF of at least -32 cm H₂O has been found to correspond with leg lift, which is indicative of the adequacy of ventilatory reserve required before tracheal extubation.^{60,61}

Preoperative Preparation

Preoperative preparation is typically done shortly before scheduled surgery, in the preoperative anesthesia clinic or in the patient's room in the hospital. Patients who are acutely ill or medically unprepared should be assessed in the preoperative area to ensure optimization of chronic diseases and to create a comprehensive individualized anesthetic plan.

Preoperative Assessment

Parents or caretakers offer valuable insight into the history of their child. It is important to establish open communication and gain the trust of the patient's family member. Parental preparation is important to allay fear and answer questions. A thorough preoperative assessment will foster trust and confidence through a courteous and understandable explanation of the anesthetic experience. Parental anxiety may be driven by negative personal past anesthetic experiences, such as painful IV catheter placement, coerced mask induction, and postoperative pain, nausea, and vomiting. When the child appears for a repeat surgical procedure, the parents may have important information that is helpful in detailing a successful plan of care for their child.

Review of Systems

Reviewing the medical record can answer many questions before approaching the patient/parents for information. Understanding congenital history can help preparation and development of a plan of care. Previous anesthetic records can be useful tools. [Table 53.2](#) lists the anesthetic implications of the review of systems and history.

TABLE 53.2

Medical History and Review of Symptoms: Anesthetic Implications

System	History	Possible Anesthetic Implications
--------	---------	----------------------------------

Central nervous and neuromuscular	Seizures	Medications: drug interactions, possible inadequate serum levels, valproate-induced hepatitis
	Head trauma	Elevated intracranial pressure
	Hydrocephalus	Possible elevated intracranial pressure
	CNS tumor	Possible elevated intracranial pressure, chemotherapeutic drugs and interactions
		Possible risk of malignant hypothermia
Cardiovascular	Heart murmur	Septal defect, avoid air bubbles in IV line
	Cyanosis	Right-to-left cardiac shunt
	History of squatting	Possible tetralogy of Fallot
	Diaphoresis with feedings	Congestive heart failure
	Hypertension	Possible coarctation of the aorta; renal disease; pheochromocytoma
	Transplant recipient	Fixed heart rate; insensitivity to anticholinergic drugs
Respiratory	Prematurity	Increased risk of postoperative apnea; possible lower respiratory tract illness
	Bronchopulmonary dysplasia	Lower airway obstruction; reactive airways; possible subglottic stenosis; possible postoperative hypoxia and apnea; pulmonary hypertension
	Lower respiratory infection, cough	Reactive airways; bronchospasm; medication history; drug interactions
	Croup	Possible subglottic stenosis or anomaly
	Snoring, sleep apnea	Perioperative airway obstruction; hypoxia
	Asthma	β -Agonist or theophylline drugs; pulmonary hypertension or cor pulmonale; steroid use; adrenal insufficiency; postoperative hypoxia
	Cystic fibrosis	Drug interactions; pulmonary hygiene, pulmonary dysfunction; reactive airways
	Recent cold	Possible lower respiratory tract infection; reactive airways
Gastrointestinal and hepatic	Vomiting, diarrhea	Electrolyte abnormality; dehydration; full stomach
	Growth failure	Possible anemia
	Gastroesophageal reflux	Risk of aspiration; reactive airways; hypoxia
	Jaundice	Altered drug metabolism; risk of hypoglycemia
	Liver transplant recipient	Altered drug metabolism; immunosuppression
	Frequency, nocturia	Unrecognized diabetes, urinary tract infection
	Renal failure or dialysis	Electrolyte abnormality; hypervolemia or hypovolemia; anemia; medication history
	Renal transplant recipient	Immunosuppression
Endocrine and metabolic	Hypoglycemia	Hypoglycemia
	Diabetes	Insulin requirement; intraoperative hypoglycemia
	Steroid therapy	Adrenal insufficiency
	Pregnancy	Teratogenic effects of N ₂ O risk of spontaneous abortion
Hematologic	Anemia	Transfusion requirement
	Bruising, excessive bleeding	Coagulopathy
	Sickle cell disease	Anemia; transfusion; hydration; oxygenation; orthopedic tourniquet use
	AIDS	Susceptibility to infection; infectious risk to medical personnel

Allergies	Medication history	Drug reactions; drug interactions
Dental	Loose teeth	Dental trauma; aspiration of a tooth

AIDS, Acquired immunodeficiency syndrome; *CNS*, central nervous system; *IV*, intravenous; *N₂O*, nitrous oxide.

Modified from Coté CJ, et al., eds. *A Practice of Anesthesia for Infants and Children*. 5th ed. Philadelphia: Elsevier; 2013.

- *Birth and development*. Was the child born prematurely or at term? Did the child experience any neonatal complications or spend any time in the neonatal intensive care unit? Does the child have any history of apnea or bradycardia? Is there any history of sudden infant death syndrome in the child's family? Are there any developmental or learning setbacks?
- *Heart disease*. Does the patient play at school without severe shortness of breath or syncope? Does the child have a heart murmur?
- *Pulmonary disorders/disease*. Does the child have asthma, bronchitis, or pneumonia? Does the child currently receive, or has the child received in the past, supplemental oxygen therapy? Has the child had a recent cold, cough, or respiratory infection? Many times the child will have a persistent runny nose due to an inner ear infection. It is important to ask the parent about the color, consistency, and duration of drainage.
- *Bleeding disorders*. Does the child have sickle cell anemia? Does the child bleed or bruise easily?
- *Liver disease*. Has the child had jaundice or liver problems?
- *Urology disorders*. Has the child had problems with the kidneys, ureters, or bladder? Any urinary tract infections?
- *Gastrointestinal disorders*. Has the child had gastric acid reflux or a hiatal hernia? Has the child experienced problems with diarrhea or vomiting?
- *Neurologic disorders*. Has the child experienced any neurologic symptoms such as seizures?
- *Obstetric history*. Could the patient possibly be pregnant? (controversial topic)
- *Airway assessment*. Does the patient have a history of a difficult intubation? Does the child have trouble opening his or her mouth?

Are there any chipped, missing, or loose teeth? Is there a history of snoring/apnea?

- *Other concerns.* Does the child have diabetes or hypoglycemia? Does the child have any problems with the thyroid or adrenal glands?
- *Medications.* Is the child currently on any medications, or has he or she taken any within the last 3 months? Has the child taken steroids within the last year? If so, for what condition?
- *Allergies.* Is the patient allergic to any medication or food? Any problems with latex or other environmental items?

Fasting Status

The risk of pulmonary aspiration in the pediatric patient is extremely low (1 in 10,000).⁶² Although the goal of preoperative fasting is to ensure an empty stomach at the time of anesthetic induction, prolonged fasting may produce irritability as a result of thirst and hunger. Prolonged fasting may also alter fluid balance, producing preinduction hypovolemia and hypoglycemia. Hypoglycemia is especially problematic in premature infants. Preoperative access to clear fluids (e.g., apple juice, water) 2 hours before anesthetic induction has been shown to have a minimal impact on gastric volume. Current recommendations by the American Society of Anesthesiologists (ASA) are 2 hours of fasting for clear liquids; 4 hours for breast milk; 6 hours for infant formula, nonhuman milk, and a light meal; and 8 hours for a regular meal including fatty foods (see [Table 42.2](#) NPO guidelines). The guidelines can be referred to as the *2-4-6-8 rule*.⁶³ These parameters are suggested for healthy patients undergoing elective surgery. No gum is to be chewed after midnight; prescribed medications can be taken with a sip of water or as a prescribed liquid mixture. If a patient has a history of hiatal hernia while preparing for elective surgery and has not been *nil per os* (NPO; nothing by mouth) for the recommended period, providers must collaborate to make the best decision with regard to patient safety. For patients scheduled for elective surgery who have not achieved the appropriate fasting time, the best decision will be to postpone surgery until the proper NPO status has been achieved.

In patients who have not achieved the proper amount of fasting time due to an injury or a disease state that increases the risk of gastric aspiration, it is important to premedicate with a nonparticulate antacid such as sodium citrate (0.5 mL/kg), metoclopramide (0.1 mg/kg), and/or an H₂ blocking agent such as ranitidine (2.5 mg/kg).

Upper Respiratory Infection

Upper respiratory infections (URIs) are common in the pediatric age group, are frequently seasonal, and may be accompanied by cough, pharyngitis, tonsillitis, and croup. The child with an active or resolving URI has increased airway reactivity, a propensity for the development of atelectasis and mucous plugging of the airways, and the potential to experience postoperative arterial hypoxemia.⁶⁴ In addition, bronchial reactivity may persist for 6 to 8 weeks after a viral lower respiratory tract infection. The presence of chronic respiratory disease (asthma or bronchopulmonary dysplasia) requires a thorough assessment and medication review to ensure that the disease is well-controlled and the child is not currently experiencing an exacerbation. A history of steroid use necessitates consideration of steroid supplementation throughout the perioperative period.

Healthy children who are scheduled for placement of tympanostomy tubes frequently have otitis and rhinitis. In deciding whether to proceed with anesthesia, additional patient history must be obtained to differentiate between a chronic allergic or an acute infectious presentation and to determine whether there is lower airway involvement. The assessment of the color and the duration of nasal drainage will assist in deciding whether rhinorrhea is chronic or acute. Purulent nasal discharge associated with pharyngitis, cough, or fever may be indicative of a bacterial or viral URI. Additional information may be obtained by questioning the parents regarding their assessment of the child's current health. Helpful questions include: Does your child appear ill? Is your child eating, sleeping, and playing normally? Is there anyone in the family (including siblings) who is currently ill? Children with chronic allergic rhinorrhea who exhibit a clear nasal drainage

without accompanying signs of illness (e.g., no cough, pharyngitis, wheezing, or associated fever) are probably in satisfactory condition for elective general anesthesia with no imposed increased risk.

Lower respiratory tract dysfunction typically accompanies viral or bacterial URI. This combination may be associated with a greater frequency of laryngospasm (fivefold greater incidence) and bronchospasm (tenfold greater incidence) during anesthetic management, particularly when endotracheal intubation is performed.⁶⁵ Although a mild URI may be inconsequential during the intraoperative period, significant problems may develop in the immediate postoperative period. Studies have noted an increase in the incidence of postintubation croup, hypoxemia, and bronchospasm in patients with URIs compared with asymptomatic children.⁶⁵⁻⁶⁷

Multiple factors must be considered when one is deciding whether to cancel an elective procedure. Children with signs and symptoms of acute airway dysfunction should have further medical evaluation performed by a pediatrician. Elective surgery should be postponed for children who have a cough and pharyngitis accompanied by fever and wheezing. Acute versus chronic symptoms need to be deciphered. Children with a fever of 38.0°C and higher, malaise, wheezing, dyspnea, rhonchi, nasal congestion, and a productive cough are signs of an acute infection necessitating the postponement of surgery.^{68,69} Evidence-based recommendations

Box 53.1 in [Box 53.1](#).

Recommendations for Patients With Upper Respiratory Tract Infections

When feasible, efforts should be made to make parents aware of the problems with respiratory tract infections and anesthesia, and parents should be encouraged to call before the day of surgery to discuss the symptoms and possible need for delay. There may be a role for pediatricians and other primary care practitioners to play in the process of perioperative evaluation and education.

First, an emergency case mandates judicious airway management, and logically must proceed regardless of the presence or absence of respiratory symptoms. In patients

undergoing elective nonurgent surgery, initial consideration should be with respect to the severity of respiratory tract symptoms. Often, careful questioning of parents can differentiate acute from chronic symptoms. Patients with severe symptoms such as fever greater than 38.4°C, malaise, productive cough, wheezing, or rhonchi should be considered for delay of elective surgery. A reasonable period of delay would be 4 to 6 weeks.

If mild symptoms are present, such as nonproductive cough, sneezing, or mild nasal congestion, surgery could proceed for those having regional or general anesthesia without endotracheal tube (ETT) placement. The intraoperative plan should include early use pulse oximetry, decision of facemask or laryngeal mask airway use, and careful suctioning of the nasopharynx and oropharynx under deep anesthesia before emergence. Additional management considerations for patients with upper respiratory tract infection (URI) or lower respiratory tract (LRI) undergoing anesthesia include hydration status, use of airway humidification, and the potential benefit of pharmacologic agents such as anticholinergics and bronchodilators to help with airway secretions and airway hyperreactivity.

However, for those patients who require ETT placement for anesthesia, especially children under 1 year of age, it is important to identify risk factors such as passive smoke exposure and underlying conditions (e.g., asthma, chronic lung disease) because these children may benefit from a slight delay of 2 to 4 weeks. Finally, those patients with resolving respiratory tract infections with severe symptoms or mild symptoms should have the same relative waiting periods fulfilled (i.e., 2 to 4 weeks after resolution of minor URI and 4 to 6 weeks after resolution of severe URI or LRI) to minimize the risks of proceeding with surgery.

Modified from McKee CT, et al. Should a child with a respiratory tract infection undergo elective surgery? In Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia: Elsevier; 2013:529–536.

Laboratory Testing

Laboratory testing should be ordered preoperatively based on the patient's medical history and physical examination. Indications for preoperative laboratory testing are listed in [Box 53.2](#). The American

Academy of Pediatrics states that routine laboratory tests do not need to be performed in healthy patients undergoing outpatient surgery.⁷⁰ However, in patients presenting with an abnormality, preoperative testing is imperative to guide the surgical and anesthetic plans.

Box 53.2

Indications for Preoperative Laboratory Testing

Complete Blood Count

- Hematologic disorder
- Vascular procedure
- Chemotherapy
- Unknown sickle cell syndrome status

Hemoglobin and Hematocrit

- Less than 6 months of age (less than 1 year of age if born premature)
- Hematologic malignancy
- Recent radiation or chemotherapy
- Renal disease
- Anticoagulant therapy
- Surgical procedures with potential for large blood loss
- Coexisting systemic disorders (e.g., cystic fibrosis, prematurity, severe malnutrition, renal failure, hepatic disease, congenital heart disease)

White Blood Cell Count

- Leukemia or lymphomas
- Recent or concurrent radiation or chemotherapy
- Suspected infectious process
- Aplastic anemia
- Hypersplenism
- Autoimmune collagen vascular disease

Blood Glucose

- Diabetes mellitus
- Current corticosteroid use
- History of hypoglycemia
- Adrenal disease
- Cystic fibrosis

Serum Chemistry

- Renal disease
- Adrenal or thyroid disease
- Previous or concurrent hemotherapy
- Pituitary or hypothalamic dysfunction
- Body fluid loss or shifts (e.g., dehydration, bowel preparation)
- Central nervous system disease

Potassium

- Digoxin or diuretic therapy

Creatinine and Blood Urea Nitrogen

- Hypertensive cardiovascular disease
- Renal disease
- Adrenal disease
- Diabetes mellitus
- Digoxin or diuretic therapy
- Body fluid loss or shifts (e.g., dehydration, bowel preparation)
- Administration of intravenous radiocontrast material

Liver Function Tests

- Hepatic disease
- Exposure to hepatotoxic agents

Coagulation Studies

Prothrombin Time

- Activated partial thromboplastin time (aPTT)
- Leukemia
- Hepatic disease
- Known coagulation disorder (e.g., hemophilia, Christmas disease)
- Concurrent anticoagulant therapy
- Severe malnutrition or malabsorption

Platelet Count or Bleeding Time

- Known coagulation disorder (e.g., hemophilia, Christmas disease)
- Purpura (increase in bruising)

Pregnancy Test

- Serum human chorionic gonadotropin (HCG) in menstruating, sexually active patient

Electrocardiogram

- Family history of prolonged QT interval
- Congenital heart disease
- History of sleep apnea or chronic airway obstruction (adenotonsillar hypertrophy)
- Possible previously undiagnosed heart murmur

Chest Radiograph

- Suspected intrathoracic pathology (e.g., tumors, vascular ring)
- Congenital heart disease
- History of prematurity with residual bronchopulmonary dysplasia
- Obstructive sleep apnea with cardiomegaly

Cervical Spine Radiograph

- Down syndrome (rule out subluxation of atlanto-occipital junction)

Preoperative laboratory tests should be ordered based on abnormal findings from the medical history and physical examination. A definitive “adequate” hemoglobin concentration

that is essential for oxygen delivery is 7 to 8 g/dL for most hospitalized adult patients. However, there have been few studies to quantify these transfusion triggers in the pediatric population. Prescribing practices vary between various medical service specialties.⁷¹

The determination of an acceptable value requires an understanding of the child's current medical history, the proposed surgical procedure, and global oxygen transport and use. The value of a routine hemoglobin determination has been questioned for some time, and has been found to rarely affect the anesthetic management of children.⁷² In a prospective study of 2649 pediatric outpatients, the frequency of asymptomatic anemia was found to be less than 1%, with 7 of 14 anemic patients younger than 1 year of age. However, the frequency of anemia may be as high as 12% in immigrant and indigent children.⁷³ Children who benefit from preoperative hemoglobin determinations include premature infants less than 60 weeks' postconceptional age, children with concurrent cardiopulmonary disease, children with known hematologic dysfunction (e.g., sickle cell disease), and children in whom major blood loss is anticipated during the surgical procedure.

Premedication

The selection and administration of premedication for the pediatric patient requires an understanding of the desired goals, the planned surgical procedure (inpatient or outpatient procedure), the familiarity with and previous experiences of the particular drug, and the availability of nursing staff to monitor the child after administration of the drug (Box 53.3). The ideal premedicant should be dependable, have a rapid and reliable onset and offset, and should have minimal side effects.⁷⁴ Table 53.3 lists commonly prescribed pediatric premedicants. Premedication must be individualized to account for differences in maturation and development and for the child's previous surgical experiences. The reliance on pharmacologic premedication in preparing the child for the surgical experience should not be routine; rather, it should be individualized to the patient's age, anxiety level, surgical procedure, and physical history. Anxiolytics and sedatives may prolong the time to discharge, thereby increasing patient care

costs.⁷⁵ Older children may benefit from anxiolytic premedication to decrease preoperative anxiety and modify behavioral changes after discharge. Analgesics are important for children experiencing pain and to provide some postoperative relief.⁷⁶ Midazolam is the most commonly used premedicant in the pediatric patient. This short-acting, benzodiazepine produces amnesia and anxiolysis and in sufficient dosages may also produce sleep (hypnosis). Other medications that have been used with success include ketamine, clonidine, and pregabalin.⁷⁷ Nonpharmacologic interventions that can decrease preoperative anxiety in the pediatric patient include playing videos of the child's choice during induction, low sensory stimulation, and handheld video games.⁷⁸

Goals for Premedication

- Anxiolysis (especially in children undergoing repeat procedures)
- Amnesia (insertion of intravenous access)
- Analgesia (children in pain)
- Antisialagogue effects (airway manipulation, but rarely needed)
- Increased gastric pH
- Reduction of gastric volume
- Reduced anesthetic requirements
- Blunting of central nervous system reflex responses
- Prevention of subacute bacterial endocarditis
- Prevention of allergic reactions (latex)
- Minimize postoperative nausea and vomiting
- Decreased incidence of infectious processes

TABLE 53.3

Commonly Prescribed Pediatric Premedicants

Drug Name	Pediatric Dose
Opioids	
Morphine sulfate	0.1–0.3 mg/kg IM 0.05–0.1 mg/kg IV
Fentanyl	0.5–1.0 mcg/kg IV 10 mcg/kg oral transmucosal
Benzodiazepines	
Midazolam	0.05–0.1 mg/kg IM 0.2 mg/kg nasally 0.025–0.05 mg/kg IV 0.25–1.0 mg/kg PO 0.5–1 mg/kg rectally
Ketamine	5–10 mg/kg PO 2–10 mg/kg IM 1–2 mg/kg IV
Clonidine	2.5–5.0 mcg/kg PO 1–2 mcg/kg IV
Dexmedetomidine	0.5–1.0 mcg/kg intranasally 2–5 mcg/kg PO 0.4–0.6 mcg/kg IV infusion in 100 mL saline
Anticholinergics	
Atropine	0.02 mg/kg PO, IV, IM
Glycopyrrolate	0.01 mg IV

IM, Intramuscular; *IV*, intravenous; *PO*, per os.

Parental Presence During Anesthetic Induction

Children may have difficulty with parental separation and may require premedication to ease their anxiety. In addition to administering preoperative medication, various anesthetic departments allow a parent to be present for anesthetic induction. The frequency with which parents are allowed to accompany a child during anesthesia induction varies widely among institutions and even among individual clinicians. Parents may stay with their children during diagnostic procedures such as bone marrow biopsy, immunization, dental rehabilitation, and the induction of anesthesia. Anesthesia departments may have age limitations, not allowing parental presence for children less than 12 to 18 months of age. Studies examining the effectiveness of parental presence are mixed. Parental presence has been demonstrated to reduce the child's anxiety, precluding the need for premedication.⁷⁹ However, an evidence-based review noted no advantage, and oral midazolam was found to be more effective for the control of the child's preoperative anxiety than parental presence.⁸⁰ Parents who are

motivated to be present in the operating room during the induction of anesthesia may be very anxious, and their children are likely to have high anxiety levels during anesthetic induction. Before entering the operating room with parent and child, a thorough explanation of the expected behavior of the child during anesthetic induction (e.g., excitement, spontaneous involuntary movements, snoring, uncoordinated breathing pattern, unconsciousness) should be provided to the parent or guardian. It is important that there be a clear line of communication between the anesthetist and the parent. In addition, the parent should agree to leave the operating room, accompanied by an escort, when the child has lost consciousness.

Anesthetic Management

Airway Management

Pediatric Breathing Circuits

In the United States, standard pediatric breathing circuits utilizing a circle system are used to provide pediatric anesthesia. An ideal pediatric breathing circuit is lightweight, minimizes dead space, provides low resistance and a low compressible volume, can be adapted for both spontaneous and controlled ventilation, is capable of providing humidification and warming of inspired gases, and permits the collection and scavenging of exhaled anesthetic gases.

Prior to modern advances in anesthesia machines and ventilator capacity, open circuit breathing systems were used during anesthesia. Open circuits are still used today in developing countries. An easy method to conceptualize pediatric breathing circuits is to characterize the circuit according to the number of valves within the circuit.⁸¹ A circuit without valves is an open circuit. The Ayre T-piece is an excellent example of an open circuit (Box 53.4). It is commonly used throughout hospitals to provide supplemental oxygen during patient transport. The T-piece was first used for the delivery of anesthesia to infants undergoing cleft palate and cleft lip repair. The T-piece, which is in a T configuration, is formed by an inspiratory limb for the delivery of oxygen and anesthetic gas, a limb directed to the patient for connection to a facemask or ETT, and an opposite expiratory limb that is open to the atmosphere for the removal of exhaled gas. This expiratory limb also may serve as a reservoir for oxygen that may be rebreathed. There are no valves within the breathing circuit, and therefore, the inspired air is drawn from both the inspiratory limb and the expiratory limb. The rebreathing of expired CO₂ can be prevented with the administration of fresh gas flows at least twice the patient's minute ventilation. The T-piece can be configured to increase oxygen delivery or decrease arterial partial pressure of carbon dioxide.

Box 53.4

Manipulation of the T-Piece (Open Circuit)

Manipulation to Increase P_{aO_2}

- Increase inspired oxygen delivery
- Increase fresh gas flow (decreases entrainment of room air from reservoir tubing)
- Increase length of reservoir tubing (increases oxygen storage capacity)

Manipulation to Decrease P_{aCO_2}

- Increase fresh gas flow (wash out expired air from reservoir tubing)
- Decrease length of reservoir tubing (decreases volume of expired air; also decreases FiO_2)

FiO_2 , Fraction of inspired oxygen, PaO_2 , Partial pressure of arterial oxygen, $PaCO_2$, partial pressure of arterial carbon dioxide.

From Litman RS, ed. *Pediatric Anesthesia: The Requisites*. Philadelphia: Mosby; 2004:102.

Modification of the Ayre T-piece with the addition of a single valve allows the delivery of positive-pressure ventilation. A variety of modifications of the Ayre T-piece have been classified by Mapleson. The Mapleson A circuit is best employed for a patient who is spontaneously breathing. The Mapleson D system contains an expiratory valve at the distal end of the expiratory limb and is used for controlled ventilation. The Mapleson E system was modified by Jackson-Reese with the addition of a reservoir bag with an adjustable valve at the tail of the bag. Spontaneous ventilation is permitted with the opening of the adjustable valve, whereas closing the valve fills the reservoir bag, and repeated manual compression allows the delivery of continuous positive airway pressure, or positive-pressure ventilation. With an expiratory pause of sufficient duration and sufficient fresh gas flows, exhaled CO_2 is washed from the reservoir tube, preventing the inhalation of exhaled CO_2 with

subsequent inspiration. Fresh gas flows of two to three times the child's minute ventilation are required to prevent rebreathing of exhaled gases. Due to the high fresh gas flow rates, this circuit is not economical for children who weigh more than 20 kg.

The circle breathing system is the standard for anesthetic gas delivery for pediatric patients in the United States. Advances in the anesthesia machine design have decreased the resistance imparted by the absorbent canisters and the one-way inspiratory and expiratory valves. Overall, system compliance is greater as compared to open breathing circuits. The breathing tubing for pediatric circle systems is a smaller diameter than the adult tubing and has a lower compression volume, allowing accurate delivery of desired tidal volumes. The circle system is characterized by the presence of CO₂-absorbent canisters and a total of three valves (a one-way inspiratory valve, a one-way expiratory valve, and a pop-off or adjustable pressure-limiting [APL] valve) that directs exhaled gas to the scavenging system. Advantages of the circle system include the conservation of potent inhalation agents, the ability to retain both heat and humidity, and the ease of collecting and scavenging waste gases.

The reservoir bag serves as a visual and tactile monitor to assess the presence and adequacy of ventilation. Reservoir bags are shaped to allow compression with one hand, and they are constructed of rubber and latex, although latex-free bags are most commonly used within the United States. They range in size from 0.5 to 6 L. The selected reservoir bag must be appropriate for the patient's size, that is, capable of containing a volume in excess of the child's inspiratory capacity. The use of an inappropriately small reservoir bag may restrict respiratory efforts, and the use of a large reservoir bag inhibits the ability to use the reservoir bag as a ventilation monitor.⁸²⁻⁸⁴

Anesthetic Induction

Inhalation (Mask) Induction

Anesthetic induction may be accomplished in a variety of ways, and it is dependent on the child's current state of health, the age and level of anxiety, the proposed surgical procedure, and the

parents' agreement with regard to the proposed anesthetic plan. Inhalation induction, which is commonly called *mask induction*, is the most popular technique and is easily accomplished in children less than 8 years of age, as well as in children who do not have initial IV access.

Sevoflurane is the volatile agent of choice for inhalation inductions, as it has minimal airway irritant properties. Oxygen or a nitrous oxide–oxygen mixture is used during the induction. It is the anesthesia provider's choice as to the initial concentration of sevoflurane to be administered. Some anesthesiologists will begin with lower concentrations (e.g., 2%) and then increase the concentration incrementally to avoid excessive myocardial depression and vasodilation. Others will begin with high concentrations of sevoflurane (e.g., 8%) to increase the speed of induction. Following loss of consciousness and prior to intubation, nitrous oxide (if used) is discontinued, and sevoflurane is administered in 100% oxygen.

Prior to establishing IV access and intubation, it is desirable for the patient to breathe spontaneously while the anesthesiologist manually assists ventilation. As the concentration of sevoflurane increases in the brain, respiratory depression and arrest can occur. After the inhalation induction is complete and the anesthesiologist deems that the child is adequately anesthetized, the inspired anesthetic concentration of sevoflurane can be decreased. During assisted ventilation, IV access should be established. For procedures that do not require an IV, it is mandatory that the anesthesiologist has the ability to rapidly gain vascular access. Additionally, it is essential to have calculated doses of emergency medications ready to be administered intramuscularly.

Establishing IV access in children prior to laryngoscopy and endotracheal intubation is most often necessary. An example of a surgical procedure that may not require IV access is the placement of myringotomy tubes. For elective surgical procedures, neonates may be managed with a 24-gauge catheter, infants with a 22-gauge catheter, and children with a 20- or 22-gauge catheter. Surgical procedures that are expected to produce large third-space fluid loss or blood loss require an additional IV catheter. Preferred sites for IV access include the nondominant upper extremity (dorsum of the hand, antecubital fossa) and the lower extremity (dorsum of the

foot, or the saphenous vein). The deep saphenous vein is most easily accessed with a 20- or 22-gauge catheter. This vein can be identified by placing the thumb over the medial malleolus and moving it toward the anterior portion of the tibia. By extending the foot, piercing the skin parallel to the tibia, and passing subcutaneously, the saphenous vein may be cannulated. To prevent the child from dislodging the catheter, a sterile bioclusive dressing can be applied. The extremity can be secured to a padded board to decrease the chance of catheter kinking or dislodgement, especially during the postoperative period. Prior to establishing IV access, the anesthetist should ensure that the patient is adequately anesthetized to avoid the potential for laryngospasm and bronchospasm.

Following the establishment of IV access, preparations are made for endotracheal intubation. Intubation may be accomplished using the inhaled anesthetic agent without muscle relaxation or subsequent to the administration of a nondepolarizing neuromuscular relaxant. The administration of a neuromuscular relaxant decreases the potential for the cardiovascular depression that accompanies the administration of high concentrations of inhalation agents that may be required to facilitate laryngoscopy and intubation. The inspired concentration required for acceptable intubating conditions with sevoflurane in children aged 1 to 8 years is $3.54 \pm 0.25\%$. The addition of 66% nitrous oxide decreases the required concentration by 40%.⁸⁵ A survey of members of the Society of Pediatric Anesthesia found that inhalation agent administration without neuromuscular blockade was used to facilitate endotracheal intubation 38% of the time in infants (0 to 12 months old) and 43.6% of the time in children (1 to 7 years old).^{86,87} Whichever method is selected, the inhalation agent should be discontinued immediately before laryngoscopy. This practice minimizes the contamination of the operating room with free-flowing inhalation agent from the patient breathing circuit, and the delivery of high inspired anesthetic concentrations is avoided immediately after intubation during the confirmation of ETT placement. Following confirmation that the ETT is secured, the tube is positioned at the alveolar ridge.

Intravenous Induction

An IV induction may be clinically indicated when the child has a full stomach or a history of gastroesophageal reflux. IV induction is rapid and dependable, facilitating unconsciousness, and this method of induction allows the anesthetist to secure the airway promptly. Venipuncture can be a frightening and a traumatic experience for children. Oral premedication with midazolam before IV insertion in the preoperative area can be given to decrease the child's anxiety and gain cooperation. The eutectic mixture (equal quantities as measured by weight) of local anesthetic (EMLA cream) is a combination of lidocaine (2.5%) and prilocaine (2.5%) that can be applied to the skin causing numbness to help facilitate IV catheter placement. The medication should be applied well in advance (30 to 60 minutes) to achieve an adequate effect. Methemoglobinemia is a rare side effect that is associated with prilocaine toxicity.

Intramuscular Induction

On rare occasions, an intramuscular (IM) administered drug may be required in children who are uncooperative and who refuse alternative routes (i.e., oral, nasal, or rectal) for premedication. Ketamine is an excellent induction agent in these situations. After IM administration, the child will develop a catatonic state. Parents who witness the administration of ketamine should be warned that their child might exhibit spontaneous involuntary movements and nystagmus. The psychogenic effects such as emergence delirium may be decreased with the concomitant administration of a benzodiazepine. Ketamine administered via the IM route in a dose of 4 to 6 mg/kg facilitates inhalation induction in children who are reluctant to be subjected to inhalation induction or venipuncture.

Pediatric Airway Equipment

The child's age, weight, and proposed surgical procedure guide the selection of essential pediatric anesthesia equipment. This includes but is not limited to a variety of sizes of anesthesia masks, airways, LMAs, laryngoscope blades, ETTs, ETT stylets, blood pressure

cuffs, pulse oximeter probes, calibrated pediatric fluid sets, syringe pumps for the delivery of both fluids and drugs, IV catheters, tape, and armboards.

Airway Equipment

The pediatric facemask is designed to fit the smaller facial features of the child and eliminate mechanical dead space. Contemporary masks are manufactured from transparent plastics, have a soft inflatable cuff that sits on the face, and do not contain latex. The transparent body of the mask allows continuous observation of skin color and the appearance of gastric contents if vomiting occurs. Appropriately sized oral airways must be readily available. The relatively large infant tongue predisposes to airway obstruction after the induction of general anesthesia. Oral airways that are too large may produce airway obstruction and inhibit venous and lymphatic drainage, producing macroglossia and further comprising the airway. The oral airway should be inserted while displacing the tongue toward the floor of the mouth to allow smooth insertion of the airway. The anesthetist must be aware of the possibility of dislodging loose deciduous teeth. Nasal airways are infrequently used in children less than 1 to 2 years of age. The internal diameter of the nasal airway may unnecessarily increase the work of breathing. Adenoid hypertrophy may make nasal airway placement difficult and produce severe epistaxis.

Endotracheal Tubes.

Since the 1960s, it has been common practice to use of an uncuffed ETT in infants and children less than 8 years of age to minimize the potential for postextubation croup. Although this practice is still widely accepted, recent literature suggests that this belief is not universally applied, is empirical rather than scientifically based, and is a perpetuated “myth” of pediatric anesthesia. The age-old argument against the use of a cuffed ETT in infants and children is quite logical; the narrowest portion of the infant and child airway is the cricoid cartilage, and the diameter of the pediatric trachea is small compared to the adult. Thus, a small amount of tracheal edema can cause increased work of breathing and possibly

respiratory distress. Cuffed ETTs have been shown to be effective for use in the pediatric population. There is no significant difference in the incidence of airway injury and postextubation croup when comparing cuffed and uncuffed ETTs.⁸⁸ Additionally, cuffed ETTs have been associated with a decreased incidence of sore throat.⁸⁹ The differences associated with the adult and pediatric airway are summarized in [Table 52.3](#).

Sizing the Endotracheal Tube.

Early detailed accounts of the laryngeal framework suggested that the larynx is shaped as a cone, with the apex at the level of the cricoid cartilage.^{90,91} The compression of the tracheal mucosa at the level of the cartilaginous cricoid ring by an oversized ETT would therefore produce mucosal edema. This traditional understanding has been challenged. Magnetic resonance imaging of sedated newborns to children 14 years of age has demonstrated that the lumen of the cricoid cartilage is not round but elliptical in shape, with the narrowest dimension in the transverse plane at the level of the vocal cords.⁹² Evidence that disputes this claim was obtained by studying video bronchoscopic images and magnetic resonance spectrographs from 135 children aged 6 months to 13 years. The laryngeal dimensions, including the cross-sectional area and the anteroposterior and transverse diameters at the level of the glottis and the cricoid were measured. This study found that the glottis rather than the cricoid was the narrowest portion of the pediatric airway. The authors also noted that, as in adults, the pediatric airway is more cylindrical than funnel shaped.⁹³ Accordingly, the pressure exerted upon the laryngeal and tracheal mucosa with the use of an uncuffed ETT is in the posterior lateral position. This has been verified, as evidenced by the associated pathologic lesions found posteriorly in the subglottis. In addition, trauma that appears within the trachea occurs anteriorly from the impingement of the distal end of the ETT upon the anterior tracheal wall. The goal of ETT selection is the placement of an appropriately sized tube that allows controlled ventilation but minimizes laryngeal or tracheal injury. Due to anatomic variability, many formulas exist for the determination of the correct ETT size and for the depth of insertion. Despite countless practitioner recommendations, there is no

consensus related to a standard formula. In addition, many practitioners fail to appreciate the differences in the internal diameter of small ETTs. ETTs for neonates are sized by the internal diameter, yet the external diameters may differ by as much as 0.9 mm among manufacturers in tubes with identical internal diameters.⁹⁴

The approximate size of an ETT for children 2 years of age and older may be determined by using the following formula: $16 + \text{age} \div 4$. Another formula used to calculate ETT size, especially for patients younger than 2, is as follows: $\text{age} \div 4 + 4$. To accommodate the variability in patient airway size, ETTs a half size larger and a half size smaller should be immediately available.

The depth of ETT insertion from the dental alveoli may be estimated using the “1, 2, 3, 4/7, 8, 9, 10” rule. For example, the ETT is inserted to a depth of 7 cm in a neonate weighing 1 kg and to a depth of 8 cm in a 2-kg neonate. Another approximate method is to insert the ETT to a depth in centimeters three times the internal diameter of the ETT in millimeters. For example, a 3-mm ETT should be inserted to a depth of 9 cm. Uncuffed ETTs are marked distally with a double black line that provides a visual indication of the depth of the ETT. During intubation, the ETT is passed until the double black line has reached the level of the vocal cords. An optimally sized ETT is one that easily passes through the glottis and subglottic regions. Clinicians who choose to utilize a cuffed ETT frequently select a cuffed ETT that is a half size smaller than an uncuffed ETT. One study suggests checking cuff pressure for long surgical procedures to decrease the incidence of edema and tracheal damage.⁹⁵ Confirmation of proper ETT placement is imperative. Positive end-tidal CO₂, chest rise, and bilateral breath sounds are checked. Lung auscultation helps confirm proper ETT position. As the ETT is secured, it is important not to dislodge or inadvertently extubate the trachea, which would necessitate re-intubation. The provider can place a stethoscope over the patient's mouth to check for a leak during manual ventilation. A desirable leak is obtained between 15 and 25 mm Hg pressure. [Table 53.4](#) lists specific airway devices and details regarding their use.⁹⁶ Alignment of the head and its effect on the airway are depicted in [Fig. 52.3](#).

TABLE 53.4**Airway Device Details**

	Preterm Neonate	Full-Term Neonate	Infant Child											Adult
			6 mo	1 yr	2 yr	3 yr	4 yr	5 yr	6 yr	8 yr	10 yr	12 yr	14 yr	
Average weight (kg)		3.5	7	10	12	14	16	18	20	25	30	40	50	70
Approx. BSA (m ²)		0.25	0.38	0.49	0.55	0.64	0.74	0.76	0.82	0.95	1.18	1.34	1.5	1.73

Laryngeal Mask Airway.

The original LMA was intended as an alternative method of securing the airway compared to endotracheal intubation. The LMA can be used for surgical procedures that do not require endotracheal intubation. Relative contraindications for use of an

LMA include increased risk of gastric aspiration, abnormal airway anatomy, laparoscopic surgery, and emergency resuscitation. The LMA can be used as an emergency airway device in a “cannot ventilate, cannot intubate” scenario. The LMA is available in sizes specific for the neonate, infant, child, and adolescent (Table 53.5). Many alternative designs for special uses are being introduced. The inflation of the pharyngeal cuff can produce undue pressure on pharyngeal structures. Like the adult ETT cuff, the LMA cuff may be expanded during the course of the anesthetic procedure with the administration of nitrous oxide. The initial volume of air injected into the laryngeal cuff may be regulated by identifying the amount of air and airway pressure that produces an audible leak. This pressure is generally between 15 and 25 cm H₂O. The LMA cuff should be inspected before each use, the volume of air required for cuff inflation should not exceed the manufacturer's recommendation, and the LMA cuff should be periodically checked during the administration of nitrous oxide to prevent overinflation.⁹⁷

TABLE 53.5
Laryngeal Mask Airway Sizes

LMA Size	Patient Weight (kg)	Suggested Inflation Volume
1	<5	up to 4 mL
1.5	5–10	up to 7 mL
2	10–20	up to 10 mL
2.5	20–30	up to 14 mL
3	30–50	up to 20 mL
4	50–70	up to 30 mL
5	70–100	up to 40 mL

LMA, Laryngeal mask airway.

From Teleflex-North America, Wayne, PA.

The LMA has traditionally been removed in the adult when airway reflexes return. Removal of the LMA in the pediatric patient can be associated with biting, pulmonary edema, severe laryngospasm, and separation of the tube from the pharyngeal mask.^{98,99} Several studies have examined the appropriate time for LMA removal in children. In one study, oxygen desaturation was more prevalent (31.3%) after awake removal, compared with

removal in a deep anesthetic plane (4.5%), whereas airway obstruction occurred more frequently (20%) with deep removal.¹⁰⁰ Researchers have reported a 10% incidence of severe laryngospasm with awake removal, compared to 5% with deep removal.¹⁰¹

Special Airway Equipment.

Specialized uncuffed and cuffed oral and nasal ETTs may be chosen for otolaryngologic, ophthalmologic, and dental procedures. The right angle endotracheal (RAE; Mallinkrodt; Argyle, New York) tube is premolded, with the acute angle of the tube designed to be positioned over the lower lip. The nasal RAE tube is premolded with a 180-degree bend that directs the tube toward the top of the head. These tubes facilitate the routing of the breathing circuit away from the surgical field. RAE tubes are longer than straight ETTs and place the distal end of the tube in closer proximity to the carina, thereby minimizing the chance of inadvertent extubation with neck extension. The RAE tube is designed with two Murphy eyes located at the distal end of the tube to facilitate uninterrupted ventilation if the tube migrates in a caudal fashion. However, proper ETT placement must be determined with confirmation of bilateral breath sounds after intubation and repositioning of the head. The use of a precordial stethoscope placed over the left anterior area of the chest will aid in the detection of right bronchial migration of the RAE tube.

The clinical application of laser technology to treat airway pathology necessitates the use of a specialized ETT. ETT ignition may occur in as many as 1.5% of patients during CO₂ laser laryngeal procedures.¹⁰² Modern polyvinylchloride ETTs absorb infrared light and may be ignited with a direct hit from a CO₂ laser or as a result of burning material in close proximity to the tube. Laser-resistant or “laser-safe” ETTs are available from several manufacturers, and are marketed for specific laser applications (e.g., CO₂; neodymium-doped: yttrium-aluminum-garnet [Nd:YAG]; and potassium titanyl phosphate [KTP]). An alternative is wrapping the external surface of a polyvinylchloride ETT with a metallic foil (see [Chapter 43](#)).

Maintenance of a Patent Airway

A variety of anatomic and neurologic interactions are essential for the maintenance of a patent airway. It is truly remarkable that airway patency is continuously maintained with changes in posture, as well as extremes of head and neck position. The larynx is innervated by a variety of receptors that, when stimulated, can initiate intense physiologic reactions. Airway patency is also dependent upon lung stretch reflexes, central and carotid body chemoreceptor reflexes, and CNS arousal mechanisms. Pharyngeal patency is established and maintained through a delicate balance of CNS-derived dilating and collapsing forces upon the pharyngeal airway.^{103,104} The pharynx may be conceptualized as a collapsible tube within a box, bordered by the tongue and soft palate, and enveloped by the bony elements of the mandible anteriorly and the cervical vertebra posteriorly. Pharyngeal patency is a function of the overall size of this box and the amount of soft tissue between the bony elements and the pharynx. An increase in the amount of soft tissue within the box (e.g., obesity, hypertrophy of adenoids and tonsils, large tongue), or a decrease in the size of the bony elements (e.g., small craniofacial structures or craniofacial deformity) will limit the content of the box, resulting in compression of the pharyngeal airway. In effect, the pharyngeal airway functions as a Starling resistor.¹⁰⁵

Airway Management of the Infant and Child

In an awake infant or child, the tongue, the upper airway muscles (i.e., genioglossus, geniohyoid, sternohyoid, and sternothyroid) interact to tent the pharynx, preventing collapse. Anesthetic agents inhibit the neural activity of these airway muscles, resulting in pharyngeal narrowing or collapse.^{106,107} The young infant depends upon compensatory mechanisms to maintain pharyngeal patency, but is disadvantaged because of an anatomic imbalance (i.e., small maxilla and mandible, large cranium, large tongue).¹⁰⁸ Steadily increasing the anesthetic depth during inhalation induction will depress these compensatory mechanisms, leading to pharyngeal narrowing and collapse.

Incomplete airway obstruction may be clinically evident early in

the inhalation induction process, as audible inspiratory or expiratory sounds are evident through the precordial stethoscope. As the obstruction increases, a tracheal tug becomes notable with attempted inspiration. The infant has a compliant chest wall, and because of forceful diaphragmatic contraction, the chest will collapse with inspiratory efforts against partial pharynx collapse. With continued inspiratory attempts, a paradoxical movement of the chest and abdomen (i.e., the contraction of the chest with abdominal expansion) also occurs. This thoracoabdominal asynchrony is an important clinical sign of upper airway obstruction. With complete pharyngeal collapse, the audible signs of obstruction are no longer observed, and thoracoabdominal asynchrony continues.

Because of the immaturity of the CNS, the regulation of the pharyngeal dilator muscles is ineffective in opening the pharyngeal airway in the infant.¹⁰⁹ The application of continuous positive airway pressure (CPAP) at 5 to 10 cm H₂O is essential in the reestablishment of a patent pharyngeal airway until the patient is sufficiently anesthetized to allow the placement of an oral airway. The application of CPAP accompanied by airway opening maneuvers (more importantly a chin lift) will reverse the anatomic imbalance, increase tidal volume, and diminish thoracoabdominal asynchrony.¹¹⁰ The chin lift is an important airway maneuver because it widens the anteroposterior diameter (at the epiglottis) and the transverse diameter (at the level of the soft palate) of the pharyngeal airway.¹¹¹

General anesthesia causes depression of CNS compensatory mechanisms for the maintenance of a patent pharyngeal airway, so tracheal extubation should be undertaken when the young infant is awake and has adequate respirations. Thoracoabdominal asynchrony appearing immediately after extubation is indicative of upper airway obstruction, and is not accompanied by traditional sounds of upper airway obstruction (i.e., snoring), as it is in the adult. Following extubation, the lateral decubitus position may be advantageous, as it has been shown to decrease the compressive effects of the soft tissue that surrounds the pharynx in individuals with obstructive sleep apnea.¹¹²

Pharyngeal patency improves during the first year of life as the

anatomic imbalance is lessened (due to continued growth of the maxilla and mandible) and CNS regulation matures. However, when airway obstruction develops during inhalation induction, the obstruction is generally easily managed with the previously cited maneuvers used to improve airway patency.

Airway Complications

Two common airway complications with a pediatric patient are laryngospasm and bronchospasm. The larynx is the superior portion of the airway that protects the lungs from aspiration of foreign material. This function is most evident during swallowing, when the glottic closure reflex is initiated by stimulation of the superior laryngeal nerve, facilitating sphincteric closure of the airway. Laryngospasm is a hyper-responsive glottic closure reflex to noxious stimuli of the superior laryngeal nerve and may persist despite the immediate removal of the stimulus. Laryngospasm can precipitate serious complications, including complete airway obstruction, gastric aspiration, postobstruction pulmonary edema, cardiac arrest, and death.¹¹³

The frequency of laryngospasm is greatest in patients with a URI (95.8/1000).¹¹³ Children exposed to secondhand tobacco smoke have a tenfold increase in the relative risk of laryngospasm (0.9% with no exposure, versus 9.4% with exposure).¹¹⁴ Although laryngospasm may be self-limiting, the clinical importance of proper management is exemplified by the fact that five of every thousand children who experience laryngospasm have a subsequent cardiac arrest.¹¹³

The incidence of laryngospasm may be greater in the pediatric population because of specific practices that are used in the anesthetic management of infants and children. Several factors are generally associated with the development of laryngospasm (Box 53.5). The risk of laryngospasm is increased when airway instrumentation is attempted before an adequate depth of anesthesia has been achieved, without the benefit of neuromuscular blocking drugs, and in infants and children with residual effects of **Box 53.5** upper respiratory tract infections.

Risk Factors for Laryngospasm

Preoperative Factors

- Exposure to secondhand tobacco smoke
- Concurrent or recent upper respiratory tract infection
- Gastroesophageal reflux (GERD)
- Mechanical irritants (oropharyngeal secretions)

Intraoperative Factors

- Excitement phase of inhalation induction
- Tracheal intubation/extubation during “light” anesthesia
- Upper airway surgical procedures (e.g., tonsillectomy, adenoidectomy, nasal/sinus procedures, palatal procedures, laryngoscopy/bronchoscopy)

The precise pathophysiologic mechanism responsible for laryngospasm remains elusive. To expand our understanding of laryngospasm and its clinical management, it is best to revisit the original description provided by Fink in 1951.¹¹⁵ The basic execution of laryngeal closure follows superior laryngeal nerve stimulation. It has been theorized that stimulation on airway structures causes an afferent sensory impulse mediated via the internal branch of the superior laryngeal nerve. The efferent response that causes the vocal cords to close is via the external branch of the superior laryngeal nerve, resulting in cricothyroid muscle contraction. The mechanism resembles a shutter, where the laryngeal inlet is closed by the action of the supraglottic folds, the false vocal cords, and the true vocal cords. Fink suggested that glottis closure is a dual mechanism, in which the first response is the closure of the vocal cords (a shutter effect) followed by a ball-valve effect with closure of the false cords and the subsequent rounding of the supraglottic tissue after the shortening of the thyrohyoid muscle. This produces an envelopment of the laryngeal inlet by the supraglottic tissue with continued inspiratory effort, producing complete airway

obstruction.

Box 53.6 lists measures that can be used to prevent laryngospasm. Prompt recognition and management are imperative to prevent **Box 53.6** hypoxemia, bradycardia and cardiac arrest.

Preventive Measures for Laryngospasm

- Avoid noxious airway/surgical stimulation during “light” anesthesia.
- Ensure sufficient depth of anesthesia prior to airway instrumentation.
- Topical application of lidocaine to suppress laryngeal sensory nerve activity.
- Intravenous lidocaine prior to extubation.
- Suction oral pharynx prior to extubation.
- Tracheal extubation when fully awake.
- Administer 100% oxygen for 3–5 minutes prior to extubation.

Incomplete airway obstruction ([Fig. 53.2](#)) may be evident as “grunting” or audible inspiratory and expiratory sounds as heard through a precordial stethoscope, accompanied by tracheal tug and thoracoabdominal asynchrony. Management consists of three essential processes. First, the noxious stimuli should be discontinued (e.g., surgical stimulation, attempted airway instrumentation during “light” anesthesia). Next, anesthetic depth should be increased by the delivery of an increased concentration of an inhalation agent or IV administration of a small dose of propofol. Third, gentle positive-pressure ventilation using 100% oxygen should be attempted using a properly applied facemask with concurrent airway opening maneuvers (i.e., slight head extension, chin lift, and jaw thrust).

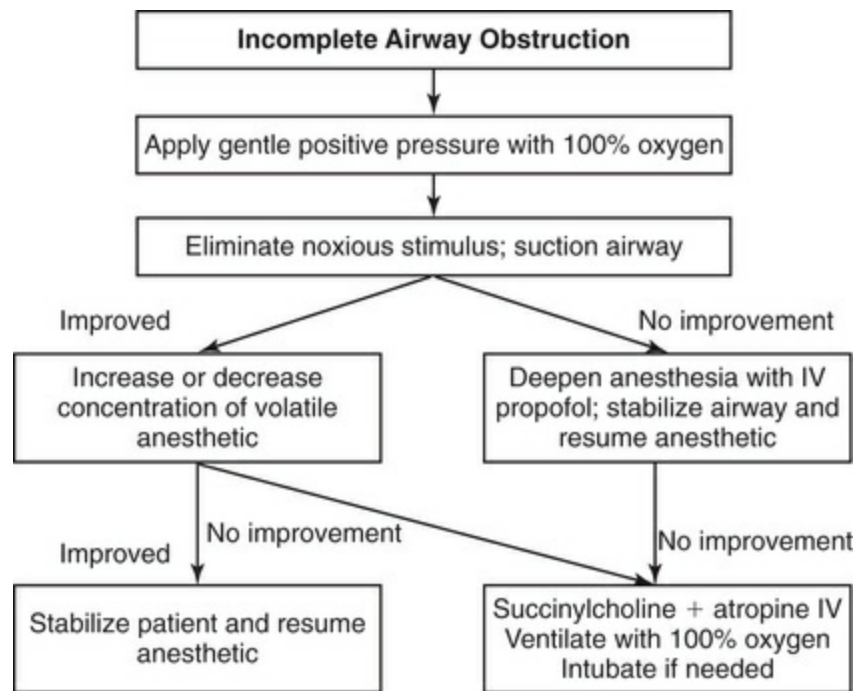

FIGURE 53.2 Incomplete airway obstruction algorithm.

(From Wittkugel E. Pediatric laryngospasm. In Atlee JL, ed. *Complications in Anesthesia*. 2nd ed. Philadelphia: Elsevier; 2007:601.)

The transition to complete airway obstruction (Fig. 53.3) becomes evident with the absence of inspiratory and expiratory sounds, as well as the inability to deliver positive-pressure ventilation. The application of positive airway pressure for treating complete airway obstruction may not be successful. Further deterioration of arterial oxygen saturation with accompanying bradycardia may occur despite the continued application of positive-pressure ventilation. The administration of succinylcholine will then be required to relieve the laryngospasm.

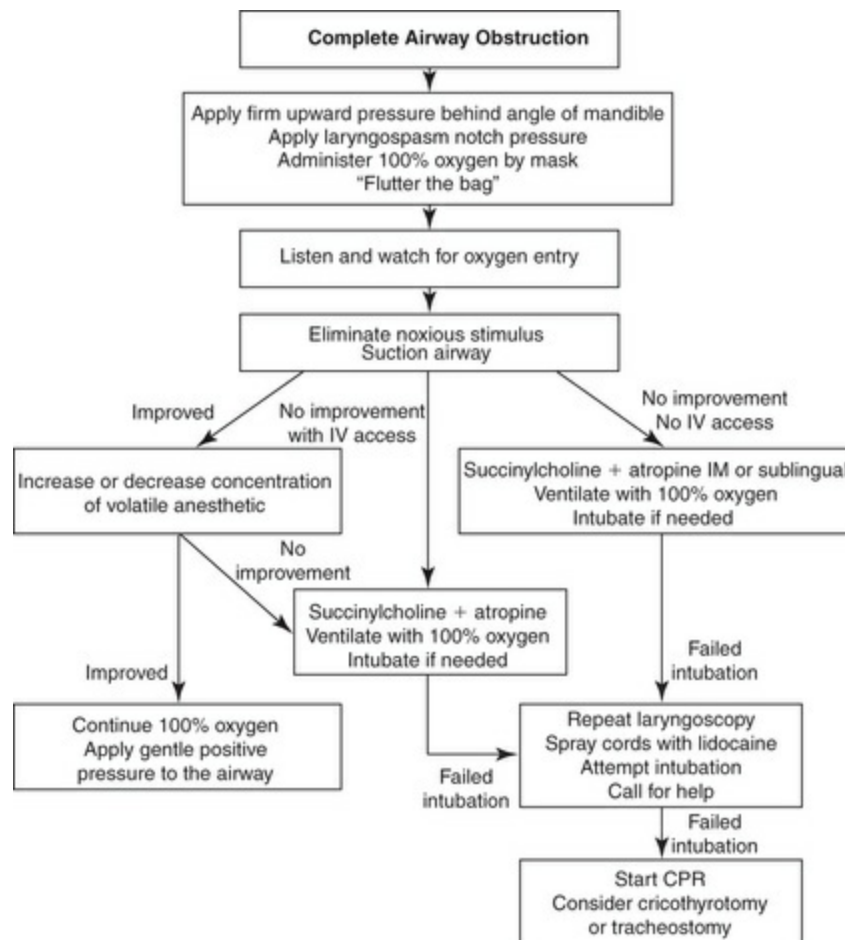

FIGURE 53.3 Complete airway obstruction algorithm. *CPR*, Cardiopulmonary resuscitation; *IM*, intramuscular.

(From Wittkugel E. Pediatric laryngospasm. In Atlee JL, ed. *Complications in Anesthesia*. 2nd ed. Philadelphia: Elsevier; 2007:600.)

The application of firm and direct bilateral pressure toward the skull base produces an anterior displacement of the mandible. In addition to producing a jaw thrust, the intense stimulation with postcondylar pressure in the lightly anesthetized patient often produces a ventilatory sigh.¹¹⁶ This maneuver may be successful for the treatment of laryngospasm.¹¹⁷ Fig. 53.4 shows the laryngospasm notch.

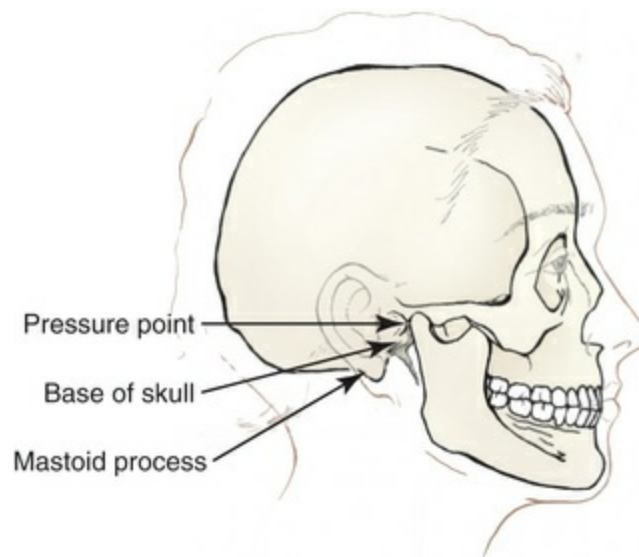

FIGURE 53.4 The laryngospasm notch.

If complete airway obstruction continues unabated, atropine and succinylcholine should be administered intravenously without delay. In the absence of IV access, IM succinylcholine (4 mg/kg) should be administered in the deltoid muscle. Following IM administration, the vocal cords will relax within 30 to 60 seconds, permitting positive-pressure ventilation and endotracheal intubation. With continued deterioration in arterial oxygen saturation, intubation may be required prior to the onset of skeletal muscle relaxation. Severe hypoxia and hypercarbia inhibit skeletal muscle function and decrease laryngospasm.¹¹⁸

Bronchospasm causes increased airway resistance that eventually resolves spontaneously or with pharmacologic intervention. It is a disorder of the smooth muscle. It is known that airway resistance increases after instrumentation of the airway. This only rarely results in bronchospasm (0.4%); however, in children with known asthma or a current URI, the incidence is increased (4.1%) and can cause the anesthesia provider some concern.¹¹⁹⁻¹²¹

Bronchospasm may manifest as an audible wheeze. The anesthetist may notice a prominent slope on the expiratory portion of the end-tidal carbon dioxide (ETCO₂) waveform that is indicative of prolonged expiration, a rise in ETCO₂, decrease in oxygen saturation, increased peak inspiratory pressures, decrease in tidal volume, and difficulty ventilating. Before the diagnosis of bronchospasm is confirmed, the anesthetist must consider other

causative factors such as anaphylaxis, fluid overload, airway manipulation, pharyngeal irritation and/or secretions, esophageal intubation, pneumothorax, and inadequate anesthetic depth.¹²²

Physical signs that are associated with bronchospasm include, but are not limited to, hypoxemia, hypercarbia, wheezing, increased peak airway pressures, inability to ventilate, chest retraction during spontaneous respirations, and altered ET_{CO₂} waveform (as described previously).

When ventilation is compromised, the first intervention is to administer 100% oxygen. Auscultation of the lungs may reveal wheezing. If the problem is severe, the surgeon should be informed to stop the surgery. The anesthetic depth should be assessed and deepened as needed, and the patient should be manually ventilated. A bronchodilator medication, such as albuterol, can be given via ETT.

In pediatric patients, the respiratory reserve is limited, and when coupled with an increased metabolic rate, rapid hypoxia can occur. Epinephrine (5–10 mcg/kg) should be administered subcutaneously if an IV has not been established.¹²³ In life-threatening emergencies, dilute a 1-mg vial of epinephrine in a 10-mL syringe and give 1 to 2 mL (100–200 mcg) IV push, in increments, for a maximum dose of 0.5 mg of a 1 : 1000 solution.¹²⁴ Another treatment for bronchospasm includes corticosteroids. IV steroids help to decrease inflammation but are not considered to be immediately effective in an acute airway emergency, due to their prolonged onset of action.

Difficult Airway.

A difficult airway may be defined as difficulty in accomplishing mask ventilation and/or endotracheal intubation. The identification of the difficult pediatric airway begins with a thorough history followed by physical examination of the mouth, head, and neck. The physical examination should focus upon the assessment of facial skeletal features, specifically the size and shape of the mandible and maxilla, the size of the tongue in relation to the oral cavity, an absence of dentition, the presence of loose dentition, and the range of motion of the neck. [Box 53.7](#) lists some features of pediatric airway physical examination. [Box 53.8](#) lists pathologic conditions that impact pediatric airway management.

Physical Examination of the Pediatric Airway

- Note the size and shape of the head.
- Facial features—size and shape of mandible and maxilla.
- Oral examination—size of tongue, loose or missing dentition, prominence of upper incisors.
- Range of motion of jaw and cervical spine.

Box 53.8

Pathologic Pediatric Airway Conditions

Nasopharynx

- Choanal atresia
- Foreign body/tumors
- Adenoid hypertrophy

Tongue

- Hemangioma
- Angioedema
- Down syndrome
- Beckwith-Wiedemann syndrome
- Mucopolysaccharidosis
- Cystic hygroma
- Lacerations

Skeletal Structure

- Pierre Robin syndrome
- Treacher Collins syndrome
- Goldenhar syndrome
- Fractures
- Juvenile rheumatoid arthritis
- Cervical spine injury
- Mandibular ankylosis
- Arnold-Chiari malformation

Pharynx and Larynx

- Laryngeal web
- Laryngeal stenosis
- Laryngomalacia
- Laryngeal papillomatosis
- Foreign body
- Postextubation croup
- Epiglottitis
- Peritonsillar abscess
- Retropharyngeal abscess

A history of snoring, difficulty breathing with feeding, current or recent upper respiratory tract infection, and past history of croup should be identified. Previous anesthetic records are a valuable

resource for determining whether a history of difficult airway management exists. However, a prior uneventful anesthetic does not preclude the possibility of difficult airway management with succeeding anesthetics.

If there is any indication from the history and physical examination of a potentially difficult airway, these guidelines should be followed:

1. Do not give neuromuscular blocking agents.
2. Prepare a variety of laryngoscope blades, ETTs, and oropharyngeal airways.
3. Plan for different induction options: awake fiberoptic; sedation, anesthetizing spray, and awake fiberoptic; inhalation induction.
4. After a deep plane of anesthesia is achieved, administer 100% oxygen.
5. Establish IV access (if not established preoperatively), and consider atropine or glycopyrrolate to decrease oral secretions.
6. Always maintain spontaneous respirations.
7. Use external manipulation of the trachea when possible to facilitate visualization of the glottis.
8. Use and/or have available adjunct airway equipment: video laryngoscopy, fast-track LMA, blind nasal intubation, light wand, Eschmann stylet, cricothyrotomy.
9. Follow the standardized difficult airway algorithm (see [Chapter 24](#)).

Emergence and Extubation

Similar to adults, the end of surgery in the pediatric patient involves the return of spontaneous breathing and weaning of anesthetic agents. It is important to have airway equipment readily available in case of the need to reestablish a patent airway. The

child should show signs of alertness such as facial grimacing, spontaneous eye opening, and purposeful movement. Children are more prone to laryngospasm during extubation, especially when it is performed during stage 2 of anesthesia. Judicious suctioning is also imperative to help prevent adverse airway events.

Deep extubation can be performed after prudent suctioning of the oropharynx and stomach in patients with a normal airway and an empty stomach. It should be carefully decided whether the patient is appropriate for a deep extubation. In addition, the anesthetist must be aware of the level of care in the postoperative care unit where the patient will be recovering. Patients that were difficult to ventilate or intubate, those with a full stomach, and neonates and young infants should be fully awake prior to extubation.

All standard monitoring should continue until extubation is complete and the patient is stable. When breathing remains satisfactory, the patient can be transported to the postanesthesia care unit (PACU). Placing the patient in a lateral position can help decrease the risk of airway obstruction and pulmonary aspiration if vomiting occurs. The use of supplemental oxygen is recommended for all pediatric patients.

Fluid Management

The maintenance of euvolemia is essential during the comprehensive intraoperative care of the pediatric patient. The restoration and maintenance of pediatric intravascular volume is crucial if cardiac output is to be optimized and tissue oxygen delivery ensured.

The intravascular fluid balance is influenced by a number of preoperative and perioperative circumstances. Preoperative IV fluid administration minimizes the degree of dehydration that accompanies the period of fasting. Unless there is a compelling reason to place an IV catheter preoperatively, IV therapy is generally avoided in the pediatric patient until general anesthesia has been induced via inhalation.

Perioperative fluid homeostasis is altered by several factors, including inhalation agent administration, the environmental temperature of the operating room, iatrogenic hyperventilation,

and surgical stress. Potent inhalation agents produce peripheral vasodilation and varying degrees of myocardial depression, decreasing systemic blood pressure and end-organ perfusion. Dehydration after prolonged preoperative oral fluid abstinence aggravates these decreases in systemic blood pressure. The delivery of cold, dry anesthetic gases via an ETT bypasses normal anatomic humidification, increasing the loss of fluid from the respiratory tract. These insensible respiratory fluid losses can be minimized by the use of active or passive humidification systems during the intraoperative period. The operating room temperature also influences fluid balance. Basal caloric and water requirements are increased in a cold environment. A 1°C increase in core body temperature may increase caloric expenditure by 12% to 14%.

General anesthesia modifies the neuroendocrine control of fluid balance. Surgical stress increases plasma glucose levels. Hyperglycemia results in an osmotic-induced renal loss of free water. Anesthetic agents modify the neuroendocrine regulation of fluids and electrolytes. Opioids increase the release of antidiuretic hormone (ADH) from the posterior pituitary.¹²⁵ ADH stimulates the release of aldosterone to conserve water through the renal reabsorption of sodium and water and the excretion of potassium. Decreased glomerular filtration, which parallels the decrease in renal perfusion, alters the kidneys' ability to handle administered fluid loads. Decreased renal perfusion stimulates the release of renin, which cleaves angiotensin I to form angiotensin II, a powerful vasoconstrictor that acts to increase systemic blood pressure. In turn, renin stimulates the release of aldosterone.

Surgical trauma modifies the fluid balance to a degree that is dependent on the invasiveness of the surgical procedure. IV fluids are used to replace intraoperative blood loss and fluid loss resulting from evaporation and third-spacing. Physiologic parameters such as temperature, heart rate, blood pressure, capillary refill time, urine output, and ongoing blood loss, are continually assessed. The rate of intraoperative fluid administration is continuously modified to maintain circulatory homeostasis. Peripheral surgical procedures (extremity procedures) have minimal evaporative or third-space fluid losses. However, intracavitary procedures (intraabdominal or intrathoracic procedures) are associated with greater blood loss,

third-space fluid loss, and substantial evaporative fluid losses that approach 10 mL/kg of body weight per hour.

Pediatric Fluid Compartments

The growth of the newborn is accompanied by a decrease in the relative TBW and ECF volumes during the first year of life, followed by additional decreases in ECF later in childhood. The TBW of the premature infant is as high as 80% of total body weight, whereas the TBW of the term infant is approximately 70% to 75% of total body weight. The adult value of TBW (55% to 60%) is reached between 6 months and 1 year of age. Knowledge of body fluid distribution is important when one is selecting specific fluids and volumes for administration. The differences in TBW, as well as in the ICF and ECF compartments in the premature infant, term infant, child, and adult, can be found in [Table 52.8](#).¹²⁶

Maintenance-Fluid Calculation

The most direct and widely accepted method for determining IV fluid requirements is based on body weight. Holliday and Segar proposed a formula for the calculation of hourly maintenance fluids based on caloric expenditure studies in children. The hourly maintenance fluid level is determined by the “4-2-1” formula, and is calculated as follows ([Table 53.6](#)).¹²⁷ For the first 10 kg of body weight, 4 mL of crystalloid IV fluid (e.g., lactated Ringer's) is administered for each kilogram of body weight per hour. The hourly maintenance fluid requirement of a child who weighs 10 kg would be calculated as $10 \text{ kg} \times 4 \text{ mL/kg per hr} = 40 \text{ mL/hr}$. Children weighing more than 10 kg but less than 20 kg would receive an additional 2 mL/kg per hr for body weight in excess of 10 kg; thus, a child weighing 14 kg would receive 4 mL/kg per hr for the first 10 kg (40 mL) plus an additional 2 mL/kg per hr, for a total of 48 mL/hr. Children weighing more than 20 kg would receive an additional 1 mL/kg per hr in hourly fluid. This hourly maintenance fluid calculation serves as a basic guideline, and does not take into account fluid deficits that develop during the NPO period and additional fluid losses (such as blood and third-space losses) that occur during the perioperative period.

TABLE 53.6**Hourly Fluid Requirements: The “4-2-1” Formula**

Weight (kg)	Fluid
0–10	4 mL/kg per hr for each kg of body weight
10–20	40 mL + 2 mL/kg per hr for each kg over 10 kg
> 20	60 mL + 1 mL/kg per hr for each kg over 20 kg
Sample Calculated Fluid Requirements	Maintenance Fluid per Hour
4 kg	16 mL
9 kg	36 mL
15 kg	50 mL
30 kg	70 mL

Preoperative fluid deficits develop during the period of time in which the child has not received oral or IV maintenance fluids. The preoperative fluid deficit is calculated by determining the hourly maintenance fluid rate and multiplying this rate by the number of hours the child has been without IV or oral intake. The following calculations are used to determine the preoperative fluid deficit of an 8-kg child who has been NPO for 6 hours:

$$\text{Maintenance fluid} = 8 \text{ kg} \times 4 \text{ mL/kg/hr} = 32 \text{ mL/hr}$$

$$\begin{aligned} \text{Deficit} &= \text{NPO hours} \times \text{maintenance fluid rate} \\ &= 6 \text{ hr} \times 32 \text{ mL/hr} = 192 \text{ mL} \end{aligned}$$

The calculated fluid deficit is replaced following the guidelines of Furman et al.¹²⁸: half the fluid deficit is replaced during the first hour, with the remainder divided in half and replaced in the subsequent 2 hours. Using the calculations just presented, the following plan for IV fluids is developed.

Weight = 8 kg	Hour 1	Hour 2	Hour 3
Maintenance fluid (mL/hr)	32	32	32
Deficit (mL/hr)	96	48	48
Hourly total (mL/hr)	128	80	80

In addition to the calculated maintenance and deficit fluids necessary to replace insensible fluid losses, additional IV fluid is required to replace third-space fluid losses that occur with surgical trauma. Lactated Ringer's solution, 0.9% normal saline, and Plasma-

Lyte are acceptable for the replacement of insensible and third-space fluid losses at a rate of 1 to 2 mL/kg per hr. Expected third-space fluid losses can be categorized as minimal surgical trauma (an additional 3–4 mL/kg per hr), moderate surgical trauma (5–6 mL/kg per hr), and major surgical trauma (7–10 mL/kg per hr). [Table 53.7](#) lists an approximation for fluid replacement and third-space losses.

TABLE 53.7

Fluid Replacement for Third-Space Fluid Losses

Expected Surgical Trauma	Administration Rate (mL/kg per hr)	Recommended Intravenous Fluid
Minimal	3–4	Lactated Ringer's
	0.9% NS, Plasma-Lyte	
Moderate	5–6	Lactated Ringer's
	0.9% NS, Plasma-Lyte	
Severe	7–10	Lactated Ringer's
	0.9% NS, Plasma-Lyte	

NS, Normal saline.

Glucose-Containing Solutions

Historically, glucose was administered during the perioperative period to prevent hypoglycemia, provide free water to replace the insensible water lost during the NPO period, conserve protein, and avoid ketosis by preventing gluconeogenesis.¹²⁹ Surgical stress (e.g., surgical incision) elicits a neuroendocrine response, increasing plasma glucose levels. Despite extended periods of fasting, studies have noted that healthy pediatric patients infrequently become hypoglycemic.^{130,131} However, very critically ill infants and those weighing less than 10 kg may develop hypoglycemia with prolonged periods of fasting. Routine dextrose administration is no longer advised for otherwise healthy children receiving anesthesia.¹³² Most clinicians administer a glucose-free IV solution (e.g., lactated Ringer's) for maintenance and replacement of third-space fluid loss and intraoperative blood loss. If the child has had an extended NPO period, glucose level may be determined intraoperatively, and appropriate adjustments in therapy can be made. Although the CNS is totally dependent on a continuous supply of exogenous glucose for the maintenance of cellular energy

requirements, the continuous administration of glucose or elevated plasma glucose levels may worsen neurologic outcome in the event of an ischemic or hypoxic event, as glucose is converted to lactate during anaerobic metabolism. This association between hyperglycemia and worsened neurologic outcome has been well established.^{133,134}

Hypoglycemia is likely to develop in a variety of clinical circumstances. Examples include infants who are premature, infants of diabetic mothers, children with diabetes who have received a portion of daily insulin preoperatively, and children who receive glucose-based parenteral nutrition. A glucose-containing IV solution is administered to these patients as a controlled piggyback infusion, with frequent plasma glucose determinations performed to avoid hyperglycemia. Infants born to mothers with diabetes and infants of mothers who receive glucose-containing solutions during labor may require a continuation of these solutions for the prevention of rebound hypoglycemia. Premature infants, who have had less time to store glycogen in the liver than term infants, are more susceptible to hypoglycemia. For this reason, premature infants may receive an infusion of 10% dextrose.

Crystalloid Intravenous Fluids

Crystalloid IV fluids contain water, various concentrations of electrolytes, and varying amounts of glucose. These solutions move freely between the intravascular and interstitial fluid compartments. Crystalloid IV solutions are advantageous for perioperative administration, because they are the least expensive of the available IV solutions and are acceptable for the replacement of preoperative, intraoperative, and postoperative isotonic fluid deficits. Unlike colloid solutions, crystalloid solutions do not produce allergic reactions. Crystalloid IV solutions can be further subdivided by their tonicity in relation to plasma (i.e., hypotonic, isotonic, or hypertonic). Tonicity is a measurement of the comparative osmolarity of solutions, which is determined by the sodium chloride content. For example, a hypotonic solution (e.g., 0.45% normal saline) has a lower sodium concentration (less than 130 mEq/L) and an osmolarity of less than 280 mOsm/L; an isotonic solution (e.g., lactated Ringer's) has a sodium concentration

between 130 and 155 mEq/L and an osmolarity between 280 and 310 mOsm/L; a hypertonic solution (e.g., 3% normal saline) has a sodium concentration greater than 155 mEq/L and an osmolarity in excess of 310 mOsm/L. These sodium-containing solutions move freely about the extracellular space, whereas sodium-free IV solutions, such as 5% dextrose in water (D₅W), will be distributed throughout all fluid compartments. [Table 53.8](#) lists the physical constituents and the osmolarities of popular crystalloid solutions. An isotonic solution does not need to be equivalent to plasma in exact physical constituents (e.g., sodium, chloride, potassium) to be considered an isotonic solution, because it is the number of particles dissolved in solution (principally sodium) that determines the osmolarity.

TABLE 53.8
Physical Characteristics of Popular Intravenous Crystalloid Solutions

	Sodium (Na) (mEq/L)	Chloride (Cl) (mEq/L)	Potassium (K) (mEq/L)	Calcium (Ca) (mg/mL)	Lactate (mg/mL)	Glucose (mg/dL)	mOsm/L
Hypotonic Solutions							
0.45% Normal saline	77	77					154
5% Dextrose in water						50	252
Isotonic Solutions							
0.9% Normal saline	154	154					308
Lactated Ringer's	130	109	4	3	28		273
Ringer's	130	109	4	3			309
Plasma-Lyte A	140	98	5				290
Hypertonic Solutions							
5% Sodium chloride	855	855					1700
7.5% Sodium chloride	1283	1283					2400

Estimation of Blood Volume

The goal of perioperative blood administration is to maintain acceptable oxygen-carrying capacity. Pediatric patients have a relatively low intravascular volume compared with adults; therefore vigilance and an accurate determination of intraoperative blood loss is fundamental to quality patient care. The intravascular volume may be estimated by multiplying the child's weight by the estimated blood volume. The estimated blood volumes are as follow: premature infant, 90 to 100 mL/kg; full-term newborn, 80 to 90 mL/kg; infants 3 months to 3 years, 75 to 80 mL/kg; children 3 to 6 years 70 to 75 mL/kg and children older than 6 years, 65 to 70 mL/kg. For example, the estimated blood volume of a 6-month-old infant who weighs 7 kg is 525 mL ($7 \text{ kg} \times 75 \text{ mL/kg} = 525 \text{ mL}$).

The determination of intraoperative blood loss can be difficult. Subjective estimates of blood loss are grossly inaccurate. Blood collected from the surgical field in suction canisters can be easily measured, but up to one half of blood lost during surgery can be contained in items such as surgical drapes, sponges, and towels, and is difficult to measure. These items need to be weighed to obtain an accurate accounting of surgical blood loss. Every 1 g of weight is approximately equivalent to 1 mL of blood loss. Ongoing surgical blood loss requires frequent reassessment of the child's blood pressure, heart rate, and urine output.

Mild dehydration is associated with a decrease in body weight of less than 5%. Signs and symptoms are blood pressure, heart rate, and capillary refill all within normal limits. Dry mouth and malaise can possibly be seen preoperatively; however, they are not evident if the patient is under general anesthesia. Urinary output of less than 1 mL/kg per hr should be maintained. Moderate dehydration is associated with a 5% to 10% decrease in the patient's body weight. Signs and symptoms associated with mild dehydration may not produce significant hypotension and tachycardia due to physiologic compensation. Severe decreases in intravascular volume are associated with a greater than 10% decrease in body weight. Signs and symptoms are tachycardia, hypotension, narrowed pulse pressure, low urine output, decreased central venous pressure, pallor, slow capillary refill, lethargy, thick and/or dry mucous membranes, and depression of the anterior fontanelle.

The patient will have a decreased level of consciousness, mottled and cool skin, and be anuric. A sudden decrease in blood pressure in neonates and infants is indicative of significant intravascular volume depletion. Fluid management for dehydrated patients includes a 10 to 20 mL/kg fluid bolus over 10 to 30 minutes. After evaluation of fluid bolus, subsequent boluses also may be given.

Permissible Blood Loss

This “transfusion trigger” has been redefined in light of the risks of blood-borne pathogen transmission, transfusion-related lung injury, and other related conditions that increase morbidity and mortality. Permissible blood loss must be defined individually for each patient based on current medical condition, surgical procedure, and cardiovascular and respiratory function. Children with normal cardiovascular function may tolerate a lower hematocrit and may compensate with an increased cardiac output if a higher inspired oxygen concentration is provided to improve oxygen delivery. An exception is the premature infant. The incidence of apnea is higher in neonates and premature infants with hematocrit levels below 30%. A definitive adequate hemoglobin concentration that is essential for oxygen delivery has been determined to be 7–8 g/dL for most hospitalized adult patients.⁷¹ Allowable blood loss may be calculated with the following formula:

$$ABL = EBV \times (H_O - H_L) / (H_A)$$

where ABL is allowable blood loss, EBV is estimated blood volume, H_O is the original hematocrit, H_L is the lowest acceptable hematocrit, and H_A is the average hematocrit. In place of H_A , $(H_O + H_L) \div 2$ can be used. For a 6-month-old infant who weighs 7 kg, with a starting hematocrit of 35% and a lowest acceptable hematocrit of 25%, we can calculate the following:

$$ABL = 525 \times (35 - 25) / (25 + 35) / 2 = 174 \text{ mL}$$

Blood loss may be replaced with suitable crystalloid solutions

(e.g., 0.9% normal saline, lactated Ringer's) by administering 3 mL for each 1 mL of blood loss. Recall that the intravascular volume is one-third of the ECF volume. Accordingly, one must administer 3 mL of an IV crystalloid solution to replace each 1 mL of blood loss. A blood loss of 100 mL therefore requires replacement with 300 mL of a crystalloid solution. Blood loss that is less than the calculated permissible blood loss may be replaced with colloid (1 mL for every 1 mL of blood loss).

When the blood loss equals or exceeds the calculated allowable loss, transfusion should be considered. Before transfusion is performed, a current hemoglobin and hematocrit should be obtained. The surgeon should be included in the decision process. These discussions and the resultant hemoglobin and hematocrit are recorded in the anesthetic record. The volume of packed red blood cells (PRBCs) to be infused may be determined by the following formula:

$$\text{Packed RBCs (mL)} = \frac{(\text{Blood loss} - \text{ABL}) \times \text{desired hematocrit (30\%)}}{\text{Hematocrit of PRBCs (75\%)}}$$

Using the previous example of a 7-kg infant, with a total blood loss of 300 mL, the volume of PRBCs to be infused would be $300 - 174 \times 30/75 = 50$ mL.

Once the blood loss exceeds one blood volume, coagulopathy can ensue. This occurs because of dilutional thrombocytopenia and a reduction in circulating clotting factors. Platelets, fresh frozen plasma, and cryoprecipitate transfusions become necessary. See [Chapter 22](#) for blood transfusion guidelines.

Blood Transfusion

Before blood component therapy is initiated, the proper equipment (e.g., filters, infusion devices, blood warming devices) should be obtained and tested. Blood is usually warmed before infusion. The American Association of Blood Banks has published standards for the use of blood-warming devices. Blood warmers must have a visible thermometer and an audible warning indicating excessive heating (greater than 42°C). Warming devices for adult transfusions

(e.g., in-line water baths, countercurrent heating with water through large-bore tubing) are cumbersome to use for the small volumes to be transfused in the pediatric patient. The selected blood component containers may be placed under the forced-air warming blanket, or the measured aliquot of blood drawn into a syringe may be warmed with the hand.

Blood used for neonatal transfusion is preferably less than 1 week old, to preserve 2,3-diphosphoglycerate levels, and irradiated to prevent graft-versus-host disease. When PRBCs are transfused, the blood should not be diluted prior to transfusion; this may contribute to hypervolemia. As a rule, 4 mL/kg of PRBCs will be required to raise the hemoglobin level by 1 g/dL.¹³⁵

Postoperative Care

Similar to an adult patient, standard monitoring is continued when the pediatric patient arrives in the PACU. Although all the parameters are important, special attention to oxygenation is crucial. Postoperative hypoxia may be the result of several factors, but postextubation croup and laryngospasm are more likely in children compared to adults.¹³⁶ Airway obstruction, obstructive sleep apnea, postextubation croup, and apnea of prematurity can all occur, and need to be recognized with prompt intervention. Airway obstruction can be due to inadequate positioning of the patient's head, or by the tongue. Simply repositioning the head can sometimes relieve this problem. Positioning and adequate oral suctioning can help prevent obstruction and possible laryngospasm.

The incidence of postextubation croup has been reported to be 1.6% to 6%. Prevention of tracheal irritation is the best way to prevent this problem. Using the right ETT size with pressures near 20 cm H₂O, prevention of friction of the tube in the trachea by securing properly, and prevention of unplanned extubation are ways to help decrease the risk of developing postextubation croup.¹³⁷

Readiness for discharge from the PACU is typically evaluated using a scoring system that includes blood pressure, heart rate, respirations, temperature, pain, nausea/vomiting, physical activity, and level of consciousness. The goal is for the patient to return to preprocedure hemodynamic and respiratory levels before discharge. One common method that is used is the modified Aldrete scoring (see [Chapter 55](#)). When evaluating a patient in the ambulatory surgery center to be “fast-tracked,” a score of 12 or higher is needed.¹³⁸ When fast-tracking is anticipated, the anesthetic can be planned to allow for short PACU times and quick discharge to home.

Regional Anesthesia

During the past 10 years, the use of pediatric regional anesthesia has become established. Regional anesthesia provides perioperative analgesia (minimizing the risk of respiratory depression), modifies the metabolic responses to anesthesia and surgery, and may improve patient outcomes.¹³⁹⁻¹⁴¹ Although the popularity of combined regional anesthetic techniques for adults has increased, the use of pediatric regional anesthesia has been more limited. Regional anesthesia is typically performed during general anesthesia, and the detection of intravascular injection and the signs of local anesthetic toxicity are masked during general anesthesia. In addition, there is a limited ability to properly assess the sensory level of block in the sedated preverbal child, and the consequences of accidental dural puncture are more difficult to assess and treat.

Unlike the adult patient, the pediatric patient will generally receive a peripherally or centrally administered regional anesthetic after the induction of general anesthesia. The child's inherent fear of needles and pain, the fear of neurologic injury in a combative child, and the difficulty in providing adequate sedation to ensure patient immobility during the introduction of the block often necessitate the execution of the regional anesthetic during general anesthesia. The risk of neurologic injury may be lower in the anesthetized child who is not resistant and combative during attempted epidural or caudal anesthesia, now that the use of ultrasound-guided blocks is routine.¹⁴² See [Chapter 52](#) for a complete description of caudal anesthesia in children.

Outpatient Anesthesia

Outpatient surgery is the mainstay of modern surgical and anesthesia practice.¹⁴³ Many specialties are performing procedures in the ambulatory surgery center, including otolaryngology, ophthalmology, general surgery, urology, plastic surgery, orthopedics, radiology, dentistry, and others. The postoperative goals are the same for all surgeries: hemodynamic stability, minimal pain and nausea, and the return of a preoperative level of consciousness. However, with ambulatory surgery, the discharge criteria are more rigid, due to the fast-paced nature of the perioperative process. It is of the utmost importance that the patient be able to take oral medications without nausea and vomiting when he or she leaves the surgery center.

There are few absolute contraindications to ambulatory surgery for the pediatric patient. Children who were born premature at less than 35 weeks' gestation, or those who are less than 60 weeks' postconceptual age, are at risk for postoperative apnea.^{144,145} These children require an overnight stay in the hospital for observation. Patients who have a personal or family history of MH should also not have outpatient surgery, as the first episode of MH can occur 12–24 hours postoperatively. Although administering anesthesia can be routine, these patients need to be observed closely for increases in temperature postoperatively. If the patient develops MH in the surgery center, immediate administration of dantrolene followed by emergency transfer to a higher level of care is necessary.

Induction, airway management, and maintenance of anesthesia are similar when giving anesthesia in the hospital and in the surgery center. When the patient is spontaneously breathing, the anesthetist can decide to extubate the patient deep or awake. Other factors that influence procedures and patient selection for a surgery center are the need for postoperative analgesia and minimizing PONV. Local anesthesia injection by the surgeon or regional anesthesia is imperative, if applicable, for multimodal pain management. Patients may also be given acetaminophen before or during surgery. Nausea can be managed by using multimodal

pharmacologic treatment and by prophylactically identifying high-risk patients and then tailoring the anesthetic with agents that are not considered to be emetogenic.^{146,147}

Pediatric Anesthetic Morbidity and Mortality

Anesthetic morbidity and mortality differ between the pediatric patient and the adult patient. Accordingly, children require individualized and specialized anesthetic care. When compared with adults, children often present for surgery with unique symptoms. Their lack of ability to communicate effectively further complicates proper diagnosis and interventions. Fortunately, with a well-conducted history and physical examination and effective caregiver communication, a safe anesthetic may be planned and executed.

The Pediatric Perioperative Cardiac Arrest Registry (POCA), an ongoing database of pediatric cardiac arrests established in 1994, is a self-reporting, voluntary registry recording institutional cardiac arrests in children up to 18 years of age from as many as 80 participating institutions in Canada and the United States. The POCA data provide a retrospective assessment of contributing factors, rather than determining causation of cardiac arrest. The initial registry results for the years 1994 to 2005 found 373 cardiac arrests in more than 1 million pediatric anesthetic experiences. One hundred and ninety-three arrests (49%) were judged to be anesthesia-related.¹⁴⁸ When cardiac arrest occurred, children with congenital or acquired heart disease (HD) were more likely to progress to cardiac arrest as compared with those without HD (50% vs 38%).¹⁴⁹ The patients with HD had higher ASA classifications (ASA III or above) and were more difficult to successfully resuscitate. Hyperkalemia from blood transfusions and hypovolemia were additional cardiovascular-related causes for cardiac arrest. Other reasons for cardiac arrest included respiratory-related causes (most often laryngospasm) and vascular injuries from central line placement. The incidence of medication-induced cardiac arrest has decreased since sevoflurane replaced halothane as the inhalation agent of choice during perioperative management. [Fig. 53.5](#) shows the causes of anesthesia-related cardiac arrest specifically associated with HD as compared to patients without

cardiac pathology.

FIGURE 53.5 Causes of anesthesia-related cardiac arrest associated with heart disease (n = 127) versus non-heart disease (n=245). *P = 0.03, **P = 0.01. (From Ramamoorthy C, et al. Anesthesia-related cardiac arrest in children with heart disease: data from the Pediatric Perioperative Cardiac Arrest (POCA) registry. *Anesth Analg.* 2010;110(5):1376–1382.)

Summary

Anesthetic morbidity and mortality is greater in the pediatric patient, and the causes are multifactorial. Pediatric subspecialty practice requires the anesthetist to have a working knowledge of the foundations of pediatric growth and development, the anatomic and physiologic changes that occur with maturation, and the influence of anesthetic agents upon immature organ systems. Anesthetic management of the pediatric patient requires integration of this specialized knowledge, refinement of the acquired technical skills of adult anesthetic management, and the ability to apply this knowledge when caring for pediatric patients.

Geriatrics and Anesthesia Practice

Sandra K. Bordi

The number of people in the world who are 65 years and older has increased by 300% over the last 50 years. It is projected that the United States will have approximately 73 million people aged 65 years and older by 2030 and 83 million by 2050, almost double its estimated population in 2012. By 2050 the surviving baby boomers will be the oldest old (85 years and older), which is estimated to triple in number and place the United States as the largest population of oldest old among the developed countries. For the first time in history the number of individuals 60 years of age and older will exceed the number of younger adults. During this time the population of older adults will become more racially and ethnically diverse; the number of African Americans over the age 65 years will double, and the number of Asian Americans and Hispanic Americans will triple.¹ The aging population will also affect hospital utilization, surgical services and health care costs. The National Hospital Discharge Survey reported that those over 65 years of age have higher rates of inpatient and outpatient surgical and nonsurgical procedures as compared to other age groups, with the oldest old having significantly higher rates of hospitalization as compared to adults 84 years and younger.² It is inevitable that surgical services and hospitalizations for older adults will increase as its population increases. Therefore the increased aging of the United States, and its diversity, will have significant implications for anesthesia practitioners and their approach to the anesthetic management of the geriatric patient.

Definitions of aging are often subjective and place an arbitrary marker on chronologic age; however, this section will operationally define “older adults” or “elderly” as persons 65 years or older. Although aging is not routinely associated with surgical risk, the

challenges related to anatomic and physiologic changes that occur with aging impact every aspect of the perioperative course.

The intent of this chapter is to provide a targeted review of the anatomic and physiologic changes that occur with aging and identify how these changes affect anesthesia. In addition, this information might offer the practitioner additional evidence to be considered in their current practice, thus providing a foundation for modifying the current options to improve perioperative outcomes if required.

Preoperative Assessment

Preoperative evaluation is thoroughly discussed in [Chapter 20](#); however, the preoperative assessment of the older adult warrants some special considerations. Because the elderly population is growing significantly, as are those who undergo surgical procedures, the identification and avoidance of untoward complications is critical.

The older adult is prone to progressive decline of baseline functions, age-related comorbid disease(s), and an increase in American Society of Anesthesiologists (ASA) physical status classification; these place older adults at greater risk for perioperative complications that are directly related to negative outcomes, including morbidity and mortality in the postoperative period and increased hospital cost. Most postoperative complications in the elderly are cardiac, pulmonary, and neurologic complications.^{3,4} Factors that influence perioperative outcomes in older adults include emergency surgery, the number of comorbidities, and the type of surgical procedure. There is an array of risk assessment tools used in the clinical setting. These vary from assessing operative risk and overall physical status in relationship to type of surgery and organ specific indices (i.e., cardiac, neurocognitive).^{3,4} Risk assessment and stratification is also important to assist in determining a multidisciplinary team approach to perioperative management. Moreover, patients and health care providers use this information as part of their surgical and anesthesia informed consent. Depending on the risk(s) deemed, a different surgical and/or anesthetic approach may be necessary, or surgery may not be performed at all. Therefore identifying perioperative risk is part of the preoperative assessment and is preferably performed prior to the day of surgery.

In order to provide high quality care for the older adult surgical patient, a comprehensive and thorough preoperative evaluation is essential. The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) and the American Geriatrics Society (AGS) developed Best Practice Guidelines for Optimal Preoperative Assessment for the elderly surgical patient.⁵

Based on these guidelines, in addition to conducting a complete and thorough history and physical examination, there are specific assessment categories that are highly recommended to provide guidance for perioperative management of this complex patient population (Table 54.1). These specific assessment categories will be discussed within the age-related physiologic body system changes of this chapter.

TABLE 54.1
ACS NSQIP/ AGS Assessment Categories

Assessment Category	Screening Tool
Cognitive Ability Capacity	Mini-Cog 3 Item Recall and clock draw
Decision Making Capacity	Legally relevant criterion: 1. Understanding 2. Appreciation 3. Reasoning 4. Choice
Depression	Patient Health Questionnaire-2 (PHQ-2)
Risk for postoperative delirium	Review: Cognitive and Behavioral Disorders Coexisting diseases/illnesses Metabolic disturbances Functional impairments Other: polypharmacy, history of UTI, constipation or presence of Foley catheter
Alcohol and Substance abuse	Modified CAGE
Cardiac	ACC/AHA algorithm for patients undergoing noncardiac surgery; METs
Pulmonary	Review: Patient related risk factors Surgical procedure risk factors
Frailty	Slowness Weight loss Grip weakness Exhaustion Decrease in physical activity
Functional Status	Proxy report TUGT
Nutritional Status	BMI Serum Albumin Unintentional weight loss
Medications	Review prescribed, herbal and OTC Beers Criteria addressed
Patient Counseling	Perioperative goals Assistance needs Advanced Directives DNR status Social support

Age-Related Physiologic Changes in the Older Adult

Aging is a time-related occurrence during the life cycle of an organism. It can be defined as a time-dependent biologic continuum that begins with birth and persists with gradual impairments of organ subsystems, and ultimately causes an organism to become more susceptible to illness and death. By the age of 30 years, most age-related physiologic functions in humans have peaked and gradually decline thereafter. Aging is not synonymous with poor physiologic function. Because chronologic age (age in years since birth), which is often used in clinical practice, and biologic age (functional status) differ, chronologic age alone is no longer a reliable indicator of morbidity or of mortality. The degree of functional status that remains with increasing age varies. For example, a 75-year-old patient who bicycles 3 miles every day, has no evidence of coexisting diseases, and lives a healthy lifestyle is considered “physiologically young.” Whereas a 75-year-old patient who is sedentary, has a history of hypertension and diabetes mellitus, and is a chronic smoker may be deemed as “physiologically old.” In addition, changes in organ function manifest as decreased margins of reserve. Aging patients may be able to maintain homeostasis, but become increasingly less able to tolerate changes or restore homeostasis when exposed to surgical stress, trauma, or diseases.

Cardiovascular System

Age-related changes in the cardiovascular system involve structural and functional changes in the heart, vessels, and autonomic nervous system. In the older adult, the heart and vascular system is less compliant, leading to a faster propagation of the pulse pressure waveform, increase in afterload, and an increase in systolic blood pressure, leading to ventricular thickening (hypertrophy) and prolonged ejection times. The combination of ventricular hypertrophy and slower myocardial relaxation often results in late diastolic filling and diastolic dysfunction. When these changes

occur, atrial contraction becomes important in the maintenance of adequate ventricular filling. Even though the elderly have higher amounts of circulating catecholamines, they exhibit decreased end-organ adrenergic responsiveness. Therefore the older adult has a reduced capacity to increase heart rate in response to hypotension, hypovolemia, and hypoxia. Prolonged circulation time causes a faster induction time with inhalation agents but delays the onset of intravenous drugs. There is calcification of the conducting system with loss of sinoatrial node cells, which predisposes the elderly to atrial fibrillation, sick sinus syndrome, first- and second-degree heart blocks, and arrhythmias. Hence a higher proportion of this population may have, or require permanent pacemakers and/or automatic internal defibrillators. Calcification is not limited to the conducting system, but may be present in the valves (primarily aortic and mitral), predisposing elderly patients to valvular stenosis or regurgitation.

Hypertension is a risk factor for perioperative complications, with the risk doubling for every 20-mm Hg systolic/10-mm Hg diastolic increase in blood pressure. With aging the pulse pressure widens because of a greater proportionate increase in systolic blood pressure compared with diastolic blood pressure. Decreased vein compliance can lead to decreased venous return and reduced atrial filling. Likewise, there is decreased sensitivity of baroreceptors in the aortic arch and carotid sinuses in response to blood pressure changes, which results in increased episodes of hypotension. Age-related changes in the cardiovascular system of the older adult also include changes in the heart's regulation of calcium, which causes the myocardium to generate force over a longer period after excitation, and prolongs the systolic phase of the cardiac cycle.⁶

The myocardium in the older adult has decreased sensitivity to β -adrenergic modulation, physiologically evident as decreased heart rate and lower cardiac dilation at the end of diastole and systole. In general, older adults may have higher blood pressures caused by increased peripheral vascular resistance, decreased arterial elasticity, and cardiac workload; likewise, older adults may have decreased cardiac output and stroke volume because of decreased conduction velocity and reduction in venous blood flow. Age-related cardiovascular changes and their anesthetic implications are

noted in Table 54.2. The combined effect of decreased cardiac reserve and decreased maximum heart rate adversely affects the compensatory mechanisms of the older adult under the stress of anesthesia and surgery.

TABLE 54.2

Age-Related Cardiovascular Changes and Anesthetic Implications

Age-Related Change	Mechanism	Consequences	Anesthetic Implications
Myocardial hypertrophy	Apoptotic cells are not replaced and there is compensatory hypertrophy of existing cells; reflected waves during late systole create strain on myocardium leading to hypertrophy	Increased ventricular stiffness; prolonged contraction; and delayed relaxation	Failure to maintain preload leads to an exaggerated decrease in CO; excessive volume more easily increases filling pressures to congestive failure levels; dependence on sinus rhythm and low-normal HR
Myocardial stiffening	Increased interstitial fibrosis; amyloid deposition	Ventricular filling dependent on atrial pressure	—
Reduced LV relaxation	Impaired calcium homeostasis; reduced β -receptor responsiveness; early reflected wave	Diastolic dysfunction	—
Reduced β -receptor responsiveness	Diminished coupling of β -receptor to intracellular adenylate cyclase activity; decreased density of β -receptors	Increased circulating catecholamines; limited increase in HR and contractility in response to endogenous and exogenous catecholamines; impaired baroreflex control of BP	Hypotension from anesthetic blunting of sympathetic tone; altered reactivity to vasoactive drugs; increased dependence on Frank-Starling mechanism to maintain CO; labile BP, more hypotension
Conduction system abnormalities	Apoptosis; fibrosis; fatty infiltration; and calcification of pacemaker and His-bundle cells	Conduction block; sick sinus syndrome; AF; decreased contribution of atrial contraction to diastolic volume	Severe bradycardia with potent opioids; decreased CO from decrease in end-diastolic volume
Stiff arteries	Loss of elastin; increased collagen; glycosylation cross-linking of collagen	Systolic hypertension Arrival of reflected pressure wave during end-ejection leads to myocardial hypertrophy and impaired diastolic relaxation	Labile BP; diastolic dysfunction; sensitive to volume status
Stiff veins	Loss of elastin; increased collagen; glycosylation cross-linking of collagen	Decreased buffering of changes in blood volume impairs ability to maintain atrial pressure	Changes in blood volume cause exaggerated changes in cardiac filling

BP, Blood pressure; CO, cardiac output; HR, heart rate; LV, left ventricular; AF, atrial fibrillation

From Sanders D, et al. Diastolic dysfunction, cardiovascular aging, and the

anesthesiologist. *Anesthesiol Clin.* 2009;27(3):497–517.

The elderly are significantly more vulnerable to adverse perioperative cardiac events. Myocardial infarction is the most common cardiac complication and the leading cause of death in the postoperative period. Therefore a complete cardiac assessment of the cardiovascular system in the older adult undergoing noncardiac surgery is essential and should be based on guidelines according to the American College of Cardiology/American Heart Association (ACC/AHA) as discussed in [Chapter 20](#). Other risk stratification tools that are highly recommended in the older adult by the ACS NSQIP/AGS include measuring the patient's functional capacity via metabolic equivalents (METs) and the perioperative cardiac risk calculator, an interactive web-based tool, which replaces the Revised Cardiac Risk Index. The interactive perioperative cardiac risk calculator quantifies risk according to the type of surgical procedure, functional status, creatinine level, ASA classification, and age.^{7,8} It provides a probability for perioperative cardiac events (i.e., myocardial infarction, cardiac arrest), which can assist in guiding perioperative management and informed consent.

The most frequently associated cardiovascular coexisting diseases in the older adult are hypertension, hyperlipidemia, coronary artery disease (ischemic heart disease), and congestive heart disease (heart failure) ([Fig. 54.1](#)).

Based on 2010 Centers for Medicare and Medicaid Services administration claims data for 100% of Medicare beneficiaries enrolled in the fee-for-service program.)

Respiratory System

There are various age-related alterations of the respiratory system that have an impact on oxygenation in the elderly patient. Older patients develop calcifications of the chest wall, intervertebral joints, and intercostal joints. These factors, along with decreased intercostal muscle mass, contributes to a decrease in chest wall compliance. In addition, there is a flattening of the diaphragm, a loss of intervertebral disc height, and changes in spinal lordosis, which may further diminish chest wall compliance. Changes also occur with the lung parenchyma. There is a generalized loss of elastic tissue recoil of the lung. Consequently there is reduced functional alveolar surface area available for gas exchange. In elderly patients, even in the absence of disease, an increase in lung compliance impairs the matching of ventilation and perfusion, increases physiologic shunt, and results in the reduction of oxygen exchange at the alveolar level. Because lung elastic recoil is necessary for maintaining small airway caliber, an increased lung compliance causes small airway diameter to narrow, and eventually increases the closing volume (i.e., lung volume at which small airways in the dependent parts of the lung begin to close). The closing volume exceeds functional residual capacity (FRC) at approximately 65 years of age in the erect position and at age 45 years in the supine position (Fig. 54.2). Other dynamic and static lung volume changes include a decrease in vital capacity, an increase in residual volume, and an increase in FRC with decreases in inspiratory reserve volume and expiratory reserve volume. Total lung capacity remains unchanged or may slightly decrease because of its correlation with height. There is also a decrease in forced expiratory maneuvers. The forced vital capacity (FVC) and the forced expiratory volume in 1 second (FEV_1) are both decreased as a result of the loss of lung elastic recoil, decrease in small airway

diameter, and subsequent airway collapse with forced expiration (Fig. 54.3). Overall the elderly have impaired efficiency of gas exchange. Impaired oxygenation is reflected by a decline in resting arterial oxygen tension (PaO_2), which remains somewhat stable at approximately 83 mm Hg, after 75 years of age. This decline in PaO_2 is attributed to the premature closing of small airways and the reduction in the alveolar surface area.⁹

FIGURE 54.2 Functional residual capacity (FRC) and closing capacity as a function of age. (In Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:29. Data from Leblanc P, et al. Effects of age and body position on 'airway closure' in man. *J Appl Physiol*. 1970;28:448–453.)

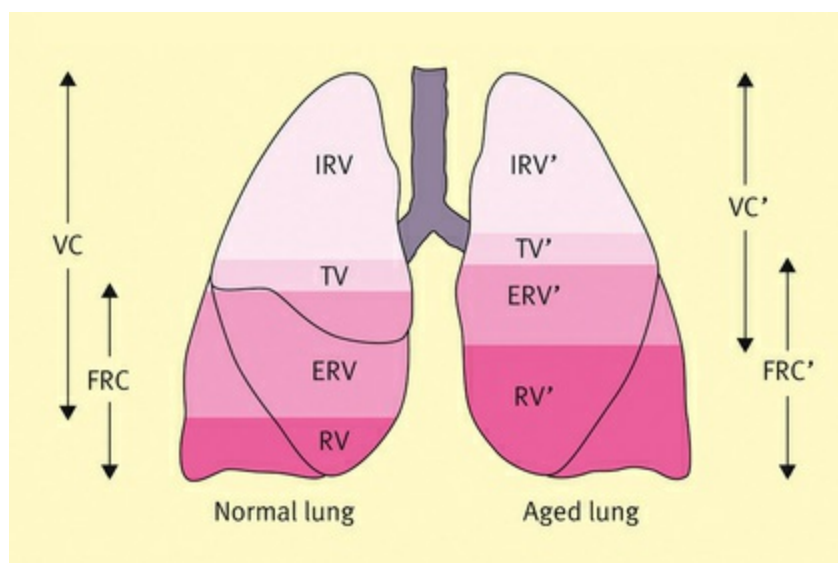

FIGURE 54.3 Schematic representation of lung volume changes associated with aging. Note that with senescence, there is a decrease in the inspiratory reserve volume (IRV'), the expiratory reserve volume (ERV'), and the vital capacity (VC'). There is a corresponding increase in residual volume (RV') and functional residual capacity (FRC') such that the total lung capacity remains approximately the same. *TV'*, Tidal volume. (In Maguire SL, Slater BMJ. Physiology of aging. *Anaesthesia & Int Care Med.* 2010;11(7):290–292. From Chan ED, Welsh CH. Geriatric respiratory medicine. *Chest* 1998;114(6):1704–1733.)

The regulation of breathing is also affected with aging. The central (medulla) and peripheral (carotid and aortic bodies) chemoreceptors affect ventilation with changes in pH, PaO₂, and partial pressure of CO₂ in arterial blood (PaCO₂). In the elderly, the ventilatory response to hypoxemia and hypercarbia is decreased, predisposing them to increased episodes of apnea. Another challenge associated with oxygenation is the progressive decrease in laryngeal and pharyngeal support that accompanies aging, which can result in airway obstruction. In addition, protective airway reflexes (i.e., coughing and swallowing) are decreased, which increases the risk for pulmonary aspiration. Age-related pulmonary changes and their anesthetic implications are noted in [Table 54.3](#).

TABLE 54.3

Age-Related Pulmonary Changes and Anesthetic

Considerations

Structural Changes	Consequences	Anesthetic Considerations
Chest wall	Impaired gas exchange	Risk for respiratory failure
Stiff/decreased compliance	Increased WOB	Careful use of NDMRs, opioids, and benzodiazepines
Flattened diaphragm		
Lung parenchyma	Impaired gas exchange	Risk for respiratory failure
Increased lung compliance	Increased V/Q mismatch	Avoid high pressure/large TV
Increased small airway closure	Increased anatomic dead space	Consider alveolar recruitment maneuvers (PEEP)
	Decreased alveolar surface area	Limit high inspired O ₂
	Decreased PCBF	Maintain PaCO ₂ near normal preoperative value
	Decreased PaO ₂	Consider regional/local with sedation
Muscle strength		Risk for respiratory failure
		Risk for aspiration
Decreased	Increased WOB	Adequate hydration
	Decreased protective airway reflexes	Consider RSI with GA
		Ensure fully reversed prior to extubation
		Consider postoperative CPAP or BiPAP
		Vigilant monitoring
		Encourage cough/deep breathing postoperatively
Control of breathing		Risk for respiratory failure
Decreased central/peripheral chemoreceptor sensitivity	Increased hypoventilation	Consider postoperative CPAP or BiPAP
	Increased apnea	Vigilant monitoring
	Decreased ventilator responses	Encourage cough/deep breathing postoperatively
		Supplemental oxygen postoperatively

BiPAP, Bilevel positive airway pressure; *CPAP*, continuous positive airway pressure; *GA*, general anesthesia; *NDMRs*, nondepolarizing muscle relaxants; *Pao₂*, resting arterial oxygen tension; *Paco₂*, partial pressure of CO₂ in arterial blood; *PCBP*, pulmonary capillary blood flow; *PEEP*, positive end-expiratory pressure; *RSI*, rapid sequence induction; *TV*, tidal volume; \dot{V}/\dot{Q} , ventilation-perfusion; *WOB*, work of breathing.

Similar to other organ systems, pulmonary changes in the elderly are extremely variable among individuals. Regardless of these variations, an in-depth assessment of the respiratory system and identification of coexisting diseases that affect the pulmonary system is important in order to optimize preoperative respiratory function.

Age alone and prevalence of co-existing pulmonary diseases, (i.e.,

chronic obstructive pulmonary disease [COPD] and asthma) increases the risk for postoperative pulmonary complications (PPCs) in the older adult. PPCs include atelectasis, bronchospasm, exacerbation of an underlying chronic lung disease, pneumonia, prolonged mechanical ventilation, and postoperative respiratory failure.¹⁰ Therefore preoperatively assessing the elderly for their risk of developing PPCs is strongly recommended by the ACS NSQIP/AGS. Additional risk factors for PPCs include patient-related and surgical-related factors (Box 54.1). Of the modifiable risk factors, strategies should be implemented to minimize risks and prevent PPCs. For example, smoking cessation at least 8 weeks prior to surgery, implementing inspiratory muscle training and lung expansion maneuvers via incentive spirometry, and medically **Box 54.1** optimizing patients with COPD and/or asthma.

Risk Factors for Postoperative Pulmonary Complications

Patient-Related Factors

- Age greater than 60 years
- Chronic obstructive pulmonary disease
- ASA class II or greater
- Functional dependence
- Congestive heart failure
- Obstructive sleep apnea
- Pulmonary hypertension
- Current cigarette use
- Impaired sensorium
- Preoperative sepsis

- Weight loss greater than 10% in 6 months
- Serum albumin level less than 3.5 mg/dL
- Blood urea nitrogen level greater than or equal to 7.5 mmol/L (\geq 21 mg/dL)
- Serum creatinine level greater than 133 mol/L ($>$ 1.5 mg/dL)

Surgery-Related Factors

- Prolonged operation ($>$ 3 hours)
- Surgical site
- Emergency operation
- General anesthesia
- Perioperative transfusion
- Residual neuromuscular blockade after an operation

ASA, American Society of Anesthesiologists.

Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg.* 2012;215(4):455.

Renal Function

Age-related changes in renal function are particularly significant because of the many roles of the kidneys. Older adults have a significant baseline decrement in renal function relative to their younger counterparts. Changes in renal function in the older patient are characterized by a progressive atrophy of kidney parenchymal tissues, deterioration of renal vascular structures, decreased renal blood flow, and an overall decrease in renal mass. The cumulative effect is a decrease in the glomerular filtration rate (GFR) resulting in decreased renal drug clearance and decreased

renal blood flow from age 20 years to age 90 years (approximately a 25%–50% decline). The combined effect is particularly apparent with diminished renal clearance of hydrophilic agents and hydrophilic metabolites of lipophilic agents.

Because of the vital role that the kidneys play in the maintenance of fluid and electrolyte balance, their contribution to acid-base balance, and to the excretion of drugs and their metabolites, it is essential that great consideration is given to the renal function of the aged patient. The decrease in GFR and impairment of the diluting segment of the nephron can easily predispose the patient to fluid overload if overzealous intravenous fluid is administered. The production of renin and aldosterone is decreased with age, causing impairment of sodium conservation. Sodium conservation and hydrogen ion excretion are decreased, resulting in an impaired ability of the kidneys to respond to changes in electrolyte concentrations, intravascular volume, and free water.¹¹ The kidneys do not respond to nonrenal loss of water and sodium, and as a result dehydration can commonly occur. The serum creatinine is often unchanged if there is no renal failure because of decreased creatinine production from the overall declining skeletal muscle mass associated with aging. Creatinine clearance is the best indicator of drug clearance. The Cockcroft–Gault equation is a common formula for estimating creatinine clearance, which in turn estimates GFR (eGFR) in the healthy older adult.¹²

$$\text{eGFR (mL/min)} = \frac{(140 - \text{age in yrs}) \times (\text{weight in kg})}{72 \times (\text{serum creatinine in mg/dL})}$$

(× 0.85 for female patients)

When this formula is applied to the critically ill or to patients taking medications that directly affect renal function, caution must be employed as it overestimates creatinine clearance. Therefore older patients with renal impairment may be at increased risk for (1) fluid overload; (2) accumulation of metabolites and drugs that are excreted by the kidneys; (3) decreased drug elimination, which can prolong the effects of a wide range of anesthetic drugs and

adjuncts; and (4) electrolyte imbalances, which can lead to arrhythmias by affecting cardiac conduction.^{11,12} In addition, overhydration in a compromised heart with marginal reserves must be cautiously avoided because the physiologic changes in the kidneys of older adults decrease the ability to excrete a large-volume load.¹¹

The elderly are at higher risk for chronic kidney disease (CKD) because of the aforementioned physiologic and functional kidney changes, the prevalence of co-existing diseases that are associated with CKD (i.e., COPD, hypertension, vascular disease) and with coinciding frailty, complex medical regimens, and polypharmacy. All, or a combination thereof, may induce CKD in the presence of marginal renal function in the elderly patient. Therefore the preoperative evaluation is focused on current renal function as this will be variable among individuals, and preventing acute kidney injury perioperatively.

Hepatic Function

The aging adult liver decreases in mass by approximately 20% to 40% and may be attributed to the decrease in its blood flow. Age related functional hepatic changes primarily affect drug metabolism and protein binding. The age-related physiologic changes in hepatic function may cause decreased metabolism, prolonged half-life, and either increased or decreased distribution of medications.

Generally, hepatic functioning is well preserved in the healthy older adult; it is the combination of coexisting diseases (i.e., hepatitis, drug-induced liver injury, cirrhosis) and lifestyle habits (i.e., smoking, alcohol consumption, poor nutrition) that affect liver function more so than the physiologic aging liver. Even so, as with other organ systems, there is a decrease in functional hepatic reserve in the elderly patient.

Phase 1 drug metabolism in the liver is somewhat variable. The phase 1 reaction of a drug involves oxidation, reduction, and hydrolysis; it is primarily mediated by the cytochrome P450 system. Phase 2 drug metabolism involves conjugation reactions, sulfonic acid, or acetylation. Age has been identified as an insignificant factor during phase 2 drug metabolism.

The liver produces key proteins such as albumin and α_1 -acid glycoprotein (AAG). In the elderly, serum albumin decreases and AAG increases. Serum albumin primarily binds acidic drugs (i.e., benzodiazepines, opioids), and AAG binds basic drugs (i.e., local anesthetics). The effects of these alterations depend on the type of protein the medication is bound to and the resultant concentration of the unbound drug. Theoretically this may result in adverse drug effects especially when malnutrition is present. However, protein binding changes with aging do not routinely require alterations in drug dosing as the protein binding on free plasma concentration is rapidly counteracted by clearance.¹³ In the presence of concomitant diseases that affect liver function, the dosing of drugs dependent on hepatic metabolism must be considered.

Endocrine System

The endocrine system also undergoes age-related changes that have widespread effects on other body systems and processes. Nevertheless, few of these changes affect anesthetic management. The most notable endocrine organ to impact the aging adult patient and postoperative morbidity is the pancreas. There is a decline in number and function of the pancreatic islet beta cells that results in decreased insulin secretion. Furthermore, insulin resistance occurs peripherally, which contributes to increased hepatic production of glucose and impaired breakdown of fats and proteins making the elderly glucose intolerant or diabetic. Diabetes is a major risk factor for cardiovascular disease, which increases the risk for perioperative and postoperative complications (i.e., stroke, myocardial infarction, ketoacidosis, infection). Patients with long-term diabetes often have compromise in one or more organ systems.¹⁴ Diabetes and its associated complications (i.e., microvascular disease, cardiovascular disease, and hypertension) places the older adult patient with diabetes at increased risk for developing complications during the perioperative and postoperative period. There are also a number of diabetic complications that have plausible relationships with the aging adult, which may have an impact on perioperative management. For example, diabetes has an effect on brain aging and is associated

with playing a role in impaired cognition and Alzheimer's dementia.^{15,16}

Assessment of the older patient with diabetes includes identification of the type of diabetes, diabetes control (hemoglobin A1c), length of disease, and complications from diabetes. Patients with a history of diabetes for greater than 10 years are particularly at increased risk for complications.¹⁷ Perioperative assessment of the degree of endocrine dysfunction is essential, along with ongoing monitoring and timely intervention when appropriate.

Body Composition and Thermoregulation

Body composition and metabolism changes occur with the aging adult. There is a decrease in the basal metabolic rate (BMR) as a result of decreased physical activity and/or decreases in serum testosterone and growth hormone levels. The decreased BMR may have an effect on muscle mass and thermoregulation. Skeletal muscle mass and strength declines with aging with 50% of skeletal mass being lost by the age of 80 years. The loss of skeletal muscle tissue (sarcopenia) is one of the causes of functional decline and independence in the elderly.¹⁸ There is also a significant loss in body protein because of a decrease in skeletal muscle mass and alterations in carrier proteins (e.g., albumin and AAG). At the same time body fat increases with the aging adult; it is distributed more so in the viscera, subcutaneous abdominal area, intramuscular and intrahepatic areas. In addition to changes in lean mass and body fat, there are changes in total body water. The total body water loss is mostly intracellular and somewhat in the extracellular compartment; blood volume decreases approximately 20% to 30 % by age 75 years. As a result of decrease in total body water, older adults are more vulnerable to hypotension and have difficulty compensating for positional changes. Overall, the body composition changes primarily affect the pharmacokinetics of medications in the elderly and is described later in this chapter.

Thermoregulation in the elderly patient is impaired. In the older adult there is a decrease in the function of the hypothalamus. Hypothermia is more pronounced and lasts longer because of a lower basal metabolic rate, a high ratio of surface to body area mass, and less effective peripheral vasoconstriction in response to

cold.¹⁹ It is particularly detrimental in the elderly patient because it slows anesthetic elimination, prolongs recovery from anesthesia, impairs coagulation, impairs immune function, blunts the ventilatory response to CO₂ and increases the chance that the patient will shiver.²⁰ Shivering drastically increases oxygen consumption, which leads to hypoxia, acidosis, and cardiac compromise. It is known that inhaled anesthetics inhibit the temperature regulating centers in the hypothalamus; thus, the aging adult has this added insult to an already inhibited hypothalamus. Thermoregulatory vasoconstriction can cause significant peripheral vasoconstriction, predisposing older adults to produce less heat per kilogram of body weight; therefore older adults may be unable to maintain their heat in the cooler environment of the operating room. Moreover, once temperature decreases in the elderly patient, it is difficult to restore normal body temperature. Methods to maintain normothermia in the older adult patient should involve prevention of heat loss and active warming initiated in the preoperative area and continued perioperatively.²⁰ Methods include the administration of all fluids and blood transfusions through a warming device, a thermal mattress or forced air warmer, and an environmental humidity higher than 50%.

The elderly have a decrease in dermal and epidermal thickness of the skin, which is caused by a loss of collagen and elastin. Because there is a decrease in subcutaneous fat and thinness of the skin, the aging adult is prone to skin tears and nerve injuries with positioning.

Central Nervous System

Age-related physiologic changes of the central nervous system (CNS) are characterized by a progressive loss of neurons and neuronal substance, decrease in neurotransmitter activity, and decreased brain volume. These losses are most prominent in the cerebral cortex, particularly the frontal lobes. The associated physiologic changes cause a decrease in cerebrospinal fluid, a decrease in nerve conduction velocity, and degeneration of peripheral nerve cells. In addition, there is a decreased number of

myelinated nerve fibers. The regulation of brain function, including neuronal membranes, receptors, ion channels, neurotransmitters, cerebral blood flow, and metabolism, is affected by general anesthetics at all levels. Consequently, there are changes in mood, memory, and motor function. In addition, cellular processes that participate in neurotransmitter synthesis and release such as intraneuronal signal transduction and the second messenger system, may be altered.²¹ The CNS changes experienced by the older patient result in an increased sensitivity to anesthetic agents; as a result, there may be an increased risk for postoperative delirium (POD) or cognitive dysfunction.²² Brain function monitoring (bispectral index monitoring) may be beneficial in the elderly surgical patient. It may assist in guiding the titration of medications and inhalation agent, thus speeding recovery times and perhaps decreasing the incidence of POD and postoperative cognitive dysfunction (POCD).²³⁻²⁵

The older patient may experience increased sensitivity to drugs because the number of receptors available are decreased. The blood brain barrier becomes more permeable, which may also contribute to the sensitivity of medications in addition to neurocognitive disorders such as Alzheimer dementia and delirium.^{26,27} As a rule older patients frequently experience an exaggerated response to CNS-depressant drugs with particular sensitivity to general anesthetics, hypnotics, opioids, and benzodiazepines.²² The dose of induction agents should be decreased by as much as 50% in older patients, arguing for very meticulous titration. Benzodiazepines should be avoided in older adults because they contribute to adverse events (i.e., falls, confusion, POD).^{28,29}

CNS changes in the elderly also affect neuraxial anesthesia. Because the number of myelinated nerve fibers are decreased, this poses a risk for neural damage with regional anesthetics. Anatomic changes in the aging patient such as decreased intervertebral disc height, narrowing of the intervertebral foramina, decreased space between the posterior spinous processes, presence of calcifications, and changes in normal lordosis, contribute to difficulties associated with patient positioning and spinal or epidural needle placement. It is also postulated that the dura is more permeable to local anesthetics and that the CSF specific gravity increases, whereas its

volume decreases. All these alterations in the nervous system may produce a more enhanced spread of local anesthetics for subarachnoid blocks.³⁰ Because elderly patients have an impaired baroreceptor response, severe hypotension refractory to adrenergic stimulation may result from postspinal sympathectomy. This could potentially be detrimental in the presence of impaired cardiac function. There is also an enhanced spread of local anesthetics with epidural blockade. In addition, the use of an epinephrine “test dose” for identification of intrathecal injection is less reliable in the elderly because of the decreased end-organ adrenergic responsiveness.³¹ Therefore, a decreased dose of local anesthetic is recommended for subarachnoid and epidural blockade. Overall, subarachnoid and epidural blockade are generally not contraindicated in the elderly patient. A plan of anesthesia should be developed, based on patient history and surgical procedure while considering the risks and benefits, in an effort to decrease postoperative morbidity and mortality.

Issues of Specific Importance in the Older Adult Preoperative Assessment

Cognitive Ability/Capability and Decision Making

As there is an increasing rate of neurocognitive disorders in the older adult, it is highly recommended by the ACS NSQIP/AGS that their cognitive ability, capacity for decision making, and risk factors for POD be assessed. A preoperative neuropsychiatric assessment establishes a clinical baseline if changes are observed postoperatively and guides perioperative management. The guidelines recommend that a screening tool be used. Several screening tools are available, but the Mini-Cog can be rapidly administered, is highly sensitive and specific for dementia, and is unbiased by variances in education or language. It consists of a three-item recall and a clock draw algorithm (Box 54.2 and Fig.

Box 54.2

Cognitive Assessment

1. Get the patient's attention, then say:

- “I am going to say three words that I want you to remember now and later. The words are: banana, sunrise, chair. Please say them for me now.”
- Give the patient three tries to repeat the words. If unable after three tries, go to the next item.

2. Say all the following phrases in the order indicated:

- “Please draw a clock in the space below. Start by drawing a large circle. Put all the numbers in the

circle and set the hands to show 11 : 10 (10 past 11).”

- If the patient has not finished clock drawing in 3 minutes, discontinue and ask for recall items.

3. Say: “What were the three words I asked you to remember?”

Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg.* 2012;215(4):455. From Mini-Cog, copyright S. Borson [soon@uw.edu].

FIGURE 54.4 Mini-Cog scoring algorithm. (In Nakhaie M, Tsai A. Preoperative Assessment of Geriatric Patients. *Anesthesiology Clinics* 2015;33(3):471–480. Adapted from Borson S, et al. The Mini-Cog: a cognitive “vital signs” measure for dementia screening in multi-lingual elderly. *Int J Geriatr Psychiatry* 2000;15(11):1024. With permission.)

Determining the older adult's decision making capacity is important in order to provide informed surgical consent. It is recommended that the surgeon identifies the decision-making ability of the patient during the informed consent. However, it is also the anesthesia provider's responsibility to ensure that the patient is able to make sound decisions. The four legally–relevant criterion for decision making capacity are: (1) understanding his/her treatment options; (2) appreciating and acknowledging his/her medical condition and likely outcomes; (3) exhibiting reasoning and engaging in a rational discussion of his/her surgical treatment options; and (4) clearly choosing a preferred treatment option.^{5,8}

Frailty

Frailty is a perioperative risk factor for complications and mortality. Frailty rates of 4.1% to 50.3% have been reported in surgical patients.^{32,33} Frail older adults are more likely to have complications postoperatively, are at increased risk for longer length of hospital stay, and are more likely to be discharged to a skilled or assisted living facility.^{32,33}

There is no agreed upon definition of frailty. This may be related to the complexity of the syndrome and the fact that frailty often overlaps with other syndromes. However, most agree that frailty is a biologic state associated with increased vulnerability to adverse outcomes that result from decreased resistance to stressors as a result of deterioration in multiple physiologic systems. Frailty is classified as primary or secondary. Primary frailty occurs as part of the intrinsic process of aging. Secondary frailty is related to the end-stage of chronic illnesses and is caused by inflammation and wasting, for example heart failure, COPD, inflammation, and wasting associated with cancer. Because frailty serves as an indicator for adverse outcomes and mortality in older adults, ACS NSQIP/AGS guidelines recommend that elderly surgical patients be assessed for frailty via a validated screening tool. Whereas there are multiple frailty screening tools, Fried et al. created an operational frailty score based on the physiologic parameters of grip strength, weight loss, walking speed, as well as energy level and physical activity. The summation of scores are categorized as frail, intermediate/prefrail, or robust.^{4,34} Unfortunately, this tool does not include mental health or psychosocial status, which can be a part of frailty. Frailty has also been operationalized as a frailty index.³⁴ The frailty index defines frailty as the proportion of accumulated deficits over time, including diseases, disability, geriatric syndromes, psychosocial risk factors, and physiologic and cognitive impairment. It is suggested that the frailty index may be more sensitive to the identification of adverse outcomes than Fried's frailty phenotype.

Nutritional Status

A nutritional assessment is imperative in the older adult surgical

patient. There is no uniform definition for malnutrition in the older adult. Most definitions include specific laboratory indices, and body mass index (BMI). However, malnutrition in older adults is common, frequently overlooked, and results in postoperative complications, increased hospital cost, and death. Malnutrition, and protein deficiency (PD) in particular, are key factors for sarcopenia, frailty, and osteoporosis; all can result in disability, loss of independence, falls, fractures and death in the elderly population.³⁵ Undernutrition and/or malnutrition is common in the elderly as a result of changes in taste, smell, a reduced ability to purchase and/or prepare food, and decreased functional status.³⁶ Other factors that may directly influence dietary intake changes include coexisting diseases, cognitive and physical decline, emotional and social changes, and depressive symptoms. Aging is associated with decreases in all the senses; thus it is speculated that the decrease in smell and taste may cause foods to be less appetizing. Practitioners must be vigilant because disease and aging cause decreased lean body mass that may mimic or be confused with malnutrition. Even so, malnutrition should not be discounted in the aging patient because it may contribute to decreased albumin levels that can affect protein binding of medications and impair wound healing. For the older adult surgical patient, decreases in caloric intake combined with illness depletes body caloric reserves necessary to withstand the stress of anesthesia and surgery. Regrettably, no clearly beneficial preoperative medication has been identified that stimulates the appetite in older adults. Multiple validated screening tools exist for identifying risk factors for malnutrition. However, there is no consensus as to which tool should be used for screening. Per the ACS NSQIP/AGS guidelines, if an older adult surgical patient exhibits any one of the following criterion: (1) a BMI less than 18.5 kg/m, (2) serum albumin less than 3.0 g/dL without evidence of renal or hepatic dysfunction, or (3) unintentional weight loss within the past 6 months of greater than 10% to 15%, he/she is deemed to be at severe nutritional risk.⁵ Those at severe nutritional risk should undergo further in-depth nutritional screening by a dietician with a plan for optimization. Postponement of the surgery may be indicated until nutritional status has improved because malnutrition and PD are associated with

increased risk of postoperative complications (i.e., surgical site infection, pneumonia), increased length of hospital stay, and mortality.

Functional Status

The assessment of functional status identifies the older adult's ability to perform self-care tasks, or activities of daily living (i.e., bathing, dressing, toileting), and instrumental activities of daily living (i.e., preparing meals, handling finances, driving or using public transportation).⁴ A preoperative functional status assessment serves as a baseline in physical capacity and assists in determining reasonable and individualized postoperative goals. Impaired preoperative functional status is a predictor for longer postoperative recovery time with poor postoperative outcome, increased risk for POD, and increased length of hospitalization.³⁷ Functional status can be assessed through proxy report (Box 54.3). In addition, assessing falls through inquiry, and visualizing gait and mobility, assists in identifying the older adults risk for falls. The Timed Up and Go Test (TUGT) can be implemented to establish mobility and gait. This entails having the older adult patient rise from a standard chair, walk approximately 10 feet, turn back, and return to the chair and sit down again. If it takes longer than 20 seconds to complete the test, the patient is determined to be at risk for falls. Longer TUGT times are associated with increased postoperative complications and 1-year mortality among older adult surgical patients.³⁸ Deficits in vision and hearing can also contribute to fall risk and should be included in the mobility assessment. The most important goals in the perioperative care of older adults are the avoidance of functional decline, and maintenance of independence postoperatively.

Functional Status Assessment Proxy

Questions to ask the older adult:

Can you...

1. Get out of bed or the chair by yourself?*
2. Dress or bathe yourself?*

3. Make your own meals?*

4. Do your own grocery shopping?*

If “no” is answered to any of the questions it warrants further in-depth screening and appropriate referrals for perioperative interventions (i.e., physical therapy, social services).

*The answer may not be reliable when neurocognitive disorders are present.

From Optimal Perioperative Management of the Geriatric Patient: Best Practices Guideline from ACS NSQIP[®] / American Geriatrics Society. American Colleges of Surgeons Website. Accessed 2016 at <https://www.facs.org/quality-programs/acs-nsqip/geriatric-periop-guideline>.

Review of Medications and Polypharmacy

A thorough review of all medications (i.e., prescription, over-the-counter [OTC], dietary supplements, herbals) that the older adult is currently taking is critical in identifying medications that should be discontinued prior to surgery, those to consider starting prior to surgery, and those to avoid administering perioperatively. In a 2016 study, it was determined that from 2010 to 2011, 15% of older adults were at risk for a potential major drug-drug interaction as compared to 2005 to 2006, which was approximately 8%.³⁹ The use of prescription medications, dietary supplements, and concurrent use of five or more medications or supplements also increased in older adults.³⁹ Polypharmacy, or multiple medication use, is common in older adults and is associated with adverse drug reactions (ADRs) or unwanted side effects. ADR's may be caused by prescribing error (e.g., large dose prescribed without taking into account decreased renal and/or hepatic clearance), or not taking into account CNS sensitivity.

To help prevent prescribing errors, medication side effects, and ADRs, the American Geriatric Society developed guidelines (*Beer's Criteria for Potentially Inappropriate Medication Use in Older Adults*) for safe prescribing of drugs to older adults. Beer's Criteria includes a list of medications that should be avoided or have their dose adjusted based on the older adult's renal function and select drug-

to-drug reactions.²⁹ Per ACS NSQIP/AGS guidelines, the preoperative review of medications should consist of: (1) discontinuing or substituting medications that have potential drug reactions with anesthesia; (2) discontinuing nonessential medications that increase surgical risk; (3) identifying medications that should be discontinued based on Beer's Criteria; (4) continuing medications with withdrawal potential; (5) avoid starting new benzodiazepines and reducing the dose prescribed to patients at risk for POD; (6) avoid administering meperidine for analgesia; (7) using caution with antihistamines and medications with strong anticholinergic effects; (8) consider starting medications that decrease perioperative cardiovascular adverse events per ACC/AHA guidelines for β -blockers and statins; and (9) adjusting dosing of medications that undergo renal excretion based on estimated GFR.⁵

A medication history may be difficult to obtain or inaccurate if the older adult suffers from cognitive or hearing impairment. Medication compliance and use of OTC, dietary and herbal supplements may be difficult to ascertain. The preferred approach to the preoperative medication review and perioperative management of the older adult is appreciation for individualized physiologic aging, pharmacokinetic and pharmacodynamics changes with aging, presence of coexisting diseases, and respect for decreased functional reserve.

Age-Related Pharmacologic Implications in the Older Adult

Exaggerated responses to anesthetic drugs and a prolonged duration of action are often seen in the elderly. These differences in drug response are the result of both pharmacokinetic and pharmacodynamic changes associated with aging. Pharmacokinetic alterations occur in the volume of distribution, renal and hepatic clearance rates, compartmental redistribution, and elimination half-lives. A decreased blood volume results in a decrease in initial volume of distribution, which produces a higher-than-expected initial concentration of drug with an intravenous bolus injection. Changes in steady-state volumes of distribution (Vd_{ss}) vary. In aging patients who have an increase in body fat, decrease in lean body mass, and a decreased total body water, there is an increased Vd_{ss} for lipophilic drugs and a decrease for hydrophilic drugs.²² Decreased plasma protein binding in the elderly theoretically results in an increase in the free plasma concentration for drugs that are highly protein bound. A decrease in renal function resulting from lower renal blood flow, glomerular filtration, and tubular secretion leads to increased serum concentration and prolonged effects of drugs dependent on renal elimination. The elimination of hepatic-dependent drugs varies. Phase I metabolism may be reduced, but phase II metabolic pathways are not affected by age.^{13,22}

Pharmacodynamics changes in the elderly include altered receptor density and binding, changes in signal transduction, and impaired cellular responses. Drug-induced changes tend to be longer lasting and require a greater length of time for recovery to preanesthetic steady state. The minimal alveolar concentration (MAC) of inhalational agents decreases roughly 6.7% per decade from the MAC value of 40-year-old adults.^{40,41}

Neuromuscular blocking drugs are not affected by the pharmacodynamics changes of the older adult. However, the pharmacokinetics is significantly altered. For all neuromuscular blocking drugs, the onset of action is usually prolonged.²² Most of

the nondepolarizing neuromuscular blockers are metabolized by the liver and excreted via the kidney, and in the presence of coexisting hepatic or renal disease, there may be a prolonged effect. This residual neuromuscular blockade, in combination with the loss of pharyngeal and muscular support that is required to protect the airway, increases the risk for postoperative respiratory failure and/or aspiration. The neuromuscular blocking medication of choice for the older adult is cisatracurium because this undergoes Hoffman elimination and ester hydrolysis and is not organ dependent.

Generally, all medications are given in a lower dose to the older adult patient. Even though this is well known, the tendency for anesthesia providers to underappreciate the elderly patients' sensitivity to medications, the pharmacodynamic and pharmacokinetic changes, may result in overmedication and potential overdosing. Currently there are no specific medication dosing guidelines for anesthesia medications for the older adult patient. Suggested dosing adjustments for perioperative medications are found in [Table 54.4](#). Postoperative pain control and analgesics in the elderly surgical patient are discussed in [Chapter 56](#).

TABLE 54.4
Recommended Dosing for Perioperative Medications

Agent	Anesthetic Considerations	Dose
Propofol	Hypotension; prolonged recovery; increased brain sensitivity	↓ bolus and infusion by 50% (manufacturer recommends 1–1.5 mg/kg bolus for induction)
Etomidate	Increased brain sensitivity; greater hemodynamic stability	↓ bolus by 50%
Opioids	Increased brain sensitivity; profound physiologic effects; slower onset and delayed recovery; consider route of metabolism and metabolites; avoid meperidine	↓ bolus by 50%
Midazolam	Increased brain sensitivity; avoid per Beers Criteria	Avoid; ↓ dose by 75%
Nondepolarizing MRs	Slower onset and delayed recovery; consider route of metabolism and metabolites; avoid long-acting NDMRs	No significant changes with intubating dose; maintenance dose per PNS twitch response
Depolarizing MR	Slower onset and delayed recovery	No dose adjustment

↓, Decreased; *MRs*, muscle relaxants; *NDMRs*, nondepolarizing muscle relaxants; *PNS*, peripheral nerve stimulator

Comorbidity in the Older Adult

Definitions for comorbidity and multimorbidity are not clear in the literature. Therefore this section will use comorbidity and multimorbidity interchangeably, and is defined as two or more chronic medical conditions within one person.^{42,43} In the United States, multimorbidity has increased with advanced age, even though mortality rates have declined. It is associated with an increased risk for death, disability, poor functional status, ADRs, and increased length of hospitalization and health care costs.^{44,45} Multimorbidity increases steeply with older adults. The prevalence of multimorbidity in those 65 to 74 years of age is approximately 62%, at ages 75 to 84 years it is 75%, and 81% in those who are 85 years of age and older.^{44,46} The most common multimorbidities in the older adult include hypertension, hyperlipidemia, diabetes, and ischemic heart disease. Prevalence varies by sex; women have more arthritis than men, and men have more heart disease than women. Prevalence also varies by race, with older adult Hispanics and African Americans having higher rates of hypertension, diabetes, and metabolic syndrome as compared to Caucasians.^{4,46}

Multimorbidity in the older adult is common and is strongly associated with frailty, which in turn is associated with poor postoperative outcomes.⁴³ Even so, older age and presence of multimorbidities should not be limiting factors for surgical treatment. Compared with younger surgical patients, the older adult is at relatively increased risk for morbidity and mortality postelective surgery, but are at 30% higher risk for postoperative complications and mortality with emergency surgery.⁴⁷⁻⁴⁹ Therefore, a multidisciplinary approach to individualized preoperative care and optimization is essential with the goal of avoiding postoperative complications and returning the older adult patient to their same presurgical state.

Ethical Issues in the Treatment of the Older Adult

The advances in medical treatment, the changes in the health care system, and the aging of the United States has given rise to specific ethical dilemmas that anesthesia providers encounter in the older adult. The older adult patient often has other complicating factors (i.e., coexisting diseases, impaired cognition, impaired decision-making capacity, insufficient social support), which adds to the complexity in ethical issues. Examples of ethical issues in the older adult surgical patient include informed consent, advanced directives, and perioperative do-not-resuscitate (DNR) orders. The basic principles in ethical decision making that apply to the older adult are the same as those that apply to all patients. In health care the most common principles are (1) autonomy, (2) beneficence, (3) nonmaleficence, and (4) justice. Ethical principles are defined in [Box 54.4](#). Certified Registered Nurse Anesthetists (CRNAs) follow the American Nurses Association Nursing Code of Ethics in their daily practice and abide by the American Association of Nurse Anesthetists (AANA) Code of Ethics in guiding ethical decision-making. As professionals we base our decisions on “ethics of obligation,” yet personally we base them on “ethics of the good.”⁵⁰ Unfortunately, difficult and complex situations arise that challenge the anesthesia providers. Personal values and biases must be recognized while acknowledging, appreciating, and upholding the [Box 54.4](#) Patient's desires and decisions regarding their health care.

Ethical Principles

- *Autonomy*: Patient's right to self-determination
- *Beneficence*: An obligation or responsibility to help the patient; “to do good”
- *Nonmaleficence*: To not intentionally harm the patient; “do no harm”

- *Justice*: To treat the patient fairly

The informed consent is the cornerstone for upholding the practice of autonomy. However, all the ethical principles are involved when a patient makes an informed decision regarding his/her health care. Older age alone is not an obstacle to practicing autonomy. An important aspect of the informed consent is assessing and assuring that the patient has the cognitive ability/capability for decision making. Informed consent is discussed in [Chapter 20](#), and assessing cognitive capability/ability for decision making is discussed earlier in the preoperative assessment portion of this chapter. Legally and ethically anesthesia providers and other practitioners must disclose factual, truthful information while being objective and free of personal bias.

Autonomy is also exercised through an advanced directive (AD). This legal document enables a surrogate or agent to act on the patient's behalf when he/she is unable to make health care decisions. The patient has communicated his/her beliefs and values about health care decisions and life-sustaining treatment and appoints a surrogate. In 1991, legislation enacted the Patient Self-Determination Act (PSDA), which requires hospitals and other health organizations that receive Medicare funds to provide information to patients regarding their right and refusal of care (i.e., ADs). Since its inception, older adults AD completion rates are at an all-time high of 72%.⁵¹ As ADs are legislated at the state level, there may be differing standards and laws for each state. Unlike an AD, a living will (LW), or directive to physicians, are death with dignity declarations, which provide specific instructions to the attending physician(s) stating the patient's desired treatment for care when his/her decision making capacity is lost because of a terminal or end-stage illness. LWs primarily direct resuscitation and withdrawal of life sustaining treatment.⁵² Unfortunately, this document is limited to delineated medical situations and does not take into account unforeseen circumstances. Regardless of which legal document the patient has, a review of the document and a conversation should take place between the practitioner(s) and patient concerning his/her health care wishes/goals during the perioperative period.⁵⁰

Informed consent is not limited to surgical procedures and anesthetic technique; it is also applicable to the perioperative DNR order. Health care providers are taught that it is their duty to provide care that is beneficial to the patient. Hence, in the presence of a patient who is undergoing surgery with a DNR status, health care providers may feel compelled to suspend the DNR in the event that heroic measures are needed. From the perspective of anesthesia providers, it is their responsibility to ensure that the patient has a positive anesthetic outcome. Even though anesthesia providers view that suspending the DNR status will inevitably help the patient in the event that cardiopulmonary resuscitation is needed, the DNR suspension may not be aligned with the patient's view of beneficence or his desires. Therefore anesthesia providers cannot assume what is best for the patient; the patient or surrogate needs to have informed consent regarding the alternatives of the DNR status while in the operating room in order to make an informed decision based on his wishes, values, and beliefs. Because of this circumstance, the ASA suggests that specific resuscitation alternatives during the surgical procedure be presented and discussed with the patient. These three alternatives include (1) the full suspension of the DNR status intraoperatively and postoperatively, (2) the acceptance or refusal of specific resuscitative interventions (i.e., chest compressions, defibrillation, vasopressor administration) with full documentation of these in the medical record, and (3) resuscitation procedures will be determined by the anesthesia provider and the surgeon based on clinical judgment, while keeping in mind the patient's values and wishes.^{53,54} The AANA also developed practice guidelines that address the reconsideration of ADs prior to surgery, which are similar to the ASA and are found in [Box 54.5](#). Facility policy is also used as a resource in guiding the practitioner in addressing DNR status of a patient undergoing surgery. Each patient and accompanying surgical procedure should be addressed on a unique case-by-case matter. After an informed discussion, an agreement should be made on the DNR status by the patient or surrogate, surgeon, and anesthesia provider. Lastly, the perioperative DNR status should be documented in the medical record to substantiate the agreement, and to inform all health care providers of the

Box 54.5 Reorganized plan.

AANA Reconsideration of Advance Directives

- *Full suspension:* All provisions of the advance directive are suspended during anesthesia and the procedure for a specified period.
- *Partial suspension or modification:* Specific provisions of the advance directive are suspended or modified during anesthesia and the procedure for a specified period.
- *No suspension:* The provisions of the advance directive remain active during anesthesia and the procedure

It is widely accepted that chronologic age is possibly an independent risk factor for anesthesia and surgery; its specific role as a risk factor is difficult to ascertain. Thus each patient should be treated fairly, regardless of age. The ethical principle of social justice is not providing the greatest good for the greatest number of people; it is treating people equally, regardless of their age, race, cultural beliefs, religion, disease processes, or resuscitation status.⁵⁰ Every patient should be informed, at a comparable level, of all the alternatives regarding resuscitation when undergoing any surgical procedure. It is a matter of justice to ensure adequate and equitable informed anesthesia consent to all surgical patients. Therefore age, as an independent factor, should not be regarded as a reason to exclude an older adult for any procedure.

Postoperative Delirium

POD and postoperative cognitive dysfunction (POCD) are the most frequently occurring neurologic phenomena in older adults. POD and POCD are distinct conditions, with age over 65 years being the predominant risk factor for both.

POD is characterized by disruption of perception, thinking, memory, psychomotor behavior, sleep-wake cycle, consciousness, and attention.^{55,56} Its clinical presentation varies with hypoactive symptoms (e.g., decreased motor activity and depression), hyperactive symptoms (e.g., aggression and agitation), or a combination thereof. In some instances, hypoactive symptoms are unrecognizable, which results in misdiagnosis of POD.^{5,57}

Symptoms typically manifest acutely within the first few days after surgery and can last for several days or weeks. The exact cause of POD is not known but is likely multifactorial. Risk factors that have been associated with the development of POD are older age, male gender, dementia, history of alcohol abuse, depression, duration of anesthesia, poor functional status, abnormal electrolytes and glucose, Parkinson disease, cardiovascular disease, dehydration, metabolic diseases (e.g., diabetes, hyperthyroidism), anticholinergic drugs used intraoperatively, patients requiring admission to the intensive care unit, inadequate pain control, ASA greater than or equal to 3, low serum albumin, and type of surgery.⁵⁸⁻⁶² Depending on the type of procedure, the rate of POD ranges from 9% to 50% with a high incidence occurring in aortic and orthopedic procedures (femoral fractures).^{5,51} POD is associated with increased risk of postoperative adverse reactions (i.e., pulmonary and cardiac), increased length of hospital stay, increased health care cost, poor functional and cognitive recovery, and death.^{62,63}

The treatment of POD begins with prevention. Preoperatively, health care providers should identify patients who are at high risk for POD, including age over 65 years, chronic cognitive decline or dementia, poor hearing or vision, presence of infection, current hip fracture, or severe illness. In combination with the risk factors, the physiologic stress of surgery, which is determined by the extent of the operation, may cumulatively contribute to the development of

POD. Once POD is diagnosed treatment is dependent on the identifying cause. After treating the underlying cause, it is recommended that health care providers use multicomponent nonpharmacologic interventions (i.e., frequent reorientation, calm environment, eliminating restraint use, and ensuring the use of hearing aids/glasses). The use of pharmacologic interventions (i.e., haloperidol, lorazepam) should be reserved for those who are highly agitated and are threatening harm to self and/or others.^{5,55} Other recommendations for anesthesia providers include: (1) administering regional anesthesia for postoperative pain control thereby potentially preventing delirium, (2) intraoperative electroencephalogram (EEG) monitoring during intravenous sedation or general anesthesia as EEG suppression has been identified as an independent risk factor for POD, and (3) conducting a thorough review of medications preoperatively while avoiding medications per Beer's Criteria.^{20,64}

Postoperative Cognitive Dysfunction

POCD is often reported as being part of the same continuum as POD. Even though they are both neurocognitive disorders that contribute to increased hospital costs, morbidity, and mortality, there are differences. POCD is characterized by an array of cognitive impairments such as memory deficits, difficulty with concentration, impaired comprehension, and delayed psychomotor speed. Unlike POD, the onset of POCD is subtle and neurocognitive deficits may not present themselves until weeks to months after surgery. This ultimately results in the inability to work, a decline in activities of daily living, and perhaps a need for assisted care.⁵⁶

Currently there are no universally accepted diagnostic criteria for POCD, nor is there a standard definition. To diagnose POCD, a battery of time-consuming and sophisticated neurocognitive tests must be done preoperatively and postoperatively in identifying cognitive decline after surgery and anesthesia. Establishing baseline cognitive function is critical because preoperative cognitive impairment may be present prior to surgery. However, preoperative test timing, specific test(s), and test interpretations remain inconsistent and debatable. Risk factors for POCD are also controversial, with advanced age being the most agreed upon. Other risks may include lower educational level, longer duration of anesthesia, preoperative depression, preoperative cognitive decline, **Box 54.6** postoperative infection, and second operation⁵⁶ (**Box 54.6**).

Risk Factors for Postoperative Cognitive Dysfunction

- Genetic disposition
- Lower educational level
- High alcohol intake or alcohol abuse
- Increasing age
- High ASA status

- Preexisting mild cognitive impairment
- History of cerebrovascular accident
- Major operations, redo operations
- Cardiac surgery
- Longer duration of surgery and anesthesia
- Intraoperative cerebral desaturation
- Postoperative delirium
- Postoperative infection

From Grape S, et al. Postoperative cognitive dysfunction. *Trends Anaesth Crit Care*. 2012;2(3):98–103.

The cause of this neurocognitive postoperative complication is still unknown and appears to be multifactorial. However, several theories have been postulated. Common theories include cerebral hypoperfusion (severe hypotension and embolic events), the inflammatory process associated with surgery, and general anesthetics.^{25,56,65–67} Similar to POD the physiologic mechanisms responsible for POCD are yet to be elucidated. However, potential mechanisms include neuroinflammation, dopamine excess and acetylcholine deficiency, and central cholinergic deficiency.^{65–67} An array of human biomarkers reflective of these mechanisms are being investigated. However, currently the diagnosis of POD or POCD is not supported by any specific biomarkers.

Presently there is no cure for POCD, and patients who suffer from it may or may not recover to their preoperative cognitive state. Because POCD pathogenesis is multifactorial and unclear, strategies should be aimed at prevention. Unfortunately, there are no proven effective strategies. However, based on the knowledge that the elderly have decreased nervous system function and decreased cognitive reserve, efforts should consist in identifying

risk factors and tailoring anesthetic management to minimize them. Recommendations are aimed at maintaining oxygenation and cerebral perfusion.⁶⁶ Because it is speculated that POCD may be caused by general anesthesia and/or surgery, it is only prudent that surgeries should be as short or as minimally invasive as possible. Overall, there is no consensus in the literature regarding the most appropriate anesthetic technique for the elderly surgical patient.

Summary

The United States is on the cusp of a very racially and ethnically diverse aging population surge. Health care providers will face many challenges in keeping pace with a more comprehensive preoperative elderly assessment, which will identify perioperative risks, assist with optimizing the older adult, and improve postoperative outcomes. The goal of anesthesia for the older adult patient is the same as any other patient; however, the physiologic changes, multimorbidities, and functional decline in all organ systems of the older adult affect every aspect of the perioperative course. Anesthesia for the elderly patient is no longer an empiric specialty; the practice of anesthesia for elderly patients is a multidisciplinary team approach built on evidence-based quality care.

Postanesthesia Recovery

Jan Odom-Forren, Joni M. Brady

The term *perianesthesia patient care* reflects a continuum of care because the patient is moved from the preanesthesia holding or admitting area to the surgery suite (operating room [OR]) and then to the postanesthesia care unit (PACU). *Postanesthesia recovery* refers to those activities undertaken to manage the patient after completion of a surgical or nonsurgical procedure in which anesthesia, analgesia, or sedation was administered. The primary purpose of postanesthesia recovery is the critical assessment and stabilization of patients after these procedures, with an emphasis on prevention and detection of complications.¹ Care in the postanesthesia phase I unit centers on providing immediate postanesthesia nursing care and transitioning the patient to the intensive care setting, the inpatient setting, or phase II outpatient care.² The focus of this chapter is on the postanesthesia care of patients with the goals of improving postanesthetic safety and quality of life, reducing postoperative adverse events, providing a uniform assessment of recovery, and streamlining postoperative care and discharge criteria.

Postanesthesia Care Unit Admission

Before the patient is transferred, PACU personnel should be notified not only to expect the transfer but also to have any necessary equipment (e.g., ventilator, nebulizer, invasive monitoring equipment, pharmacologic infusions, and capnograph) ready and waiting. Knowledge of the patient's acuity enables the PACU staff to best plan the patient's care and assign that care to an appropriately experienced practitioner.

Both the anesthesia provider and the PACU nurse should collaborate in the patient's admission to the PACU. The immediate priority is evaluation of respiratory and circulatory adequacy. During this initial assessment, any signs of inadequate oxygenation or ventilation are identified, as well as the cause ([Boxes 55.1](#) and [55.2](#)). Although many of the signs of respiratory compromise could have multifactorial explanations, assessment of the adequacy of oxygenation and ventilation ensures that respiratory inadequacy is not contributory. Any evidence of respiratory compromise requires [Box 55.1](#) immediate correction.

Signs and Symptoms of Inadequate Oxygenation

Respiratory

- Shallow, rapid respirations or normal, infrequent respirations
- Tachypnea
- Dyspnea
- Oxyhemoglobin saturation less than 90%

Neurologic

- Anxiety, restlessness, inattentiveness
- Altered mental status, confusion

- Dimmed peripheral vision
- Seizures
- Unresponsiveness

Skin

- Diaphoresis
- Cyanosis

Cardiac

- *Early:* Tachycardia
- Increased cardiac output
- Increased stroke volume
- Increased blood pressure
- *Late:* Bradycardia, hypotension
- Dysrhythmias

ASA, American Society of Anesthesiologists.

From Grape S, et al. Postoperative cognitive dysfunction. *Trends Anaesth Crit Care*. 2012;2:98–103.

Box 55.2

Causes of Hypoxemia

- *Hypoventilation*—Alveolar ventilation is abnormally low in relation to oxygen uptake or carbon dioxide output; causes a raised arterial PCO₂ and arterial hypoxemia
- *Diffusion limitation*—Oxygen, carbon dioxide are affected as they cross the blood-gas barrier by simple passive diffusion

- *Shunt*—The entry of blood into the systemic arterial system without going through ventilated areas of lung
- *Ventilation-perfusion relationships*—A mismatch of ventilation and blood flow

PCO₂; Partial pressure of carbon dioxide.

Modified from Powell, et al. Ventilation, blood flow, and gas exchange. In Mason RJ, et al. *Murray and Nadel's Textbook of Respiratory Medicine*. 6th ed. Philadelphia: Elsevier; 2016:44–75.

Electrocardiographic (ECG) monitoring is initiated for determination of cardiac rate and rhythm. Any deviation from preoperative or intraoperative findings is noted and evaluated. In addition, blood pressure is measured, and adequacy of organ perfusion is determined. Any necessary invasive monitoring, such as an arterial line, is initiated. Any evidence of cardio-circulatory compromise requires immediate correction.

The anesthesia provider should be active during the patient's transfer and stabilization in the PACU. Assistance in the initiation of oxygen therapy, maintenance or verification of airway adequacy, and assessment of circulatory status familiarizes PACU personnel with the patient and fosters a smooth transfer of care. After initially stabilizing the patient, the anesthesia provider can communicate relevant preoperative and intraoperative data to the PACU nurse.

Anesthesia Report

To ensure patient safety and continuity of care, the anesthesia provider must give a verbal handoff report to the PACU nurse that specifies the details of the surgical and anesthetic course, the preoperative conditions that warrant or influence the surgical and anesthetic outcome, and the PACU treatment plan, including suggested interventions and end-points. Transfer of the patient from the OR to the PACU is a critical patient handoff and should include an opportunity for the PACU nurse to ask questions and the anesthesia provider to respond. Communication errors can occur during the process of a handoff. Proper handovers have been hampered by inadequate preparation on how to perform handovers, a lack of a standardized process, inadequate communication skills, lack of time for transfer of information, information loss, distractions, interruptions, and limited opportunity to ask questions or voice concerns.³ To decrease these communication errors, handoff information needs to be standardized and communicated in a logical and meaningful manner.³ A coherent order for the presentation of this information is presented in [Box 55.3](#).

Anesthesia Admission Report

General Information

- Patient name
- Patient age
- Surgical procedure
- Name of surgeon and anesthesia provider(s)
- Type of procedure

Patient History

- Acute (indication for surgery)
- Chronic (medical history, medication use, allergies, obstructive sleep apnea)

Intraoperative Management

- Anesthetic agents, including dose and technique
- Time of last opioid administration
- Administration of reversal agents
- Intraoperative medications (antibiotics, antiemetics, vasopressors)
- Estimated blood loss
- Fluid and blood administration
- Urine output

Intraoperative Course

- Unexpected response to anesthetic administration
- Unexpected surgical course
- Laboratory results (arterial blood gas, glucose, hemoglobin)

Postanesthesia Care Unit Plan

- Potential and expected problems
- Pain and comfort management interventions
- Other suggested interventions
- Limits of acceptability of laboratory tests
- Discharge criteria

- Responsible contact person

The importance of the anesthesia report is reflected in the American Association of Nurse Anesthetists (AANA) guideline from the *AANA Scope and Standards for Nurse Anesthesia Practice*:

“Standard VII: “Evaluate the patient's status and determine when it is safe to transfer the responsibility of care. Accurately report the patient's condition, including all essential information, and transfer the responsibility of care to another qualified health care provider in a manner that assures continuity of care and patient safety.”

AANA goes further to state that “the anesthesia professional is also responsible for assuring that the patient is not released into a setting that is unable to safely provide for that patient's postanesthesia care needs.”⁴ The American Society of Anesthesiologists (ASA) points to the importance of a verbal report to the responsible PACU nurse but also goes on to state, “The member of the Anesthesia Care Team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient”.⁵ Anesthesia personnel must assist in management of the patient until PACU providers secure admission vital signs and attach appropriate monitors. To optimize safety, the anesthesia provider cannot shift responsibility to PACU personnel until the patient's airway status, ventilation, and hemodynamics are appropriate.^{4,5}

Initial Postanesthesia Care Unit Assessment

Accurate and vigilant nursing assessment is vital because of how quickly a patient's condition can change in the PACU. Many postanesthesia assessment approaches (e.g., head to toe, major body systems assessments, and scoring systems) are currently used in PACUs, and each approach has its benefits and limitations. The assessment approach should accomplish the following:

- Determine the patient's physiologic status at the time of admission to the PACU.
- Allow the periodic reexamination of the patient so that physiologic trends become obvious.
- Establish the patient's baseline level so that the effect of previous medical conditions can be assessed and predicted as they affect current physiology.
- Assess the ongoing status of the surgical site and its effect on any preexisting conditions and recovery.
- Assess the patient's recovery from anesthesia and note residual effects.
- Prevent or immediately treat complications that occur.
- Provide a safe environment for the patient who is impaired either physically, mentally, or emotionally.
- Allow the compilation and trend analysis of patient-specific characteristics that relate to discharge or transfer criteria.^{1,6}

Aldrete Scoring System

The most commonly used assessment approach is a combination of a scoring system and a major body systems assessment. The Aldrete postanesthetic scoring system⁷ is the most widely used scoring system in PACUs, although its predictive value in determining recovery from anesthesia has not been studied prospectively (Box 55.4). No consensus exists to date regarding the variables any scoring system instrument should contain. In a systematic review

conducted to investigate assessment criteria of adult patients, the key recommendations were that pain, conscious state, blood pressure, and nausea/vomiting should be assessed before discharge.⁸ The use of urinary output and oral fluid intake as criteria needs further research. The American Society of PeriAnesthesia Nurses (ASPAN) does not require a scoring system nor recommend any one scoring system while recognizing that a postanesthesia scoring system may be a component of the facility's discharge criteria.²

Postanesthesia Recovery Score

Activity

- 0 = Unable to lift head or move extremities voluntarily or on command.
- 1 = Moves two extremities voluntarily or on command and can lift head.
- 2 = Able to move four extremities voluntarily or on command. Can lift head and has controlled movement. *Exceptions:* Patients with a prolonged block such as with bupivacaine (Marcaine), who may not move an affected extremity for as long as 18 hours; patients who were immobile preoperatively.

Respiration

- 0 = Apneic; condition necessitates ventilator or assisted respiration.
- 1 = Labored or limited respirations. Breathes by self but has shallow, slow respirations. May have an oral airway.
- 2 = Can take a deep breath and cough well; has normal respiratory rate and depth.

Circulation

- 0 = Has abnormally high or low blood pressure; blood pressure within 50 mm Hg of preanesthetic level

1 = Blood pressure within 20–50 mm Hg of preanesthetic level

2 = Stable blood pressure and pulse. Blood pressure 20 mm Hg of preanesthetic level (minimum 90 mm Hg systolic). *Exception:* Patient may be released by anesthesia provider after drug therapy.

Neurologic Status

0 = Not responding or responding only to painful stimuli.

1 = Responds to verbal stimuli but drifts to sleep easily.

2 = Awake and alert; oriented to time, place, and person.

O₂ Saturation

0 = O₂ saturation less than 90%, even with O₂ supplement.

1 = Needs O₂ inhalation to maintain O₂ saturation greater than 90%.

2 = Able to maintain O₂ saturation greater than 92% on room air.

Modified from Ead H. From Aldrete to PADSS: reviewing discharge criteria after ambulatory surgery. *J Perianesth Nurs.* 2006;21:259–267.

Major Body Systems

The major body systems assessment systematically evaluates the body systems that are most affected by anesthesia and the surgical procedure. After the patient is admitted to the PACU, an assessment of cardiorespiratory stability and a more in-depth cardiac assessment are performed. Respiratory assessment comprises rate, depth of ventilation, auscultation of breath sounds, oxygen saturation level, and end-tidal carbon dioxide, if appropriate. Type of oxygen delivery system and presence of any artificial airway should be noted.⁹ The heart is auscultated, and the quality of heart sounds, the presence of any adventitious sounds, and any irregularities in rate or rhythm are noted. Unexpected findings are compared with preoperative data. Arterial pulses are

evaluated for strength and equality. An ECG strip is obtained on admission to the PACU and compared with the preoperative ECG. In addition, body temperature, as well as skin color and condition are assessed and the findings documented.

After respiratory and cardiac assessments are completed, the neurologic system is evaluated, with a focus on the level of consciousness, orientation, sensory and motor function, and pupil size, equality, and reactivity. The patient is assessed on ability to follow commands and move extremities purposefully and equally.⁶

The renal system assessment focuses on fluid intake and output (e.g., blood, crystalloids, and colloids), as well as on volume and electrolyte status. The anesthesia provider relates intraoperative fluid totals in the verbal report, and the PACU nurse notes and documents all intravenous (IV) lines, irrigation solutions, and infusions that enter the patient. All output devices, including drains, catheters, and tubes, are inspected, and the color and consistency of any drainage are noted.

The surgical site is examined. The amount and color of any drainage on the bandage are noted. The patient is also assessed for pain or discomfort, such as nausea, with appropriate interventions administered.

All data obtained in the admission assessment should be documented in a manner that facilitates data collection, trend analysis, and retrieval. Recommended criteria for the initial assessment of a patient in the PACU are included in [Box 55.5](#).

Criteria for Initial Assessment: Phase I Postanesthesia Care Unit

Initial assessment and documentation include:

1. Integration of data received at transfer of care
 - a. Pertinent medical history
 - b. Surgical/procedural status (reason for surgery, procedure performed)

- c. Anesthesia/sedation technique and agents
 - d. Length of time anesthesia/sedation administered
 - e. Pain and comfort interventions and plan
 - f. Medications administered
 - g. Estimated fluid deficit/blood loss and replacement
 - h. Complications during course of anesthesia and response to treatment
 - i. Emotional status preprocedure
2. Vital signs
- a. Respiratory status—airway patent, breath sounds, type of artificial airway, mechanical ventilatory settings, oxygen saturation, end-tidal CO₂ (if indicated)
 - b. Blood pressure—non-invasive or arterial line
 - c. Pulse—apical, peripheral
 - d. Cardiac monitor, rhythm documented
 - e. Temperature/route
 - f. Hemodynamic pressure readings: central venous,

pulmonary artery, and wedge; intracranial pressure as indicated

g. Pregnancy related assessments (e.g. fetal heart tones)

3. Pain and comfort level

4. Sedation level

5. Neurologic function to include level of consciousness; pupillary response as indicated

6. Sensory and motor function as appropriate

7. Position of patient

8. Condition and color of skin

9. Patient safety needs (e.g. medication reconciliation, fall risk assessment)

. Neurovascular: peripheral pulses and sensation of extremity(ies) as applicable

. Condition of dressings and visible incisions

. Type and patency of drainage tubes, catheters, and receptacles; effectively secured

. Amount and type of drainage

. Fluid intake (e.g., intravenous, oral, feeding tube)

. Intravenous assessment: location of lines,

condition of IV site, type of solution infusing

- . Procedure-specific assessment (i.e., firmness of abdomen)

- . Nursing actions with outcome

- . Inclusion of family in physical, spiritual, emotional care as indicated

- . Postanesthesia scoring system if used (not required—facility developed discharge criteria that may include a scoring system as a component of the assessment.)

Modified from American Society of Perianesthesia Nurses (ASPAN). *Perianesthesia Nursing Standards and Practice Recommendations 2015–2017*. Cherry Hill, NJ. ASPAN; 2014.

Ongoing Assessment

Perioperative and postanesthetic management of the patient includes ongoing assessment and monitoring of the following^{2,10}:

- Respiratory function (e.g., obstruction, hypoxemia, hypercarbia)
- Cardiovascular function (e.g., hypotension, hypertension, dysrhythmias)
- Neuromuscular function (e.g., inadequate reversal of neuromuscular blockade)
- Mental status (e.g., delayed awakening, emergence delirium)
- Pain
- Temperature (e.g., hypothermia)
- Nausea and vomiting
- Fluids
- Urine output and voiding

Respiratory Function

The most common cause of airway obstruction in the immediate postoperative phase is the loss of pharyngeal muscle tone in a sedated or obtunded patient. The loss of pharyngeal muscle tone immediately after surgery is mainly due to the lasting effects of the anesthetic agents, neuromuscular blocking drugs, and opioids.¹¹

Obstruction

In postanesthesia patients, the tongue causes most upper airway obstructions. Obstruction occurs when the tongue falls back into a position that occludes the pharynx and blocks the flow of air into and out of the lungs.

Signs and symptoms of an upper airway obstruction include snoring and activation of accessory muscles of ventilation. Intercostal and suprasternal retractions may be noted. However, patients are usually somnolent and may be difficult to arouse. Risk factors for an upper airway obstruction include anatomy (e.g., obesity, large neck, or short neck), poor muscle tone (secondary to

opioids, sedation, residual neuromuscular blockade, or neuromuscular disease), or swelling (secondary to surgical manipulation, edema, or anaphylaxis).

The goal for the relief of a tongue obstruction is a patent airway. Treatment consists of a series of interventions. The initial intervention may be as simple as stimulating the patient to take deep breaths, or it may require repositioning of the airway via a jaw thrust or a chin lift. Placement of an oral or a nasal airway may be required. The nasal airway is tolerated much better by patients emerging from general anesthesia, and, unlike the oral airway, it is unlikely to cause gagging or vomiting. If the obstruction remains unrelieved, reintubation may be required, with or without adjunctive mechanical ventilation.

Laryngeal obstruction may occlude the airway as a result of partial or complete spasm of the intrinsic or extrinsic muscles of the larynx. Laryngospasm may be the result of a reflex closure of the glottis (intrinsic muscles) or the larynx (extrinsic muscles). Glottic closure usually manifests as intermittent obstruction; laryngeal closure manifests as complete obstruction. Airway irritation that predisposes a patient to laryngospasm may be the result of laryngoscopy, secretions, vomitus, blood, artificial airway placement, coughing, bronchospasm, or frequent suctioning. Symptoms that suggest laryngospasm include agitation, decreased oxygen saturation, absent breath sounds, and acute respiratory distress. Incomplete obstruction may manifest as a crowing sound or stridor.

Treatment of laryngospasm must be immediate. A jaw thrust maneuver in conjunction with continuous positive airway pressure (CPAP) (up to 40 cm water [H₂O]) is often sufficient to disrupt the laryngospasm. If this intervention is ineffective, a subparalytic dose of IV succinylcholine (0.15–0.5 mg/kg) or 4 mg/kg intramuscularly [IM]) may be given by the anesthesia provider.¹¹ If succinylcholine is administered, assisted ventilation for 5 to 10 minutes is required, even if the obstruction has been relieved. Reintubation is undesirable and should be used only if severe airway edema is present or if the obstruction persists despite treatment interventions. During the crisis, the anesthesia provider should consider medication for sedation, such as midazolam, to alleviate

the possibility of an awake or partially awake patient.

Steroids and topical or IV lidocaine have been included in the prevention and management of airway irritability. Other preventive strategies include obtaining meticulous hemostasis during surgery, suctioning the oropharynx before extubation to clear any retained blood or secretions, and extubating the patient when they are either in a very deep plane of anesthesia or the awake state. When obstruction occurs, rapid intervention is imperative.¹¹

Obstructive Sleep Apnea.

Obstructive sleep apnea (OSA) is associated with diminished muscle tone in the airway which leads to airway obstruction during sleep.¹² There is a high prevalence of diagnosed and undiagnosed OSA with an estimated 12 to 18 million adults undiagnosed.¹³ OSA is associated with an increased incidence of complications including difficult intubation, length of stay in the PACU, unplanned admission, and other respiratory and cardiovascular complications.¹³ The ASA and the ASPAN have practice recommendations/guidelines for care of the patient during the perioperative period.^{12,14} **Box 55.6** includes an overview of the ASPAN practice recommendations. Use of standardized screening improves preoperative diagnosis of OSA. The screening instrument with the highest validity and ease of use is the STOP-Bang clinical scale. (<http://www.stopbang.ca>).¹² Patient management includes a well-planned anesthetic including regional anesthesia with minimal sedation when appropriate. Postoperative management includes analgesia, positioning, oxygenation, and monitoring concerns.¹⁵ When a patient has a known diagnosis of OSA, plans should be made preoperatively to provide CPAP in the immediate postoperative period, and those patients should be asked to bring their CPAP machines with them on the day of surgery.¹¹ Each institution should have a multidisciplinary guideline that addresses the needs of this patient population.

ASPAN's Practice Recommendation 10 OSA

1. Assess and screen patients for risk factors/comorbidities associated with OSA.

2. Assess and screen undiagnosed patients for signs and symptoms of OSA.
3. Incorporate the use of a standardized screening tool to identify patients at risk for OSA.
4. Initiate postanesthesia management of the patients with diagnosed or suspected OSA.
5. Plan for patient discharge with diagnosed or suspected OSA.
6. Provide discharge education to patients with suspected/diagnosed OSA.

ASPAN, American Society of PeriAnesthesia Nurses; *OSA*, obstructive sleep apnea.

Modified from American Society of PeriAnesthesia Nurses. Practice Recommendation 10 – Obstructive Sleep Apnea in the Adult Patient. From *ASPAN: 2015–2017 Perianesthesia Nursing Standards, Practice Recommendations and Interpretive Statements*. 2014. Cherry Hill, NJ: ASPAN.

Hypoxemia

Hypoxemia, defined as low arterial oxygen pressure (PaO_2) (usually less than 60 mm Hg), is characterized by nonspecific signs and symptoms ranging from agitation to somnolence, hypertension to hypotension, and tachycardia to bradycardia. Pulse oximetry may confirm low oxygen saturation (less than 90%); arterial blood gas analysis may confirm a PaO_2 of less than 60 mm Hg. Hypoxemia, if untreated, can result in organ ischemia.

Hypoxemia can be the result of a delivered airway obstruction, low concentration of oxygen, hypoventilation, impaired alveolar-capillary diffusion, ventilation-perfusion mismatches, or increased intrapulmonary shunting.^{11,16} The most common causes of hypoxemia in the PACU include atelectasis, pulmonary edema, pulmonary embolism (PE), aspiration, bronchospasm, and hypoventilation. A brief explanation of these pathologic states follows.

Clinical issues with pulse oximetry have to be considered when

used to determine oxygen saturation levels. The relationship between percent of hemoglobin saturated with oxygen (SaO_2) and the partial pressure of oxygen in the blood (PaO_2) is symbolized by the oxyhemoglobin dissociation curve. Shifts in the curve are caused by abnormal values of pH, temperature, partial pressure of carbon dioxide, and 2,3-diphosphoglycerate. The patient's level of hemoglobin must also be considered, because if too low, even fully saturated hemoglobin is not adequate to meet tissue needs.¹

Atelectasis

Atelectasis is the most common cause of postoperative arterial hypoxemia and can lead to an increase in right-to-left shunt. Atelectasis may be the result of bronchial obstruction caused by secretions or decreased lung volumes. Hypotension and low cardiac output conditions can also contribute to the development of decreased perfusion and atelectasis. Treatment includes the use of humidified oxygen, coughing, deep breathing, postural drainage, and increased mobility. Incentive spirometry and intermittent positive-pressure ventilation also may be used.¹⁷

Pulmonary Edema

Pulmonary edema, which is caused by fluid accumulation within the alveoli, may be the result of an increase in hydrostatic pressure, a decrease in interstitial pressure, or an increase in capillary permeability.

An increase in hydrostatic pressure is usually the result of fluid overload, left ventricular failure (especially in the presence of systolic hypertension), mitral valve dysfunction, or ischemic heart disease. Increased capillary permeability may be the result of sepsis, aspiration, transfusion reaction, trauma, anaphylaxis, shock, or disseminated intravascular coagulation and is frequently referred to as *adult respiratory distress syndrome*.¹⁶

A decrease in interstitial pressure is often seen after prolonged airway obstruction, such as laryngospasm. Acute pulmonary edema that occurs shortly after relief of severe upper airway obstruction is called *postobstruction* or *negative-pressure pulmonary edema* or *noncardiogenic pulmonary edema*. The airway obstruction

causes extreme negative intrapleural pressure that increases the pulmonary transvascular hydrostatic pressure gradient. The rapid movement of fluid from pulmonary vasculature to interstitium exceeds the clearing capacity of the pulmonary lymphatic system, and the alveoli become flooded.¹⁸ Other causes of noncardiogenic pulmonary edema are bolus dosing with naloxone, incomplete reversal of neuromuscular blockade, or a significant period of hypoxia.¹⁹

Pulmonary edema is characterized by hypoxemia, cough, frothy sputum, rales on auscultation, decreased lung compliance, and pulmonary infiltrates seen on chest radiography. Treatment of pulmonary edema is directed toward identification of the cause and reduction of hydrostatic pressure within the lungs. Oxygenation must be maintained (particularly in the presence of profound hypoxemia) via oxygen mask or CPAP with mask, or if necessary, intubation, mechanical ventilation, and the addition of positive end-expiratory pressure (PEEP) ventilation. Diuretics (most commonly furosemide) and fluid restriction are a part of treatment. Dialysis may be used if the fluid retention results from renal failure. Preload and/or afterload reduction, which is achieved through the use of nitroglycerin or sodium nitroprusside, may be used to decrease myocardial work.¹⁶ Patients with noncardiogenic pulmonary edema usually recover quickly after the acute phase and have no permanent sequelae.¹⁹

Pulmonary Embolism

PE is a leading cause of morbidity and mortality, accounting for 60,000 to 100,000 deaths annually in the United States. Most cases of PE are not fatal; however, sudden death is the first symptom in approximately 25% of people who have a PE.²⁰ Patients are considered to be at risk for PE if three conditions, known as *Virchow's triad*, exist: venous stasis, hypercoagulability, and abnormalities of the blood vessel wall. These conditions are accentuated in the presence of obesity, varicose veins, immobility, malignancy, congestive heart failure, increased age, and after pelvic or long-bone surgery or injury. However, 90% of all pulmonary emboli arise from deep veins in the legs.²¹ Thrombosis in postoperative patients seems to be related to surgical tissue trauma

and liberation of tissue factor that leads to thrombin formation.

A PE should be suspected in a patient who complains of or whose presenting signs include acute-onset tachypnea, dyspnea, and tachycardia, particularly when the patient is already receiving oxygen therapy. Signs and symptoms also may include dyspnea, chest pain, hypotension, hemoptysis, dysrhythmias, and congestive heart failure. Although the clinical symptomatology may be suggestive of a PE, confirmation requires pulmonary angiography. Multidetector computed tomography (CT) pulmonary angiography has largely replaced ventilation-perfusion lung scanning for PE diagnosis and can provide rapid results.²¹ Pulmonary angiography is infrequently performed because of its high risk and associated mortality. See [Table 55.1](#) for pretest likelihood of PE.

TABLE 55.1

Wells' Clinical Prediction Rule for Likelihood of Pulmonary Embolism

Variable	Points

DVT, Deep vein thrombosis; *PE*, pulmonary embolism; *VTE*, venous thromboembolism.

From Weitz JI. Pulmonary Embolism. In Goldman L, Schafer AI. Goldman-Cecil Medicine. 25th ed. Philadelphia: Elsevier; 2015:620–627.

Treatment of a PE is directed toward the correction of hypoxemia and support of hemodynamic stability. Preventive measures may include the use of antiembolic stockings or sequential compression devices. Subcutaneous heparin therapy also may be initiated. Once the occurrence of a PE has been confirmed, IV heparin therapy is

started for the prevention of further clot formation. The goal of heparin therapy is an activated partial thromboplastin time that is 1.5 to 2 times the control value. Subcutaneous low molecular weight heparin or fondaparinux or oral rivaroxaban can be used for intermediate- or low-risk PE patients and do not require coagulation monitoring. However, heparin is the drug of choice in the case of renal disease.²¹

Aspiration

Aspiration is a potentially serious airway emergency that can compromise patient safety and stability on the induction of, or the emergence from, anesthesia. Aspiration may occur in the OR, in the PACU, or at any time during transfer. Patients may aspirate foreign matter (e.g., a tooth), food, blood, or gastric contents. Each type of material is associated with a characteristic clinical presentation.

Foreign matter aspiration may result in cough, airway obstruction, atelectasis, bronchospasm, and pneumonia. A profound reflex sympathetic nervous system (SNS) response might also cause hypertension, tachycardia, and dysrhythmias. In the absence of complete upper airway obstruction, complications are often localized and treated with supportive care once the foreign matter has been expelled or removed by bronchoscopy.¹⁵

Aspiration of blood may result from trauma or surgical manipulation and may also cause minor airway obstruction that is rapidly cleared by cough, resorption, and phagocytosis. Massive blood aspiration interferes with gas exchange through mechanical blockage of airways and leads to chronic fibrinous changes in air spaces or pulmonary hemosiderosis from iron accumulation in phagocytic cells. Aspiration of blood may result in infection, particularly if particles of soft tissue are aspirated along with the blood. Treatment involves correction of hypoxemia, maintenance of airway patency, and initiation of antibiotic therapy, if indicated.¹⁹

Aspiration of gastric contents is the most severe form of aspiration and may result in a chemical pneumonitis. Patients have diffuse bronchospasm (secondary to reflex airway closure), hypoxemia (compromised alveolar-capillary membrane), atelectasis (loss of surfactant), interstitial edema (loss of capillary integrity), hemorrhage, and adult respiratory distress syndrome. Gastric

aspiration also may cause laryngospasm, infection, and pulmonary edema.

For this reason, the prevention of gastric aspiration, rather than its treatment, is the goal. Patients who are at risk for gastric aspiration (e.g., obese or pregnant patients or those with a history of hiatal hernia, peptic ulcer, or trauma) may be given histamine-2 (H₂) blockers, gastrokinetic agents, nonparticulate antacids, or anticholinergics before anesthesia induction. Prophylactic medications are not recommended for those patients who are not at risk.²² Rapid-sequence induction is likely used. Intraoperatively, a nasogastric tube may be inserted and is usually then removed to decrease gastric volume and decompress the stomach. Postoperatively the patient should be left intubated until airway reflexes return.

Treatment of gastric aspiration is directed toward correction of hypoxemia and maintenance of hemodynamic stability. Antibiotics are indicated only if signs of infection (e.g., fever, leukocytosis, positive culture results) are present. No beneficial effect of corticosteroids has been determined. Administration of corticosteroids produce no positive effects, but may contribute to bacterial superinfections.¹⁵

If aspiration causes hypoxemia, increased airway resistance, atelectasis, or pulmonary edema, institution of support with supplemental oxygen, PEEP, or CPAP and mechanical ventilation is often necessary. Pulmonary edema is usually secondary to increased capillary permeability, so diuretics should not be used to decrease intravascular volume. Bacterial infection does not always occur, so prophylactic antibiotics might merely promote colonization by resistant organisms. If evidence of secondary bacterial infections appears, specific antibiotic therapy is instituted, based on sputum samples obtained for Gram stain and culture or on prevailing colonization experience within the institution.^{15,19}

Bronchospasm

Bronchospasm results from an increase in bronchial smooth muscle tone, with resultant closure of small airways. As a result of the strong increase in inspiratory force against these closed airways,

airway edema develops, causing secretions to build up in the airway. Clinically, the patient demonstrates wheezing, dyspnea, use of accessory muscles, and tachypnea. Airway resistance is increased, and increased peak inspiratory pressures are noted if the patient is receiving mechanical ventilation.

Bronchospasm may result from aspiration, pharyngeal or tracheal suctioning, endotracheal intubation, histamine release secondary to medications, or an allergic response, and it may be seen in greater frequency in patients with a history of asthma or chronic obstructive pulmonary disease.

Treatment of bronchospasm requires confirmation and removal of the precipitating cause. Pharmacotherapy is instituted, with the goals of decreasing airway irritability and promoting bronchodilation. Medications used in the management of bronchospasm include β_2 -agonists such as albuterol (Proventil, Ventolin), the long-acting agent salmeterol (Serevent) and, if the condition is life threatening, IV epinephrine. Anticholinergics such as atropine sulfate, glycopyrrolate and ipratropium have been given via nebulization to decrease secretions. Both IV and inhaled lidocaine attenuate histamine-induced bronchospasm; however, inhaled lidocaine works at a lower serum level than IV lidocaine. Steroids have been used if the underlying cause is an inflammatory disease such as asthma.^{19,23} Bui, et al.²⁴ describe, in a case study, the potential benefit of sevoflurane as rescue therapy for severe, refractory bronchospasm.

Hypoventilation

Hypoventilation is a common, easily recognizable complication in the PACU. It is manifested clinically by a decrease in respiratory rate that results in an increase in PaCO₂ secondary to a decrease in alveolar ventilation. This may occur because of a decrease in central respiratory drive, poor respiratory muscle function, or a combination of both.¹¹

Depression of central respiratory drive can occur with both IV and inhalation anesthetics. Central respiratory depression is most profound on admission to the PACU, although the time and route of anesthetic administration may suggest otherwise. For example,

an IV dose of fentanyl given just before the patient emerges from anesthesia may not peak until later in the PACU. An intramuscular dose of an opioid takes substantially longer to peak than does an IV dose.¹⁵

Patients also may demonstrate a secondary stage of respiratory depression once certain stimuli are removed. For example, a patient may be admitted awake and breathing to the PACU with an endotracheal tube in place. After extubation, because of the loss of stimulation from the endotracheal tube, the patient may become hypercarbic secondary to residual opioid effects and hypoventilation. Verbal and tactile stimulation, deep breaths, and repositioning the patient may increase ventilatory function and decrease carbon dioxide. Pulse oximetry monitors oxygenation, but does not reflect the adequacy of ventilation.¹¹ Capnography measuring end tidal CO₂ is of use in patients at risk.^{1,19}

Poor respiratory muscle function can result from many conditions. Some of the most common situations are inadequate reversal of neuromuscular blocking agents, surgery involving the upper abdomen, positioning, obesity, OSA, and diseases involving the neuromuscular system.

Inadequate reversal of neuromuscular blocking agents can result in hypoventilation secondary to respiratory muscle weakness. Factors that can adversely affect neuromuscular blockade and reversal include certain medications, hypokalemia, hypermagnesemia, hypothermia, and acidosis²⁵ (see [Chapter 12](#)).

Medications that have been associated with prolongation of blockade include the aminoglycoside antibiotics (e.g., gentamicin, clindamycin, and neomycin), as well as magnesium and lithium. Hypermagnesemia and hypothermia may potentiate neuromuscular blockade. Hypokalemia and respiratory acidosis inhibit reversal.²⁵

Upper abdominal surgery also can affect respiratory muscle function. Hypoventilation occurs because of a reduced vital capacity secondary to poor diaphragmatic function. A reduction in vital capacity of up to 60% has been noted on the first postoperative day.¹¹ Obesity, especially when combined with upper abdominal surgery, further contributes to hypoventilation because of the increased intraabdominal pressure in obese patients.

Diseases of the neuromuscular system can also affect ventilation. Patients with muscular dystrophy, myasthenia gravis, Eaton-Lambert syndrome, Guillain-Barré syndrome, or other muscle diseases can exhibit postoperative muscle weakness (see [Table 12.9](#)). Patients with severe scoliosis also exhibit poor respiratory muscle function. It is often in the best interests of patients with these disorders that they remain intubated in the PACU until complete return of function occurs, and any residual anesthetic effects are absent.

Cardiovascular Function

Hypotension

Classically, *hypotension* has been defined as a fall in arterial blood pressure (BP) of more than 20% below baseline, or an absolute value of systolic BP (SBP) below 90 mm Hg, or of mean arterial pressure (MAP) below 60 mm Hg.²⁶ However, the clinical signs of hypoperfusion, rather than numeric values, should be the indicators of compromise. Because the autonomic nervous system preferentially maintains blood flow to the brain, heart, and kidneys, signs of hypoperfusion to these organs (including disorientation, nausea, loss of consciousness, chest pain, oliguria, and anuria) reflect the failure of physiologic compensation. Hypoxia, which results from hypoperfusion, may cause lactic acidosis. Intervention must be implemented in a timely fashion so that cerebral ischemia, cerebrovascular accident (CVA), myocardial infarction or ischemia, renal ischemia, bowel infarction, and spinal cord damage do not develop.²⁷

Hypotension in the PACU is most commonly caused by hypovolemia secondary to inadequate replacement of intraoperative fluid and blood loss (decreased preload) ([Fig. 55.1](#)). Hypovolemia may be due to volume depletion as a result of inadequate fluid replacement during surgery, blood loss during surgery, or ongoing blood loss postoperatively.²⁸ As a result, initial treatment should focus on restoring circulating volume. The patient should be assessed for active bleeding and a 300 to 500 mL fluid bolus of physiologic saline or lactated Ringer's solution should be given. If no response is noted, myocardial dysfunction should be

considered the cause of hypotension.

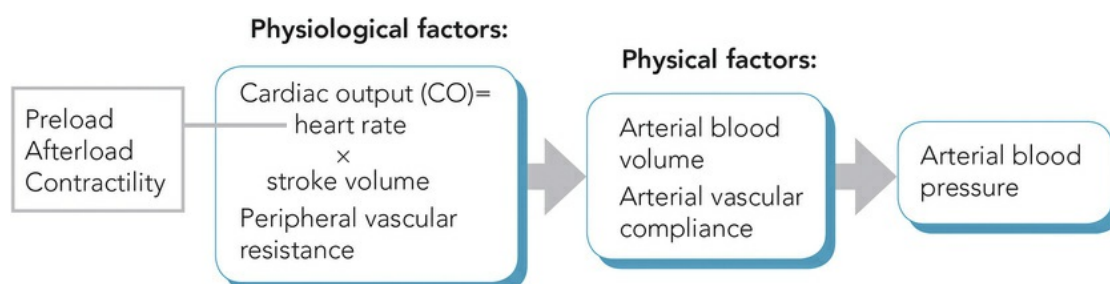

FIGURE 55.1 Both physiological and physical factors affect arterial blood pressure. Cardiac output is the result of heart rate \times stroke volume. Heart rate is affected by preload, afterload, and contractility. (In Seifert PC, Wadlund DL. Crisis management of hypotension in the OR. *AORN J.* 2015;102:67. From Pappano AJ, Wier WG. *Cardiovascular physiology: Mosby monograph series.* 10th. St. Louis: Elsevier; 2013:236.)

Cardiogenic hypotension (intrinsic pump failure), as is the case with myocardial infarction, tamponade, or embolism, results in an acute fall in ventricular emptying and cardiac output. Secondary cardiac dysfunction occurs as a result of the negative chronotropic and negative inotropic effects of medications. The surgical procedure and the patient's preoperative cardiac risk and medical condition are important indicators in a differential diagnosis.¹¹

Decreased afterload or low systemic vascular resistance (SVR) also can contribute to hypotension. Numerous anesthetic agents cause histamine release with subsequent vasodilation (e.g., morphine, atracurium), whereas others cause vasodilation by directly relaxing arterial smooth muscle (e.g., volatile inhalation anesthetics, local anesthetics used for producing spinal anesthesia). Sensitivity to vasodilators such as hydralazine, sodium nitroprusside, and nitroglycerin also can produce profound hypotension. See [Table 55.2](#) for medications associated with a hypotensive crisis. Sepsis may be another cause of low SVR.

TABLE 55.2

Medications Associated With a Hypotensive Crisis

Medication	Mechanism of Action

Anesthetic Agents ¹	May cause a drop in blood pressure as a result of the release of histamine during an anaphylactic reaction to anesthetic medications, which occurs most commonly with neuromuscular blocking agents
Antibiotics ²	Cause an allergic reaction as a result of a release of histamine that is characterized by flushing and hypotension; antibiotics are the most common class of medications to cause allergic reactions
Antihypertensive Agents ³	May cause refractory hypotension in the hypertensive patient who is taking angiotensin-converting enzyme inhibitors
Epinephrine ³	May cause vasodilation and subsequent hypotension at low doses because epinephrine stimulates the β -adrenergic receptors
Hypnotics ²	Cause hypotension through vasodilation
Induction Agent – Propofol ⁴	May cause an allergic reaction in patients allergic to eggs and soybeans
Inhalation Agent – Halothane ¹	Depresses myocardial contractility, thereby lowering cardiac output
Inhalation Agent – Isoflurane ²	Reduces preload and afterload through vasodilation
Intravenous Contrast Agents ⁵	May cause a hypotensive event in 5%–8% of patients who experience IV contrast–related reactions, which is a result of anaphylaxis or release of vasoactive substances
Latex Products (allergic reaction) ¹	Cause a delayed anaphylactic reaction when an allergic patient is exposed to latex products; hypotension and vascular collapse occur approximately 40 min after exposure
Local Anesthetics ³	Cause a toxic central reaction if systemic or inadvertent intravascular injection occurs
Methyl Methacrylate ⁶	May cause hypotensive episode from 30–60 sec up to 10 min after placement of the cement as a result of: <ul style="list-style-type: none"> • tissue damage secondary to the exothermic reaction that occurs within the cement; • release of vasoactive substances when the cement is hydrolyzed to methacrylate acid; • embolization as the bone is reamed; or • vasodilation caused by absorption of the volatile monomer
Opioids ²	Cause hypotension as a result of decreasing sympathetic tone, which then causes bradycardia
Neuromuscular Blocking Agents ²	Cause the release of histamine with resultant hypotension after rapid injection
Regional Anesthetics ⁷	Cause vasodilation with subsequent hypotension, which occurs below the level of the regional block secondary to the blockade of sympathetic conduction fibers

From Seifert PC, Wadlund DL. Crisis management of hypotension in the OR. *AORN J*. 2015;102:67.

Dysrhythmias that interfere with cardiac conduction and subsequently compromise cardiac output also can produce hypotension. Tachydysrhythmias prevent optimal ventricular filling and emptying. Conduction blocks compromise myocardial effectiveness, resulting in a lowered cardiac output and hypotension. See [Box 55.7](#) for a differential diagnosis of [Hypotension](#) in the postoperative patient.

Differential Diagnosis of Hypotension in the Postanesthesia Care Unit

Intravascular Volume Depletion

- Persistent fluid losses
- Ongoing third space translocation of fluid
- Bowel preparation
- Gastrointestinal losses
- Surgical bleeding

Increased Capillary Permeability

- Sepsis
- Burns
- Transfusion-related acute lung injury

Decreased Cardiac Output

- Myocardial ischemia or infarction
- Cardiomyopathy
- Valvular disease
- Pericardial disease
- Cardiac tamponade
- Cardiac dysrhythmias
- Pulmonary embolus
- Tension pneumothorax
- Drug induced (β -blockers, calcium channel blockers)

Decreased Vascular Tone

- Sepsis
- Allergic reactions (anaphylactic, anaphylactoid)
- Spinal shock (cord injury, iatrogenic high spinal)
- Adrenal insufficiency

From Nicholau TK. The postanesthesia care unit. In Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2015:2935.

Intervention should always include supplemental oxygen therapy and elevation of the legs while the cause of the hypotension is being investigated.¹⁹ Volume status should be evaluated, and preoperative and intraoperative fluid administration should be considered. Hypotension caused by artifact of the measurement system also should be considered (for example, a blood pressure cuff that is too large or too small or an inappropriate transducer height).²⁶ The presence of hypotension secondary to myocardial dysfunction suggests the need for coronary vasodilators, inotropic therapy, and afterload reduction (e.g., through nitroglycerin

therapy, dobutamine therapy, or both). Secondary myocardial dysfunction may require that administration of the causative medications be discontinued. Vasodilation resulting in lower SVR and symptomatic hypoperfusion can be treated with vasoconstrictive agents, either by IV bolus (ephedrine [5 to 50 mg], epinephrine [10 to 100 mcg], phenylephrine [50 to 200 mcg], or vasopressin [1 to 4 units]) or by infusion (dopamine or epinephrine).²⁶

Hypertension

Hypertension, defined as a rise in arterial BP of more than 20% above baseline or an absolute value of arterial BP above age-corrected limits,²⁶ is a common finding in the PACU and can be caused by stimulation of the SNS as well as pain, respiratory compromise, visceral distention, and significant increases in plasma catecholamine levels that produce vasoconstriction (Box 55.8). Pain remains the leading cause of hypertension and tachycardia in the PACU and results in stimulation of the somatic afferent nerves, producing a pressor response known as the *somatosympathetic reflex*.²⁷ The use of analgesics attenuates the sympathetic response, thereby normalizing blood pressure.

Factors Leading to Postoperative Hypertension

- Preoperative hypertension
- Arterial hypoxemia
- Hypervolemia
- Emergence excitement
- Shivering
- Drug rebound
- Increased intracranial pressure

- Increased sympathetic nervous system activity
- Hypercapnia
- Pain
- Agitation
- Bowel distention
- Urinary retention

From Nicholau TK. The postanesthesia care unit. In Miller R, et al, eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015:2935.

Hypoxemia and hypercarbia cause direct stimulation of the vasomotor area of the medulla, resulting in increased vasomotor tone, increased arteriolar constriction, and increased blood pressure.²⁷ Correction of the respiratory compromise should result in normalization of blood pressure.

Distention of the bladder, bowel, or stomach causes stimulation of afferent fibers of the SNS, producing an increase in plasma catecholamine levels. Catheterization of the bladder and decompression of the bowel or stomach remove the offending stimulus.

Hypertension also may develop as a sequela of hypothermia. Increased catecholamine secretion is an important endocrine response to cold.²⁷ As cooling occurs, blood vessels become more sensitive to catecholamines, resulting in arteriolar and venous constriction. Rewarming reverses the process. As vasodilation occurs, reperfusion of the extremities and skin decreases systemic elevations in pressure.

Preexisting hypertension exists in many of the patients who develop hypertension in the PACU. Thirty percent of the general population in the PACU have preexisting hypertension. The degree of elevation in pressure is greater if preoperative antihypertensive medications are withdrawn suddenly. Preoperatively, all antihypertensive drugs should be continued, except angiotensin converting enzyme (ACE) inhibitors or angiotensin II antagonists, for which no clear consensus exists.²⁹ Hypertension also may be

seen secondary to revascularization and baroreceptor stimulation after vascular or cardiac surgery, including carotid endarterectomy. Pharmacologic intervention is required for the protection of graft sites and the prevention of hemorrhage. Sodium nitroprusside and nitroglycerin are agents of choice for vasodilation.

A significant number of patients, especially those with a history of essential hypertension, will require pharmacologic blood pressure control in the PACU.¹¹ Agents that may be used for the reduction of BP include hydralazine (2 to 4 mg) and labetalol hydrochloride (5 to 10 mg). Hydralazine relaxes vascular smooth muscle, preferentially favoring the arteriolar circulation. Labetalol is both an α - and a β -blocking agent, causing peripheral vasodilation and slowing of the heart rate. Other β -blockers used postoperatively include metoprolol (1 to 2 mg) and esmolol (10 to 50 mg).²⁶ β -Blockers assist in controlling the sympathetic responses of patients during recovery. α -2-Agonists also can be used postoperatively to assist when needed. Many other agents are available and may include the patient's usual prescription antihypertensive for mild increases. Patients who were on β -blockers prior to surgery should have them continued throughout the perioperative period. One of the surgical care improvement project (SCIP) measures that is evaluated during the perioperative period is SCIP-cardiovascular-2. SCIP cardiovascular-2 measures the number of "surgery patients on a β -blocker prior to arrival who received a β -blocker during the perioperative period."³⁰

Dysrhythmias

Dysrhythmias seen in the PACU are often transient¹¹ and most commonly have an identifiable cause that is not an actual myocardial injury. The major postanesthetic and surgical factors that lead to a relatively high incidence of perioperative dysrhythmias include hypokalemia, excess fluid administration, anemia, hypoventilation with subsequent hypercarbia, altered acid-base status, substance withdrawal, and circulatory instability.¹¹ Medications commonly administered in the perioperative period have been linked to significant prolongation of the QT-interval. Although the rationale for and clinical relevance of this relationship are not well defined, an associated risk for torsades de pointes

development related to prolonged QT-interval should be considered post general anesthetic administration.³¹

Arterial desaturation is a common postoperative complication that may result from obstruction or hypoventilation³² and less commonly from PE, pulmonary edema, or aspiration. A direct consequence of hypoxia is myocardial ischemia and depression of cardiac contractility. Signs of cardiac irritability may be manifested by atrial and ventricular dysrhythmias, conduction delays, and heart block.

Hypercarbia caused by reduced alveolar ventilation results in elevation of the arterial carbon dioxide tension, which in turn stimulates the SNS and sensitizes the myocardium to the arrhythmic effects of endogenous catecholamines. Among the earliest signs of hypercarbia are tachycardia and hypertension, which may progress to ventricular dysrhythmias.

Hypokalemia may occur secondary to hyperventilation, respiratory alkalosis, gastric suctioning, insulin administration, and diuretic use. The ECG may demonstrate widening of the QRS complex, U waves, and ST-segment abnormalities that may progress into premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation.

Acid-base disturbances may occur as a result of alterations in ventilation, gastrointestinal losses, and lactic acid production during hypotension or shock. The cardiovascular effects include increased cardiac excitability and irritability.

Hypotension may result in impaired oxygen transport and compromised coronary circulation, leading to myocardial ischemia with associated conduction deficits.²⁶ The use of vasoconstrictive medications designed to treat the hypotension also may contribute to the development of dysrhythmias. Patients with preexisting heart disease, particularly those who have a history of myocardial infarction or pulmonary hypertension,³² are at continued risk for myocardial ischemia throughout the perioperative period.

Hypothermia resulting from general and neuraxial anaesthesia³³ prolongs the refractory period, contributing to the development of sinus bradycardia and atrial fibrillation. Conduction deficits may progress to atrioventricular block and eventually to ventricular fibrillation.

Vagal reflexes are usually transient and are produced by the Valsalva maneuver or direct eye, vagal nerve, or carotid sinus pressure. Severe sinus bradycardia with possible ventricular escape beats may occur. Vagotonic medications such as neostigmine also can produce these dysrhythmias.

The presence of residual anesthetics in both blood and tissue in patients admitted to the PACU may contribute to dysrhythmias. Ketamine may contribute to sympathetic stimulation, resulting in tachyarrhythmias and hypertension, as can vagolytic drugs such as atropine and glycopyrrolate. Opioids such as morphine, fentanyl, and sufentanil may result in the indirect development of dysrhythmias. Opioid-induced ventilatory impairment, a potential side effect of opioids, may result in hypoxemia and hypercarbia,³⁴ each known to be dysrhythmogenic. Anticholinesterase agents may produce severe bradyarrhythmias or heart block.²⁵

Surgical stress and pain can significantly increase plasma catecholamine levels. Although this sympathetic response may be mitigated by anesthetic administration, norepinephrine and epinephrine concentrations are consistently elevated in PACU patients who are experiencing acute pain. Administration of analgesic medications may blunt this sympathetic response; however, cardiac irritability, tachycardia, and conduction dysrhythmias may occur.

Neuromuscular Function

Reversal of Neuromuscular Blockade

Incomplete reversal of neuromuscular relaxation can lead to postoperative pulmonary complications including obstruction and hypoventilation. Patients who received a reversal agent often exhibit signs of residual neuromuscular blockade in the PACU,³⁵ particularly the elderly.³⁶ Therefore, objective monitoring measures (e.g., train-of-four ratio < 0.90) should be performed regularly in the early postanesthesia phase to determine depth of residual blockade and prevent pulmonary complications.³⁵ (See [Chapter 12](#) for a complete discussion of residual neuromuscular agent paralysis.)

Residual paralysis compromises cough, airway patency, ability to overcome airway resistance, and airway protection. Intraoperative

use of shorter-acting relaxants might decrease the incidence of residual paralysis but does not eliminate the problem. Reversal agents such as neostigmine and edrophonium chloride will be given in conjunction with either atropine or glycopyrrolate.²⁵ Sugammadex, a newer generation reversal agent, is specifically designed to reverse rocuronium. The main advantage of sugammadex is reversal of neuromuscular blockade without relying on inhibition of acetylcholinesterase,^{37,38} and earlier spontaneous postoperative ventilation.³⁹ Marginal reversal can be more dangerous than near-total paralysis, because an agitated patient exhibiting uncoordinated movements and airway obstruction is more easily identified. A somnolent patient exhibiting mild stridor and shallow ventilation from marginal neuromuscular function might be overlooked. Insidious hypoventilation leading to respiratory acidemia or regurgitation with aspiration can occur later into recovery. Patients with coexisting neuromuscular abnormalities such as myasthenia gravis,²⁹ Eaton-Lambert syndrome, or muscular dystrophies exhibit exaggerated or prolonged responses to muscle relaxants. Even without muscle relaxant administration, such patients can exhibit postoperative respiratory insufficiency from inadequate neuromuscular reserves (see [Table 12.9](#)).

Because residual neuromuscular blockade is associated with increased mortality,⁴⁰ its assessment and management is essential in the early postanesthesia phase. Simple bedside tests help evaluate mechanical ability to ventilate. Forced vital capacity of 10 to 12 mL/kg and inspiratory pressure more negative than -25 cm H₂O imply that strength of ventilatory muscles is adequate to sustain ventilation. Sustained head elevation in a supine position, hand grip, and ability to bite down, swallow, and stick out the tongue are easily assessed parameters. These measures, along with tactile train-of-four and double-burst stimulation assessment, more accurately predict a patient's ability to maintain sustained ventilation.

Mental Status

Postoperative mental status changes may be associated with poor

anesthetic outcomes; therefore, periodic mental and behavioral status assessments are recommended from the time of emergence and throughout the early postanesthesia recovery period.⁵

Emergence Delirium

Postoperative emergence delirium is the alteration in neurologic functioning that causes the most concern to the practitioner. Emergence delirium has been associated with a risk of bodily injury to the patient and caregiver, increased resource utilization and an extended PACU length of stay. *Delirium* is defined as a condition characterized by extreme disturbances of arousal, attention, orientation, perception, intellectual function, and affect. It is most commonly accompanied by fear and agitation.⁴¹⁻⁴³

Attempts have been made to differentiate emergence delirium from agitation,^{44,45} with *agitation* defined as mild restlessness and mental distress. Agitation can be due to pain, physiologic compromise, or anxiety. Delirium can be confused with agitation or be the source of agitation, and the two conditions can be very difficult to differentiate.⁴³

The incidence of postoperative delirium has been reported to occur in 5% to 10% of the general surgery patient cohort; with the incidence as high as 62% after operative hip procedures.⁴² Emergence delirium also appears to occur with greater incidence among combat veterans compared with the general military population of the same age.⁴⁵ The causes of postoperative delirium have been classified into four categories: withdrawal psychosis, toxic psychosis, circulatory and respiratory origin, and functional psychosis.⁴¹

Withdrawal psychosis is caused by withdrawal of various substances such as alcohol and illicit drugs. Alcohol withdrawal can be dangerous because it can cause delirium tremens. Clinical symptoms of delirium tremens may include hallucinations, extreme combativeness, and confusion.⁴¹

Amphetamine-induced delirium usually appears 1 hour after amphetamine use and disappears within 6 hours of use. Cocaine-induced delirium results from alteration of neurotransmitters. Management of withdrawal psychosis may include protection of patient safety and use of benzodiazepines or other sedatives.⁴¹

Toxic psychosis is caused by exposure to toxins,⁴¹ including toxic fumes that may occur in the OR, as from a malfunctioning laser. Adherence to the Occupational Safety and Health Administration's regulations and its mandates on monitoring help to limit the occurrence of these events.

Circulatory and respiratory causes of emergence delirium most commonly include hypoxemia and hypercarbia, which may be the result of central respiratory depression, airway obstruction, or perfusion deficits. The primary cause of postoperative emergence delirium is always considered to be hypoxemia⁴² until proved otherwise. As a result, sedation of the agitated patient should never be considered until hypoxemia has been ruled out as the cause of agitation.

Functional psychosis is defined as a brief reaction of paranoia and other changes not caused by an organic abnormality. This diagnosis is made by exclusion after known organic causes have been ruled out.⁴²

Although this classification is useful, other more frequently occurring causes of emergence delirium may be seen in the PACU. Confusion and agitation are common during recovery from inhalation anesthetics. Sevoflurane in particular has been associated with emergence delirium in children.⁴⁶ Many drugs used during the perioperative period have been reported to contribute to postoperative delirium. Ketamine, a phencyclidine derivative, is associated with hallucinations, delirium, and unpleasant dreams, particularly in patients between 16 and 65 years of age. Local anesthetics can cross the blood-brain barrier and may cause postoperative delirium. Nitrous oxide may cause acute mental status changes with prolonged exposure. Other anesthetic adjuncts associated with delirium include butyrophenones (e.g., droperidol), naloxone, and muscle relaxants, which can cause dissociative reactions, heightened pain perception, and hypoxemia, respectively. Delirium also has been reported as a side effect of antibiotic therapy (e.g., cefazoline, penicillin, streptomycin, chloramphenicol), antituberculosis drugs (e.g., isoniazid, cycloserine), antiviral agents (e.g., acyclovir), anticonvulsant medications (e.g., carbamazepine, phenytoin), and antiparkinsonian agents (e.g., levodopa, bromocriptine). Adverse reactions to

medications that result in delirium have been reported with digitalis, antidysrhythmic medications (e.g., amiodarone, flecainide, lidocaine, mexiletine), β -blockers, calcium channel blockers, contrast dye, corticosteroids, chemotherapeutic agents, immunosuppressants, H₁ and H₂ blockers, antipsychotic medications, and clonidine.^{47,48}

Premedicants, including anticholinergics, benzodiazepines, and opioids, may induce untoward reactions. Anticholinergics, specifically atropine and scopolamine, have been noted to cause central anticholinergic syndrome. These drugs cross the blood-brain barrier, altering the neurotransmitter balance and causing agitation, combativeness, and lack of cooperation. Benzodiazepines may contribute to postoperative delirium, especially in the elderly.⁴³ Flumazenil (Romazicon) remains the only benzodiazepine antagonist available to reverse the effects of benzodiazepine-induced delirium. Flumazenil 0.2 mg should be given over a 15-second interval with a redose after 1 to 2 minutes if the desired level of consciousness is not achieved. The doses may be repeated up to 1 mg with a 3-mg total to be administered within an hour. Seizures have been known to occur rarely, so the patient should continue to be observed. Perioperative opioids have been cited as a contributing factor to postoperative delirium in the PACU and on the first postoperative day,⁴³ and possibly secondary to respiratory depression and hypoxemia. If naloxone is given to reverse the opioid, the dose should be administered in very small increments until the desired effect is observed.

Metabolic disturbances associated with postoperative delirium include acidosis and alkalosis, electrolyte imbalance (e.g., magnesium, calcium, sodium)¹¹ and porphyria. Treatment is directed at correction of the cause.

Procedure severity has been identified as a significant factor for a patient to experience delirium post surgery.⁴³ Other causes of postoperative delirium include pain, visceral distention (bowel and bladder), anxiety (including separation anxiety in children), hyperthermia, and hypothermia.⁴⁹ Again, treatment is directed at correction of the cause. Common causes of emergence delirium include presence of an endotracheal tube, pain, and anxiety. In children, determination of cause and treatment of delirium is

complex, with pain and anxiety more easily recognized and treated than other anesthetic-related causes. Voepel-Lewis et al.⁴⁹ developed an algorithm for assessment, reassessment, and treatment decisions in children with emergence delirium.

Once hypoxemia has been eliminated as a cause of postoperative delirium, and all known causes have been evaluated, sedation may prove useful in controlling the agitation and providing for patient safety. Fig. 55.2 summarizes the factors that contribute to postoperative delirium and treatment options.

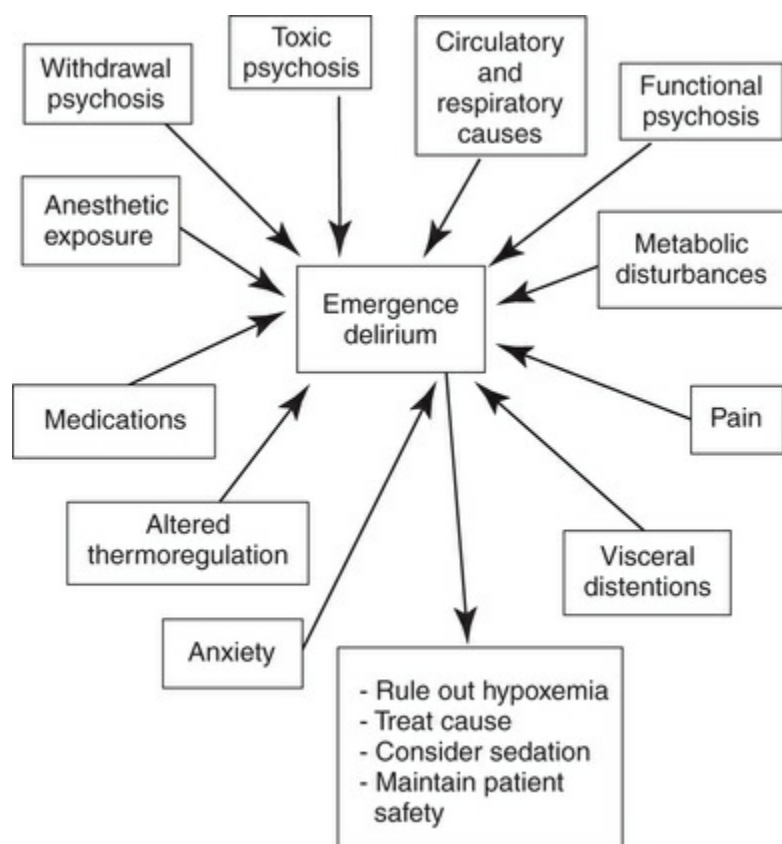

FIGURE 55.2 Emergence delirium in the postanesthesia care unit: contributing factors and treatment.

Delayed Awakening

Delayed awakening is a common, often easily explained postoperative finding and can be defined as a clinician's expectation in a specific circumstance that the patient “should be awake by now” but is not.⁵⁰ Although delayed awakening may slow turnover

of PACU beds and delay patient discharge from the PACU,¹¹ the causes and consequences of delayed awakening are rarely serious. The most common causes of delayed awakening are as follows:

- Prolonged action of anesthetic drugs
- Metabolic causes
- Neurologic injury

Prolonged action of anesthetic drugs is the most common cause of delayed awakening.¹¹ This may occur secondary to alterations in drug pharmacokinetics and pharmacodynamics. Pharmacokinetic alterations include changes in drug distribution secondary to mobilization of drugs from body tissue stores, redistribution, or decreased protein binding; changes in metabolism; and excretion secondary to renal or hepatic dysfunction. Pharmacodynamic alterations include increased patient sensitivity to drug effects because of extremes of age, hypothermia, or concomitant alcohol and drug use.⁵¹ Other patients at risk for delayed awakening are those with preexisting cognitive or psychiatric disorders, patients who chronically take sedative medications, patients who were intoxicated with alcohol or illicit drugs at the time of anesthesia, and those who were physically exhausted prior to surgery.

Prolonged effects of inhalation anesthetics may be seen secondary to alterations in ventilation. Hypoventilation limits exhalation and prolongs elimination of inhalation agents.²³ Retention of carbon dioxide contributes to narcosis, particularly in the presence of inhalation agents, and compounds the problem.

The potentiating effects of combining inhalation agents with IV anesthetics and opioids can also contribute to delayed awakening.⁴⁸ Premedications, particularly the long-acting benzodiazepines diazepam and lorazepam, may contribute to delayed awakening, especially in the elderly.⁵² Prolonged effects of inhalation and IV agents also may occur secondary to multiple drug interactions. Prolonged neuromuscular blockade may mean the patient is awake but unable to move. Some herbal supplements, especially kava kava, St. John's wort, and valerian, have the potential to interact with anesthetic medications and cause delayed awakening.⁵²

Metabolic causes contributing to delayed awakening include hypoglycemia, hyperglycemia, electrolyte disturbances, and

hypothyroidism.⁵¹ Diabetic patients have an increased risk of postoperative hypoglycemia. Taking the usual insulin dose (or half the dose) on the morning of surgery, the patient's nothing-by-mouth (NPO) status, and the stress of surgery all contribute to the development of hypoglycemia.^{11,52} It is important to monitor serum glucose levels intraoperatively and postoperatively. Central nervous system changes may occur as blood glucose levels fall below 50 mg/dL.²³ It is good practice to obtain a baseline blood glucose level of all diabetic patients before they are admitted to surgery. Procedures requiring general anesthesia lasting longer than 2 hours will have greater glucose variations and require more frequent monitoring and treatment. Blood glucose levels of greater than 600 mg/dL can produce hyperosmolar, nonketotic, hyperglycemic coma. Approximately half of these patients have type 2 diabetes, but the syndrome can occur with severe dehydration (especially in the elderly), uremia, pancreatitis, sepsis, pneumonia, CVA, and large surface burns. Minimizing blood glucose variability during the perianesthesia period should be part of any glycemic control strategy.⁵²

Electrolyte disturbances,⁵¹ specifically alterations in sodium, calcium, and magnesium, can prolong awakening. Dilutional hyponatremia, occurring secondary to water intoxication, may develop after transurethral prostate resection surgery, producing sedation, coma, or even hemiparesis. Hypocalcemia, seen after parathyroidectomy and occasionally thyroidectomy, may delay awakening. Hypermagnesemia, which may occur after prolonged administration of magnesium sulfate to women with eclampsia or preeclampsia, may result in sedation and muscle weakness after general or regional anesthesia for cesarean section.⁵²

Neurologic injury is a rare cause of delayed awakening of the nonneurosurgical patient. Potential causes of neurologic injury include CVA, intracranial hemorrhage, increased intracranial pressure, uncontrolled extreme hypertension (especially in the anticoagulated patient), air or fat emboli, and uncontrolled hypotension (especially in patients with hypertension or occlusive carotid disease).²³

Evaluation of the patient who fails to awaken begins with an assessment of the patient's preoperative status and a review of

intraoperative events.⁴⁹ Oxygenation and gas exchange must be assessed and verified with pulse oximetry, physical assessment, and arterial blood gas analysis. When prolonged drug effects are suspected as the cause of delayed awakening, care must be taken to ensure the adequacy of ventilation and oxygenation through appropriate patient monitoring.⁵

Residual drug effects should be considered. If possible and not contraindicated, reversal of medications should be attempted. Flumazenil reverses benzodiazepines, and naloxone reverses the opioids.⁵¹

If other contributing factors are found, intervention should be initiated. Hypothermia necessitates rewarming, and electrolyte disturbances require correction. Hypoglycemia and hypocalcemia are treated with the IV administration of glucose and calcium, respectively. Hyperglycemia is treated with IV insulin to lower blood glucose levels and 0.5% normal saline to correct dehydration.

A neurologic cause of delayed awakening is usually either a diagnosis that is initially expected because of patient status or known because of intraoperative events or a diagnosis of exclusion (i.e., suspected after all other causes have been ruled out). At this point, a CT scan and neurologic consultation are warranted for a more in-depth evaluation.¹¹

Serotonin Syndrome

The age, comorbidity status and number of surgical patients being treated with combination medication therapy is increasing, particularly in those diagnosed with chronic pain. These patients are at greater risk for developing serotonin syndrome, a possibly fatal condition that can affect patients across the lifespan. The condition is associated with medication treatment-related serotonin level elevation.^{53,54}

Serotonin syndrome may be precipitated by the concurrent administration of two or more serotonergic medications, such as the monoamine oxidase inhibitors, tricyclic antidepressants, selective serotonin reuptake inhibitors, and serotonin and norepinephrine reuptake inhibitor agents. Concomitant fentanyl administration has been associated with serotonin syndrome development in several documented cases.^{53,54}

Symptom onset occurs quickly and severity of this syndrome varies. In the mild form, the patient may exhibit dilated pupils, diaphoresis, myoclonus, tachycardia, anxiety, and restlessness. In its worst form, the patient may present with a fever, mental status changes, muscle rigidity, and multiple organ failure.⁵³

Serotonin syndrome can be difficult to diagnose because its symptoms may mirror other concerning postanesthetic conditions, such as malignant hyperthermia and delayed awakening.⁵⁴ Currently, the only diagnostic criteria available (i.e., Hunter Serotonin Toxicity and Sternbach's) have limited application in the early postanesthesia period.⁵³

Differential diagnosis is made through direct clinical observation and by ruling out other possible causes. Therefore, knowledge of the patient's medication history and its related potential to precipitate serotonin syndrome is very important. Future expansion of Cytochrome P450 2D6 (CYP2D6) genetic testing can better support the preemptive identification of patients at greatest risk for developing serotonin syndrome.⁵⁴

Treatment is based on the severity of symptoms with early intervention desirable in order to mitigate further complications. Prudent PACU measures include cardiac monitoring, intravenous fluid resuscitation, oxygen administration, discontinuation of serotonergic medications, and stabilization of vital signs. Benzodiazepine administration may help to control tremors and support physical safety for the agitated patient across the syndrome severity spectrum. Active teamwork, specialty consultation and provision of supportive care often resolves concerning symptoms within one day of onset, but may require continued vigilance for patients taking serotonergic medications having a longer duration of action. A further discussion of serotonin syndrome can be found in [Chapter 14](#).

Pain

Relief of surgical pain with minimal side effects is a primary goal of PACU care and a very high priority for both anesthesia provider and patient. Patients should be assessed on admission to PACU and at frequent intervals using a verbal rating scale or visual analog scale to assess for severity of pain ([Fig. 55.3](#)).^{9,55,56} When prioritizing

pain assessment, the patient's self-report is the most important measure of pain. Other measures used to assess pain intensity include the patient's exposure to painful procedures; behavioral signs, such as crying or agitation; a proxy pain rating by someone who knows the patient well; and physiologic indicators, such as elevated vital signs.⁴² Inadequate postoperative analgesia is a major source of preoperative fear. Postoperatively, pain often impedes mobility and recovery, and is a major source of dissatisfaction in surgical patients. Whereas clinicians have increasingly adopted the use of coordinated multimodal strategies to promote comfort and allay opioid side effects,⁵³ over 80% of postoperative patients experience acute pain, with two-thirds of those patients reporting pain described as moderate, severe or extreme.^{57,58} In addition to minimizing distress and improving patient comfort, relief of pain reduces SNS response and helps avoid hypertension, tachycardia, and dysrhythmias (Table 55.3).

FIGURE 55.3 Pain intensity scales. (A-C from Acute Pain

Management Guideline Panel. *Acute Pain Management in Adults: Operative Procedures: Quick Reference Guide for Clinicians* [AHCPR Publication No. 92-0019]. TABLE 55.3
Harmful Effects of Unrelieved Pain

Domains Affected	Specific Responses to Pain
Endocrine	↑ ACTH, ↑ cortisol, ↑ ADH, ↑ epinephrine, ↑ norepinephrine, ↑ GH, ↑ catecholamines, ↑ renin, ↑ angiotensin II, ↑ aldosterone, ↑ glucagon, ↑ interleukin-1, ↓ insulin, ↓ testosterone
Metabolic	Gluconeogenesis, hepatic glycogenolysis, hyperglycemia, glucose intolerance, insulin resistance, muscle protein catabolism, ↑ lipolysis
Cardiovascular	↑ Heart rate, ↑ cardiac workload, ↑ peripheral vascular resistance, ↑ systemic vascular resistance, hypertension, ↑ coronary vascular resistance, ↑ myocardial oxygen consumption, hypercoagulation, deep vein thrombosis
Respiratory	↓ Flows and volumes, atelectasis, shunting, hypoxemia, ↓ cough, sputum retention, infection
Genitourinary	↓ Urinary output, urinary retention, fluid overload, hypokalemia
Gastrointestinal	↓ Gastric and bowel motility
Musculoskeletal	Muscle spasm, impaired muscle function, fatigue, immobility
Cognitive	Reduction in cognitive function, mental confusion
Immune	Depression of immune response
Developmental	↑ Behavioral and physiologic responses to pain, altered temperaments, higher somatization, infant distress behavior, possible altered development of the pain system, ↑ vulnerability to stress disorders, addictive behavior, and anxiety states
Future pain	Debilitating chronic pain syndromes: postmastectomy pain, postthoracotomy pain, phantom pain, postherpetic neuralgia
Quality of life	Sleeplessness, anxiety, fear, hopelessness, ↑ thoughts of suicide

ACTH, Adrenocorticotrophic hormone; *ADH*, antidiuretic hormone; *down arrow* (↓), decreased; *GH*, growth hormone; *up arrow* (↑), increased.

From Pasero C, McCaffery M. *Pain Assessment and Pharmacologic Management*. St. Louis: Elsevier; 2011. Copyright Pasero C, McCaffery M. Used with permission.

A multiple logistic regression model determined that severe postoperative pain occurred significantly more often in patients with the CYP2D6 poor metabolizer (PM) genotype and smokers. Advances in genomic testing can provide specific information on the rate at which a patient metabolizes an opioid based on individual variability in genetic makeup, and may increasingly support more effective procedural pain treatment interventions.^{59,60}

Incisional pain may be effectively treated with careful titration of

IV opioids with frequent cardiorespiratory assessments. Short-acting IV opioids are useful to expedite discharge and minimize nausea in ambulatory settings. Ketorolac or IV acetaminophen are effective analgesics with antiinflammatory characteristics that lower opioid requirements and reduce the risk for opioid induced respiratory depression.^{34,60}

Other analgesic modalities interfere with nociception at multiple levels along the neural pathway to promote effective pain relief beyond the PACU. IV opioid loading in the PACU is helpful for smooth transition to patient-controlled analgesia. Continuous lidocaine or ketamine infusion in the early postoperative period has been shown to be effective in the chronic pain patient population. Use of a continuous subcutaneous local anesthetic device or peripheral nerve catheter promotes early ambulation and opioid sparing goals. Injection of opioids into the epidural or subarachnoid space during anesthesia or in the PACU often yields prolonged postoperative analgesia.⁶⁰ Epidural opioid analgesia is effective after thoracic and upper abdominal procedures and helps wean patients with obesity or chronic obstructive pulmonary disease from mechanical ventilation. Epidural analgesia may also improve surgical outcomes after orthopedic and urologic procedures. With epidural or intrathecal opioid administration, immediate and delayed ventilatory depression can occur⁶¹ along with other side effects, such as nausea and pruritus.

Patient-controlled analgesia (PCA) allows patients to administer their own pain medication. The most commonly used methods of PCA are intravenous or epidural. Patient therapy should be initiated in the PACU after the patient's initial pain level is under control. Oral opioids are often used with outpatients and have been studied in appropriate orthopedic patients with success.⁴⁰ Nonopioids available in an intravenous format include acetaminophen, ketorolac, and ibuprofen. Inclusion of opioid sparing medications should always be considered for use with the postoperative patient when developing a multimodal plan for pain management.⁶¹

Placement of long-acting regional analgesic blocks reduces pain, controls SNS activity, and often improves ventilation, particularly when analgesic requirements surpass a single injection's efficacy.⁵⁸

For example, an interscalene block yields almost complete pain relief from shoulder or upper extremity procedures, with only moderate inconvenience from motor impairment. Paralysis of the ipsilateral diaphragm can impair postoperative ventilation in patients with marginal respiratory reserve. The adductor canal and/or femoral nerve block promote pain relief for total knee replacement surgery.⁶¹ Caudal analgesia is effective in children after inguinal or genital procedures, whereas infiltration of local anesthetic into joints, soft tissues, or incisions decreases the intensity of pain. Other uses of local anesthesia include continuous wound infusion, in which the catheter is inserted at the end of the case by the surgeon, and perineural infusions, in which the anesthesia provider inserts the catheter near the affected peripheral nerves or a nerve plexus.⁵⁸ Deposition of long-acting liposomal formulations of bupivacaine (Exparel) to the surgical site can provide pain relief post discharge.

Opioid treatment for postoperative or chronic pain is frequently associated with adverse effects, the most common being dose-limiting and debilitating bowel dysfunction. Postoperative ileus, although attributable to surgical procedures, is often exacerbated by opioid use during and after surgery. Postoperative ileus is marked by increased inhibitory neural input, heightened inflammatory responses, decreased propulsive movements, and increased fluid absorption in the gastrointestinal tract. The current management of opioid-induced bowel dysfunction among patients receiving opioid analgesics consists primarily of nonspecific ameliorative measures. Several drugs for opioid induced constipation (OIC) are available including alvimopan (Entereg), naloxegol (Monantik) and methylnaltrexone (Relistor) which can normalize bowel function without blocking systemic opioid analgesia.⁶² They are opiate receptor antagonists which are not absorbed systemically so they do not interfere with systemic analgesia. Their action is confined to the bowel. A chloride channel activator called *lubiprostone* (*Amitiza*) is also approved for OIC. Nonpharmacologic interventions may include positioning for comfort, verbal reassurance, touch, applications of heat or cold, massage, transcutaneous electrical nerve stimulation, relaxation techniques, imagery, biofeedback-controlled breathing, and use of the patient's support system (e.g.,

parent or significant other), particularly in children. Nonpharmacologic interventions should supplement and not replace pharmacologic therapy.⁹

Guidelines for pain management may be generalized and thus lack specific application for different types of surgery. An excellent resource for evidence-based guidelines in the field of pain management are procedure-specific guidelines offered via a web-based program called *PROSPECT (Procedure-Specific Postoperative Pain Management)*. An international panel of surgeons and anesthesiologists reviews procedure-specific pain research and grades the evidence. Then clinical practice guidelines and recommendations are developed after consensus by the working group and presented in a comprehensive web based platform. The PROSPECT website offers current procedure-specific guidelines for managing pain associated with abdominal hysterectomy, Caesarean section, herniorrhaphy, open colon resection, laparoscopic cholecystectomy, reconstructive breast surgery, thoracotomy, total hip and total knee arthroplasty.⁶³ These recommendations are typically incorporated into enhanced recovery after surgery protocols.

Hypothermia

Hypothermia is a condition marked by an abnormally low internal body temperature (below 36°C), that occurs when systemic heat loss exceeds heat production.⁶⁴ Many patients are admitted into the PACU with hypothermia, which can prolong recovery, compromise physiologic stability, and contribute to postoperative morbidity. The patient's interaction with the environment determines the degree of heat loss. Heat loss may occur via radiation, convection, conduction, or evaporation.

Radiant heat loss involves the loss of heat from a warm or hot surface (the body) to a cooler one (the environment). It does not require that the two surfaces be in direct contact with each other. Radiant heat loss accounts for 40% to 60% of heat loss to the environment. It is especially profound in the elderly, debilitated, and neonatal populations.⁶⁵

Convective heat loss depends on the existence of a temperature gradient between the body and the ambient air. This type of heat

loss may occur in the OR, particularly in laminar flow rooms, and accounts for 25% to 50% of heat loss.⁶⁵

Conductive heat loss involves loss of heat from a warm surface that comes into contact with a cooler one; it accounts for as much as 10% of heat loss in the OR, where patients lose heat to cooler OR tables, sheets, drapes, skin preparation fluids, and IV fluids or irrigants.⁶⁵

Evaporative heat loss involves transfer of heat during the change from a liquid to a gas. Evaporative heat loss occurs via perspiration, respiration, or exposed viscera during surgery. Evaporation accounts for as much as 25% of heat loss in the OR.⁶⁶

Patients at high risk for the development of hypothermia can be identified. Elderly patients are at risk because of their decreased subcutaneous fat and alterations in their hypothalamic function. Neonates are at risk because of their immature thermoregulatory center and their high surface-to-volume ratio. Intoxicated individuals are at risk because of vasodilation and depression of their heat regulatory center. Patients taking vasodilators, nonsteroidal antiinflammatory agents, and phenothiazines have alterations in thermoregulation that are caused by either vasodilation or suppression of the thermoregulatory center.⁶⁶ Other risk factors are female gender, decreased ambient room temperature, length and type of surgery, preexisting conditions such as peripheral vascular disease or burns, use of cold irrigants, and use of general or regional anesthesia.⁶⁵

General anesthetics depress the thermoregulatory center, with a usual temperature drop of 1°C to 3°C. General anesthesia reduces the vasoconstriction threshold; general anesthesia and regional anesthesia both cause peripheral vasodilation, which results in a core-to-peripheral redistribution of heat. Opioids and muscle relaxants depress voluntary shivering as a mechanism for the generation of heat. Any patient in whom a body cavity is entered may lose heat via convection and evaporation. Irrigation solutions used in genitourinary procedures or with cardioplegia in cardiac surgery cause internal cooling.⁶⁶

Physiologically, hypothermia results in decreased oxygen availability by shifting of the oxyhemoglobin dissociation curve to the left. Shivering may increase oxygen demand by 400% to 500%.

Metabolically dependent processes slow, thereby decreasing drug biotransformation. Renal transport processes are slowed, thereby decreasing glomerular filtration. Cardiac rate and rhythm disturbances, including bradydysrhythmias and premature ventricular contractions, may occur. Central nervous system depression may be profound.⁶⁷ Other adverse effects of perioperative hypothermia include patient discomfort, increased adrenergic stimulation, coagulopathy, impaired wound healing, surgical site infection, and increased hospital costs.⁶⁶

Treatment of hypothermia should ideally be focused on prevention. Assessment of the patient's need for prewarming begins preoperatively, and active warming measures can be instituted for hypothermic patients.^{9,67} As a result of positioning, operating time, and anesthetic exposure, therapeutic intervention most often begins in the PACU. Every patient in the PACU should be assessed for hypothermia and care provided as suggested in the multidisciplinary ASPAN evidence-based clinical practice guideline for the promotion of perioperative normothermia (Fig. 55.4).⁶⁴ Passive rewarming is designed to maximize basal heat production. Active rewarming consists of the use of external rewarming techniques and may include the use of heated blankets, heated water blankets, and radiant warmers. In a systematic review, Moola and Lockwood⁶⁷ determined that single strategies such as forced-air warming were more effective than passive warming; however, combined strategies, including using prewarming preoperatively, use of warmed fluids plus forced-air warming as other active strategies were more effective in vulnerable groups. Forced-air rewarming systems are the most effective method for treating hypothermia.⁵

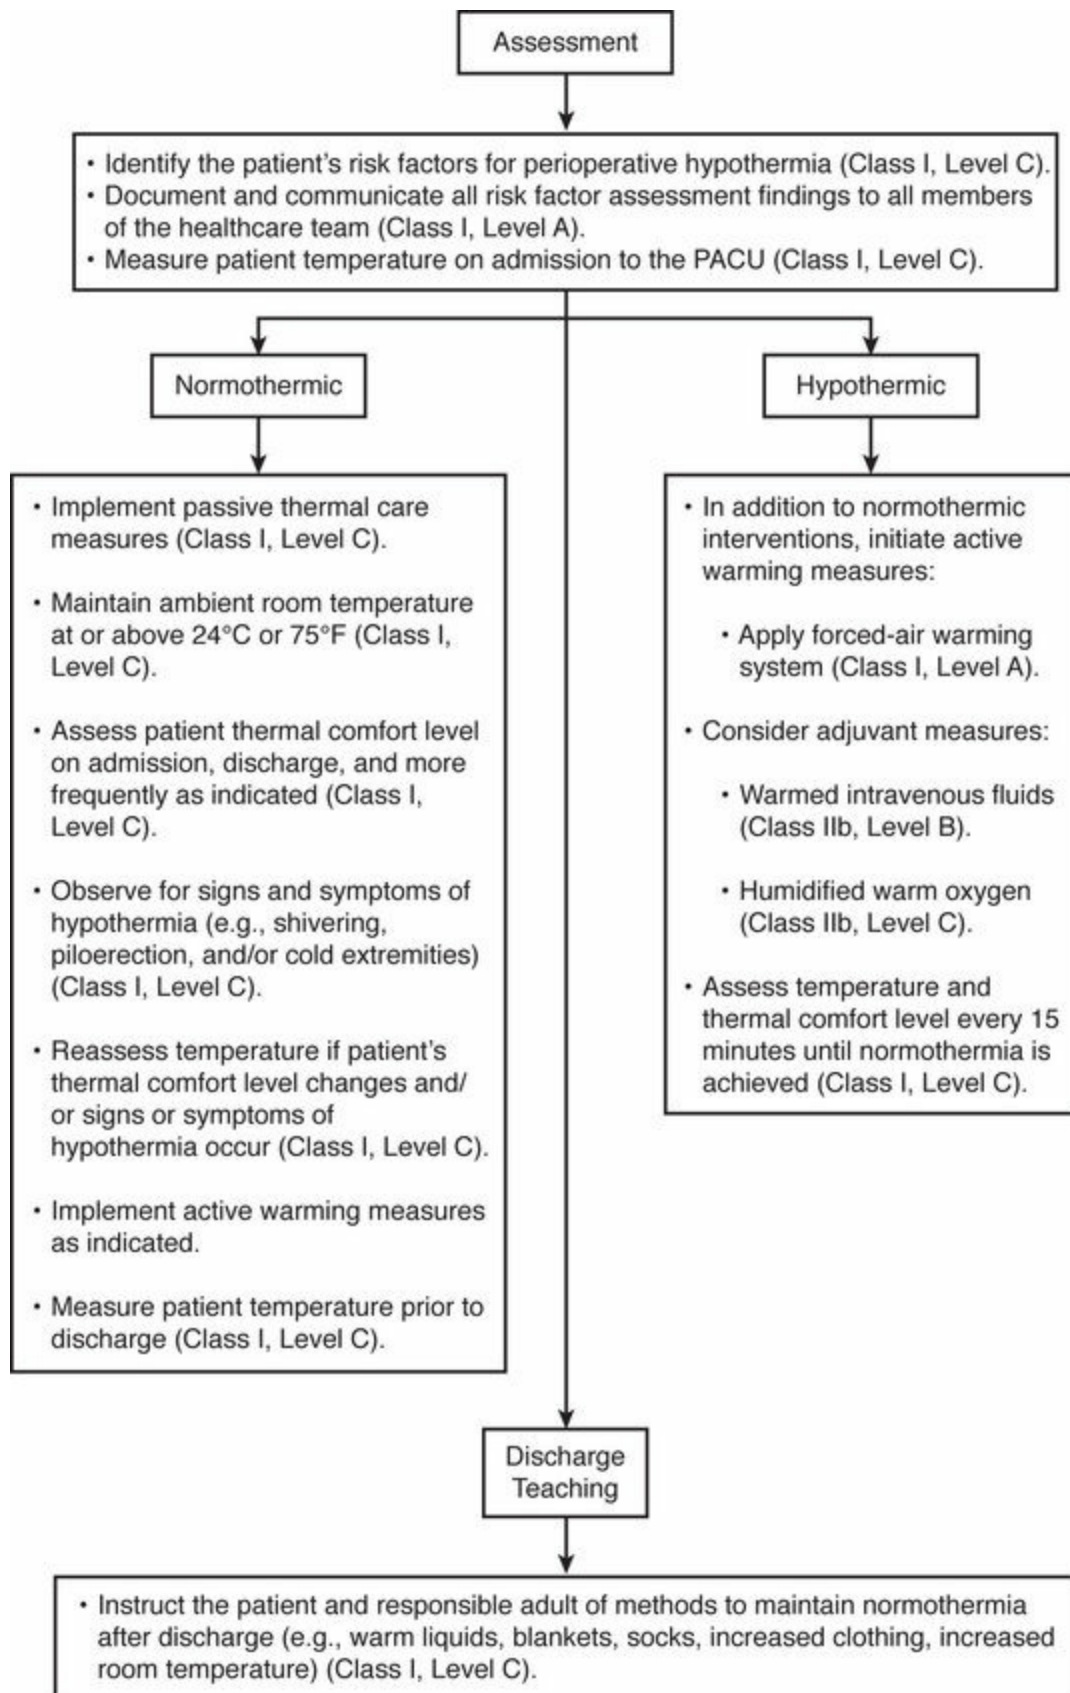

FIGURE 55.4 Preoperative, intraoperative, and postoperative patient management recommendations for promotion of normothermia. *PACU*, Postanesthesia care unit. (From Hooper et al. *ASPAN's evidence-based clinical practice*

Postoperative shivering consists of muscular tremor and rigidity. It is often associated with body heat loss, although hypothermia alone does not fully explain the occurrence of shivering. Shivering is self-limiting, never becomes chronic, and is rarely associated with major morbidity. However, it affects the comfort of patients and may sometimes lead to more serious complications.⁶⁶ Treatment is rewarming. However, when clinically indicated, small doses of meperidine, tramadol, ketamine, dexmedetomidine, granisetron, magnesium sulfate, or clonidine can be effective in the treatment of shivering during emergence and recovery.⁶⁸

Nausea and Vomiting

In 1914 the first journal devoted solely to the topic of anesthesia featured an original article titled “Prophylaxis of Postanesthetic Vomiting.”⁶⁹ More than 100 years later, postanesthetic vomiting is still one of the major problems faced in the PACU. Postoperative nausea and vomiting (PONV) affects 20% to 30% of all surgical patients, and the chance for PONV can be as high as 70% to 80% for high-risk patients.⁷⁰ Postdischarge nausea and vomiting (PDNV) is now considered as an equally troublesome and all-too-frequent patient complication. The incidence of vomiting is lower than nausea.^{71,72} The patient-specific risk factors listed in [Box 55.9](#) are independent predictors for PONV. Females experience PONV two to three times more often than males, although these differences do not show up until after puberty. Being a nonsmoker and having a history of motion sickness or PONV are also independent predictors of PONV. One theory is that smoking may be protective because of functional changes in neuroreceptors from chronic exposure to nicotine and that the smoker's susceptibility to PONV is reduced due to nicotine withdrawal.⁷³ The risk of PONV also increases with age.⁷⁴ Other associated factors are migraines and better health status as defined by the ASA risk classification. Whereas anxiety may influence PONV, it is not clinically relevant as a predictor.^{73,74} Children ages 11 to 14 experience an increased incidence of PONV. The highest rate occurs in young adults but

Box 55.8 increases in older adults.^{70,74,75}

Primary Risk Factors Associated With Postoperative Nausea and Vomiting

Patient Specific

- Female gender
- Age less than 50 years old
- Nonsmoker
- History of PONV
- History of motion sickness

Anesthetic Related

- Use of volatile anesthetics
- Duration of anesthesia
- Use of nitrous oxide
- Postoperative opioid use

Surgery Related

- Type of surgery, especially laparoscopy, gynecological, cholecystectomy (conflicting evidence)

PONV, Postoperative nausea and vomiting.

Data from Apfel CC, et al. Who is at risk for postdischarge nausea and vomiting after ambulatory surgery? *Anesthesiology*. 2012;117(3):475–486; Apfel CC, et al. Evidence-based analysis of risk factors for postoperative nausea and vomiting. *Br J Anaesth*, 2012;109:742–753; Gan, T, et al. Consensus guidelines for the management of postoperative nausea and vomiting. *Anesth Analg*. 2014;118:85-113.

When examining anesthetic related risk factors, the use of volatile anesthetics is the strongest predictor of PONV. It occurs more often

with inhalation anesthetics than with total intravenous anesthesia (TIVA) techniques, and the risk of PONV decreases significantly after regional anesthesia. Desflurane, isoflurane, and sevoflurane have not shown significant differences in the incidence of nausea and vomiting after their use. Propofol, used as an induction agent and IV anesthetic, is associated with a lower incidence of PONV, whereas etomidate and ketamine may increase this adverse effect.⁷⁶ Propofol does not appear to reduce the incidence of PDNV, possibly due to its short half-life.⁷⁷ Postoperative use of opioids is strongly correlated with PONV, as is duration of anesthesia and use of nitrous oxide.⁷³ Interestingly, one study of 203 ambulatory surgery patients over 5 days postoperatively found significantly more PDNV in patients with a high level of pain than those with lower levels of pain, even when controlling for opioid use.⁷⁸

The duration of surgery contributes to the incidence of PONV. Longer procedures are associated with a longer exposure to inhalation agents and possibly a larger dose of opioids during the surgery. The type of surgical procedure also has been cited as a contributing factor in PONV, although the evidence is conflicting about site and types of surgeries.^{73,74} In children, strabismus and orchiopexy surgery are associated with a higher incidence of PONV.⁷⁹ In adults, an increased incidence of nausea and vomiting has been noted in patients undergoing laparoscopy procedures, especially cholecystectomy and, gynecologic surgery.⁷⁶ Simplified risk-assessment instruments are available that identify patients' risk for PONV. The use of risk assessment tools decreases the incidence of both PONV and PDNV.⁷⁶ One tool in widespread use is Apfel's risk assessment tool.^{70,74} The patient is scored based on four risk factors: gender, smoking status, history of PONV or motion sickness, and postoperative use of opioids. A patient's risk increases with the number of risk factors present. An assessment of risk factors should be done preoperatively and the management of patients at risk guided by the number of risk factors and chance of PONV. An ambulatory surgery patient can be further assessed for the development of PDNV. Apfel's risk assessment for PDNV includes female gender, history of motion sickness and/or PONV, age less than 50 years, the use of postoperative opioids, and PONV in the PACU.⁷² The expected incidence of PONV and PDNV based

on the number of risk factors is noted in [Table 55.4](#). A simplified risk score to predict postoperative vomiting (POV) in children was developed by Eberhart et al. and includes the following four variables: duration of the surgical procedure greater than or equal to 30 minutes, age older than or equal to 3 years, strabismus surgery, and a personal history of POV or PONV in immediate relatives.⁷⁹

TABLE 55.4

Incidence of PONV and PDNV Based on the Number of Risk Factors

Number of PONV Risk Factors	Incidence %
1	10–20
2	40
3	60
4 or more	80
PONV risk factors include: female gender, age younger than 50 years, history of motion sickness and/or PONV, nonsmoking, and the use of postoperative opioids.	
Number of PDNV Risk Factors	Incidence %
0	10
1	20
2	30
3	50
4	60
5	80

PDNV risk factors include: female gender, history of motion sickness and/or PONV, age less than 50 years, the use of postoperative opioids, and PONV in the PACU.

PACU, Postanesthesia care unit; *PDNV*, postdischarge nausea and vomiting; *PONV*, postoperative nausea and vomiting.

Data from Gan, T, et al. Consensus guidelines for the management of postoperative nausea and vomiting. *Anesth Analg*. 2014;118:85–113; Apfel CC. Postoperative nausea and vomiting. In Miller RD, et al., eds. *Miller's Anesthesia*. Philadelphia, 2015, Elsevier.

The Society for Ambulatory Anesthesia (SAMBA) offers clinical practice guidelines and recommendations for antiemetic prophylaxis and treatment of PONV and PDNV. ASPAN is one of several organizations, including AANA, that supports the SAMBA consensus guidelines for PONV and PDNV.^{74,80}

Management of nausea and vomiting should originate from a prophylactic rather than a therapeutic approach, particularly in

patients identified as at risk. See [Fig. 55.5](#) for an algorithm for management of PONV. The patient who experiences PONV may begin with nausea, a subjective feeling of discomfort, or need to vomit. Nausea can be rated on a verbal descriptor scale or numeric rating scale to determine its severity. Every individual clinician and anesthesia department has developed techniques to address these issues. Commonly, antiemetic prophylaxis will be given to patients at risk. The number and variety of agents administered will be increased according to the number of risk factors present in a multimodal approach. Smaller doses of drugs with differing mechanisms are chosen to allow for a broader array of potential coverage. If a patient experiences PONV and has already received an antiemetic, a rescue drug or drugs with a different mechanism are chosen.⁸¹ Other rescue interventions should be implemented, including verification of adequate hydration, as supplemental IV crystalloids or colloids are associated with a lower incidence of several PONV outcomes.⁷⁴ Drugs that block the serotonin receptors (5-HT₃) are ondansetron, dolasetron, granisetron, and palonosetron. Ondansetron, granisetron and dolasetron should be administered at the end of surgery.⁷⁴ Due to a 40-hour half-life, palonosetron should be administered at the beginning of surgery.⁸¹ Droperidol blocks the dopamine (D₂) receptor sites (although the Food and Drug Administration [FDA] black box warning about QT prolongation and required ECG monitoring must be kept in mind). Haloperidol in low doses is sometimes used as an alternative to droperidol, but the half-life is longer.^{81,82} Other D₂-blocking agents are prochlorperazine or metoclopramide. For histamine receptors, promethazine or diphenhydramine can be used. Glycopyrrolate or scopolamine patches may be used for the muscarinic receptors. Dexamethasone is often given in conjunction with a 5-HT₃ blocking agent or droperidol. Substance P is another neurotransmitter that belongs to the neurokinin family of neurotransmitters. Substance P has affinity for neurokinin 1 (NK-1) receptors. The only neurokinin antagonist in use at the time of writing is aprepitant, which can be given orally as a prophylactic agent.^{15,81}

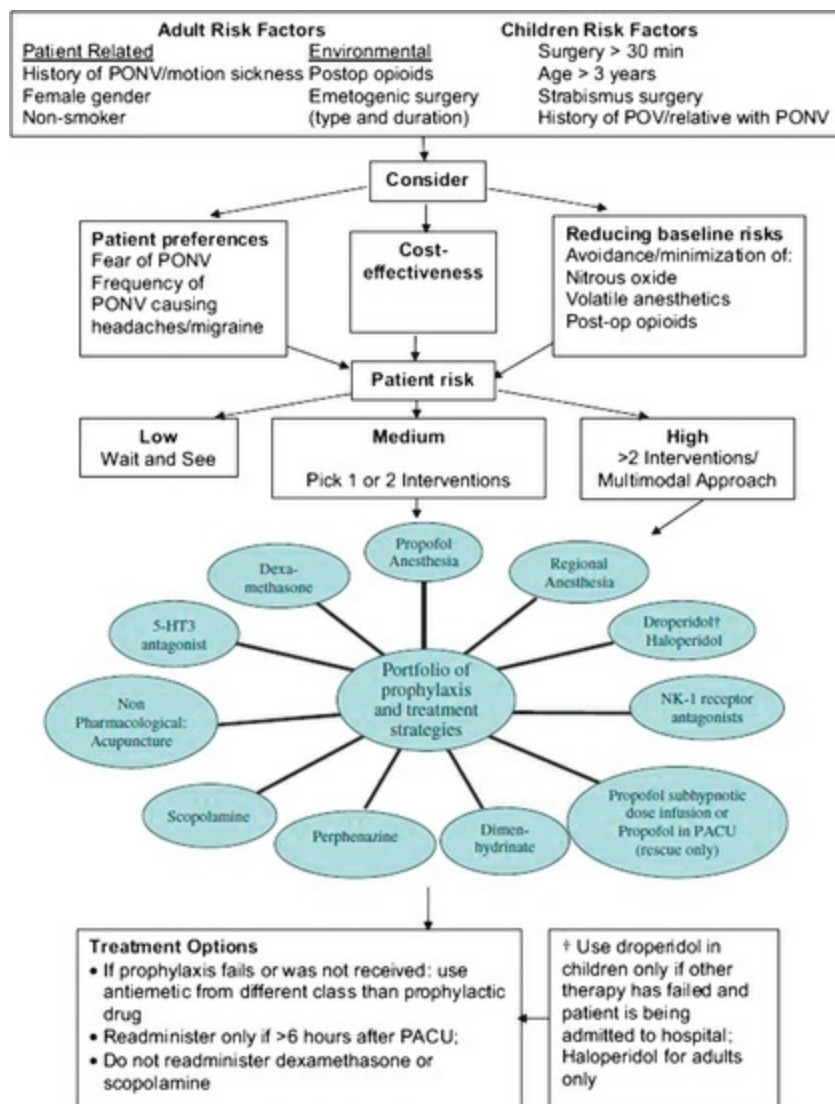

FIGURE 55.5 Algorithm for management of postoperative nausea and vomiting (PONV). PACU, Postanesthesia care unit; POV, postoperative vomiting. (From Gan TJ, et al. Consensus guidelines for the management of postoperative nausea and vomiting. *Anesthesia and Analgesia*. 2014;118:85–113.)

Side effects (e.g., agitation, restlessness, drowsiness) may be associated with the use of some antiemetics. Prophylaxis using a combination of antiemetic drugs has been suggested as an effective strategy for minimizing PONV.⁷⁴ Ephedrine also has been used for maintaining systemic blood pressure, thereby minimizing cerebral ischemia and preventing PONV. The FDA warning for droperidol is intended to increase awareness of the potential for cardiac dysrhythmias during drug administration and to encourage consideration of alternative medications for patients at high risk for cardiac dysrhythmias. Droperidol currently carries a warning about

cases of sudden death at high doses (greater than 25 mg) in patients at risk for cardiac dysrhythmias. Recent research has shown QT prolongation (i.e., delayed recharging of the heart between beats) within minutes after injection of a dose of droperidol at the upper end of the labeled dose range.⁸² Prolonged QT is dangerous as it may result in a fatal heart arrhythmia known as *torsades de pointes*. Historically, the typical dose of droperidol given to adults with symptoms of PONV is in the range of 0.625 to 2.5 mg IV.

Nonpharmacologic interventions also may be appropriate for the patient with PONV in addition to pharmacologic interventions.^{15,74,82} Acupuncture, transcutaneous electrical nerve stimulation, acupoint stimulation, and acupressure have been shown to be effective in reducing the incidence of PONV and need for rescue medication. P6 stimulation has been shown to be effective, as well as Korean hand acupoints.^{74,81} Aromatherapy (e.g., isopropyl alcohol, peppermint oil) has been used to treat PONV.^{15,82–85} Controlled breathing has been shown to be as effective alone as in combination with isopropyl alcohol in the treatment of PONV.⁸⁵ Some commonly used antiemetics for PONV and PDNV are listed in [Table 14.7](#).

Pathways for nausea and vomiting are shown in [Fig. 55.6](#).

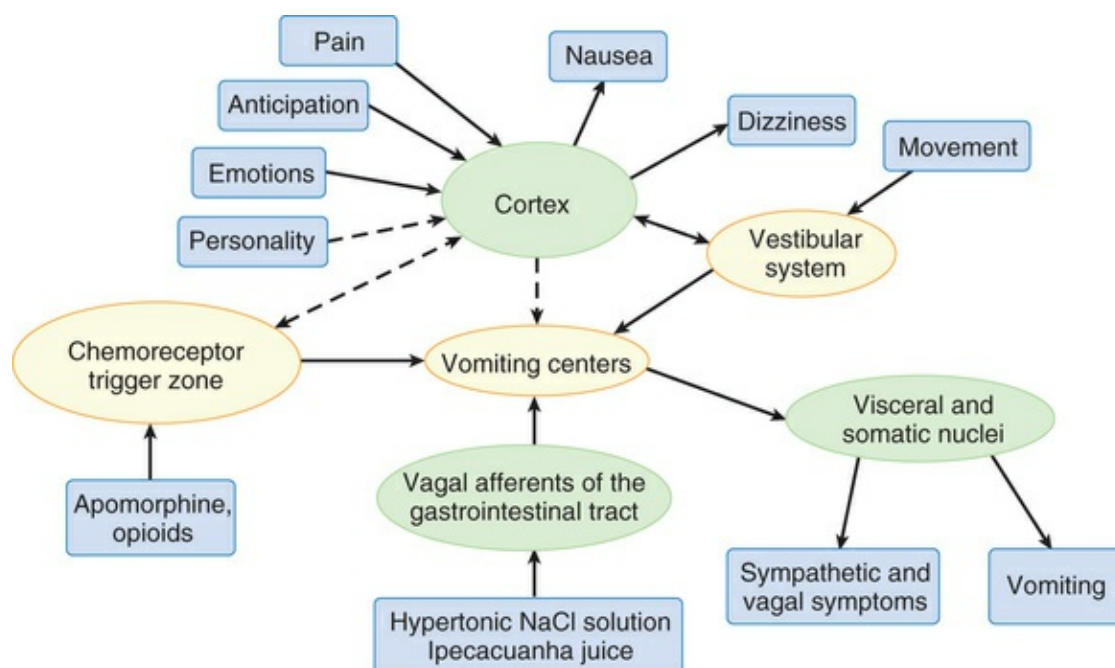

FIGURE 55.6 Pathways for nausea and vomiting. Dotted

lines are hypothetical pathways with only indirect evidence.
NaCl, Sodium chloride. (Created by Christian Apfel, MD, PhD.)

Apfel⁸² supports a rational approach to management of PONV/PDNP based on current knowledge and understanding and advocates following a rule of three: (1) risk assessment for prevention, (2) adjustment of preventive measures used (includes a modification of the anesthetic technique) based on the patient's need, and (3) follow up on the patient with use of rescue treatment immediately, by targeting mechanisms that have not been tried before (including nonpharmacologic methods).

Fluids

The goal of fluid management during the perioperative period is to maintain adequate intravascular fluid volume, left ventricular filling pressure, cardiac output, systemic blood pressure, and oxygen delivery to tissues. Appropriate concentrations of body fluid and electrolytes in the perioperative patient is essential to normal physiologic function of all body systems.⁷⁷ According to the ASA practice guidelines,⁵ routine perioperative assessment of patients' hydration status and fluid management reduces adverse outcomes and improves patient comfort and satisfaction. The principles of goal directed fluid therapy (GDFT), particularly in the high risk surgical population,⁸⁶ support prevention of postoperative fluid overload. Recent research (2016) has shown that hospital length of stay and postoperative complication rates can be reduced through adherence to GDFT principles.⁸⁷

On the patient's admission to the PACU, intravascular volume is estimated, with consideration given to preoperative status, type and duration of surgery, estimated blood loss, fluid replacement, and hemostasis. Monitoring urine output as an index of intravascular volume can be misleading. Surgery and anesthesia impair renal tubular concentrating ability, and glycosuria causes osmotic diuresis, each falsely indicating that intravascular volume is adequate. Central venous pressure, pulmonary arterial pressure, or transesophageal ultrasound monitoring can help clarify volume status. Symptoms such as poor skin perfusion (for example, cool, pale, and clammy skin), particularly in the feet; oliguria;

hypotension; tachycardia; and tachypnea can indicate hypovolemia.^{77,82}

A reduction in circulating intravascular volume decreases ventricular filling and cardiac output. SNS-mediated tachycardia, increased SVR, and venoconstriction might compensate for a 15% to 20% loss of intravascular volume. Greater deficits can cause hypotension. Failure to replace preoperative fluid deficit and fluid or blood lost during surgery frequently causes hypovolemia. In the PACU, ongoing hemorrhage, sweating, and exudation of fluid into tissues (i.e., third-space losses) exacerbate hypovolemia. Blood loss is often occult, as with retroperitoneal bleeding, diffuse oozing related to coagulopathy, or hemorrhage into muscle after trauma or orthopedic procedures. Third-space losses can continue for up to 48 hours after surgery and can be massive during high-permeability pulmonary edema or accumulation of ascites. In a hypothermic, vasoconstricted patient, a low intravascular volume might maintain cardiac output on PACU admission but cause hypotension when venous capacity increases during rewarming.^{33,50}

Urinary Output and Voiding

Monitoring kidney function during recovery reduces morbidity in patients with marginal cardiovascular or renal status. The ability to void after spinal or epidural anesthesia should be assessed because autonomic effects of regional anesthetics or opioids interfere with sphincter relaxation and promote urine retention.^{83,88,89} Intrathecal anesthetic administration impacts the lower urinary tract at a higher rate and thus increases the threat of urine retention. Opioids, ketamine, general anesthetics, and nonsteroidal antiinflammatory medications may also increase the risk of postoperative urine retention (POUR) because they impede lower urinary tract function.⁸⁹⁻⁹¹

Urinary retention is common after urologic, inguinal, and genital surgery and frequently delays discharge. It is reasonable to discharge inpatients to a surgical floor and selected ambulatory surgical patients from the facility before they void.⁵ However, it is important to ensure that urine output is monitored after discharge from the PACU to avoid urinary retention. A predictor of POUR was the presence of greater than 400–500 mL of urine in the bladder

immediately after spinal anesthesia.^{8,91} The amount of urine retained in the bladder can be assessed with use of a bladder scanner.⁸⁸ A decision can be made at that time if it is appropriate to do an in-and-out catheterization to drain the urine. It is prudent to give ambulatory patients who are discharged without voiding a specific time interval in which to void (e.g., 6 to 8 hours after discharge). If retention persists, the patient should be instructed to contact a health care facility. Patients with indwelling catheters should have urinary output recorded hourly.

Urine color is not useful for assessment of renal tubular function such as concentrating ability, but color can signal hematuria, hemoglobinuria, or pyuria. Urine osmolarity is a more reliable index of tubular function than specific gravity, which is affected by molecular weight.

Oliguria (less than 0.5 mL/kg per hr) occurs frequently during recovery and usually reflects an appropriate renal response to hypovolemia or systemic hypotension.¹¹ Low urine output may also result from intentional GDFT, which should be considered as an intended causative factor.⁹² However, a decreased urine output might indicate abnormal renal function. The acceptable degree and duration of oliguria vary with underlying renal status, the surgical procedure, and the anticipated postoperative course. If events related to the surgical procedure could jeopardize renal function (e.g., aortic cross-clamping, severe hypotension, massive transfusion), oliguria must be aggressively evaluated. In patients without catheters, bladder volume and interval since last voiding should be checked to help differentiate between oliguria and inability to void. Urinary catheters should be checked for kinking and obstruction by blood clots or debris. Patient position might also place the catheter tip above the urinary level in the bladder.⁸⁸

Polyuria, a state of profuse urine output, usually reflects generous intraoperative fluid administration. Osmotic diuresis caused by hyperglycemia and glycosuria is another cause, particularly if glucose-containing crystalloid solutions have been infused. Polyuria might also reflect intraoperative diuretic administration. Sustained polyuria (4 to 5 mL/kg per hr) can indicate abnormal regulation of water clearance, especially if urinary losses compromise intravascular volume and systemic

blood pressure. Polyuria related to diabetes insipidus occurs secondarily to intracranial surgery, pituitary ablation, head trauma, increased intracranial pressure, and inadvertent omission of preoperative vasopressin. The diagnosis is made by comparing urine and serum electrolytes and osmolarity. High-output renal failure also should be considered as a cause.¹⁵

Discharge From the Postanesthesia Care Unit

The patient leaving the PACU may be discharged to home, an ambulatory surgical unit, a surgical inpatient unit, or an intensive care unit. The choice of a discharge facility should depend on the patient's need and physical status and the availability of appropriate resources.

When possible, before discharge, each patient should be sufficiently oriented to assess his or her physical condition and be able to summon assistance. Airway reflexes and motor function must be adequate to prevent aspiration. Ventilation and oxygenation should be acceptable and demonstrate sufficient reserve to safely cover minor deterioration in unmonitored settings. To detect hypoxemia, oxygen saturation should be monitored for an appropriate period after discontinuation of supplemental oxygen. Before discharge, patients should be observed for a period after the last IV opioid or sedative is administered to assess peak effects, as well as side effects. Hemodynamic measurement and indexes of peripheral perfusion should be relatively constant. Achievement of normal body temperature (greater than 96.8°F) should occur before discharge home or to a medical floor; the intensive care unit (ICU) staff can continue an active warming process. Resolution of shivering is important. Acceptable analgesia must be achieved and vomiting appropriately controlled. Likely surgical complications must be determined (e.g., bleeding, vascular compromise, pneumothorax, complications of coexisting diseases such as coronary artery disease, diabetes, hypertension, or asthma). The results of postoperative diagnostic tests should be reviewed. The routine requirement for urination before discharge should not be part of a discharge protocol and may be necessary only for selected day-surgery patients. Likewise, the requirement of drinking clear fluids should not be a part of a discharge protocol and may be necessary only for selected patients (e.g., diabetic patients) and determined on a case-by-case basis.⁵

Outcome indicators applied to discharge criteria should be

written with a patient focus; for example, “Before discharge, the patient will maintain vital signs within the preoperative range.” Examples of discharge criteria are found in [Box 55.10](#). The patient's ability to meet these criteria constitutes clearance for discharge from the PACU but does not imply readiness for discharge to home. Two scoring systems designed to evaluate the patients for outpatient discharge have been piloted by clinicians Aldrete⁷ and Chung et

Box 55.10

Postanesthesia Care Unit Discharge Criteria

- Regular respiratory pattern
- Respiratory rate appropriate for age
- Absence of restlessness and confusion
- Vital signs within preoperative range
- Pulse oximetry indicates 95% saturation* or value equal to preoperative saturation
- Arterial blood gas values within normal limits†
- Ability to maintain patent airway
- Surgical stability of operative site or system

*Unit policies may dictate another number needed for oxygen saturation on discharge. There is no known accepted saturation level for discharge; most units require at least 92%.

†Not routinely obtained before discharge.

The Aldrete modified postanesthesia recovery (PAR) score is a modification of the original Aldrete score for PAR ([Table 55.5](#)). This modification of the scoring system changed assessment of “color” to assessment of “oxygen saturation.” This scoring system is for use

when patients are discharged from PACU phase I. A further modification of the Aldrete scoring system for outpatients' street fitness is given in [Table 55.6](#).

TABLE 55.5
Aldrete Postanesthesia Scoring System

		Admit	15 min	30 min	45 min	60 min
Activity	Able to move voluntarily on command	Four extremities	2	2	2	2
		Two extremities	1	1	1	1
		No extremities	0	0	0	0
Respiration	Able to breathe deeply, cough freely		2	2	2	2
	Dyspnea or limited breathing		1	1	1	1
	Apnea		0	0	0	0
Circulation	BP \pm 20 mm Hg of preanesthesia level		2	2	2	2
	BP \pm 20–50 mm Hg of preanesthesia level		1	1	1	1
	BP \pm 50 mm Hg of preanesthesia level		0	0	0	0
Consciousness	Fully awake		2	2	2	2
	Arousable on calling		1	1	1	1
	Not responding		0	0	0	0
O ₂ Saturation	Able to maintain O ₂ saturation greater than 90% on room air		2	2	2	2
	Needs O ₂ inhalation to maintain O ₂ saturation greater than 90%		1	1	1	1
	O ₂ saturation less than 90% even with O ₂ supplementation		0	0	0	0

BP, Blood pressure; O₂, oxygen.

From Marshall S, Chung F. Assessment of 'home readiness' discharge criteria and post-discharge complications. *Curr Opin Anesthesiol.* 1997;10:445–480.

TABLE 55.6
Modified Postanesthesia Recovery Score for Outpatients' Street Fitness

Parameter	Description	Score
Activity	Able to move four extremities voluntarily on command	2
	Able to move two extremities voluntarily on command	1
	Able to move no extremities voluntarily on command	0
Respiration	Able to breathe deeply and cough freely	2
	Dyspnea or limited breathing	1
	Apneic	0
Circulation	BP \pm 20 mm Hg of preanesthetic level	2
	BP \pm 21–49 mm Hg of preanesthetic level	1
	BP + 50 mm Hg of preanesthetic level	0

Consciousness	Fully awake	2
	Arousable on calling	1
	Not responding	0
O ₂ Saturation	Able to maintain O ₂ saturation greater than 92% on room air	2
	Needs O ₂ inhalation to maintain O ₂ saturation greater than 90%	1
	O ₂ saturation less than 90% even with O ₂ supplement	0
Dressing	Dry	2
	Wet but stationary	1
	Wet but growing	0
Pain	Pain free	2
	Mild pain handled by oral medications	1
	Pain requiring parenteral medications	0
Ambulation	Able to stand up and walk straight*	2
	Vertigo when erect	1
	Dizziness when supine	0
Fasting and feeding	Able to drink fluids	2
	Nauseated	1
	Nausea and vomiting	0
Urine output	Has voided	2
	Unable to void but comfortable*	1
	Unable to void and uncomfortable	0

*May be replaced by Romberg's test or picking up 12 clips in one hand.

From Aldrete JA. The postanesthesia recovery score revisited. *J Clin Anesth.* 1995;7:89–91.

Chung et al.⁹³ developed the Postanesthesia Discharge Scoring system as a simple, objective tool to assess the readiness of patients to be discharged to home (Box 55.11). A score of 9 is needed for the patient to be discharged. Although studied retrospectively, the scoring system has yet to be tried as a predictive index in a widespread clinical trial. Regardless of the method used to assess readiness for discharge, the assessment should be documented in an objective manner using criteria agreed upon by the departments of anesthesia, nursing, and surgery.

Postanesthesia Discharge Scoring System

Vital Signs

2 = Within 20% of preoperative value

1 = 20%–40% of preoperative value

0 = Greater than 40% of preoperative value

Activity and Mental Status

2 = Oriented 3 separate times and a steady gait

1 = Oriented 3 separate times or a steady gait

0 = Neither

Pain, Nausea, Vomiting

2 = Minimal

1 = Moderate, requiring treatment

0 = Severe, requiring treatment

Surgical Bleeding

2 = Minimal

1 = Moderate

0 = Severe

Intake and Output

2 = Postoperative fluids and void

1 = Postoperative fluids or void

0 = Neither

From Chung F, et al. A post-anesthetic discharge scoring system for home-readiness after ambulatory surgery. *J Clin Anesth.* 1995;7:500–506.

More research to support PACU patient discharge criteria is needed.⁹⁴ Fixed PACU discharge criteria must be used with caution, because variability among patients is tremendous. Scoring systems that quantify physical status or establish thresholds for vital signs are useful for assessment¹¹ but cannot replace individual evaluation.

Fast-tracking outpatients after general anesthesia has assumed

increased importance in ambulatory anesthesia because of the cost-savings potential when patients are transferred directly from the OR to the less labor-intensive phase II recovery area. Given the inherent risks of complications associated with bypassing the PACU, effective and reliable fast-track criteria that allow anesthesia providers to rapidly assess a patient's postoperative alertness, physiologic stability, and comfort level immediately before transferring the patient from the OR are clearly needed.⁹⁴ An outpatient should be discharged to a responsible adult, who will accompany the patient home and able to report any postprocedure complications. In addition, outpatients should be provided with written instructions regarding postprocedure diet, medications, activities, and a phone number to call in case of emergency.¹

Ideally, each patient should be evaluated for discharge by a qualified anesthesia provider using a consistent set of criteria that take into consideration the severity of the underlying disease, the anesthetic and recovery course, and the level of care at the destination, especially for ambulatory patients.

Summary

Postanesthesia care units are vital to the safe recovery of patients from surgery and anesthesia. Nurses provide the skillful bridge to ensuring a successful perioperative experience. They assess and monitor patients for residual anesthetic effects and surgical complications and reinstitute care for preexisting medical problems. Integrating care provided by the nurse with that of the anesthesia and surgical teams is essential in the modern surgical center.

Acute Pain

Physiology and Management

Sandra K. Bordi

In the United States it is estimated that approximately 100 million people suffer from chronic pain; this number does not account for acute and/or surgical pain.¹ Even though advances have been instituted to help practitioners recognize and treat pain, the incidence of unrelieved pain continues to be a major concern. In 1992, the Agency for Healthcare Research and Quality devised the first clinical practice guidelines (CPGs) for pain management. Subsequently, other groups including the American Pain Society, American Society of Anesthesiologists, and the American Academy of Pain Management have instituted CPGs for management of acute and chronic pain. In addition to these associations, others have developed CPGs specific to patient populations (e.g., the elderly and pediatrics) and to types of pain (e.g., cancer pain, postoperative pain, and chronic noncancer pain) in an effort to improve pain management. Even though there are CPGs, pain management remains inadequate. Several professional and regulatory groups have proposed standards, responsibilities, and outcome measures to improve pain management. The Joint Commission (TJC) developed pain management standards that were implemented in 2001. TJC clearly outlined the responsibilities of hospitals, home care agencies, nursing homes, behavioral facilities, and outpatient clinics seeking accreditation. In 2015, TJC released clarification of the pain management standards to include nonpharmacological therapies, a broader definition of useful medications, and a mandate to refer patients, if needed² (Box 56.1). The implementation and clarification of these standards is a momentous step in the improvement of pain management.

The Joint Commission Pain Management Standards

The Joint Commission pain management standards require organizations to:

- Recognize the right of patients to appropriate assessment and management of pain
- Assess patients for pain that are consistent with the patient's age, condition, and ability to understand; the assessment includes the nature and intensity of the pain
- Record the results of the assessment in a way that facilitates regular reassessments and follow-up
- Establish policies and procedures that support the appropriate treatment (pharmacologic and/or nonpharmacologic) or referral for treatment
- Educate patients and their families about effective pain management
- Address patient needs for symptom management in the discharge planning process
- Ensure staff education regarding pain assessment and management

From Berry PH, Dahl JL. The new JCAHO standards: implications for pain management nurses. *Pain Manag Nurs*. 2000;1(1):3–12. Accessed at https://www.jointcommission.org/assets/1/18/Clarification_of_the_Pain_Management__Sta

As providers of anesthesia care in the United States, certified registered nurse anesthetists (CRNAs) are integral to the research and management of acute and chronic pain. CRNAs practice both autonomously and in collaboration with other health providers to deliver high-quality, holistic, evidence-based anesthesia, and pain care services.³ CRNAs are recognized as experts in the area of pain management, and their knowledge and skills are essential in

pursuing effective pain management modalities.

Pain

Definition

Pain remains a very complex and multidimensional experience. It was defined by the International Association for the Study of Pain (IASP) as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”⁴ The inherent context of this definition is that pain is a physiologic, emotional, and a behavioral experience.⁵

Box 56.2 Commonly used pain terminology is listed in [Box 56.2](#).

Pain Terminology

Algesia: Increased sensitivity to pain

Algogenic: Pain producing

Allodynia: A normally nonharmful stimulus is perceived as painful

Analgesia: The absence of pain in the presence of a normally painful stimulus

Dysesthesia: An unpleasant painful abnormal sensation, whether evoked or spontaneous

Hyperalgesia: A heightened response to a normally painful stimulus

Neuralgia: Pain in the distribution of a peripheral nerve(s)

Neuropathy: An abnormal disturbance in the function of a nerve(s)

Paresthesia: An abnormal sensation, whether spontaneous or evoked

Classification of pain is primarily based on longevity (acute versus chronic) and/or the underlying pathophysiology (nociceptive or nonnociceptive). Nociceptive pain is associated with the stimulation of specific nociceptors and can be either somatic or visceral. *Somatic pain* refers to pain that has an identifiable locus as a

result of tissue damage causing the release of chemicals from injured cells that mediate pain. Somatic pain is well localized, sharp in nature, and generally hurts at the point or area of stimulus. Conversely, *visceral pain* is diffuse, can be referred to another area, and is often described as “dull,” “cramping,” “squeezing,” or vague in nature. Visceral pain is often associated with the distention of an organ capsule or the obstruction of a hollow viscus. It is also often accompanied with autonomic reflexes such as nausea, vomiting, and diarrhea.⁶ In contrast, nonnociceptive pain can be categorized as being *neuropathic*. *Neuropathic pain* is caused by damage to peripheral or central neural structures resulting in abnormal processing of painful stimuli. It is a dysfunction of the central nervous system (CNS) that allows for spontaneous excitation in chronic pain states. Neuropathic pain is often described as “burning,” “tingling,” or “shocklike.”⁷ Lastly, unlike neuropathic pain, *inflammatory pain* is a result of sensitization of the nociceptive pathway from multiple mediators being released at the site of tissue inflammation without neural injury. Patients in chronic pain states often exhibit more than one type of pain.⁸

Anatomy and Physiology

Somatic nociceptive pain is most commonly defined in terms of four processes: transduction, transmission, perception, and modulation. *Transduction* is the transformation of a noxious stimulus (chemical, mechanical, or thermal) into an action potential. A noxious stimulus is detected by pain receptors, or nociceptors, which are free nerve endings. These peripheral nociceptors that conduct noxious stimuli to the dorsal horn of the spinal cord are categorized according to morphology (diameter, myelination, and conduction velocity). The myelinated A-delta ($A\delta$) primary afferent neurons conduct action potentials at velocities between 6 and 30 m/s and elicit fast-sharp pain. They are responsible for the initial mechanical or thermal pain that is felt and alert an individual of tissue damage, thereby resulting in the reflex withdraw mechanism. The smaller nonmyelinated C fibers conduct at velocities significantly slower, between 0.5 and 2 m/s. Because C fibers respond to mechanical, thermal, and chemical injuries, they are also known as *polymodal fibers*. As a result of their slow conducting

velocity, a delayed, slow, second pain is elicited by C fibers.⁸ Slow pain is commonly described as “dull,” “burning,” “throbbing,” and “aching.”

Consequently, when peripheral tissues (skin, bone, and viscera) receive chemical, thermal, or mechanical stimuli or are traumatized by either surgery or injury, a series of biochemical events take place in peripheral pain transduction. These events include the release of chemical mediators from the inflammatory response and the release of neurotransmitters from nociceptive nerve endings (Fig. 56.1). The chemical mediators and neurotransmitters released are extensive, with the more prominent substances in the following list:

FIGURE 56.1 Inflammation and peripheral nociception.

After tissue injury, mast cells, macrophages, and neutrophils are activated and/or are recruited to the area.

In addition, small nociceptive nerve endings are also triggered. A variety of algogenic substances are released as a result of the inflammatory response and from the nociceptive nerve endings. These algogenic substances

contribute to the pain process either directly (i.e., increasing excitability of nerves) or indirectly via second messenger (i.e., PKA, PKC) responses. *5HT*, 5-Hydroxytryptamin receptor; *ATP*, adenosine triphosphate; *B2/B1*, bradykinin 1 and bradykinin 2 receptor; *EP*, prostaglandin E receptor; *H⁺*, excess free hydrogen ion; *H₁*, histamine-1 receptor; *iGluR*, ionotropic glutamate receptor; *IL-6*, interleukin-6; *IL-1 β* , interleukin-1 β ; *IL-1r*, interleukin 1 receptor; *LIF*, leukemia-inhibiting factor; *mGluR*, G protein-coupled metabotropic glutamate receptor; *NGF*, nerve growth factor; *P2X2*, primary receptor family for ATP; *PAF*, platelet-activating factor; *PGE₂*, prostaglandin E₂; *PKA*, protein kinase A; *PKC*, protein kinase; *TNF- α* , tumor necrosis factor- α ; *TrkA*, tyrosine kinase receptor A. (Modified from Dougherty P, et al.

Neurochemistry of somatosensory and pain processing. In: Benzon HT, et al., eds. *Essentials of Pain Medicine*. 3rd ed. Philadelphia: Elsevier; 2011:8–

15.)

- *Substance P* is a peptide found and released from the peripheral afferent nociceptor C fibers and is involved with slow, chronic pain. It acts via the G-protein-linked neurokinin-1 receptor resulting in vasodilation, extravasation of plasma proteins, degranulation of mast cells, and sensitization of the stimulated sensory nerve.⁹
- *Glutamate* is a major excitatory neurotransmitter released in the CNS and from the A δ and C primary afferent nerve fibers. Its effects are instantaneous, producing initial, fast, sharp pain.⁹
- *Bradykinin* is a peptide released during the inflammation process and is notably algescic. It has a direct stimulating effect on peripheral nociceptors via specific bradykinin receptors (B1/B2).
- *Histamine* is an amine released from mast cell granules, basophils, and platelets via substance P. It reacts with various histamine receptors to produce edema and vasodilation.
- *Serotonin (5-hydroxytryptamine [5-HT])* is an amine stored and released from platelets after tissue injury. It reacts with multiple receptor subtypes and exhibits algescic effects on peripheral nociceptors. Like histamine, serotonin can potentiate bradykinin-induced pain.
- *Prostaglandins (PGs)*, along with *thromboxanes* and *leukotrienes*, are

a metabolite of arachidonic acid. PGs, specifically, are synthesized from cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). They are associated with chronic pain; PGs sensitize peripheral nociceptors, causing hyperalgesia.

- *Cytokines* are released in response to tissue injury by a variety of immune and nonimmune cells via the inflammatory response. Cytokines including interleukin-1 β (IL-1 β), interleukin-6 (IL-6), and tumor necrosis factor- α (TNF- α) can lead to the increased production of PGs, thereby exciting and sensitizing nociceptive fibers.¹⁰
- *Calcitonin gene-related peptide (CGRP)* is a peptide found and released from the peripheral afferent nociceptor C fibers. It is responsible for producing local cutaneous vasodilation, plasma extravasation, and sensitization of the stimulated sensory nerve.

These chemical mediators and neurotransmitters stimulate the peripheral nociceptors, causing an influx of sodium ions to enter the nerve fiber membranes (depolarization), and a subsequent efflux of potassium ions (repolarization). An action potential results, and a pain impulse is generated.

Transmission is the process by which an action potential is conducted from the periphery to the CNS. There are multiple pathways that carry noxious stimuli to the brain. The spinothalamic (anterolateral) system, which carries pain signals from the trunk and lower extremities, will be discussed here. The primary afferent neurons (A δ and C fibers) have cell bodies located in the dorsal root ganglia of the spinal cord. Upon entering the dorsal cord these fibers segregate and ascend or descend several spinal segments in the tract of Lissauer. After leaving the tract of Lissauer, the axons of the primary afferents enter the gray matter of the dorsal horn where they synapse with second-order neurons and terminate primarily in Rexed laminae I, II, and V (Fig. 56.2). Two types of second-order neurons exist: (1) nociceptive neurons, which receive input solely from primary afferent A δ and C fibers, and (2) wide-dynamic-range (WDR) neurons that receive input from both nociceptive (A δ and C fibers) and nonnociceptive (A β) primary afferents. WDR neurons are therefore activated by a variety of stimulants (innocuous and noxious) (Fig. 56.3).

FIGURE 56.2 Transmission of both “fast-sharp” and “slow-chronic” pain signals into and through the spinal cord on their way to the brain. A δ fibers transmit fast-sharp pain, and C fibers transmit slow-chronic pain. (From Hall JE, ed. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:623.)

FIGURE 56.3 Ascending lateral spinothalamic tract. (From Patton KT, Thibodeau GA. *Anatomy and Physiology*. 9th ed. St. Louis: Elsevier; 2016:465.)

Second-order neurons then cross the midline of the spinal cord through the anterior commissure and ascend in the anterolateral pathway of the spinothalamic tract to the thalamus. In the lateral thalamus and the intralaminar nuclei second-order neurons synapse with third-order neurons, which then send projections to the cerebral cortex. *Perception* of pain occurs once the signal is recognized by various areas of the brain, including the amygdala, somatosensory areas of the cortex, the hypothalamus, and the anterior cingulate cortex.

Modulation of pain transmission involves altering neural afferent activity along the pain pathway; it can suppress or enhance pain signals. Suppression of pain impulses occur through local inhibitory interneurons and descending efferent pathways. The descending efferent modulatory pathways from the brain are considered the body's analgesia system or pain control system.⁹ It is proposed that the descending dorsolateral efferent pathway is activated via a noxious stimulus. Descending axons from the cerebral cortex, hypothalamus, thalamus, periaqueductal gray area (PAG), nucleus raphe magnus, and locus coeruleus (LC) via the dorsolateral funiculus (DLF) synapse with and suppress pain transmission to the brainstem and the spinal cord dorsal horn. Several neurotransmitters and their receptors play critical roles in the inhibitory modulation of pain, including the inhibitory endogenous opioids (enkephalin/dynorphin). Action potentials arrive at the substantia gelatinosa via the DLF and activate enkephalin-releasing neurons. Enkephalin then binds to the opiate receptors on presynaptic first-order or postsynaptic second-order afferent fibers, which decrease substance P release, thereby suppressing ascending pain transmission. Other inhibitory neurotransmitters released via the descending pathway include glycine, norepinephrine, serotonin, and gamma-aminobutyric acid (GABA) (Table 56.1). Pharmacotherapies for pain control are aimed at many of these neurotransmitters and their receptors.

TABLE 56.1
Pain-Modulating Neurotransmitters

Neurotransmitters Receptor	
Excitatory Neurotransmitter	
Substance P	Neurokinin-1 (NK1), Neurokinin-2 (NK2)
Glutamate	NMDA, AMPA, kainite, mGluRs
Inhibitory Neurotransmitter	
Glycine	Chloride linked (GlyR)
GABA	GABA _A , GABA _B , GABA _C
Enkephalin	Mu, delta
Serotonin	5-HT (5-HT ₁₋₃)
Norepinephrine	Alpha ₂ adrenergic

5HT, 5-Hydroxytryptamine; *AMPA*, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; *GABA*, gamma-aminobutyric acid; *GlyR*, glycine receptor; *mGluRs*, metabotropic glutamate receptors; *NMDA*, N-methyl-D-

aspartate.

Physiologic Consequences

Acute pain is caused by noxious stimulation resulting from traumatic injury (chemical, thermal, or mechanical), surgery, or acute illness. Generally, the intensity of acute pain diminishes over the course of healing; however, social, cultural, and personality factors may affect this. Its duration is usually self-limited and resolves within healing of the underlying injury, which may take from 1 day to 6 months. Acute pain is responsive to pharmacotherapy and treatment of the precipitating cause. Unfortunately, poorly controlled acute pain may lead to chronic pain states. Therefore optimal pain management is crucial in expediting the healing process and for the prevention of chronic pain.

It is well documented that acute pain causes adverse physiologic consequences involving multiple organ systems, which can contribute to morbidity and mortality in surgical patients. Neuroendocrine responses that are triggered primarily by the sympathetic nervous system (SNS) in response to surgical stress and pain initiate these effects. Factors such as the extent of the surgical field, the number of pain receptors involved in the area, bleeding, infection, anxiety, and presence of coexisting diseases may accelerate the endocrine stress response.

The activation of the SNS in response to the stress of pain from surgery or trauma results in many cardiovascular responses. The increased release of catecholamines from the SNS and adrenal glands, along with cortisol, produces an increased heart rate, increased vascular resistance (peripheral, systemic, and coronary), increased myocardial contractility, and increased arterial blood pressure. These ultimately increase the myocardial demand and myocardial oxygen consumption. Additionally, in the presence of coexisting cardiovascular disease, atherosclerotic plaque from vascular walls may rupture, thereby decreasing oxygen supply further. This may lead to dysrhythmias, angina, myocardial ischemia, and myocardial infarction. Overall, the incidence of increased myocardial oxygen demand and decreased myocardial oxygen supply can have deleterious effects in those patients with

coexisting cardiovascular disease. Therefore aggressive pain management is essential in reducing the incidence of postoperative cardiac complications.¹¹

The presence of pain can have significant effects on the respiratory system. These effects are most pronounced in those patients having surgery or trauma in the upper abdominal area and thorax. Inadequate pain management causes a measurable decrease in tidal volume because of limited thoracic and abdominal movement. Specifically, there are decreases in vital capacity, inspiratory capacity, and functional residual capacity (FRC), in addition to a decreased physical ability to clear the airway because of unrelieved pain. Additionally, muscle spasm below and above the site of injury caused by the noxious stimuli promotes limited movement of the respiratory muscles. Patients often voluntarily decrease the movement of the thorax and abdomen (splinting), and are reluctant to breathe deeply or cough in an attempt to limit pain, which can lead to atelectasis and pneumonia.^{12,13} These pulmonary alterations may be aggravated in those patients with preexisting pulmonary dysfunction (e.g., asthma, chronic obstructive pulmonary disease) or in those with decreased FRC (e.g., morbidly obese, elderly). Consequently those affected by postoperative respiratory compromise as a result of inadequate pain management also may be at risk for deep venous thrombosis and subsequent pulmonary embolism caused by a decrease or delay in mobilization. See [Table 56.2](#) for physiologic consequences of acute pain.

TABLE 56.2
Physiologic Effects of Acute Pain

Organ System	Physiologic Effect	Adverse Outcome
Cardiovascular	Increased heart rate	Dysrhythmias
	Increased PVR	Angina
	Increased ABP	Myocardial ischemia
	Increased myocardial contraction	Myocardial infarction
	Increased myocardial work	
Pulmonary	Decreased VC	Ventilation/perfusion mismatch
	Decreased TV	Atelectasis
	Decreased TLC	Pneumonia
	Muscle spasms (respiratory/abdominal)	Hypoventilation
	Decreased ability to cough/deep breathe	Hypoxia
		Hypercarbia

Gastrointestinal	Decreased gastric emptying	Nausea/vomiting
	Decreased intestinal motility	Paralytic ileus
	Increased smooth muscle sphincter tone	
Coagulation	Increased platelet aggregation	Thrombosis
	Venostasis	DVT/PE
Immunologic	Decreased immune function	Increased risk of infection
Genitourinary	Increased urinary sphincter tone	Oliguria
		Urinary retention
Psychological		Fear
		Anxiety
		Depression
		Feelings of helplessness
		Anger

ABP, Arterial blood pressure; *DVT*, deep vein thrombosis; *PE*, pulmonary embolism; *PVR*, peripheral vascular resistance; *TLC*, total lung capacity; *TV*, tidal volume; *VC*, vital capacity.

Adapted from Joshi GP, Oqunnaik BO. Consequences of inadequate postoperative pain relief and chronic persistent postoperative pain. *Anesthesiol Clin North America*. 2005;23(1):21–36.

The physiologic effects and the consequences of inadequate pain management have been reported to have an impact in prolonging postoperative stay and patient recovery, and an overall increase in health care costs.¹⁴ It also negatively impacts the patient's surgical/hospitalization experience, resulting in reduced patient satisfaction.

Acute Pain Assessment

To devise a plan for intraoperative and postoperative surgical pain management, a preoperative pain assessment and discussion with the patient should be conducted. A thorough preoperative assessment should involve a physical and medical history assessment, including laboratory and diagnostic tests that are patient and surgery specific. Inquiries specific to preoperative pain also should be addressed; these are found in [Box 56.3](#). Part of the preoperative pain assessment process also should consist of identifying those at high risk for increased postoperative acute pain. Predictors of acute postoperative pain after elective surgery include: (1) the presence of preoperative pain, (2) patient fear regarding the outcome of his/her surgery, (3) patients who catastrophize pain, and (4) expected postoperative pain.^{15–19} Overall, goals for pain management should be based on patient physical/medical assessment, history, invasiveness of the surgical

procedure, an individual's pain response, and prediction of identifying those who are at high risk for developing increases in acute pain postoperatively. The patient should be informed of the varying modalities for postoperative pain control, and a unique pain management plan should be implemented by both the patient and care providers. Furthermore, realistic expectations for postoperative pain control should be discussed.

Box 56.3

Preoperative Pain Assessment

- Determine the existence of chronic pain
- Current medications (prescription and OTC)—continuous or prn for pain
- Inquiry regarding previous injuries
- Location of pain
- Quality of pain
- Intensity of pain
- Adjunctive therapies (e.g., acupuncture, TENS, injection therapy, SCS)
- Exacerbating factors
- Alleviating factors
- Limitations in movement
- Coexisting psychological diseases

OTC, Over-the-counter; *prn*, as needed; *SCS*, spinal cord stimulator; *TENS*, transcutaneous electric nerve stimulation.

As discussed earlier, adequate postoperative pain control is essential in the recovery process. Assessing the adequacy of postoperative pain control through vigilance and by using simple

assessment tools is vital. Because pain is subjective, the most reliable pain assessment tool is primarily via self-report. Pain assessment scales, which are both clinically valid and used in research, are available, and are based on measuring pain intensity. The common pain intensity scales include the visual analog scale (VAS), the numerical rating scale (NRS), and the Wong-Baker FACES scale. Even though these scales are available and are used in the clinical setting, they are not all-inclusive. The NRS, VAS, and Wong-Baker FACES scales assign a numerical value to an individual's pain, which is subjective and multidimensional. In addition, they do not take into consideration the patient's age or variations in cognitive level. The NRS is most often used by practitioners in assessing pain by asking the patient "What is your pain level on a scale of 1 to 10, with 10 being the worst pain you have ever experienced and 0 being pain-free?" Although this is a quick tool used to assess pain, it lacks the depth of determining the quality of pain or exacerbating factors that affect pain. Inevitably it is the provider's responsibility to investigate the patient's pain, be it surgical or nonsurgical, and intervene with a treatment modality. Key to successful acute pain control is vigilant reassessment and evaluation of the patient's response to a given treatment and changing treatment modalities, if necessary, in an effort to alleviate pain.

Preemptive Analgesia

Preemptive analgesia is a concept first postulated approximately 100 years ago. It was asserted that by administering analgesics prior to noxious stimulation a decreased pain response would result. The premise is that peripheral and central sensitization results from noxious stimulation, thereby causing an increase in postoperative pain. Preemptive analgesia in preventing central sensitization remains controversial.²⁰⁻²⁴ Even so, a multimodal approach to acute and chronic pain management is common practice. Multimodal pain management consists of using a combination of analgesics that work on a variety of receptors with different mechanisms of action, both peripherally and centrally, resulting in additive or synergistic effects in an effort to improve pain control (Fig. 56.4).

FIGURE 56.4 Pharmacotherapy and pain processing targets. The four processes of somatic nociceptive pain are signal transduction, transmission, modulation, and perception. Pharmacotherapy has an overall inhibitory effect on these processes. Modulation occurs primarily in the dorsal horn of the spinal cord, but also takes place in supraspinal structures. The endogenous descending inhibitory modulating pathway is also involved in pain inhibition, and it is not present in this illustration. *LA*, Local anesthetic; *NMDA*, N-methyl-D-aspartate antagonist; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PNB*, peripheral nerve block; *SNRI*, selective serotonin-norepinephrine reuptake inhibitor; *TCA*, tricyclic antidepressant.

Pharmacology

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are best known for their use in the management of mild to moderate postoperative pain and pain related to inflammatory conditions. They are the most common analgesic adjuvants used in multimodal analgesia remedies. When using NSAIDs and opioids together, a synergistic effect results in analgesia along with an overall decreased dose of opioids and decreased opioid side effects. NSAIDs vary in chemical structure but all possess antiinflammatory, antipyretic, and analgesic properties. They produce their therapeutic effects by inhibiting COX and thereby preventing conversion of arachidonic acid to prostaglandins (Figs. 56.5 and 56.6). Prostaglandins (primarily PGE₁ and PGE₂) are responsible for sensitizing and amplifying peripheral nociceptors to the inflammatory mediators (substance P, bradykinin, and serotonin), which are released when tissue is traumatized. Therefore prostaglandins do not directly produce pain but instead contribute to hyperalgesia. Centrally, prostaglandins mediate pain by enhancing the release of substance P and glutamate in first-order neurons, increasing nociceptive transmission at second-order neurons, in addition to inhibiting the release of descending inhibitory neurotransmitters. For a further description of NSAIDs see [Chapter 11](#).

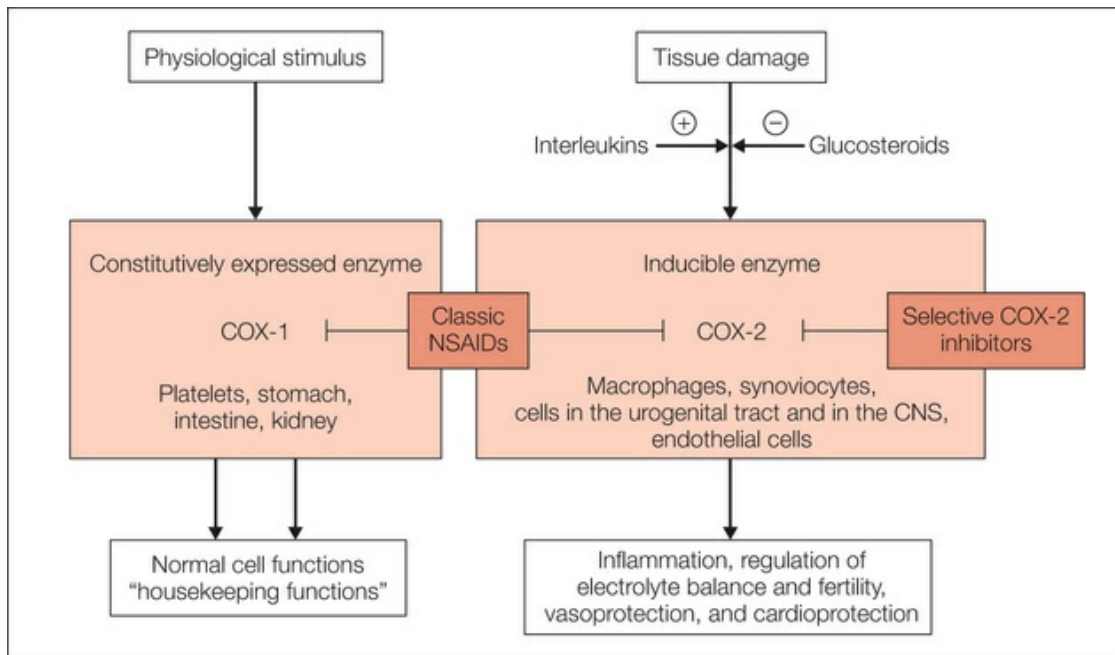

FIGURE 56.5 Simplified description of the physiological and pathophysiological roles of cyclooxygenase-1 (COX-1) and COX-2. COX-1 is expressed constitutively in most tissues and fulfills housekeeping functions by producing prostaglandins. COX-2 is an inducible isoenzyme that is expressed in inflammatory cells (e.g., macrophages and synoviocytes) after exposure to pro-inflammatory cytokines and is down-regulated by glucocorticoids. In the kidney (macula densa) and other areas of the urogenital tract and in the central nervous system (CNS), COX-2 is already significantly expressed even in the absence of inflammation. Induction of expression of COX-2 in peripheral and central nervous tissues appears to be most prominent in connection with inflammatory painful reactions. Both enzymes are blocked by classic acidic antipyretic analgesics (non-steroidal anti-inflammatory drugs [NSAIDs]). CNS, Central nervous system. (From McMahon S, et al. *Wall and Melzack's Textbook of Pain*. 6th ed. Philadelphia: Elsevier; 2013:445.)

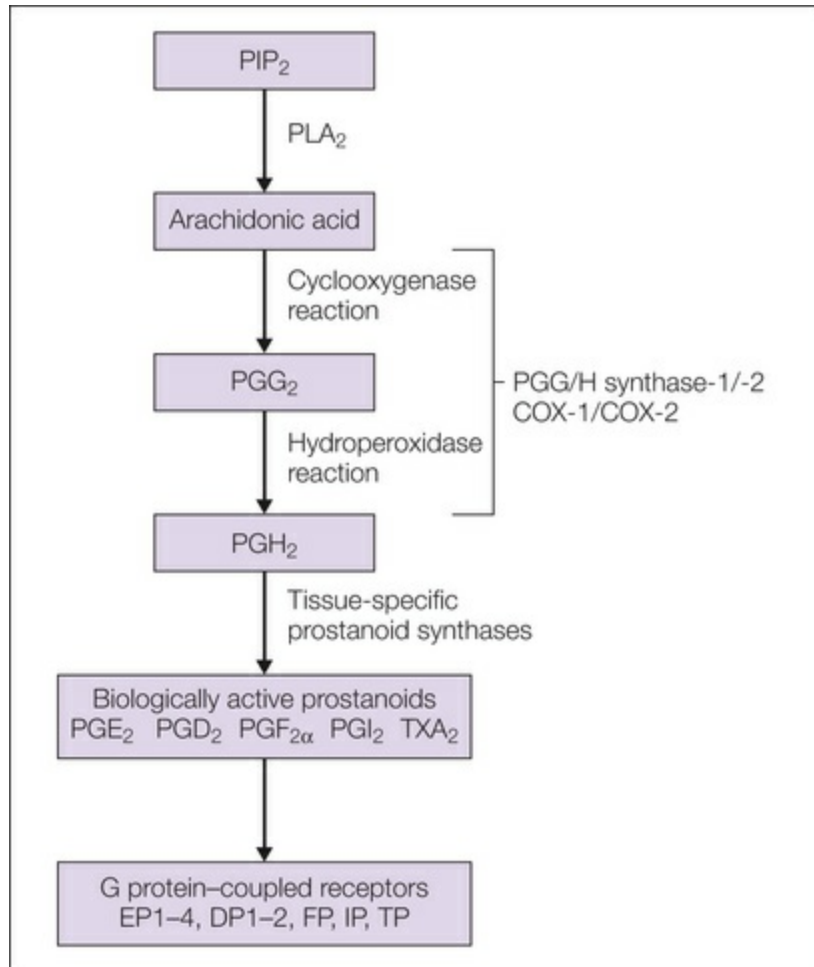

FIGURE 56.6 Classic prostanoid biosynthesis pathway.

Prostanoid biosynthesis starts with the release of arachidonic acid from cell membranes, mainly through cytosolic phospholipase A₂ (PLA₂)-dependent hydrolysis. Arachidonic acid is subsequently metabolized by either one of the two cyclooxygenases (COX-1, COX-2). Prostaglandin H₂ (PGH₂) is biologically largely inactive but serves as a substrate for tissue-specific prostaglandin synthases, which produce the different biologically active prostanoids. These prostanoids exert their biological action through binding to specific G protein-coupled receptors.

PIP₂, phosphatidylinositol 4,5,-bisphosphate; TXA₂, thromboxane A₂. (From McMahon S, et al. *Wall and Melzack's Textbook of Pain*. 6th ed. Philadelphia: Elsevier; 2013:445.)

Ketorolac

Ketorolac, a nonselective COX inhibitor, is also available for short-term acute postoperative pain, administered either alone or in combination with other analgesic modalities. Ketorolac can be

administered orally, intravascularly, intramuscularly, and intranasally. Comparatively the analgesic potency of ketorolac 30 mg intramuscular (IM) is equivalent to approximately 12 mg of morphine IM.²⁵ Because of the potential adverse effects caused by the inhibition of COX-1, ketorolac should not be administered beyond 5 days.²⁶ Contraindications for administering ketorolac include coagulopathies, renal failure, active peptic ulcer disease, gastrointestinal bleeding, history of asthma, hypersensitivity to NSAIDs, and surgery that involves a high risk for postoperative bleeding. In addition, controversy exists regarding bone healing and ketorolac administration.^{27,28} Ketorolac's inhibition of COX-1, COX-2, and prostaglandin synthesis interrupts normal prostaglandin effects on osteoblast and osteoclast functioning that promotes bone healing.²⁹ However, there are currently no recommendations regarding ketorolac administration and orthopedic procedures.

Acetaminophen

Even though it is not a true NSAID, acetaminophen reduces prostaglandin synthesis by an uncertain mechanism. It has minimal antiinflammatory effects with mainly analgesic and antipyretic properties. It is suitable for acute, mild to moderate postoperative pain and fever. Oral acetaminophen is frequently combined with weak opioids (e.g., oxycodone, hydrocodone, codeine) for the treatment of moderate postoperative pain and chronic pain syndromes. Because it lacks the negative effects of typical NSAIDs (e.g., platelet inhibition, gastrointestinal irritation, renal toxicity), acetaminophen is an ideal drug for multimodal analgesia for surgical pain. Acetaminophen is metabolized primarily by the liver and is therefore contraindicated in patients with liver failure. The Food and Drug Administration (FDA) has limited the strength of acetaminophen to 325 mg per tablet, capsule, or other dosage unit, when combined with weak opioids, thereby limiting severe reactions related to acetaminophen. Parenteral acetaminophen (Ofirmev) is also available for the treatment of acute, mild to moderate pain, and is effective in treating moderate to severe pain with adjunctive opioid analgesics.³⁰ Dosing for adults weighing over 50 kg is 1000 mg every 6 hours or 650 mg every 4 hours

infused over 15 minutes to a maximum of 4000 mg/day. Dosing in children over 2 years of age and under 50 kg is 15 mg/kg every 6 hours or 12.5 mg/kg every 4 hours to a maximum of 75 mg/kg per day. Onset of action is approximately 10 minutes with a duration of action of 4 to 6 hours. Adverse effects of IV acetaminophen are rare when dosed accordingly, with more common side effects being nausea, vomiting, headache, and insomnia.³¹

Opioids

Opioid analgesics remain the drugs of choice for treatment of moderate to severe pain in the early postoperative period. Opioids produce analgesia by binding to and activating G protein-coupled opioid receptors (GPCRs) peripherally and in the CNS. Centrally, opioid receptors are predominantly found in the dorsal horn of the spinal cord, specifically Rexed lamina II of the substantia gelatinosa, and supraspinally in the PAG, medial thalamus, amygdala, and limbic cortex. Peripherally they are found on afferent sensory nerve fibers, as well as in the gastrointestinal tract, lungs, and joints.³² There are several subtypes of opioid receptors with the principal ones being mu (μ), delta (δ), and kappa (κ). When bound by opioids presynaptically, these GPCRs cause a biochemical change that decreases adenylate cyclase activity, thus inhibiting calcium channels and resulting in a decreased release of excitatory neurotransmitters such as substance P. Postsynaptically, there is an increase in outward potassium conductance with a subsequent hyperpolarization and an inhibition of excitatory neurotransmission.³³

A thorough understanding regarding opioid pharmacodynamics and pharmacokinetics is essential when choosing a specific opioid. This is discussed in [Chapter 11](#). Perioperatively, the more common opioids used for acute pain are fentanyl, morphine, and hydromorphone. These are predominantly administered parenterally but can be administered in a variety of routes depending upon the opioid (e.g., oral, epidural, intrathecal, intraarticular, and transdermal). Common side effects found with most opioids are dose dependent and include respiratory depression, pruritus, urinary retention, constipation, and nausea and vomiting.

Fentanyl

Intravenously, fentanyl's analgesic potency is approximately 80 to 100 times more than morphine. Its short onset of action (2 to 5 minutes) makes it an ideal opioid for treating acute pain. The duration of action of fentanyl is approximately 20 to 40 minutes because it is metabolized by the liver via *N*-dealkylation into inactive metabolites and excreted by the kidneys. Fentanyl can be administered intrathecally, epidurally, and intravenously via postoperative patient-controlled analgesia (PCA). It is also available transdermally for the treatment of chronic pain. Because fentanyl is highly lipophilic, its administration intrathecally is limited because of its short duration of action, with a single dose lasting 2 to 4 hours.^{34,35} The duration of action for a single dose of epidural fentanyl (50 to 200 mcg) will be approximately 2 to 3 hours.³⁶ Intrathecal and epidural fentanyl can be given as a single dose or a continuous infusion and is discussed in [Chapter 49](#).

Morphine

Morphine is the prototypical opioid by which all others are compared and is the most widely used for acute and chronic pain management. Metabolism of morphine is via hepatic glucuronidation resulting in the metabolites morphine-3-glucuronide and morphine-6-glucuronide (M6G), with the latter being the active metabolite. Both metabolites are excreted via the kidneys; however, in patients with renal failure M6G may result in prolonged effects.

Morphine is commonly used to treat moderate to severe perioperative and postoperative pain. Morphine can be administered intravenously, intrathecally, epidurally, or orally. When administered IV, the onset of analgesia is approximately 20 minutes with duration of action being approximately 4 to 5 hours depending on the dose administered. Unlike fentanyl, morphine is hydrophilic, making penetration of the blood-brain barrier and spinal cord more difficult. This results in a delayed onset of action (20 to 30 minutes) and a prolonged duration of action (8 to 24 hours) for single-dose intrathecal or epidural morphine. Similar to fentanyl, morphine can be given in a single dose or continuous

intrathecal or epidural infusion. PCA intravenously is also an option for morphine administration.

Hydromorphone

Hydromorphone is a derivative of morphine and is approximately 7 to 8 times more potent. Metabolism of hydromorphone is via hepatic conjugation; however, unlike morphine, it lacks the active metabolite M6G. Therefore administration in renal patients is considered safe. IV administration results in analgesia in approximately 15 minutes with a duration of action equivalent to morphine, approximately 4 to 5 hours. Hydromorphone is an ideal opioid for moderate or severe acute perioperative pain and is used for chronic pain management. Modes of administration include oral, intrathecal, epidural, intraarticular, and intravenous PCA. When administered via single dose intrathecally or epidurally, onset of action is more rapid than morphine (approximately 15 minutes), with a duration of action of approximately 10 to 16 hours.³⁷ The common side effects associated with morphine administration remain similar to hydromorphone when equivalent doses are administered. However, histamine release is less likely to occur with hydromorphone compared to morphine.³⁸

Analgesic Adjuncts

N-Methyl-D-Aspartate Antagonists

Ketamine, a noncompetitive N-methyl-D-aspartate (NMDA) antagonist and a phencyclidine derivative, is primarily used as an anesthesia induction agent. It is also used as part of a multimodal approach for perioperative pain control in conjunction with other medications. Ketamine prevents the activation of the NMDA receptor, which has been associated with the development of “wind-up” or central sensitization and chronic pain states along with the AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor. The NMDA receptor remains closed at rest because of a magnesium plug. Activation of the receptor involves the simultaneous binding of the excitatory neurotransmitter glutamate, which causes an influx of calcium,

resulting in an increase in second messengers. The up-regulation of second messengers produces a hyperexcitability of the NMDA receptors, which causes neuronal plasticity, excitability, and wind-up. In addition, research suggests that ketamine may exhibit antiinflammatory effects.³⁹

Ketamine is rapidly acting; an anesthetic IV dose response is seen in 30 to 40 seconds with a duration of 80 to 180 minutes. In addition to IV administration, it can be administered intramuscularly, nasally, rectally, via epidural, and intrathecally. Metabolism of ketamine is predominantly by the liver and produces norketamine.

Because ketamine exhibits both anesthetic and analgesic effects, its use has drawn more interest in the perioperative setting. Its administration at higher doses and as the sole anesthetic is less desirable because of psychotomimetic adverse effects. Ketamine has been used in “low doses” either as a single dose administered on induction of anesthesia and/or as a continuous infusion for acute perioperative pain. There is no conclusive, consistent consensus in regard to what is considered low-dose ketamine. Studies report minimal adverse effects with subanesthetic doses of ketamine, in addition to decreased perioperative opiate consumption.⁴⁰⁻⁴² However, randomized control trials and reviews have noted mixed results regarding efficacy of low-dose ketamine and postoperative analgesia.⁴⁰⁻⁴⁶

Alpha₂ Adrenergic Agonists

Clonidine and dexmedetomidine are α_2 adrenergic agonists that are used as analgesic adjuncts for multimodal anesthesia. They exhibit their analgesic effect by interacting with the G protein–coupled α_2 receptors, both centrally (dorsal horn of the spinal cord) and peripherally. Activation of the α_2 receptor results in inhibition of adenylyl cyclase and decreased cyclic adenosine monophosphate (cAMP) levels. It also activates postsynaptic potassium channels while inhibiting presynaptic voltage-gated calcium channels, thus reducing neurotransmitter release. In addition, it is suspected that activation of central α_2 adrenoreceptors in the LC are responsible for supraspinal analgesia.^{47,48}

Clonidine, a centrally acting selective partial α_2 adrenergic

receptor agonist, can be administered orally, intravenously, rectally, transdermally, intrathecally, epidurally, and via an intraarticular route. For acute pain management, clonidine is administered primarily intrathecally or epidurally. Its half-life is approximately 5 to 13 hours. Metabolism of clonidine is via the liver with the remainder of the drug being excreted unchanged in the urine. Because clonidine exerts its effects on both α_2 and α_1 receptors (400 : 1 α_2 to α_1), side effects such as sedation, hypotension, and bradycardia can occur.⁴⁹ Clonidine has been reported to decrease postoperative opioid requirements and prolong the duration of analgesia when administered via epidural with local anesthetics.⁵⁰⁻⁵² When combined with local anesthetics in peripheral nerve blocks, it is reported to prolong postoperative analgesia.⁵³⁻⁵⁵

Dexmedetomidine is a highly selective α_2 adrenergic agonist. It is approximately 7 to 10 times more selective for the α_2 receptors (1600 : 1 α_2 to α_1) when compared with clonidine.⁴⁹ Like clonidine, it exhibits sedative, anxiolytic, analgesic, sympatholytic, and vagomimetic effects with little or no respiratory depression. Dexmedetomidine is most commonly administered intravenously; however, it can be administered intramuscularly, transdermally, or intranasally. It has a rapid onset of action, approximately 5 minutes, with a short duration of action and an elimination half-life of approximately 3 hours. Metabolism of dexmedetomidine occurs via extensive hepatic glucuronide conjugation with the absence of active metabolites. Hepatic clearance may be decreased in the presence of liver disease. Dexmedetomidine is often used for procedural sedation in nonintubated patients, sedation for intubated and mechanically ventilated patients, as well as a general anesthesia adjunct. In a Cochrane review, it was reported that when dexmedetomidine was administered perioperatively for acute pain in abdominal surgery patients, there were some opioid-sparing effects. However, there were no significant differences in postoperative pain when compared to placebo.⁵⁶

Local Anesthetics

Unlike the previous analgesics whose actions are targeted at specific receptors on primary nociceptors and in the CNS, resulting

in reduced presynaptic transmitter release and decreased postsynaptic excitability, local anesthetics inhibit conduction of action potentials along a nerve fiber. Local anesthetics block sodium channels in both afferent and efferent neuronal membranes, thereby inhibiting pain transmission. They are often given as the sole anesthetic; however, for optimal postoperative analgesia, local anesthetics should be administered with adjuvant medications.

Nerve morphology (diameter and myelination) affects the sensitivity of nerve blockade achieved. An understanding of local anesthetic properties such as potency, onset of action, and duration of action is crucial in choosing a specific local anesthetic. These are addressed in [Chapter 10](#). Metabolism of local anesthetics is determined by the chemical class. Amide local anesthetics are metabolized primarily by the liver, whereas ester local anesthetics are metabolized via plasma cholinesterase. Conditions that alter liver function (hepatic disease) and/or decrease plasma cholinesterase levels will inevitably reduce the rate of metabolism.

Methods for administering local anesthetics are listed in [Table 56.3](#). The most common techniques for acute pain management are local infiltration of the operative area, peripheral nerve blocks, as well as epidural and subarachnoid blocks with adjuvant medications (primarily opioids). Prior to surgical incision, a local anesthetic can be injected intradermally or subcutaneously near the incisional area to decrease the inflammatory response; local anesthetic infiltration reduces up-regulation of peripheral nociceptors. Common local anesthetics used for operative area infiltration include bupivacaine or ropivacaine because of their longer duration of action.

TABLE 56.3

Methods of Administering Local Anesthetics

Route	Technique	Mode of Delivery
Topical		SS
Local infiltration	Subcut, subdermal	SS
	Intraarticular	SS, C
Neuraxial	Subarachnoid	SS, C, PC
	Epidural	
	Caudal	
Peripheral nerve blocks	<i>Lower extremity</i>	SS, C, PC
	Lumbar and sacral plexus	

	Femoral	
	Sciatic	
	Popliteal	
	Ankle	
	<i>Upper extremity</i>	
	Brachial plexus	SS, C, PC
	Cervical plexus	SS, C
	Intercostal	SS, C, PC
	IV regional (Bier block)	SS
	Digit	SS
Systemic	IV	SS
Diagnostic/interventional	Trigger point injection	SS
	Somatic nerve blockade	SS
	Sacroiliac injection	SS
	Facet injection	SS
	Epidural steroid injection	SS
	Selective sympathetic blockade	SS
	Intervertebral disc injection	SS
	Differential nerve blockade	SS

C, Continuous; IV, intravenous; PC, patient-controlled; SS, single shot; *Subcut*, subcutaneous.

Peripheral nerve blocks can be administered as a single injection or via a continuous catheter technique. [Chapters 49](#) and [50](#) provide a thorough description of regional techniques and peripheral nerve blocks. Most peripheral nerve blocks consist of a bolus dose of local anesthetic injected to infiltrate an area or a peripheral nerve site. These techniques are primarily used for minor surgical procedures that provide analgesia in the immediate postoperative period. The use of continuous catheters or continuous peripheral nerve blocks (CPNBs) involves an initial bolus dose of local anesthetic followed by a continuous infusion near the surgical site and adjacent to a nerve. CPNBs are increasing in popularity; they provide prolonged analgesia in those patients who are expected to have moderate-to-severe postoperative pain lasting more than 24 hours, and are commonly used for the brachial plexus, intercostal, femoral, and sciatic nerves.

Both subarachnoid and epidural blockade (primarily epidural) have been found to be useful in the management of postoperative pain. The primary site of action of local anesthetics when injected in the subarachnoid or epidural space is the nerve roots of the spinal cord. Because neuraxial anesthesia (local anesthetic with or without opioids) provides profound analgesia, some clinicians use the epidural technique with light general anesthesia during the surgical procedure; at the end of the procedure, the epidural catheter is left

in place for postoperative pain management. Medications (e.g., local anesthetics, opioids, and adjuvant medications) can then be administered as bolus injections, continuous infusion, or via a patient-controlled device. The continuous epidural technique can be used for thoracic, abdominal, and lower-extremity surgery.

Intravenously infused lidocaine, as a component of a multi-modal analgesia, should be considered in patients undergoing open and laparoscopic abdominal surgeries.⁵⁷ Studies involving these surgical procedures reported a decrease in postoperative pain scores when compared to placebo. In addition, patients had a shorter duration of ileus postoperatively.^{58,59}

Local anesthetics are used not only for acute postoperative pain management but also commonly used in the diagnosis and treatment of several chronic pain states. Examples of diagnostic and interventional uses include facet joint injection, sacroiliac injection, selective sympathetic blockade, and trigger point injection. Therapeutic injections and nerve blocks for chronic pain are discussed in [Chapter 57](#).

Patient-Controlled Analgesia

PCA was developed in the early 1970s with the advent of microprocessor technology. This administration technique has changed the face of acute pain management and has become a standard technique for postoperative pain control. Intravenous PCA involves self-administration of predetermined doses of analgesics. This ideally results in the patient's ability to self-medicate to his/her pain needs and allows for more effective pain control while avoiding peaks (opioid side effects) and troughs (pain) in plasma concentrations that are commonly present with "as needed" IV administration. Current PCA models have different variables for administration allowing for selective dosing. These variables include: (1) an initial loading dose, (2) a demand dose or bolus dose, (3) a lockout interval, (4) a basal continuous infusion rate, and (5) 1 hour and 4 hour maximal dose limits.^{60,61} The initial loading dose is administered by the programmer or postanesthesia care nurse for initial set-up in titrating the analgesic and/or for "breakthrough pain." The demand or bolus dose is the quantity of analgesia administered to the patient on activation of the PCA

demand button. The length of time after a demand dose is given by the patient, during which another demand dose will not be delivered, is the lockout interval. The lockout interval prevents overdosage with continual demand, with lockout intervals between 5 and 10 minutes being optimal.^{60,61} A basal or continuous infusion is the administration of analgesics at a constant given rate regardless of the patient using the demand button. Continuous infusion rates are predominantly only administered in chronic opioid-dependent patients because continuous infusion in opioid-naïve patients may result in overdose and increased risk for respiratory depression/arrest. For chronic opioid-dependent patients, a continuous infusion may suffice their daily equivalent dose of opioid with demand doses assisting with their postoperative analgesia. However, extreme caution and vigilance should be used in monitoring these patients. A maximal dose limit of 1 hour or 4 hour intervals is proposed to be another safety mechanism against overdose. Nevertheless, this remains controversial because opponents argue that if a patient reaches his or her 1 hour or 4 hour demand dose limit, then he or she probably requires more analgesia.

Because PCA requires the patient to control the delivery system, candidates for PCA must be cooperative, able to understand the concept, follow the directions of use, and be able to push the demand button. In addition, education should be provided to the patient and family members regarding the PCA delivery system.

The medications most often used for PCA are morphine, hydromorphone, and fentanyl. Meperidine is not recommended because of its neurotoxic metabolite, normeperidine. The neurotoxic side effects that are not reversible with naloxone include shakiness, tremor, twitches, multifocal myoclonus, and grand mal seizures.^{62,63} Other medications that can be used via IV PCA include local anesthetics, ketamine, and clonidine. Dosing guidelines for specific medications are institution specific. A sample IV PCA dosing guideline for opioid-naïve patients is found in [Table 56.4](#).

TABLE 56.4**Intravenous Patient-Controlled Analgesia Regimens**

Drug Concentration	Size of Bolus	Lockout Interval (min)	Continuous Infusion
Agonists			
Morphine (1 mg/mL)			
Adult	0.5–2.5 mg	5–10	—
Fentanyl (0.01 mg/mL)			
Adult	10–20 mcg	4–10	—
Hydromorphone (0.2 mg/mL)			
Adult	0.05–0.25 mg	5–10	—
Methadone (1 mg/mL)	0.5–2.5 mg	8–20	—

Acute Pain Management in Special Populations

Acute Pain in a Patient with Chronic Pain

Because millions of Americans are affected with chronic pain, it is inevitable that anesthesia providers will be faced with challenges in providing acute surgical pain management for those who have a chronic pain condition. The IASP defines chronic pain as pain that has no apparent biologic value and lasts longer than 3 months in duration or beyond the normal course of healing. It is often associated with insomnia, lost work days, impaired mobility, and emotional distress (i.e., anxiety, depression, anger, and fear). Management of the chronic pain patient is complex with cultural, emotional, biologic, and social influences all needing to be addressed. Chronic pain physiology and treatment are discussed in [Chapter 57](#). Medical regimens can be very complex in this patient population and warrants an in-depth review preoperatively. In addition to the acute pain analgesics previously presented, other common analgesics used for the treatment of chronic pain syndromes are discussed here.

Chronic Pain Analgesics and Adjuncts

Anticonvulsants.

Anticonvulsants or antiepileptics are commonly used in certain neuropathic pain syndromes when treatment is refractory to traditional analgesics. First-generation anticonvulsants such as carbamazepine and phenytoin have been used for many years for neuropathic pain; however, more recently the second-generation anticonvulsants gabapentin (Neurontin) and pregabalin (Lyrica) are the most widely used. Anticonvulsants inhibit neuronal excitation and stabilize nerve membranes in an effort to decrease repetitive neural ectopic firing, which is common in neuropathic pain.

Gabapentin and pregabalin are used for the management of postherpetic neuralgia, diabetic neuropathy, trigeminal neuralgia,

and other neuropathic pain and chronic pain syndromes. Their mechanism of action is similar; it is believed that both block the alpha 2 delta ($\alpha_2\delta$) subunit of the presynaptic voltage-gated calcium channels in the CNS, thereby preventing excitatory neurotransmitter release.⁶⁴ Pregabalin and gabapentin are structural analogs of GABA, which lack affinity to the GABA receptors. Both exhibit anticonvulsant, anxiolytic, and antihyperalgesic effects.⁶⁴⁻⁶⁶ When compared with gabapentin, pregabalin displays a pharmacokinetic profile that requires less dosing with fewer side effects.^{64,66}

Common side effects are dose dependent and include dizziness, somnolence, peripheral edema, and weight gain. Currently pregabalin and gabapentin are available in the oral form only. Because neither drug undergoes hepatic metabolism, drug-to-drug interactions are minimal. The unchanged form of the drug is excreted by the kidneys; therefore, patients with compromised renal function may require dose modifications.^{64,66} Pregabalin and gabapentin use is not limited to chronic pain syndromes. They are also being effectively used in multimodal techniques for acute postoperative pain management, which has resulted in lower reported pain scores and lower opioid consumption.⁶⁷⁻⁷¹ Lastly, patients scheduled for surgery who are routinely taking anticonvulsants as part of a chronic pain syndrome treatment regimen should continue taking their medication throughout the perioperative period because this will optimize their pain management.

Antidepressants.

Several antidepressants are being used for chronic pain syndromes. Similar to anticonvulsants they are effective in the treatment of neuropathic pain syndromes. Common antidepressants include the tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and selective norepinephrine and serotonin reuptake inhibitors (SNRIs) (Table 56.5). In the presence of central sensitization the descending inhibitory pathway, which uses inhibitory neurotransmitters (i.e., serotonin and norepinephrine), is altered. It is believed that antidepressants may exert their analgesic effects by blocking the reuptake of serotonin and norepinephrine in

the CNS, thereby increasing their availability. They may also act at other sites via: (1) blocking of sodium and calcium channels, (2) decreasing PGE₂ and TNF- α , (3) blocking NMDA receptors, and (4) enhancing opioid receptors, which may account for additional analgesic effects. Analgesic dosage is much lower than the recommended antidepressive dose, and their analgesic effects may not occur until 4 to 10 days after initiating treatment.

TABLE 56.5
Common Antidepressants Used for Chronic Neuropathic Pain

Drug Class	Generic Name	Trade Name
TCAs	Amitriptyline	Elavil
	Nortriptyline	Pamelor
	Imipramine	Tofranil
SNRIs	Venlafaxine	Effexor
	Duloxetine	Cymbalta
	Milnacipran	Savella
SSRIs	Fluoxetine	Prozac
	Citalopram	Celexa

SNRI, Selective serotonin-norepinephrine reuptake inhibitors; *SSRI*, selective serotonin reuptake inhibitors; *TCA*, tricyclic antidepressant.

TCAs (amitriptyline and nortriptyline) tend to have more side effects than the SSRIs and SNRIs because they antagonize other receptors including muscarinic (e.g., dry mouth, blurred vision, and urinary retention), histaminergic (e.g., sedation, appetite stimulation with subsequent weight gain), and adrenergic (e.g., orthostatic hypotension, prolonged QT interval). They are contraindicated in patients with a history of a recent myocardial infarction, prolonged QT interval, cardiac dysrhythmias, or unstable congestive heart failure. Drug levels can be monitored to ensure unintentional overdose. The metabolism of all antidepressants is primarily hepatic. TCAs are commonly used for the treatment of postherpetic neuralgia, headaches, and fibromyalgia.^{72,73}

SNRIs (duloxetine, venlafaxine) are generally better tolerated than the TCAs because of the lack of affinity for the adrenergic, histaminergic, and cholinergic receptors. Therefore they are preferred for those patients with cardiac disease. Both drugs (duloxetine and venlafaxine) have similar side effects: nausea, dry

mouth, somnolence, headaches, and sexual dysfunction.^{72,73}

Likewise, the concomitant use of SNRIs with SSRIs or triptans is not recommended because this may precipitate a *serotonin syndrome*.

Serotonin syndrome is an acute toxicity of serotonin manifesting as anxiety, agitation, delirium, seizures, hyperthermia, diaphoresis, tachycardia, hypertension or hypotension, hyperreflexia, myoclonus, and muscle rigidity. Symptoms vary from mild to life threatening, and diagnosis is based on patient medication history, physical examination, and exclusion of other neurologic disorders.^{74,75}

SSRIs for the treatment of chronic pain are still under investigation because very few clinical trials have been done. They are primarily used for the treatment of depression, and their analgesic effects, thus far, are relatively weak.^{72,73} Regardless of the type of antidepressant being taken for chronic pain, they should be continued throughout the perioperative period.

Corticosteroids.

Exogenous corticosteroids (glucocorticoids) are administered in a variety of routes (e.g., oral, intravenous, epidural, caudal, and intraarticular) as adjunct analgesics for multiple types of acute onset and chronic pain syndromes. They exert multiple effects on the body including autoimmune, antiinflammatory, antiedema, and antiallergic. Typical disease processes and pain syndromes that are treated with corticosteroids include rheumatoid arthritis, osteoarthritis, herpetic neuralgia, chronic low back pain, and chronic neck pain. In the treatment of acute and chronic pain syndromes, corticosteroids exert their effects in several ways. They are primarily known for their antiinflammatory effect because they prevent the release of arachidonic acid by inhibiting phospholipase A2 on cell membranes (Fig. 56.6). Through this mechanism they decrease inflammatory cytokines (IL-6, IL-1, TNF- α) and prostaglandins. When corticosteroids are injected epidurally, it is also purported that they exhibit nociceptive properties by blocking C fiber transmission. In addition, they suppress ectopic firing of nociceptors in the presence of nerve injury, which produces a direct membrane-stabilizing effect.^{76,77}

Side effects of corticosteroids are reflective of supraphysiologic

doses that usually exceed the rate of endogenous steroid production, which is approximately 20 mg per day of hydrocortisone or its equivalent for more than 3 weeks.⁷⁸ Many organ systems can be affected with long-term steroid use (Box 56.4). These effects are variable among patients and are dependent upon the degree of hypothalamic-pituitary-adrenal axis (HPA) suppression, which is attributed to the type of steroid, duration of use, frequency of ingestion, route of administration, and dosage. However, when corticosteroids are administered as an intermittent injection (e.g., epidural, intraarticular, caudal) versus chronic daily use, side effects are usually mild and transient. It has been purported by Kay et al.⁷⁹ that weekly epidural steroid injections given over 3 weeks caused dramatic HPA suppression with normal cortisol levels returning within 1 month. Similarly, it has been found that a single epidural steroid injection can cause HPA suppression from 4 to 5 days following injection and lasting up to 5 weeks. Currently there is no consensus among pain management specialists on the dosing, frequency, or total number of repeated steroid injections. Regardless, in the event of a major surgical procedure after the recent administration of an epidural steroid, it is prudent to administer a dose of exogenous steroid.

Systemic Effects of Steroids

Endocrine

- Adrenal-pituitary insufficiency
- Hypercortisolism
- Hyperglycemia
- Cushing syndrome

Cardiovascular

- Hypertension
- CHF

- DVT
- Cardiomyopathy

Musculoskeletal

- Muscle weakness
- Osteopenia/osteoporosis
- Avascular necrosis of bone
- Pathologic fractures
- Truncal obesity

Dermatologic

- Skin thinning
- Alopecia
- Petechiae
- Facial flushing
- Striae
- Hirsutism

Renal

- Sodium and water retention

Gastrointestinal

- Peptic ulceration
- Gastritis

- Hyperacidity

Neurologic/Psychological

- Headache
- Vertigo
- Euphoria
- Restlessness
- Insomnia
- Mood swings
- Depression

CHF, Congestive heart failure; *DVT*, deep vein thrombosis.

Methadone.

Methadone is a synthetic opioid historically used for the treatment of opioid addiction in detoxification or treatment programs. Recently its use is increasing for the treatment of severe acute pain in addition to chronic cancer and noncancer pain management. Structurally methadone is a racemic mixture of two enantiomers, d-isomer (S-methadone), and l-isomer (R-methadone). The d-isomer is responsible for antagonizing the NMDA receptor and inhibiting serotonin and norepinephrine uptake, which possibly contributes to its benefits in the treatment of neuropathic pain, along with the prevention of opioid tolerance and hyperalgesia.⁸⁰ The l-isomer is responsible for binding to opioid receptors thereby giving its analgesic effects.

Methadone is a viable option for chronic pain patients who have tolerance (intolerable side effects or inadequate analgesia) to current opioids. It can be administered orally, intravenously, rectally, and subcutaneously. As a result of its high degree of lipid

solubility, it is well absorbed via the gastric mucosa with peak analgesic effects in 30 to 60 minutes. When given intravenously, the drug has peak effects that are seen in 15 to 20 minutes. Unlike other opioids, methadone has a long half-life of approximately 15 to 60 hours. This long half-life is ideal for maintenance programs and preventing withdrawal symptoms. However, when methadone is administered for chronic pain states, it is difficult to initiate, to titrate, and to convert from another opioid, which makes dosing a challenge.^{81,82}

Metabolism of methadone is primarily via the CYP450 enzyme, specifically CYP3A4 and CYP2B6, into inactive metabolites that are excreted in the urine.⁸³ Therefore any medications that inhibit (e.g., phenytoin, carbamazepine) or induce CYP450 may dramatically alter methadone metabolism.⁸⁴

Side effects of methadone are similar to other opioids including respiratory depression and excessive sedation; respiratory depression peak effects occur later than the analgesic peak effects. A unique side effect of methadone includes QT interval prolongation, which could lead to potentially lethal ventricular tachyarrhythmias and torsades des pointes. Patients taking methadone on a continuous basis should be carefully monitored with a cardiac evaluation. An electrocardiogram (ECG) should be obtained pretreatment and periodically thereafter depending upon dose changes, baseline ECG findings, and other risk factors for QT prolongation. A QT interval that exceeds 500 ms is deemed a risk factor for lethal arrhythmias, and discontinuation of methadone or a dose reduction is advisable.⁸⁴

As a result of methadone's long half-life, its use in acute pain management is limited but effective. In complex surgical procedures, it has been reported that methadone administered intraoperatively decreased postoperative pain scores and reduced postoperative opioid requirements.^{85,86} In the event that methadone is chosen as an analgesic for perioperative pain management, an ECG is warranted preoperatively with identification of those at risk for prolonged QT interval. These risk factors include the concomitant use of antiarrhythmic agents, some TCAs and calcium channel blockers, the presence of hypokalemia, and a history of prolonged QT interval. Furthermore, chronic pain patients are often

taking a combination of medications such as benzodiazepines and other CNS depressants, which poses an added risk for respiratory depression and sedation.⁸⁴

Methadone's lack of active metabolites, long half-life, and low cost make it desirable for chronic nonmalignant pain management. Nonetheless, prolonged use of methadone and other opioids for the treatment of chronic pain are associated with the risks of dependence, tolerance, addiction, and in rare instances, misuse.

Dependence can be either physiologic or psychologic in nature. Physiologic dependence is a pharmacologic property of opioid drugs defined by the manifestation of a “withdrawal syndrome” after abrupt discontinuation of the opioid, or after the administration of an opioid antagonist (naloxone) or a mixed agonist-antagonist. Because opioids inhibit cAMP, any abrupt discontinuation of the opioid can cause a rebound disinhibition of cAMP and subsequent withdrawal symptoms. Withdrawal symptoms include autonomic nervous system responses such as increased irritability, restlessness, tremors, chills, muscle cramps, sweating, mydriasis, abdominal pain, diarrhea, and tachycardia.³³ Physiologic dependence should always be assumed to exist after repeated administration of an opioid for more than a few days.^{33,87} To prevent opioid withdrawal syndrome opioids should always be tapered before being discontinued, and daily scheduled opioids should be continued perioperatively.

Psychological dependence is defined by the American Society of Addiction Medicine (ASAM) as a “subjective sense of need for a specific psychoactive substance, either for its positive effects or to avoid negative effects associated with its abstinence.”⁸⁸ Psychological dependence is inappropriately referred to as “addiction” and is more accurately described as a component of addiction.

In contrast, *addiction* is defined by the ASAM as a “primary, chronic disease of brain reward, motivation, memory, and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social, and spiritual manifestations. This is reflected in an individual pathologically pursuing reward and/or relief by substance use and other behaviors.”⁸⁸ Features of addiction include cravings, obsessive thinking over a drug, impaired

behavioral control, compulsive drug taking, and the inability to recognize one's problems with interpersonal relationships and one's own behaviors.^{88,89} Unlike physical dependence and tolerance, the incidence of addiction among patients taking chronic opioids for noncancer pain is rare.⁸⁹ However, those with preexisting vulnerabilities (i.e., history of substance abuse, younger age) may be at increased risk.^{90,91}

Pseudoaddiction is often confused with psychological dependence because the behavior of the patients can be the same. Patients with both these conditions exhibit what appears to be drug-seeking behavior. However, in the patient who has pseudoaddiction, the origin of the behavior is inadequate analgesia. When these patients receive adequate analgesia, they no longer demonstrate drug-seeking behavior.

Tolerance refers to a change in the dose-response relationship induced by repeated exposure to the drug and manifested as a need for a higher dose to maintain an analgesic effect. Tolerance may be the result of several mechanisms such as enzyme induction caused by continued opioid administration, or down-regulation of opioid receptors.⁹² Other mechanisms involved with tolerance continue to be debated and include changes in drug-receptor interactions, cellular alterations, and long-term adaptations in gene expression.^{93,94} The development of tolerance to an opioid is a normal physiologic response. When tolerance to an opioid occurs, opioid rotation is suggested. Opioid rotation involves switching from one opioid to another in an effort to improve analgesia and decrease side effects.

Opioid-induced hyperalgesia (OIH) is a phenomenon that usually occurs with chronic opioid therapy, which attributes worsening pain to high, escalating doses of opioids. OIH has been reliably demonstrated in animal studies.⁹⁵⁻⁹⁷ However, there is limited research documenting the development of OIH in humans. Even so, case reports corroborate that OIH may be clinically significant in chronic opioid dependent patients.⁹⁸⁻¹⁰¹ Manifestations of OIH include complaints of pain in locations different from the original pain area, whole-body hyperesthesia, allodynia, agitation, multifocal myoclonus jerks, and seizures.^{101,102} OIH is often improved by reducing or discontinuing the opioid. The exact

mechanism of action of OIH is not fully understood. However, there are many proposed theories. For instance, central activation of NMDA receptors via glutamate may play a role in OIH,¹⁰³ and also a shifting of the pain modulation system from a descending inhibitory pathway to a facilitating pronociceptive pathway.¹⁰⁴ It has also been suggested that neuroinflammation (via astrocytes and microglia) may contribute to the development of OIH.^{105–107} Diagnosing OIH is difficult because it resembles opioid tolerance. Once diagnosed, treatment strategies consist of weaning the patient from high-dose opioids and starting nonopioid analgesics (e.g., NMDA receptor antagonists, NSAIDs, COX-2 inhibitors).^{108–110}

Opioid Tolerance

Chronic opioid therapy (COT) for the treatment of chronic nonmalignant pain and for drug maintenance programs for opioid addiction is escalating in the United States. COT patients who require elective or emergent surgery present many challenges for the anesthesia provider in regard to perioperative analgesia. A 2011 observational study found that patients using COT are at risk for higher than normal levels of postoperative pain and slower pain resolution than those not on COT for chronic pain or without preexisting chronic pain.¹¹¹ Thus it is imperative to collaborate with the patient and the surgical team to develop a unique and realistic perioperative pain management plan. As with treating patients in acute pain, a multimodal approach to pain management should be implemented.

Perioperative Management

Preoperative Management.

Preoperatively, preferably prior to the day of the surgical procedure, an investigation regarding the types of medications, dosages, and duration of therapy is helpful in determining the extent and severity of the chronic pain syndrome. Inquiries specific to preoperative pain and the patient's chronic pain state should be addressed; these are shown in [Box 56.3](#). If the patient is on an opioid maintenance program for addiction, methadone dosage

should be verified by the prescribing physician/clinic. Chronic opiate therapy, including methadone, should be continued throughout the perioperative period because this will provide uninterrupted dosing for the patient's baseline opioid requirement and avoid withdrawal. If the patient has not taken his/her daily scheduled opioid, an equivalent dose of opioid should be administered preoperatively. In the event the patient has a transdermal fentanyl patch, it should remain on throughout the perioperative period unless a collaborative decision has been made based on the invasiveness of the surgical procedure to remove it. If the patch is removed, a continuous IV infusion of fentanyl should be initiated and maintained perioperatively. Alternatively, equipotent morphine also can be administered. If a patient has an implanted intrathecal or epidural opioid infusion system, it should continue perioperatively.¹¹² Other medications taken for chronic pain (e.g., antidepressants, anticonvulsants, α_2 agonists) should be continued on the day of surgery.

The preoperative assessment is the ideal setting in which to establish a positive rapport with the patient, especially in the presence of a chronic pain state or a maintenance program. Chronic opiate therapy patients can be highly anxious, fearful, or depressed, and reassurance that their pain will be aggressively treated is paramount. Furthermore, realistic expectations regarding pain control should be discussed. Administering a benzodiazepine, along with initiating multimodal analgesia with adjuvant analgesics, is optimal and should be started within 1 to 2 hours prior to surgery.⁸² This is also the time to discuss options for regional anesthesia/analgesia techniques. These techniques would be of great benefit for intraoperative and postoperative analgesia in the COT patient.

Intraoperative Management.

There are no data supporting a specific opioid for pain control intraoperatively for COT patients, nor have any specific dosing guidelines been established. The specific opioid selected is an anesthesia provider preference with patient coexisting diseases and surgical procedure dictating one versus another. The intraoperative opioid selected should provide adequate baseline opioid

requirements and also render intraoperative and postoperative analgesia. Intraoperative opioids may need to be increased 30% to 100%¹¹³ when compared with the opioid-naïve patient because of receptor down-regulation and/or tolerance. Titration of opioids to heart rate and blood pressure response, in addition to pupil size, may be useful for estimating adequate analgesia with general anesthesia. Respiratory rate and depth may also be monitored in the spontaneously breathing, awake, or anesthetized patient to estimate adequate analgesia. In the event that a specific opioid is not efficacious, opioid rotation is recommended.¹¹⁴ Cross tolerance among opioids may be incomplete. Hence, a specific opioid will not produce a similar degree of tolerance as a different opioid within the same class. Opioid antagonists and agonist-antagonists should be avoided because these will precipitate an acute withdrawal syndrome.

Nonopioid analgesic adjuncts (ketamine, clonidine, and dexmedetomidine) should also be a part of the multimodal approach to perioperative pain management. Several studies corroborate that when ketamine is administered intraoperatively at a continuous infusion in COT patients, there is a decrease in postoperative opioid requirements¹¹⁵ and pain scores.¹¹⁶

Lastly, it is recommended that regional anesthesia with local anesthetics and opioids be a part of the anesthetic plan whenever possible in COT patients; this will reduce opioid requirements and provide analgesia. If regional anesthesia is used, intrathecal, and/or epidural opioid administration is not adequate for baseline opioid therapy. Equipotent IV opioids should be given as the baseline therapy for the prevention of withdrawal.¹¹⁷ Another option for perioperative analgesia includes peripheral nerve blocks with a continuous catheter infusion of local anesthetic.

Postoperative Management.

If the patient is not a candidate for regional anesthesia/CPNB or did not benefit from it, then intravenous PCA should be considered. Setting appropriate parameters for the PCA in the COT patient can be very challenging. A basal continuous infusion is suggested to replace the daily dose of opioid with demand doses varying among individuals.^{117,118} When COT patients are able to resume oral intake,

dosing is variable among individuals with gradual weaning to their presurgical therapy regimen. Consultation with a pain specialist regarding PCA dosing and opioid conversion for various routes of administration for COT patients is highly recommended. Other recommendations for perioperative pain management for the patient on COT are found in [Table 56.6](#).

TABLE 56.6

Recommendations for Perioperative Management of the Chronic Opioid Therapy Patient

Preoperative	Intraoperative	Postoperative
Pain assessment	Continue baseline opioid (oral, transdermal, IV, intrathecal pump)	Multimodal analgesic techniques
Precise opioid use (dose/type)—continue DOS	Increases in intraoperative opioids because of tolerance—titrate or continuous infusion	Maintain baseline opioid
Adjuvant medications for CP—continue DOS	Consider opioid rotation	Titrate opioids aggressively to achieve adequate pain control
Reassurance and address fears/anxiety	Multimodal approach	PCA—primary or supplementary for epidural/regional
Multimodal pain plan—consider NSAIDs, acetaminophen, 1–2 hr prior to surgery, anxiolytics	Consider regional, LA wound infiltration, PNB, CPNB, epidural/SAB	Continue applicable regional techniques
Consult with addiction specialist/clinic if indicated—continue methadone maintenance	Consider adjuvants—ketorolac, ketamine, clonidine, dexmedetomidine	Continue ketamine or low-dose ketamine infusion, if started in the OR
Plan for postoperative analgesia	Anticipate increases in inhalation agent	Monitor for respiratory depression
	Avoid opioid antagonists and mixed agonists	Continued assessment of analgesia
		Implement nontraditional comfort measures

CP, Chronic pain; *CPNB*, continuous peripheral nerve block; *DOS*, day of surgery; *IV*, intravenous; *LA*, local anesthetic; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PCA*, patient-controlled analgesia; *PNB*, peripheral nerve block; *SAB*, subarachnoid blockade.

Elderly

In the United States, 20% of the population will be 65 years of age and older by 2030.¹¹⁹ With the advances in medical technology older adults are undergoing surgical procedures to improve functionality, quality of life, and thus, living longer. Common surgical procedures

include joint replacement surgery, emergent orthopedic procedures for fall-related injuries, coronary artery bypass grafting, aneurysmal repairs, and surgeries for cancer. All these are associated with significant postoperative pain, which, when not adequately treated, can alter the postoperative outcome and increase morbidity and mortality in the older adult. Acute surgical pain management in the older adult is challenging. As described in [Chapter 54](#), the physiologic changes, multimorbidities, changes in pharmacokinetics and pharmacodynamics, and functional decline in organ systems all have an effect on analgesics administered in the elderly patient. Specific to pain physiology, the aging adult has alterations in pain processing and perception. Peripherally there is a decrease in nociceptive processing via the C and A δ fibers that results in a decrease in the older adults' ability to sense and respond to initial fast-sharp pain. There are also decreases in concentrations of substance P and calcitonin gene related peptide, which results in loss of integrity or cellular elements of the nociceptive pathway. In the CNS, there are reductions in neurotransmitters (i.e., GABA, serotonin, norepinephrine, acetylcholine, and endorphins) that may cause inadequate pain signal transmission and/or neuromodulation. It is also suggested that there is a dysfunction of the descending inhibitory pathway in the older adult.¹²⁰⁻¹²² Pain perception is altered in the elderly; the pain threshold increases and pain tolerance decreases. Generally, the threshold for pain varies based on the stimulus (i.e., increases with heat, decreases with mechanical pressure and ischemia). Unfortunately, this has led health care providers to assume that the elderly do not experience pain.¹²¹

Another challenge with pain management in the older adult includes the increased risk for adverse side effects from analgesics compared to younger counterparts. This is the result of the increased incidence of polypharmacy, altered drug metabolism, presence of comorbidities and end-organ function, and increased sensitivity to medications. There is also the incidence of frailty and malnutrition that may predispose the older adult to drug toxicity.

Pain assessment in the older adult is a component of any preoperative assessment. Therefore any preexisting pain prior to surgery should be extensively queried. According to the National

Health and Aging Trends Study, the overall prevalence of bothersome pain in the last 30 days afflicts approximately half of the older aged (≥ 65) adult population.¹²³ Chronic pain in the elderly is addressed in [Chapter 57](#). As discussed earlier, multiple pain assessment scales are utilized to assess pain with patient self-report being the gold standard. Because the elderly have a decrease in all the senses, it is suggested that when presenting the chosen pain assessment tool, it should be in large, clear letters or numbers. In addition, the elderly may require repeated explanations and more time for responses to questions during the pain assessment. Pain assessment via self-report in the older adult with neurological disorders such as dementia might be compromised and insufficient. In advanced dementia, self-report may be unobtainable because of impaired communication, cognitive, and memory function. Those with dementia are at increased risk of having pain and for being undertreated.^{124–126} Therefore undertreated pain can lead to chronic pain, which will adversely affect the older adult's ability to function and his/her quality of life. Several pain assessment tools have been validated for the older adult who is cognitively impaired and are in [Table 56.7](#).

TABLE 56.7

Pain Assessment Tools for Cognitively Impaired

Visual Analog Scale	Marks a score on a graded line representing no pain to severe pain	Cognitively intact patients; difficulty speaking
Numeric Rating Scale	0–10 score for no pain to severe pain	Cognitively intact patients; validated in mild to moderate cognitive impairment. Preferred
Verbal Descriptor Scale	Ranks “mild, moderate, severe pain”	Cognitively intact patients; validated in mild to moderate cognitive impairment. Preferred
Faces Scale	Ranks pain on a series of smiling to frowning faces	Validated in mild to moderate cognitive impairment
Pain Assessment Checklist for Seniors with Limited Ability to Communicate Pain Assessment in Advanced Dementia Doloplus-2	—	Validated in severe cognitive impairment
Visual scales, assistive hearing devices	—	Hearing impairment

In McKeown JL. Pain management issues for the geriatric surgical patient. *Anesthesiology Clin.* 2015;33:563–576; Data from Falzone E, et al.

Postoperative analgesia in elderly patients. *Drugs Aging* 2013;30(2):81–90; Gagliese L, Katz J. Age differences in postoperative pain are scale dependent: a comparison of measures of pain intensity and quality in younger and older surgical patients. *Pain* 2003;103(1–2):11–20.

A multimodal approach to perioperative pain management should be instituted while making a risk-to-benefit assessment for each patient. Analgesics used in healthy younger adult surgical patients may present risks to the older adult. Some considerations for medication selection include comorbidities, renal and hepatic functioning, current medication regimen, type of surgery, frailty, and nutritional status. In addition, the safe prescribing guidelines (*Beer's Criteria for Potentially Inappropriate Medication Use in Older Adults*) developed by the American Geriatric Society should be considered.¹²⁷ Beer's Criteria includes a list of medications that should be avoided or have their dose adjusted based on the older adult's renal function and select drug-to-drug reactions. Regional and neuraxial analgesic techniques are also an option in the elderly population. In some instances, these may be a safer approach than opioid analgesia because of their adverse effects and increased risk for postoperative respiratory depression. However, opioid analgesics are the first-line treatment for major surgery. Because the elderly have an increased sensitivity to medications, it is prudent to administer the lowest dose and titrate more as needed. Similar to healthy younger adults, intravenous PCA with an opioid is the mainstay treatment for acute moderate to severe postsurgical pain. However, the use of nonopioid analgesics (i.e., NSAIDs, acetaminophen), regional nerve block techniques with local anesthetics, in combination with opioids is optimal, thereby minimizing opioid side effects (i.e., sedation, respiratory depression), and in some instances postoperative delirium.^{128,129} Postoperatively once the older adult surgical patient is able to resume taking fluids by mouth, oral opioids and/or nonopioids should be substituted for the intravenous route.

Pediatric

Acute pain management is equally important in the neonatal and pediatric populations. Pain physiology in the neonate is also discussed in [Chapter 52](#). Nociceptive pathways are well developed

in premature and full-term infants. However, the maturation of the descending pathway precedes that of the ascending neural pathway. Therefore pain perception and the stress response may be more exaggerated in the premature neonate. Neonates are subjected to painful procedures within the first few days of life with immature newborns receiving the highest number of painful events (i.e., heel lancing, suctioning, venous catheter placement). The repeated exposure to untreated painful stimuli early in life can result in central sensitization, an increase in stress-related markers, and elevated free radicals after simple procedures,^{130,131} which can have short- and long-term consequences on future pain perception, and behavioral and neurological outcome. For example, in a systematic review, infants who were born at 29 weeks' gestation or earlier received the greatest number of painful procedures, and this was associated with delayed postnatal growth, poor quality of cognitive and motor development at 1 year of age, and altered brain development (cortical thickening) at 7 years of age.¹³²

In neonates, several pain assessment tools are utilized at the bedside that primarily assess pain through physiologic monitoring (i.e., changes in heart rate, respiratory pattern, blood pressure, oxygen saturation), and behavioral responses (i.e., crying, body movements, facial expressions). Tools commonly used in the neonatal intensive care unit for assessing procedural pain includes the Premature Infant Pain Profile (PIPP), Neonatal Facial Coding System, and the Behavioral Infant Pain Profile.¹³¹ Neonatal tools that assess postoperative pain include the *crying, requires increased oxygen administration, increased vital signs, expression, sleeplessness* (CRIES) scale and PIPP.^{133,131} Confounding factors, such as mechanical ventilation, pharmacologic interventions, physical restraint and gestational age, can alter the behavioral and physiologic responses in the neonate. Unfortunately, there is no reliable or specific physiologic or behavioral indicator for demonstrating the presence of pain in the preterm neonate. Generally a combination of physiologic and observational pain assessment tools is used to assess pain in infants and toddlers (up to 3 to 4 years of age). Children 5 years of age and older can self-report pain with use of several validated visual or faces scales (Faces Pain Scale, Visual Analog Scale); standard adult pain

assessment tools are instituted at approximately 7 to 8 years of age.^{134,135}

Neonatal acute pain management consists of reducing the number of painful procedures performed, decreasing the number of bedside disruptions as this may increase pain responses, and integrating nonpharmacologic and pharmacologic approaches. Nonpharmacologic approaches to acute pain management consist of swaddling, facilitated tucking (holding the infant in a flexed position and supporting their hands or feet while allowing them to control their own movements), kangaroo care or maternal skin-to-skin contact, massage therapy, acupuncture, and nonnutritive sucking. Nonpharmacologic therapies are beneficial for minor pain and as adjuncts to pharmacologic therapy in moderate to severe pain.¹³⁶ In older children nonpharmacologic therapies include guided imagery, relaxation techniques, hypnosis, and distraction techniques (i.e., cartoon videos, video games). In addition, a multimodal approach to acute surgical pain management in pediatrics is recommended. This may include opioids, nonopioid analgesics (i.e., NSAIDs, acetaminophen), local anesthetics, α_2 -adrenergic agonists, NMDA antagonists being administered via different routes and at varying times perioperatively in an effort to maximize postoperative analgesia and minimize adverse effects. The pharmacodynamics and pharmacokinetics of analgesics vary with the neonate and pediatric patient and are discussed in [Chapters 52](#) and [53](#). Similar to acute pain management in adults, opioids are the first-line agent for moderate to severe postoperative pain. Routes of administration are similar to adults and are discussed earlier in this chapter. Opioid administration via IV PCA is an option for the pediatric patient. Children as young as 5 to 6 years of age can safely use IV PCA, as long as there is the mental capacity/understanding, manual dexterity, and ability (muscle strength) to initiate a demand dose. In those who cannot administer the PCA independently, the use of nurse-controlled or parent-controlled analgesia is common in pediatrics. However, the activation of a PCA by an unauthorized agent (i.e., parent) is not endorsed by TJC because of safety issues.¹³⁷ Even so, health care providers must continuously monitor the patient who is receiving PCA, whether nurse or parent-controlled, and be anticipatory to the

risk of opioid overdose, respiratory depression, and suboptimal analgesia. Therefore continuous monitoring via pulse oximetry and/or capnography is prudent in this vulnerable population. Morphine, hydromorphone, and fentanyl are the most commonly used opioids for PCA. Depending on the surgical procedure and analgesic requirements, a basal infusion of opioid may be required postoperatively for pain control. However, extreme vigilance is warranted as this may increase the risk of respiratory depression and sedation. A sample IV PCA dosing guideline for pediatric patients is found in [Table 56.8](#).

TABLE 56.8

Intravenous Patient-Controlled Analgesia Dosing Regimens for Pediatrics

Drug	Continuous Basal Infusion* mcg/kg per hr (Range)	Demand Dose mcg/kg (Range)	Lockout Interval Minutes (Range)	Number of Demand Doses/hr (Range)	4-Hour Limit (mcg/kg)
Morphine (standard 1 mg/mL; younger patients 0.2 mg/mL; tolerant or high need patients 10 mg/mL)	20 (10–30)	20 (10–30)	8 (6–15)	5 (1–10)	250–400
Fentanyl (>30 kg 0.02 mg/mL; 10–29 kg 0.01 mg/mL; <10 kg 0.005 mg/mL; tolerant or high need patients 0.05 mg/mL)	0.5 (0.2–1)	0.5 (0.2–1)	15 (6–15)	4 (1–10)	7–10
Hydromorphone (standard 0.2 mg/mL; tolerant or high need patients 1 or 5 mg/mL)	4 (2–6)	4 (2–6)	8 (6–15)	5 (1–10)	50–80

* A basal infusion is not always used. It may increase the risk of respiratory depression and excessive sedation.

From Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia: Elsevier; 2017:437.

Regional anesthesia, when used in combination with general anesthesia or alone, is another technique for intraoperative and postoperative analgesia in the pediatric patient. Anesthesia providers must be familiar with the physiologic and pharmacologic differences in the pediatric patient versus the adult. Developmental, physiologic, and anatomic differences are explained in [Chapters 52](#) and [53](#). Regional anesthesia techniques in pediatric patients include caudal block, subarachnoid block, lumbar and thoracic epidural

blocks (with and without continuous catheters), and peripheral nerve blocks (with and without continuous catheters). Various peripheral nerve blocks and potential surgical uses are described in [Table 56.9](#). A thorough description of regional techniques and peripheral nerve blocks is beyond the scope of this chapter, but can be found in [Chapters 49](#) and [50](#). Local anesthetics possess pharmacokinetic and pharmacokinetic differences in the pediatric patient compared to the adult; these are discussed in [Chapters 10](#), [52](#), and [53](#). The decision to administer a regional anesthetic should be based on the type of surgical procedure (i.e., duration, invasiveness, anticipated pain area), patient criteria (i.e., absence of coagulopathies, infection), parental consent, and skill and comfort level of the anesthesia provider performing the regional technique. For safety reasons regional anesthetic techniques are usually performed in the pediatric patient under general anesthesia. However, in older children who are able to cooperate, regional anesthesia can be administered with mild sedation.

TABLE 56.9
Peripheral Nerve Blocks and Indications in Pediatrics

Block	Indications
Head and Neck	
• Infraorbital	Cleft lip/palate repair; Nasal septal surgery
Upper Extremity	
• Interscalene	Shoulder and upper arm surgery
• Supraclavicular	Upper extremity procedures
• Infraclavicular	Distal upper extremity procedures
• Axillary	Forearm and hand procedures
• Digital	Finger procedures
Lower Extremity	
• Lumbar plexus	Low abdominal, groin and upper leg surgeries
• Femoral	Above-the-knee (thigh) surgeries
• Sciatic	Below-the-knee (foot/knee) surgeries
Truncal	
• Transverse Abdominis Plane (TAP)	Abdominal wall surgeries
• Ilioinguinal/Iliohypogastric	Groin and hernia surgeries

Summary

Pain is a complex, multidimensional and personal experience which requires an interdisciplinary approach for treatment. If acute pain is left undertreated or mismanaged, it can progress to chronic pain, which can affect an individual's quality of life and well-being. As an integral component of the interdisciplinary team, it is essential that nurse anesthetists are knowledgeable and current with the advances in pain physiology, assessment, management, and treatment modalities. Acute pain management no longer consists of monotherapy; a multimodal and individualistic approach to pain management across the life span is required. Likewise, adequate pain management is equally important in special populations because they possess inherent and distinctive challenges. Overall, CRNAs are in a unique position to provide effective, innovative, high quality and holistic pain management across the continuum in an effort to improve the health and well-being of patients.

Chronic Pain

Physiology and Management

Steve Wooden

Pain is a subjective term that is individually defined, and there is great variability in one's perception of its intensity. Its purpose is integrally tied to the human central nervous system (CNS) and the human response to physical threats. However, when pain persists and no longer serves as a survival response, it can cause damage to the nervous system, decrease productivity, and result in disability. Persistent pain is defined in a variety of ways but is universally recognized as containing negative physical, psychological, and quality of life components¹, and at the same time negatively impacting the United States economy to a greater degree than cancer, heart disease, and diabetes.²

Persistent pain associated with a distinct period of uninterrupted pain of 3 months or more that includes a negative sensory and emotional experience, is referred to as *chronic pain*.³ Other definitions of chronic pain often contain a category (psychogenic, inflammatory, or neuropathic) and a time period, which ranges from 2 to 6 months. The categories of chronic pain are important to understand because each type demonstrates unique characteristics related to spinal cord and sensory neuron changes.⁴ In addition, understanding the neurochemical markers related to the generation of chronic pain in each category may be important in helping to identify treatment options for chronic pain patients. However, chronic pain is a complex phenomenon, which often contains elements of inflammatory, neuropathic, and emotional components.

Chronic pain has been linked to divorce, poverty, homelessness, despair, and sometimes suicide.⁵ The management of chronic pain is often elusive because the source is not always clear. The

assessment and treatment requires a health care professional that can appreciate the physical, psychological, and social aspects of the multidimensional nature of chronic pain. Advanced practice nurses are particularly well suited to address this problem using nursing theory, evidenced based intervention, multidisciplinary collaboration, and their unique skills as a nurse.

Anatomy and Physiology of Pain

The body is under constant sensory stimulation. The pain transmission inhibitory systems are what keep us from experiencing constant pain. A normal balance of sensory transmission and inhibition is what keeps us from being overwhelmed. However, the body needs an appropriate amount of sensory information to respond to potential harm.

There are three heuristic subdivisions of painful stimulation. They are, painful stimulation without tissue damage, tissue damage without nerve damage, and nerve damage.⁶ It is important to understand the normal response of each subdivision of painful stimulation so that we can target the ideal individualized treatment.

If we perceive pain, but there is no tissue damage, then we would normally withdraw from the stimulation. This withdrawal should terminate the feeling and response. Under normal circumstances, the painful stimulation is specific to the site of potential injury and does not radiate beyond that site.

If there is tissue injury, pain would persist after removal of the stimulus. The area of injury will exhibit an intensified response to tactile stimulation, and the sensation of pain will spread beyond the local area of injury. The local and extended response is intended to protect the body and promote healing. Tissue damage releases a number of substances that activate and support the response system. These substances include potassium, red cells, white cells, clotting factors, peptides, prostaglandins, inflammatory substances (which cause vascular leaking and swelling), and other substances which promote neurotransmission through nerve membrane channel activation.

The final subdivision is damage that includes nerve injury. This can be caused by disease, accidental tissue injury involving nerve fibers, or by unintentional or unavoidable nerve injury during a surgical procedure. The extent of nerve injury can be classified into demyelinating or axonal injury. The type of injury to the nerve may indicate the likelihood of return to normal function with treatment.⁷

Normal activation of neurotransmission is an important part of recognizing injury and limiting further damage. Once stimulated,

A-delta and C nociceptive fibers produce an action potential mediated via the release of substance P and other excitatory amino acids appropriate to the intensity and duration of stimulation. The sensory stimulation proceeds through the afferent nervous system to the dorsal horn of the spinal cord. At this point, inhibitory mechanisms play an important role in modulating sensation and response. If the stimulation is sufficient to overcome the inhibitory mechanisms of the spinal neuroanatomy, then the sensory information proceeds to the pain perception centers in the brain. This information is used to provide a motor response to pain, in addition to building experience, expectation, and mood.

Pain Pathophysiology

As described previously, pain is not just a localized phenomenon. There are three anatomical regions that are associated with every pain response. The peripheral, spinal, and cerebral areas contribute to various aspects of pain recognition and response. When pain is present for an extended period of time, it can create dysfunctional changes in these three areas that may become irreversible. This dysfunctional activity is the basis for chronic pain. In order to treat chronic pain, it is not always sufficient to simply remove the source of the pain. We must address the source of the pain, which generally is located outside of the CNS and created by soft tissue or nerve tissue damage. If the pain has become chronic, inhibitory mechanisms in the peripheral and spinal nervous systems may have become ineffective, and removing the original source of pain will be insufficient to eliminate the negative sensation. For that reason, the dysfunctional inhibitory mechanism in the peripheral and spinal nervous system must also be addressed. Finally, pain perception in the cerebrum is normally a protective mechanism that allows us to anticipate painful stimulation and avoid it. However, chronic pain may create havoc with these perceptive functions, and addressing the dysfunction in this area is an important part of chronic pain management.

Treatment of chronic pain must include all three areas involved in pain transmission and perception. Return to normal function means that the pain generator is removed, the peripheral system is once again able to block noxious stimulation, the spinal ascending inhibitory system can be returned to balance, and the forebrain perception of stimulation is normalized.⁸

Types of Chronic Pain

Psychogenic

Although the term *psychogenic pain* is still used, many pain practitioners feel it is a meaningless term because all pain experiences have a psychological component. The fact that a physical generator cannot be identified does not indicate that the pain is “psychosomatic” or physical pain originating purely from a psychological component. Psychosomatic pain is thought to exist by some groups of practitioners, but the phenomenon appears to be rare and difficult to validate. Using such a description in the absence of any physical evidence related to pain may only stigmatize the patient and perhaps ignore the real possibility that an occult physical condition has contributed to some sort of psychopathology.⁹

Inflammatory

Tissue damage in the human body results in a cascade of neurochemical responses. These responses are both local, at the site of injury, and sensory, which involves the peripheral and central nervous systems. The localized response serves as a protective mechanism to help prevent further tissue damage, initiates a healing process, and begins a sensory response through the peripheral and central nervous systems to create the perception of pain and trigger further protective mechanisms.¹⁰ The localized response includes the release of inflammatory mediators that produce capillary vasodilatation, smooth muscle contraction, and promote synaptic transmission of pain impulses to the CNS. These mediators include histamine, bradykinin, and substance P.¹¹ Increases in substance P and substance P receptors are specifically associated with inflammatory pain, while diminished or absent in neuropathic and cancer pain respectively.⁴

The sensory portion of the inflammatory response is often called *nociception*. Nociception begins at the point of injury. Inflammatory mediators create an action potential, which is carried to the dorsal horn of the spinal cord, and then ascend to the thalamus where the

perception of pain occurs.¹¹

Neuropathic

When nerves are injured, pain radiates along a dermatome, or sensory pathway supplied by the nerve. Nerve injury often leads to a condition called *allodynia*.¹² Allodynia is the triggering of a pain response from stimuli which do not normally provoke pain. Individuals with allodynia often have an intense burning sensation, with small changes in temperature or light touch, typically along the dermatome of the injured nerve.

Pain and pain response to a normal inflammatory process is distinctly different from neuropathic pain in three ways. First, the pain associated with tissue injury improves within a reasonable period of time, and the inflammatory response resolves. In contrast, neuropathic pain is persistent, even with evidence of tissue healing, and often an apparent or occult inflammatory response continues. The second difference is the presence of allodynia with neuropathic pain, which is absent with normal inflammatory response. Finally, the third difference is that neuropathic pain is not able to be adequately managed with nonsteroidal antiinflammatory agents.¹³

The Unique Problem of Chronic Postsurgical Pain

Chronic postsurgical pain (CPSP), sometimes called *persistent postsurgical pain*, is a particularly troublesome type of chronic pain that has a reported incidence of between 5% and 50% depending on the particular type of surgical procedure.¹⁴ Large gaps exist in evidence that may help to define and identify the reasons for CPSP.¹⁵ The International Association for the Study of Pain defines CPSP as “a persistent pain state that is apparent more than 2 months postoperatively that cannot be explained by other causes such as recurrence of disease, apparent inflammation, or others”. This very simplistic and obscure definition does little to help identify and treat the causative factors.

Much of the research into CPSP has been focused on specialty surgical procedures, but a compilation of studies related to CPSP reveals a grouping of the most common surgical procedures related

to CPSP, and various attempts to predict and prevent it. Although CPSP appears to be neuropathic in nature, it is not always associated with identifiable nerve injury.^{16,17}

The most common surgical procedures associated with CPSP are those that require a thoracotomy or thoracic penetration. These procedures include mastectomy, thoracotomy, cholecystectomy, nephrectomy, sternotomy, and other chest and upper abdominal procedures. Other common types of surgery that report a high incidence of CPSP are amputation, and inguinal surgical procedures such as a hernia repair. Nearly one out of four patients who undergo thoracic surgery develop CPSP, but only one-third of them have an identifiable nerve injury.¹⁸ This would suggest that multiple factors are responsible for CPSP. Even in the absence of evidence that nerve injury is the causative factor, in most cases nerve compression, entrapment, and other types of nerve damage are often suspected.

Predictors of CPSP do help to isolate likely candidates, but do little to identify a treatable source of pain. Some studies suggest that CPSP is functional,¹⁹ whereas others identify psychological factors.²⁰ Preoperative pain appears to be a predictor of CPSP, and it can fall into either a functional or psychological category. However, in at least one study preoperative pain was the most significant clinical predictor of CPSP.²¹ Still others indicate multiple predictive factors such as thyroid function, occult wound infection, or even secondary gain as possible contributors to CPSP.²² There are a few factors that predict a low incidence of CPSP, which include young age,²³ and immunosuppressant therapy. The latter suggests that autoimmune issues may play a role in CPSP because those who are immunosuppressed postoperatively have a significantly lower incidence of CPSP for identical surgical procedures when compared with those who are not immunocompromised.

Treatment of CPSP continues to be elusive, but some research have identified benefits of preventative measures in reducing central sensitization through the use of regional anesthesia and preoperative doses of antiinflammatory agents and other antihyperalgesia medications such as ketamine.²⁴⁻²⁶ Aggressive postoperative treatment appears to be important in the treatment of recognized CPSP. Antidepressants should be a first-line treatment,

followed by short-term opioid use, along with selective use of anticonvulsants, topical agents, and N-methyl-D-aspartate (NMDA) antagonists.²⁷⁻²⁹

It is very apparent that CPSP is complex and that successful treatment can be difficult to determine. With every type of chronic pain, it is important that we understand the anatomy and physiology of pain, pathophysiology of pain, and how chronic pain is thought to develop. Only then can we begin to understand how to develop a reasonable plan of treatment for CPSP.

Evolution of Chronic Pain (Wind-Up)

Repetitive stimulation from chronic inflammation or nerve damage can lead to a condition referred to as *windup*. Windup is a cyclical response to pain that leads to an abnormal pain response and chronic pain sensation. It can contribute to physical and psychological debilitation. Preventing windup is critical to the prevention of chronic pain. It is critically important to treat the underlying cause of pain and not ignore pain symptoms. Health care providers often label those who complain about pain as “drug seekers,” “chronic complainers,” or even “crazy.” These types of statements indicate that the provider does not understand the history and physical issues that have placed the patient in a position to find anything possible to stop the pain. Chronic pain is not a psychological condition, but it can lead to psychological dysfunction.⁶

The windup phenomenon is a chronic discharge of neurons that leads to overwhelming of the inhibitory systems of neuro pathways. A simple example of one pathway associated with chronic pain is as follows:

1. Chronic repetitive stimulation
2. Increased cellular calcium
3. Release of inflammatory substances
4. Cyclooxygenase production

5. Synthesis of prostaglandins, which are responsible for reduction in inhibition
6. Increased neurologic pathway excitability
7. Formation of hyperalgesia, which leads back to point number 1

The pathway to chronic pain can be complex and pervasive. There are a number of systems that contribute to chronic pain and hyperalgesia. They include:

I. Interneuronal networks

- a. Glutamate release — activating of NMDA receptors
- b. Loss of gamma-aminobutyric acid (GABA) and glycine inhibition

II. Bulbospinal Systems

- a. Serotonergic (5-hydroxytryptamine) pathway and receptor dysfunction

III. Nonneuronal Cells

- a. Glial cells (toll-like receptors) dysfunction

Neuronal plasticity changes the somatosensory system with exposure to repeated noxious stimuli are shown in [Fig. 57.1](#).

Neuronal Adaptation with Repetitive Noxious Stimuli

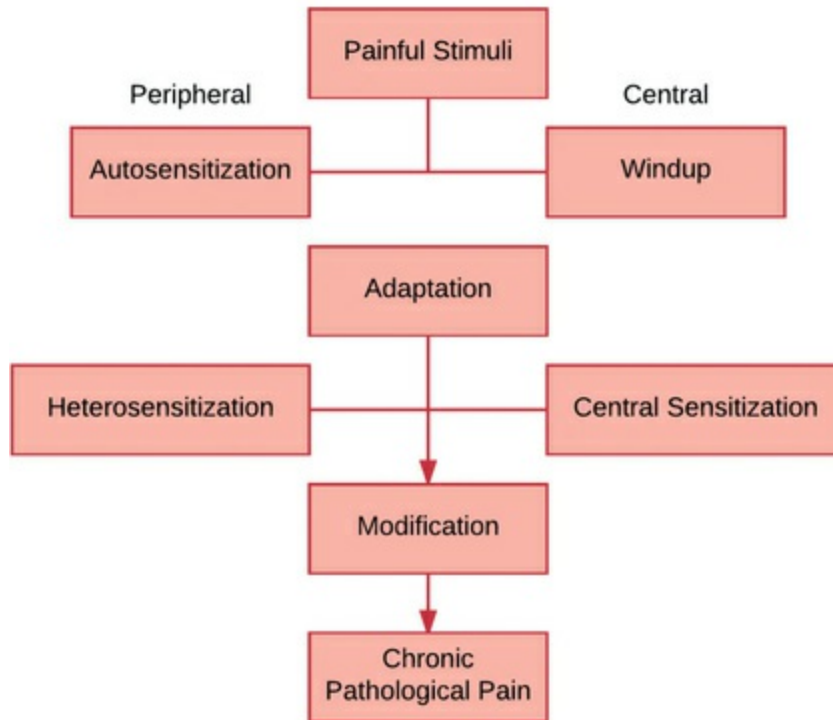

FIGURE 57.1 Neuronal plasticity changes of the somatosensory system with exposure to repeated noxious stimuli.

Treating Chronic Pain

Treatment goals for chronic pain should be multifaceted. Goals should address the removal of the stimulus which is typically located in the peripheral area. Once the original source of pain is addressed, then it is important to reset the inhibitory mechanisms of the central spinal area, and address the psychological impact of chronic pain located in the prefrontal cerebral area.

Peripheral

A normal response to potentially traumatic peripheral stimulation is to withdraw. This response is initiated by the transmission of sensory impulses through the afferent peripheral nervous system, to the spinal nervous system, and into the perceptive centers of the brain, which in turn initiates a motor response. The peripheral fibers responsible for this quick response are myelinated, fast, and moderate-acting nociceptors called *A fibers*. These fibers are responsible for sensations that mediate the perception cold temperature, pressure, and sharpness. The unmyelinated afferent peripheral C fibers are slow acting and are responsible for secondary sensations such as warmth, burning, itching, and touch. Neuropathic pain is thought to involve dysfunctional activity of both A and C fibers.

Upon normal stimulation of A and C fibers, substance P and excitatory amino acids are released which activate neurokinins. Neurokinins generate an action potential which carries sensory impulses up the afferent nerve pathways to the CNS appropriate to the intensity and duration of stimulation. Under normal conditions, NMDA receptors remain inactive because of magnesium stability. However, in pathologic chronic pain magnesium is displaced, NMDA receptors are activated, and calcium ions enter cells, causing an exaggerated release of substance P and excitatory amino acids. This dysfunctional activation of NMDA receptors contributes greatly to this pain activation pathway.

Spinal

The spinal neuroanatomy has many complex features. There are similar cross-sectional structures, and they function at all spinal cord levels. This system relays sensory information from the body to the CNS via afferent fibers, and it performs the initial processing of this information. Motor neurons in the ventral horn project their axons into the periphery to innervate skeletal and smooth muscles that mediate voluntary and involuntary reflexes. It contains neurons whose descending axons mediate autonomic control for most visceral functions.

Various substances reside in the spinal anatomy and play a role in neurotransmission. Galanin, one of those substances, is a neuropeptide that functions as a cellular messenger. Galanin is multifunctional and includes inhibition of action potentials as a protective mechanism. Galanin is also implicated in many dysfunctional physiologic activities, some that may be connected with chronic pain including depression and eating disorders.^{30,31} Chronic pain may trigger inappropriate activation of neuropeptides creating negative consequences.

Cerebral

One of the least understood but important areas of pain activity is the brain. Various regions of the brain are involved in pain modulation. The human brain is capable of recognizing prior pain experiences, developing attention and expectations related to those experiences, and creating anticipatory responses that are not always proportional to the situation. Pain experiences and cerebral responses to painful activity affect mood, create anxiety, and can also lead to depression.³²

One of the most intriguing aspects of pain modulation related to cerebral activity is the placebo effect. What was once thought to be a purely psychological event appears to actually be associated with neurophysiologic responses.³³ Placebo analgesia is a prime example of cognitive modulation of pain.³² This cognitive modulation includes the release of endogenous opioids, which may imply that placebo activity is actually a neurochemical event. It is evident that cerebral involvement in pain modulation is a complex system of events that include both psychologic and physiologic activities resulting in the promotion of protective mechanisms when

functioning properly, but detrimental with conditions that are associated chronic pain.

It is interesting to note that our own perception of other's pain responses may be related to our individual experiences with pain. Empathy, which is the ability to understand and share the feelings of others, is influenced by the cerebral mechanisms that help to protect us. Studies suggest that first hand emotional experience with pain is an important aspect of empathetic development, and analgesics may have the unwanted effect of reducing empathy and concern for others.³⁴

Pharmacology

In the fight against chronic pain, healthcare practitioners often rely on prescribing pharmaceuticals. Some pharmaceuticals are effective in reducing the dysfunctional activity associated with chronic pain development, some are effective in helping the body return to normal function after the development of chronic pain, and others simply treat pain perception and do little or nothing to reduce the dysfunctional cycle of chronic pain.

Nonsteroidal Antiinflammatory Drugs

The category of drugs referred to as *nonsteroidal antiinflammatory drugs* (NSAIDs) have properties well suited to help reduce the development of chronic pain and to treat ongoing chronic pain symptoms. Drugs in this category have antipyretic, antiinflammatory, and analgesic properties. Their primary mechanism of action is the acetylation of cyclooxygenase (COX), which prevents the synthesis of prostaglandins from arachidonic acid. Arachidonic acid is present in cellular tissue, and it is released when the cellular membranes are disrupted by injury or disease. Prostaglandins are localized hormones that are responsible for inflammatory activity (vasodilation, erythema, edema, and fever) and nociceptor sensitization, among other things.^{35,36} Elevated levels of prostaglandins, consistent with the intensity of tissue damage, is related to trauma and surgery.³⁷

Although acetaminophen is often included in this category, it is not included in the NSAID class of drugs because it lacks significant antiinflammatory properties. Acetaminophen does inhibit COX activity, but it is thought to provide this inhibition in the CNS rather than peripherally. This explains the lack of antiinflammatory activity. Pain relief is thought to be provided by a reduction in nociceptor activity in the CNS.³⁸

There are two types of COX enzymes in the human body ([Table 57.1](#)). The first is referred to as COX-1, which is a constitutive enzyme continually produced to protect gastric mucosa, reduce gastric acid secretions and pepsin content, and promote platelet

aggregation. The other enzyme, COX-2, is activated or induced by tissue damage and is responsible for inflammation, fever, some anticoagulation activity, modulation of cell proliferation, and pain sensation.^{39,40}

TABLE 57.1

Cyclooxygenase Activity

Understanding the pharmacokinetics of NSAIDs is critical to a long term treatment plan. Distribution and elimination of any drug plays an important role in effectiveness, side effects, and toxicity. Oral NSAIDs are absorbed in the stomach and small intestines. Peak plasma concentrations of NSAIDs occur in 1 to 4 hours and are delayed by food consumption; however, taking NSAIDs with food does not reduce the negative gastric mucosa effects. This class of drugs is weakly acidic, highly plasma bound, and lipophilic, and only the unbound portion of the drug is effective. Elimination is accomplished primarily through hepatic oxidation and conjugation. Less than 10% is eliminated through renal activity. Some of these drugs have active metabolites. Generally, NSAIDs have similar targets of action, but their therapeutic profiles are different. Some are more COX selective than others, peak plasma times differ, distribution profiles vary, and elimination profiles may be impacted by individuals with kidney and liver disease differently.

Nonsteroidal antiinflammatory drugs are the most widely used analgesics in the United States, with over 30 million users. They are reasonably safe when used as intended, but serious side effects still exist. The most significant side effects of long-term NSAID use

include nephrotoxicity, thrombotic events, peptic ulceration, and bleeding. The antiinflammatory effects of NSAIDs make them ideal for back pain related to neuraxial inflammation, but their distribution profile requires maximum recommended doses in order to be effective. Ibuprofen for example has an over-the-counter (OTC) dosing limitation of 6 tablets (1200 mg) in a 24-hour period, but some studies indicate that an effective minimum dose of ibuprofen in a 24-hour period for the treatment of inflammatory back pain is 1600 mg (8 tablets). Even at doses of 1600 mg per day, the risks associated with ibuprofen are limited.

Acetylsalicylic acid (ASA) is a nonselective COX inhibitor. It has excellent long-term antipyretic and antiinflammatory properties, but unlike other NSAIDs ASA causes irreversible COX inhibition. The irreversibility may contribute to more serious side effects that cannot be limited by discontinuation of the drug. ASA has a significant impact on platelet aggregation that may be prolonged. In small doses ASA has been shown to help reduce cardiothrombotic events. Its effectiveness to decrease pain is tempered by its potential side effects and irreversibility.

Acetaminophen, has no significant antiinflammatory activity. For this reason, it is not well suited for treatment of chronic pain related to inflammatory processes. Studies indicate that acetaminophen used for back pain was no more effective than a placebo.⁴¹ However, unlike opioids, acetaminophen is not addictive and it has a reasonably safe therapeutic profile when doses are limited to less than 1 g per dose or 4 g/day.⁴² Because the action of acetaminophen is thought to be the inhibition of prostaglandin production in the CNS rather than peripherally, many hematologic side effects associated with other NSAIDs do not occur. For this reason, it is a safe alternative in reduction of pain symptoms for those patients who are at high risk for hematologic or cardiovascular problems.

Acetaminophen is the leading cause of acute liver failure in the United States because of accidental overdose.⁴³ Accidental overdoses are often related to the fact that acetaminophen is combined with many common prescription and OTC drugs. Careful monitoring of total acetaminophen intake for chronic pain patients is essential in prevention of liver toxicity.

The side effect profile of NSAIDs is relatively safe but not

inconsequential (Table 57.2). At the higher doses and long-term therapy necessary for the treatment of chronic inflammation and chronic pain, side effects need to be considered when designing a chronic pain plan of care. Select NSAIDs and their dosing are given in Chapter 14.

TABLE 57.2
Side Effects—Nonsteroidal Antiinflammatory Drugs

Side Effect	Observed Frequency
Gastric mucosa degradation	30–40%
Dyspepsia	15%
Decreased renal function	18%
Hepatic side effects	3%

Opioids

Similar to acetaminophen, opioids act in the CNS and do not have peripheral effects. This prevents opioids from being effective at decreasing pain at its source, but they are valuable for short-term relief of operative and traumatic injury. Their mechanism of action includes binding to opioid receptors within the CNS that inhibit nociception. It is helpful to understand the primary receptor site activity of each therapeutic opioid in order to minimize undesirable side effects (Table 57.3).

TABLE 57.3
Opioid Receptors and the Effects of Receptor Stimulation

Receptor	Positive Effects	Negative Side Effects
Mu	Analgesia, euphoria	Respiratory depression, sedation, decreased GI motility, pruritus
Kappa	Spinal analgesia	Respiratory depression, dysphoria, sedation, dyspnea, dependence
Delta	Dopamine release	Psychomimetic effects, dysphoria

GI, Gastrointestinal.

Many of the side effects associated with opioids are caused by metabolites. Some metabolites can produce hyperalgesia. Morphine is the prototype opioid to which all other opioids are compared.⁴⁴ It acts at the mu and delta receptors. Oxycodone, one of the most widely prescribed semisynthetic opioids, has significant kappa activity, making it highly addictive. Oxymorphone has more mu

receptor activity, some delta activity, and less kappa activity. Hydromorphone is primarily a mu agonist with significant kappa activity. Hydrocodone produces mu activity and some delta activity. Methadone is an interesting synthetic mu agonist. It is also an NMDA antagonist like ketamine, a mu receptor agonist like morphine, and does not have any metabolites. The unique properties of methadone have generated renewed interest in its use for chronic pain. However, it does have a complicated dosing profile and, with the potential cardiotoxic effects, it is inappropriate for some outpatient applications.

Opioid therapy for chronic pain treatment is an inadequate long-term solution because of the substantial negative side effects and lack of value in treating the source of pain. In addition to potentially fatal side effects, tolerance develops over time, which reduces the therapeutic value and increases risk.

In consideration of the use of opioids for patients with chronic pain, it is important to understand their limited value in such situations, the need to develop individualized opioid treatment plans, and the need to use dosing strategies that maximize the value of such drugs. Dosing strategies include the use of nonopioid drugs that help to reduce opioid use by enhancing the positive opioid effects (Table 57.4). Rotation of opioids improves analgesia and reduces side effects. Close monitoring of opioid use and effectiveness can help minimize dependence and reduce opioid-related deaths.

TABLE 57.4
Side Effects—Opioids and Related Frequency

Opioid Side Effect	Observed Frequency	Notes
Constipation	40–95%	Caused by opioid receptors in the gut Does not resolve over time
Nausea	25%	Direct stimulation of the chemotactic trigger zone, gastric distention, and increased vestibular sensitivity
Pruritus	10%	Some histamine release, but more significantly a direct stimulation of mu receptors
Sedation	60%	Transient
Respiratory depression	Dose dependent	Long term opioid use may lead to sleep apnea
Endocrine	52–74%	Amenorrhea and low testosterone
Immunologic	?	Inhibition of cellular immune response

Pharmaceutical research continues to pursue development of a pain medication that provides analgesia without the unwanted side effects and dependence.^{45,46} The pursuit of such a drug is elusive. In the meantime it seems prudent, safer, and less costly to find ways to reduce opioid use for chronic pain. Opioids are discussed in detail in [Chapter 11](#).

Antidepressants for Chronic Pain

Antidepressants can play a very important role in treating chronic pain. Pain perception is a chemically mediated event and can often be addressed with the addition of antidepressants to the treatment plan in chronic pain situations. Antidepressants can also improve mood, increase treatment compliance, and reduce opioid use. Some of the older tricyclic antidepressants are effective for treating pain, but they have significant side effects that make them unacceptable for pain treatment in many cases. The serotonin-norepinephrine reuptake inhibitors (SNRI) are effective and produce more tolerable side effects. Selective serotonin reuptake inhibitors (SSRI) can also be effective but appear to be less effective in most cases than SNRIs.

Antidepressants can take days or weeks to be effective, so they are not appropriate for acute pain management. Extended-release compounds appear to be most effective. The SNRIs and SSRIs are generally well tolerated. Antidepressants are sometimes rejected by patients as a treatment for chronic pain because they may feel taking this class of drugs will label them as psychologically impaired. Viagra is an example of a drug used for purposes beyond its original intent. It was originally designed for treatment of cardiovascular issues but was found to be beneficial for other physiological purposes.⁴⁷ Select antidepressants and their doses are listed in [Chapter 14](#).

Anticonvulsants for Neuropathic Pain

The use of anticonvulsants for chronic neuropathic pain is controversial. Some studies have found little to no value in using anticonvulsants for chronic neuropathic pain, whereas others have demonstrated some efficacy for specific anticonvulsants.^{48,49} Anticonvulsants that have been found to provide some value are

gabapentin and pregabalin. In a 2014 Cochrane Review, both drugs were found to be associated with modest pain reduction when used for diabetic neuropathy and postherpetic neuralgia when compared with a placebo.⁵⁰ Pregabalin has become a widely prescribed drug for use in patients with chronic pain. Until further evidence exists, anticonvulsants should be limited to the treatment of diabetic neuropathic pain, fibromyalgia, and trigeminal neuralgia.

The Role of NMDA Receptors in Chronic Pain

NMDA receptor antagonists have been available for many years. Because of recent research (2015) that indicates a significant role of NMDA receptors in the development of chronic pain, interest in this drug class is reemerging.⁵¹ It is thought that NMDA receptor systems are involved in the development of chronic pain windup, and preemptive treatment may be effective in the prevention of postoperative pain hypersensitivity. The mechanisms behind the development of postoperative pain hypersensitivity are poorly understood. However, NMDA receptors are thought to support synaptic plasticity, CNS pain processing, and modulation of central pain sensitization induced by incision and tissue damage.⁵²

Ketamine blocks NMDA receptor site activity and may be useful in the treatment and prevention of chronic pain. Further study is necessary to support such a conclusion, but low-dose ketamine (0.25–0.5 mg/kg) has been used successfully as an adjunct to general anesthesia while reducing postoperative opioid requirements. Side effects associated with ketamine have concerned providers, but research on low-dose and postoperative infusion of ketamine in surgical patients does not support these concerns. In fact, a reduction in nausea was common, and other adverse events such as hallucinations and vivid dreams were not reported.⁵³

Muscle Relaxants and Pain Treatment

Many patients with chronic back pain are routinely given muscle relaxants such as cyclobenzaprine (Flexeril). These drugs are not without risk and should not be routinely prescribed. Relaxing muscles does not provide source treatment, and such drugs become ineffective within a few weeks. They should only be used for short-

term symptomatic relief of muscle spasms. The most commonly prescribed muscle relaxant is cyclobenzaprine (Flexeril). It is chemically related to the antidepressant amitriptyline, and its effectiveness begins to decline within 4 days of therapy. When used alone for back pain, it is less effective than ibuprofen.

Cyclobenzaprine is best used as an adjunct to NSAIDs. Other muscle relaxants that have been prescribed for chronic back pain such as carisoprodol (Soma) have a high potential for dependence, tolerance, and mental impairment. Carisoprodol has been taken off the market in some countries because of its high potential for abuse and dependence.⁵⁴ There have also been some efforts to reclassify the drug in the United States as a controlled substance because of the potential for abuse.⁵⁵ Other drugs developed for muscle spasms such as baclofen should never be used for muscle spasms related to acute or chronic pain. Baclofen was designed for extreme spasmodic conditions such as cerebral palsy, tetanus, and multiple sclerosis. Withdrawal from baclofen can cause respiratory failure, hemodynamic changes, seizures, and delirium. It is highly toxic, and the benefits do not outweigh the risks in most situations.

Topical Anesthetics for Pain

Topical NSAIDs and topical anesthetic agents are important adjuncts for the treatment of chronic pain. Some patients and providers confuse topical agents with drugs that are delivered systemically through a dermal delivery system. Topical agents work without significant systemic absorption, their therapeutic benefit is high, and their safety profile is more favorable than oral comparisons when used in therapeutic doses.⁵⁶ The most common side effect of topical agents is skin irritation. One of the reasons that these drugs may not be used more frequently is because of their relative high cost.

Topical anesthetic agents are effective with chronic pain because some chronic pain conditions require continued peripheral nerve stimulation. Application of anesthetic agents to the source of pain may promote reestablishment of the normal peripheral nociceptive inhibitory systems. Select topical agents and their doses are listed in Chapter 10.9.

Sleep Aids and Pain Management

Sleep is essential to life and the healing processes. It plays an important part of cellular regulation and regeneration, which is an important part of healing and return to homeostasis after injury.⁵⁷ Chronic pain disrupts sleep, which in turn impairs cellular regeneration. Lack of sleep can also lead to depression, which also complicates the treatment of chronic pain.⁵⁸ Sleep deprivation resulting from chronic pain can become a vicious cycle. For this reason, promotion of quality sleep is an important part of chronic pain therapy. Current sleep aids are not without risk. Some pharmaceutical sleep aids can lower the quality of sleep by disrupting rapid eye movement sleep. Thus treatment of sleep deprivation associated with chronic pain should start with mechanical aids such as better pillows, stretching before bed, proper positions, and white noise.

Withdrawal, Tolerance, and Dependence

Most of the medications used for chronic pain management can create dependence, require increased concentrations over time because of tolerance, and can have adverse physiologic and psychologic responses when withdrawn.^{59,60} These issues need to be considered as part of a long term care plan with chronic pain patients. Strategies to reduce dependence and tolerance include multimodal therapy, alternating drug classes, and implementation of psychologic and social support systems. Withdrawal of any therapeutic agent can have potentially devastating consequences under some circumstances. It is usually not advisable to completely withdraw any long term medication without considering tapering the dose over time. Patients should be monitored closely for withdrawal symptoms when medication is discontinued or modified and treated appropriately. Some multimodal treatment options for chronic pain therapy are listed in [Table 57.5](#).

TABLE 57.5

Multimodal Treatment Options for Chronic Pain Management

Multimodal

Treatment Modalities	Types
Medications	Antiinflammatory medications (NSAIDs, tylenol), muscle relaxants, opioids, neuropathic medications (anticonvulsants, TCA, SNRI), SSRI, NMDA antagonist, α_2 agonist, topical medications
Rehabilitation	Physical therapy, occupational therapy, TENS, bracing
Psychology	Cognitive behavioral therapy, biofeedback, relaxation therapy, support groups
Interventional pain management	Epidural injections, facet joint injections, peripheral nerve block, major joint / bursa injections
Implantable therapies	Spinal cord stimulator therapy and intrathecal pumps
Complementary and alternative treatments	Acupuncture, chiropractic manipulation, massage, craniosacral therapy
Nutrition counseling	Weight loss, bone density
Vocational counseling	Return to work

NMDA, N-methyl-D-aspartate; *NSAIDs*, nonsteroidal antiinflammatory medications; *SNRI*, selective norepinephrine reuptake inhibitor; *SSRI*, selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressant; *TENS*, transeletrical nerve stimulation.

From Dinakar P. Principles of pain management. In Daroff RB, et al. eds. *Bradley's Neurology in Clinical Practice*. 7th ed. London: Elsevier; 2016:723.

Polypharmacy in Pain Management

Multiple prescription and nonprescription drugs are often necessary for the treatment of chronic pain. Use of multiple pharmaceutical agents, often called *polypharmacy*, has the inherent risk of negative medication interaction, unnecessary duplication of medication, toxicity, disruption of important physiologic functions, and an increased mortality rate.^{61,62} The risk of negative drug interactions can range from 13% with two medications to 82% with seven or more medications.⁶³

Among medications common to chronic pain and used in combination with other drugs are anticonvulsants, antidepressants, and NSAIDs. Anticonvulsants present a higher incidence of toxicity secondary to competition for metabolic pathways with other drugs. Some antidepressants increase warfarin levels, whereas those that inhibit the reuptake of serotonin pose a risk of fatal serotonin syndrome when combined with monoamine oxidase inhibitors used to treat atypical depression. Some drugs can inhibit hepatic enzyme activity and increase the risk of elevating other drugs to toxic levels because of diminished hepatic degradation. Adequate

renal clearance is critical for many drugs, and competition for renal clearance is maximized when multiple drugs are administered. The competition for renal clearance also increases the blood levels of active metabolites found in many pain medications.

Targeted Pain Management

Imaging and Radiation Safety

The use of radiation for imaging during the diagnosis and treatment of chronic pain is not only common, but also necessary to identify pathology, to validate treatment plans, and to safely provide interventional treatment.

There are two general categories of radiation. The first is nonionizing radiation such as visible light, infrared, microwave, radio waves, ultrasound, and magnetic resonance. Nonionizing radiation is thought to be harmless to human tissue. The second category of radiation is called *ionizing radiation*. Ionizing radiation can cause cellular damage. Examples of ionizing radiation are alpha and beta particles, gamma waves, and X-rays. The most common type of ionizing radiation used in imaging is X-ray. It is critically important that the risks of ionizing radiation are understood by all health care providers. Even those health care providers who do not utilize ionizing radiation may find their patients and themselves exposed to risks by simply being in proximity to its utilization.⁶⁴

Due to improvements in modern radiographic equipment and strict regulation, radiation exposure is limited. However, it must be kept in mind that the effects of ionizing radiation are cumulative, and multiple exposures over time will increase the risk of cellular damage. Damage to organic cells is called the *stochastic effect*. The stochastic effect can take place at any dose, therefore there is no known minimum safe dose of ionizing radiation. Although the Occupational Safety and Health Administration has established standards for maximum acceptable doses of ionizing radiation, these standards could be based on inaccurate assumptions.⁶⁵ The best course of action is to use the concept of “As low as reasonably achievable (ALARA)”, when using ionizing radiation. It is also important to understand and use techniques that help shield health care providers and patients from the potential hazardous effects of ionizing radiation. The main principles of ALARA are reduced expose time, reduced exposure dose, shielding all body parts as much as practical, and being aware that rapidly replaced cells are at

highest risk of stochastic effect.⁶⁶ Those rapidly replaced cells include reproductive, thyroid, cornea, hair, and skin cells.

Fluoroscopy is the most common form of imaging used to treat chronic pain. It provides good detailed images of bony landmarks, quick identification of needle placement, and real-time visualization of injection. The risk of fluoroscopy is that there is no soft tissue visualization so that needle placement within a nerve cannot be easily identified, and vascular placement of a needle can only be identified by injection of a contrast agent. The other risk of fluoroscopy is the high ionic radiation exposure to patients and health care providers.

Computed tomography (CT) scanning is used by some practitioners for interventional treatment of chronic pain. Using CT makes the procedure more technically complex, but the images of bony landmarks are very detailed. Three-dimensional technologies for CT are emerging that will make the images even more valuable, especially for difficult needle placements. However, CT is time consuming, there are limited real-time injection capabilities, the positioning is often uncomfortable for patients, and the ionizing radiation exposure is significantly higher as compared to fluoroscopy.

Ultrasound is emerging as an alternative to ionizing radiation for some, but not all, interventional techniques. There is no ionizing radiation risk, and proximal bony landmarks can help guide the initial needle approaches for therapy. Ultrasound cannot reliably provide real time injection images, so the risk of vascular injection is increased with this imaging modality. Ultrasound is also not capable reproducing accurate images where dense tissue is observed (e.g., bone).

Magnetic resonance imaging (MRI) is more helpful for diagnosis than it is for interventional purposes. It provides excellent soft tissue imaging, which aids in the identification of inflammation and other pain generators. There is no ionizing radiation risk, but special equipment is needed if interventional therapy is provided with MRI assistance because of the image distortion created by metal objects like needles.⁶⁷

The risks and benefits of using imaging must be considered for both the patient and the providers. Knowledge of radiation safety

should be required for all health care providers who use, or are exposed to ionizing radiation.

Interventional Treatment

The global management of chronic and acute pain issues that are not related to expected postsurgical pain management is referred to as *nonsurgical pain management* (NSPM). Interventional pain management is more narrowly defined within the area of NSPM as the use of special techniques, equipment, implanted devices, and injections to diagnose and treat pain-related disorders. When considering the narrow focus of interventional treatment, the most common interventional approach is to treat the occult inflammatory processes by injecting therapeutic substances to reduce pain and inflammation. These techniques are aimed at helping improve sensory and motor function and promote healing, and they are also thought to help reset inhibitory pathways and processes that were damaged by chronic pain dysfunction. Long-term and more-invasive interventional treatments include the implantation of electrical nerve stimulators or high-concentration opioid pumps. [Table 57.6](#) lists some commonly used interventional pain management techniques and their indications.

TABLE 57.6

Commonly Used Interventional Pain Management Techniques and Indications

Name of Procedure	Indication
Celiac plexus block	Pancreatic cancer, chronic pancreatitis
Diskography	Diagnosis of anatomical localization of discogenic pain
Epidural corticosteroid injection	Lumbar, cervical, or thoracic radiculopathy
Facet joint block/medial branch block	Lumbar, cervical, or thoracic facet joint syndrome
Facet joint rhizotomy/radiofrequency lesioning	Lumbar or cervical facet joint syndrome
Gasserian ganglion block Maxillary nerve block	Trigeminal neuralgia
Greater occipital nerve block Lesser occipital nerve block Superficial cervical plexus block	Occipital neuralgia
Intravenous regional block	Complex regional pain syndromes
Lumbar sympathetic block	Complex regional pain syndromes of the legs
Percutaneous disk decompression	Lumbar or cervical disk herniation
Sacroiliac joint injection	Sacroiliac joint pain
Sphenopalatine ganglion block	Headache and facial pain
Spinal cord stimulator	CRPS, PVD, low back pain, angina

Stellate ganglion block	CRPS of arm, neck, and head; headache
Suprascapular nerve block	Shoulder pain
Vertebroplasty	Vertebral fracture
Motor cortex stimulation	Neuropathic pain
Deep brain stimulation	Neuropathic pain

CRPS, Complex regional pain syndrome; PVD, peripheral vascular disease.

Therapeutic Injections

A variety of spinal, soft tissue, and joint conditions are associated with nerve irritation and inflammation, which often respond well to interventional treatments. The conditions in the spinal column include disc herniation, spondylosis, nonspecific radiculopathy, spinal stenosis, disc degeneration, and postlaminectomy syndrome. Facet and sacroiliac joints also respond well to therapeutic treatment when the nerves within the joints become inflamed. Under some conditions, injection of therapeutic agents into tendon sheaths, along ligaments, around intercostal and cranial nerves, into ganglion cysts, in addition to carpal and tarsal tunnels can provide therapeutic or diagnostic results.

Placement of a needle near spinal nerve roots and injecting therapeutic substances remains controversial. Some studies suggest that the routine use of epidural steroid injections provide no better pain relief than a placebo, whereas other studies indicated that injections tailored toward specific conditions have therapeutic value.⁶⁸

Lumbar epidural injections are the most common interventional pain management procedure for lower back pain. There are two common approaches for placing therapeutic medication, usually a combination of corticosteroids and local anesthetic agents, around the injured spinal nerve root. One approach is placing a needle through the intervertebral lamina and into the epidural space near the affected nerve root, and the other is placing the needle into the neuroforamen of the affected nerve root. The former is called an *interlaminar epidural steroid injection* (IESI), whereas the latter is often described as a *transforaminal epidural steroid injection* (TESI). The TESI is thought to have better therapeutic outcomes because it provides more precise placement of concentrated medication to the

affected nerve root.⁶⁹ However, IESI is technically easier and safer to accomplish in most circumstances.

Specific lumbar conditions that are thought to respond best to either type of ESI include disc degeneration, disc herniation, spinal nerve root compression, spinal nerve root inflammation, postherpetic neuralgia, and spinal stenosis.⁷⁰⁻⁷³

Spinal nerve root inflammation is not isolated to the lumbar region. Although less common, interventional therapy is also effective in the sacral, thoracic, and cervical region. However, there are a number of anatomical and safety considerations that need to be considered when injecting at various levels in the spinal column.

Anatomically the sacral epidural space is easy and relatively safe to access through the sacral hiatus. This approach is called a *caudal ESI* and may be just as effective for lower back pain as a lumbar ESI in some situations and may also help most patients avoid surgical intervention.⁷⁴

Thoracic ESIs are useful for postherpetic neuralgia and discogenic pain associated with inflammation. However, needle placement is often more difficult because of the increased angulation of the vertebra at this level, and the risk of arterial injury is higher with a TESI because of the proximity of the artery of Adamkiewicz.⁷⁵

The cervical ESI has a high therapeutic value but also a high risk. The anatomic and pathologic conditions involving the cervical spine create conditions that present a very narrow space. Very small vertebral arteries travel along the transverse foramen from C6 to C1, creating the possibility of arterial damage or thrombosis, which could lead to a catastrophic complication. The risks of TESI in the cervical region have prompted a call for elimination of that approach to interventional treatment, and some suggest that all steroid injections in the epidural space should be eliminated.^{76,77}

Contraindications to interventional therapy are dependent on location, injectate, and other patient factors. Patient factors include refusal, known hypersensitivity to agents, local or systemic infection, local malignancy, certain hematologic therapies, or disorders that may predispose a patient to bleeding risks, congestive heart failure, and uncontrolled diabetes mellitus. Risks associated with interventional therapy include infection, bleeding,

nerve injury, transient numbness or weakness, paralysis, contrast agent reactions, adrenal suppression, fluid retention, pneumothorax, total spinal blockade.

Regardless of technique and location, interventional pain management should be provided only by practitioners with adequate education and training, who take every precaution possible to avoid complications and are prepared to identify and treat possible complications. A well-planned and executed approach to interventional treatment is important. That must start with a thorough evaluation, identification of a target point, proper patient positioning, proper use of imaging, verification of needle placement, and use of a minimum effective dose and volume of the therapeutic agent.⁷⁸

Other Therapeutic Nerve Blocks for Chronic Pain

An often underdiagnosed and poorly treated chronic pain condition is occipital neuritis. This condition is caused by chronic irritation of the occipital nerve as it travels along the superior nuchal angle at the base of the skull. It causes neck pain and cluster headaches and responds well to anesthetic agents and steroid injections near the greater occipital nerve at the base of the skull. Occipital injections do not effectively treat migraine headaches.⁷⁹

Zygapophyseal joints, which are often called *facet joints*, are synovial joints between and along the lateral aspect of each vertebrae that help to limit movement and resist excessive biomechanical forces. These joints sometimes become dysfunctional and inflamed causing localized back pain and muscle spasms. Chronic inflammation of the facet joint can also affect the medial branch of the spinal nerve that corresponds to the particular pathological facet. Diagnosis and short term treatment of facet joint pain can be accomplished by injecting the joint with anesthetic agents and steroids.⁸⁰ Once a definitive diagnosis is made by diagnostic block, a long-term therapeutic remedy is denervation by radiofrequency ablation.⁸¹

Intercostal blocks can provide pain relief to the torso when epidural injections are difficult or contraindicated. Clinical

applications for chronic pain management include chronic postsurgical pain, cancer, costochondritis, postherpetic neuralgia, and localized torso pain. The risks specific to intercostal blocks include pneumothorax, intravascular injection, and local anesthetic systemic toxicity secondary to rapid uptake.

The sacroiliac joint (SI) is the largest joint in the human body. It supports the spine, and it acts to transfer weight and decrease stress to the pelvis and spine. Like the facet joint, the SI joint can become dysfunctional, inflamed, and painful. Injecting local anesthetic agents and steroids into the joint can be both diagnostic and therapeutic.⁸²

Sympathetic Blocks for Chronic Pain

Targeted sympathetic nerve blocks to treat chronic pain is a controversial approach to short- and long-term treatment of many conditions. The sympathetic chain travels from the cervical spine to the coccyx along the lateral aspect of vertebral column, branches off at nerve bundles, or ganglion, and supplies targeted organ systems. The major sympathetic ganglions, which can be blocked for short- and long-term treatment of chronic pain, include the sphenopalatine (facial pain), stellate (upper extremity and thoracic pain, hyperhidrosis, angina, postherpetic neuralgia), celiac (abdominal pain caused by cancer or chronic pancreatic), and hypogastric (chronic pelvic pain).⁸³⁻⁸⁸ There has also been some promising research in the use of stellate ganglion blocks for the treatment of posttraumatic stress syndrome.⁸⁹

Some studies have shown little use for sympathetic blocks for most complex chronic pain issues.⁹⁰ However, specific conditions and some blocks have shown promise. Specific conditions include pain from vascular spasms such as Raynaud disease, hyperhidrosis, and terminal cancer pain. The procedure includes a diagnostic short-term block, followed by a therapeutic long-term block. After a diagnostic block with local anesthetic provides successful resolution of the unwanted symptoms, without unwanted side effects, a longer-term or permanent block can be performed with alcohol, phenol, or radiofrequency ablation. The risk of such long-term blocks includes partial or incomplete sympathectomy. These blocks should only be performed with adequate patient informed consent

and only by experienced providers.⁹¹

Steroids

Corticosteroids and local anesthetic agents are the most common medications used for the interventional treatment of chronic pain. Local anesthetic agents are beneficial for the immediate reduction or elimination of pain symptoms, as well as identifying proper placement of steroids in the targeted area. Research has indicated that local anesthetic agents alone may provide long-term pain relief for certain chronic pain conditions,⁹² which suggest that blocking pain responses for even short periods of time may help to reset inhibitory nociceptor mechanisms.

Corticosteroids are thought to support release of antiinflammatory proteins and repress proinflammatory proteins. They are also known to suppress COX activity, which reduces the formation of prostaglandins and decreases pain. The most common steroids used in interventional therapy are moderate- to long-acting particulate steroids such as triamcinolone (Kenalog), betamethasone (Celestone), and methylprednisolone (Depo-Medrol). The vehicle, which contains particles, helps to provide localized long-acting antiinflammatory action. However, the particles contained in these solutions can lead to catastrophic complications if accidentally injected into the vascular system. This risk is especially pronounced in the cervical spine region where arteries are small, and infarction with accidental injection of particulate material is more likely to occur.

Contrast Agents

In order to reduce the risk of inadvertent vascular injection and provide assurance that the needle is properly placed, radiographic imaging is essential for most interventional injections. Because ionizing radiation does not provide an image of soft tissue, contrast agents are used to enhance the visibility of soft tissue under ionizing radiation. This can help identify needle placement in joints and near nerves, and also demonstrate expected therapeutic flow patterns in spaces. Most importantly it can identify inadvertent intravascular needle placement before a particulate steroid is

accidentally injected.

There are two types of contrast agents commonly used in pain management: iodinated agents, and nonionic agents. The nonionic agents are safer because they have less free iodine, which has been implicated in serious allergic reactions. Both agents are excreted by the kidneys; therefore it is imperative that adequate renal function is present before contrast agents are used. There are many potentially negative adverse reactions associated with contrast agents. The most common include nausea, hypotension, bronchospasm, hives, and anaphylactic reactions.

Implantable Devices

In the absence of chronic pain and when the nervous system is functioning properly, inhibitory systems in the dorsal horn of the spinal cord prevent continuous pain sensation. For individuals with chronic pain, this mechanism appears to be dysfunctional. In theory, this inhibitory mechanism can be stimulated by electrical impulses applied to the dorsal column of the spinal cord producing changes within the ascending sensory fibers that modulate the sensation of pain.⁹³ An external device called a *transcutaneous electrical nerve stimulator* (TENS) unit accomplished this through nonpainful stimulation that competes with nociceptive fibers in the dorsal horn to impede painful sensory perception through the same inhibitory pathways. Implantable devices that directly stimulate the spinal cord have been attempted with varying success.⁹⁴⁻⁹⁶

Another highly invasive method for treating chronic pain is the use of implanted intrathecal drug delivery systems. These devices can be surgically implanted in the body and programmed to deliver continuous doses of highly concentrated microdoses of medication into the CNS. The reservoir is typically implanted in the abdomen, and an infusion catheter is tunneled to the intrathecal space. The value of intrathecal drug delivery systems is the ability to better manage side effects and tolerance.⁹⁷ These devices are most useful for those with chronic pain related to terminal illness and failed back surgery where conservative methods are ineffective at providing the patient with an adequate quality of life.⁹⁸

Complications and Management

Complications of interventional therapy are uncommon when proper technique and precautions are followed. However, even in the best of hands and with the safest techniques, complications still occur. Follow-up, recognition of complications, and the ability to manage and treat patients who develop complications are all an important part of the plan of care.

One of the most common complications includes persistent pain from a traumatic injection or failure to respond to the therapeutic agent. Occasionally, a needle placement can disrupt the dura membrane and create a temporary leakage of spinal fluid, leading to a postural headache. Dural punctures most often heal spontaneously without necessary intervention and the body will replace the spinal fluid within a few days. However, the headache that develops, usually in approximately 24 to 48 hours, is often debilitating. An epidural blood patch, which involves placing approximately 20 mL of the patient's blood in the epidural space at the puncture site under sterile conditions, can immediately and permanently resolve this condition.

In rare circumstances, subdural or epidural hematoma may cause spinal compression, paralysis, and possibly death if left unrecognized and untreated. Caution is needed for patients who are being treated with medications that can increase bleeding. Spinal cord trauma, injection into spinal arteries, anaphylaxis, and arachnoiditis are among the other rare but possible complications that must be recognized and properly treated to prevent a catastrophic outcome.

Age-Related Considerations

There are significant physiological differences between various age groups. These differences are more pronounced in the pediatric and geriatric populations. There are physical and functional implications that can create significant barriers to proper assessment, diagnosis, and treatment. It is important to recognize and incorporate age-related physiology into any plan of care.⁹⁹

Pediatric Patients

It must always be kept in mind that infants are not simply young adults. They have specific physiologic differences that must be considered when treating pain. One of the more challenging aspects of pain management in the very young is identification. Pain is often ignored in this age group because of their inability to vocalize discomfort.

Alternative assessment methods for infants is necessary. The most sensitive and reliable method for pain assessment is facial expression. Infants who are in pain do not always cry. Body motion, facial expression, and vital signs are all part of a comprehensive assessment necessary to accurately determine if an infant is in pain. Relying only on one parameter, especially vital signs, may yield inaccurate information, leading to mismanagement of pain treatment. Limited neurological development and illness may constrain the infant's response and complicate assessment.

Conventional pain therapy, especially pharmaceuticals, is not always the safest or most effective treatment plan. The most common treatments for pain in infants are topical and local anesthetics, opiates, and acetaminophen. Alternative treatments are often a more effective and safer approach. They include nonnutritive sucking that stimulates the oro-tactile centers in the brain, increasing endorphins, which naturally relieves pain. Breast feeding can also reduce painful sensations through the same mechanism. Swaddling, holding, rocking, skin-to-skin contact, and auditory stimulation are all mechanical methods for treating pain. The olfactory centers of infants are very effective in dealing with

painful stimulation. The smell of amniotic fluid, mother's milk, and baby oil have all been shown to reduce pain in infants.

The negative psychological and physical impact of untreated and undertreated pain on the very young should not be ignored. There is evidence that chronic painful stimulation in infants can lead to permanent changes in the CNS and, as a result, alterations in responsiveness of the neuroendocrine and immune systems to stress as they mature.¹⁰⁰

Geriatric Patients

Aging is an inconsistent and complex phenomenon that involves the progressive degeneration of organ systems.¹⁰¹ It involves changes in cellular homeostasis, organ function, and functional reserve, which impair an individual's ability to cope with stress, pain, and other health care challenges.¹⁰²

Aging adults report a greater incidence of chronic pain, and studies indicate a reduced tolerance to pain.¹⁰³ A theory behind this observed increase in pain and reduced tolerance in older adults suggests that aging nerve fibers show damage similar to younger tissue that develops neuropathic pain.¹⁰⁴ In addition to progressive tissue damage with aging, chronic inflammatory responses play a role in increased pain, pain perception, and development of chronic pain.¹⁰⁵

Health care providers sometimes assume that the elderly have reduced pain perception. This misconception and several others about pain in the elderly probably stems from several factors. Some, if not most health care providers assume that pain is a natural part of aging. This notion is not supported in the literature.¹⁰⁶ Pain perception may be elevated, but pain response is often diminished because of changes in cognitive, communication, and motor functions. Also, the elderly are often reluctant to report pain because of fears of pathology or negative social issues related to acknowledgement of pain.¹⁰⁷

Assessment and management of pain in this patient population may be difficult to adequately accomplish. One of the reasons that pain therapy can be difficult is that the elderly often have multiple pain generators or limitations in treatment options based on multiple health issues associated with aging. Therapeutic choices

can also be limited by potential interactions with other medication being taken for chronic conditions that do not include pain. Opioids may be considered for short-term pain relief, but their use should be limited due to potential side effects, which include dysphoria, respiratory depression, drug interactions, and constipation. Immobility contributes to painful conditions and also limits options for physical therapies. Conventional treatment that is effective in a younger population is not always an appropriate choice for the elderly.

It is important to develop a unique plan of care specific to each elderly patient, understanding how comorbidities, polypharmacy, communication, in addition to functional and cognitive impairment may affect assessment and treatment. Treatment of acute and chronic pain in the elderly can be challenging, but it is a critical component to improving the quality of life of individuals in this population.

Patient-Centered Approach

Nurses bring a unique philosophical and theoretical approach to patient care and pain management. Nursing care plans often bring in strategies that include effective communication, partnership, and health promotion.¹⁰⁸

Patient-centered care is especially important when treating the multidimensional problems associated with chronic pain. A patient-centered approach allows for a foundation for creating an assessment and treatment plan based on the physical, psychological, and social needs of the patient, while working to avoid constraints often found in more traditional medical models.¹⁰⁹

As part of a patient-centered approach, it is important to utilize expertise from multiple health care resources, incorporating a variety of philosophies, and various treatment regimens. A pathway toward reasonable goals in management of chronic pain often requires cooperative care and sometimes unconventional treatment. Reasonable therapeutic goals should include functional improvement in activities of daily living, psychological improvement, rational pharmacologic management of ongoing pain, and return to productive activities. Treatment teams should develop a joint plan of care based on unique patient goals, contributing the resources available to help meet those goals, establish primary and secondary treatments plans, identify support systems, and include appropriate spiritual resources as requested by the patient.

A “one size fits all” approach is seldom effective. Consumer and health care providers have a tendency to compartmentalize their health care problems by seeking a “specialist.” This kind of approach often narrowly focuses the treatment and excludes complimentary therapies that may enhance, rather than interfere with each other. One example of a cooperative approach is the combination of interventional therapy with physical therapy or chiropractic care. Evidence exists that this multidisciplinary approach to pain care is often more successful than a single discipline or treatment.¹¹⁰

Failure to Treat Pain

We seldom consider what happens when we fail to treat pain. In fact, it is not unusual to find patients and health care providers who take a “hands-off approach” to chronic pain symptoms and believe that they will resolve themselves without intervention.

Most of the barriers that prevent timely and appropriate treatment of chronic pain are caused by patient issues. The most common issues include lack of access to adequate health care, fear of treatment, misinformation, and cultural barriers. However, provider issues can also create barriers. Sometimes preconceived notions play a role in mismanagement of chronic pain. Such misplaced notions can hinder judgment and lead to erroneous assumptions about their patient.¹¹¹ Being empathetic without preconceived judgment is essential for building a solid rapport with the patient and more effectively treating chronic pain.¹¹²

Summary

Unlike the story of Androcles and the Lion depicted in Aesop's fable, treatment of chronic pain is far more complex than “removing a thorn from the paw” or simply addressing a single source of pain. Identification and treatment of the original source of injury is important to the overall goals of pain management, but chronic pain includes a complex and vicious cycle of dysfunction, which leads to a breakdown in homeostasis. Returning homeostasis requires addressing peripheral, spinal, and cerebral mechanisms that have become dysfunctional because of repetitive nociceptive stimulation. Absent or inappropriate treatment of chronic pain can result in debilitation, lower quality of life, depression, unemployment, bankruptcy, homelessness, divorce, or suicide. The longer proper treatment is delayed, the more likely that the problem can become irreversible or unmanageable. It often requires a significant time commitment from both the patient and the provider to identify a pathway to functional improvement and return to homeostasis.

Nonoperating Room Anesthesia

Renata Sobey, Andy Tracy

Considering the evolving patient population and dynamic needs of a health care system under redesign, it should come as no surprise that the world of anesthesia is also under reconstruction. Although most anesthetics were traditionally administered in the operating room, it is no longer unusual for services to be provided outside the operating suite in a variety of locations that are far from the traditional setting. Estimates today indicate that up to 55% of the procedures that require anesthesia services are taking place outside the conventional operating room.¹ These include diagnostic, interventional, and traditional surgery involving cardiology, vascular, emergency department, gastroenterology, gynecology, hematology, oncology, thoracic, neurologic and neurosurgical, plastic, ophthalmology, orthopedic, psychiatric, radiology, and other diagnostic and dental procedures.² Patients treated in these remote settings require the same safe, vigilant attention, anesthetic administration, and recovery care as those patients treated in the operating suite. The key for the anesthesia provider is to ensure that the therapeutic and diagnostic environment where anesthesia is to be performed is as familiar, as well equipped, and as safe as it is in the operating room.

Although certain therapeutic and diagnostic procedures are sometimes performed without anesthesia, the patient's condition, or the requirements of the test or procedure, may necessitate administration of an anesthetic. Anesthesia could range from local anesthetic infiltration and regional anesthesia techniques to monitored anesthesia care involving enteral minimal sedation, parenteral moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia. Patients can range in age from pediatric to geriatric. In remote locations, patients who require anesthesia may be confused or disoriented, uncooperative, unwilling or unable to

understand the requirements of the procedure, claustrophobic, anxious, or mentally disabled. Older and medically higher-risk patients are being treated more often in this environment.^{1,3-5} Of the patients treated in these settings, 20% are over the age of 70 and 69% have physical status classifications of 3 to 5.^{1,3,4}

Several challenges to deliver anesthesia exist that are unique to remote locations. These include working with support staff who are unfamiliar with anesthetic management, and who may not recognize an impending critical situation. Variation of the physical set-up of the procedure room and monitoring equipment may result in decreased familiarity by the anesthesia provider. Equipment may be poorly maintained, availability of necessary supplies may be inadequate, and scheduling of the procedure utilizing anesthesia services may be inefficient resulting in expeditious patient preparation. Lastly, remote positioning of the patient during a potentially lengthy procedure creates unique challenges that are exacerbated in unfamiliar locations. Given the rapid advances in medical knowledge and technology, coupled with a strong societal impetus to reduce health care costs, more therapeutic and diagnostic procedures will be performed in remote locations.^{1,3}

Administration of Anesthesia in Remote Locations

Special Considerations

The operating room provides an ideal environment for the administration of anesthesia and the performance of surgical procedures because of the familiarity of the physical layout, the rapid availability of anesthesia equipment, medications, supplies, and the accessibility of well-trained adjunct personnel. The anesthesia setting in a remote location must possess the same level of safety and high standards. Many considerations and plans must be executed before a patient can safely receive anesthesia for a therapeutic or diagnostic procedure in a remote location. [Box 58.1](#) provides a comprehensive checklist of the requisites that will facilitate planning and assembling necessary equipment, supplies, and medications.

Requisites for Administration of Anesthesia in Remote Locations

Utilities

- Adequate workspace
- Adequate overhead lighting
- Adequate number of and current-carrying capacity of electrical outlets
- Electrical service with either isolated electric power or ground fault circuit interrupters, including backup generator power
- Adequate communication pathway, within the department and outside the department
- Suitable area for postprocedure recovery (All building codes, fire codes, safety codes, and facility standards must be met.)

Equipment

- Patient chair, cart, or operating surface that can be quickly placed into Trendelenburg position
- Regularly serviced and functioning equipment
- Patient monitors
- Pulse oximeter
- Electrocardiograph
- Blood pressure monitor with a selection of adequate-sized cuffs
- Capnography
- Body temperature monitor
- Oxygen supplies
- Minimum of two oxygen sources must be available with regulators attached (compressed oxygen should be the equivalent of an E cylinder)
- Positive-pressure ventilation sources, including a self-inflating resuscitator bag capable of delivering at least 90% oxygen and a mouth-to-mask unit
- Defibrillator— manual biphasic or automatic external defibrillator (AED) (charged, ready, and easily accessible)
- Suction source or a suction machine (electric-powered suction, battery-powered suction, or foot pump suction devices are available), tubing, suction catheters, and Yankauer suctions
- Lockable anesthesia cart to permit organization of supplies, including endotracheal equipment, laryngeal mask airways, tube of water-soluble lubricating jelly, an assortment of various-sized disposable facemasks, nasal cannulas, oral and nasal airways,

syringes (1 mL tuberculin syringe, 3 mL, 5 mL, 10 mL, 20 mL, 60 mL), needles, intravenous catheters, tourniquet, intravenous fluids and tubing, alcohol pads, adhesive tape, sterile intravenous site covers, disposable gloves, stethoscopes, precordial stethoscope with monaural earpiece and extension tubing, precordial stethoscope adhesive disks, and appropriate anesthetic medications

- Battery-powered flashlight for the illumination of the patient, the anesthesia machines, and the monitors along with spare batteries
- Syringe pump, wall plug/transformer, and spare batteries
- Warm blankets, electric blanket (check with hospital policy before using an electric blanket), or forced-air warming devices with the appropriate blanket, towels, or hat to cover the patient's head to preserve body warmth
- Blankets, towels, or foam for padding for protection of skin integrity, bony prominences, and body extremities
- Emergency medications may include: atropine, dextrose 50%, diphenhydramine, ephedrine, epinephrine, flumazenil, hydrocortisone, lidocaine, naloxone, nitroglycerin, phenylephrine, succinylcholine, vasopressin, and a bronchial dilator inhaler such as albuterol or nebulized epinephrine (Note that some anesthetic medications must be kept refrigerated until ready for use.)
- Preoperative anesthesia evaluation forms
- Anesthesia consent form

Additional Requirements for General Anesthesia

- Oxygen fail-safe system
- Oxygen analyzer
- Waste gas exhaust scavenging system

- End-tidal carbon dioxide (ETCO₂) analyzer, extra ETCO₂ filter, and extension sample tubing
- Vaporizers—calibration and exclusion system
- Respiratory monitoring apparatus (for the anesthesia circuit reservoir bag)
- Alarm system
- In addition to the emergency medications listed previously, consider the following:
- Premedication drugs—midazolam,, ketamine, nitrous oxide, diazepam, chloral hydrate
- Induction drugs—propofol, etomidate, ketamine
- Maintenance drugs—bottles of sevoflurane, isoflurane, desflurane, propofol, ketamine, dexmedetomidine
- Narcotics—fentanyl, alfentanil, sufentanil, remifentanil
- Muscle relaxants—succinylcholine, rocuronium, cisatracurium, vecuronium
- Muscle relaxant reversal agents—edrophonium, neostigmine, atropine, glycopyrrolate
- Cardiovascular drugs—labetalol, esmolol, verapamil, hydralazine
- Narcotic reversal drugs—naloxone
- Antiemetic drugs—ondansetron, dolasetron, granisetron, metoclopramide
- Emergency cart and equipment
- Laryngoscope handle with assorted blades, laryngeal mask airways (LMA's) in assorted sizes, and endotracheal tubes (adult and pediatric)

- Self-inflating resuscitator bag (Ambu bag)
- Difficult airway equipment including an emergency cricothyrotomy kit
- Malignant hyperthermia emergency drugs, equipment, and the phone number for the Malignant Hyperthermia Association of the United States (MHAUS) for live help during the treatment of malignant hyperthermia on-site (United States and Canada: 1-800-MH HYPER or 1-800-644-9737. Outside the United States and Canada: 001-1-315-464-7079). More information is available at the Malignant Hyperthermia Association of the United States website at: <http://www.mhaus.org>.

A policy must be developed that outlines the organization of emergency services for either in-hospital or office-based facilities. Office-based facilities should have a plan for regular emergency training of personnel, interoffice communication during an emergency, communication with emergency medical personnel, and transportation to the nearest hospital emergency department.

An anesthesia machine and portable anesthesia cart with the listed equipment, supplies, and medications should be dedicated strictly for use in remote locations. This can save preparation time whenever a procedure is required in a remote location. It also increases patient safety and decreases the risk of a mishap resulting from lack of necessary equipment and materials.

As part of the planning process before patient treatment, it is important to familiarize oneself with the personnel and the work area in the remote environment. The workplace allotted for anesthesia care may be small, crowded, and different from the usual operating room setting. Preplanning is vital to make this unique location familiar to the anesthetist and safe for the patient. All remote locations should have the ability to manage a variety of anesthetic procedures, and include equipment, medications, supplies, positive-pressure ventilation, resuscitation, and suction as a means to provide safe patient care.

The American Association of Nurse Anesthetists (AANA),⁶ the American Society of Anesthesiologists (ASA),⁷⁻⁹ and The Joint

Commission¹⁰ have established written standards and professional commentary to provide for the basic rights and safety of patients along with the safety of anesthesia providers and ancillary personnel. As technology advances these standards are adapted and new recommendations are made.

Licensed registered nurses, who are not qualified anesthesia providers, have become involved in the monitoring of patients and the administration of medications for procedural sedations involving therapeutic and diagnostic procedures, in addition to certain surgical procedures.

The AANA and the ASA separately and together have issued statements in regard to criteria (Box 58.2) that must be met by nonanesthesia providers to protect the safety and well-being of the

Box 58.2¹²

Criteria for the Management and Monitoring of Patients Undergoing Sedation Delivered for Therapeutic or Diagnostic Procedures by Nonanesthesia Providers

- Guidelines for patient monitoring, drug administration, and protocols are available for dealing with potential complications or emergency situations, developed in accordance with accepted standards of anesthesia practice.
- A qualified anesthesia provider or attending physician selects and orders the agents to achieve sedation and analgesia.
- Registered nurses who are not qualified anesthesia providers should not administer agents classified as anesthetics, including but not limited to ketamine, propofol, etomidate, nitrous oxide, and muscle relaxants.
- The registered nurse managing and monitoring the patient receiving an analgesia sedation shall have no other responsibilities during the procedure.

- Venous access shall be maintained for all patients having sedation and analgesia.
- Supplemental oxygen shall be available for any patient receiving sedation and analgesia, and when appropriate, in the post procedure period.
- Documentation and monitoring of physiologic measurements including but not limited to blood pressure, respiratory rate, oxygen saturation, cardiac rate and rhythm, and level of consciousness should be recorded at least every 5 minutes.
- An emergency cart must be immediately accessible to every location where analgesia sedation is administered. This cart must include emergency resuscitative drugs, airway and ventilatory adjunct equipment, defibrillator, and a source for administration of 100% oxygen. A positive-pressure breathing device, oxygen, suction, and appropriate airways must be placed in each room where analgesia sedation is administered.
- Back-up personnel who are experts in airway management, emergency intubations, and advanced cardiopulmonary resuscitation must be available.
- A qualified professional capable of managing complications is present in the facility and remains in the facility until the patient is stable.
- A qualified professional authorized under institutional guidelines to discharge the patient remains in the facility to discharge the patient in accordance with established criteria of the facility.

Standards for the Delivery of Anesthesia in a Remote Location

A Perform a Complete Preanesthesia Assessment

The patient, parent(s), or legal guardian(s) must be thoroughly

interviewed and assessed before the performance of any anesthetic procedure. The preanesthesia assessment should be performed in consideration of the patient's right to privacy and confidentiality, and which safeguards their dignity and respects aspects of their psychological, cultural, and spiritual values. During this assessment, information is obtained regarding the patient's medical history (prior allergy must be assessed), anesthesia history (noting any prior complications and responses to prior anesthetic experiences), surgical history, and medication history (including tobacco, alcohol, and any substance abuse). A complete physical assessment of the patient is made, along with inspection of the head, neck, mouth, and airway. The patient's NPO status must be assessed in addition to any recent change in condition that may complicate or prohibit the delivery of anesthesia for a nonemergent procedure. Review of diagnostic data such as patient laboratory values, radiographs, and electrocardiogram (ECG) is completed and important findings are noted in the patient's anesthesia record. A physical status classification is then assigned to the patient. [Box 58.3](#) outlines specific patient conditions that alert the anesthetist to the need for special attention related to the delivery of anesthesia during therapeutic and diagnostic procedures.

Specific Patient Conditions that Warrant Anesthesia-Care Vigilance

- Mental impairment with an inability to cooperate
- Severe gastroesophageal reflux; delayed gastric emptying; aspiration risk
- Orthopnea; obstructive sleep apnea
- Decreased level of consciousness; depression of airway protection reflexes
- Increased intracranial pressure
- Difficult airway; oral, dental, craniofacial, cervical, or thoracic abnormalities that could preclude airway access and maintenance

- Respiratory tract infection
- Morbid obesity
- Therapeutic or diagnostic procedures that impede access to the airway
- Therapeutic or diagnostic procedures that are complex, lengthy, painful, or invasive
- Positioning that is complex, atypical, painful; prone position
- Patient suffering acute trauma
- Patients with extremes of age
- Prematurity
- Physical status 3 or 4

B Obtain Informed Consent for the Planned Anesthetic Intervention From the Patient or Legal Guardian

The anesthesia provider should discuss the course of the anesthetic plan of care and enumerate the following in understandable terms appropriate for the patient or guardian:

- How the anesthetic procedure will be performed
- Possible risks of the anesthetic procedure
- Pertinent possible reactions or complications the patient might expect while receiving a typical anesthetic, along with informing the patient or guardian that the anesthesiologist has permission to make changes or adjustments as deemed necessary in his or her professional judgment
- Possible options to the type of anesthetic to be received by the patient
- The ability for the patient/parent(s)/guardian(s) to have any concerns addressed and questions answered

At times, anesthesia for therapeutic and diagnostic procedures will require only minimal, moderate, or deep sedation, which by definition may not include patient amnesia. Only general anesthesia ensures amnesia as a standard of care. Therefore discussion of what the patient can reasonably expect should take place at this time.¹³ It is far easier to discuss these points with the patient before the anesthetic procedure than to explain these issues postprocedure.

C Formulate a Patient-Specific Plan for Anesthesia Care

The art and science of anesthesia mandate that the safest and least invasive anesthetic technique be administered to the patient to avoid complications for the patient and promote positive patient outcomes while practicing at a remote setting.

D Implement and Adjust the Anesthesia Care Plan Based on the Patient's Physiologic Response

Immediately before implementation of anesthesia, reassess the patient (e.g., vital signs, airway status, and response to preprocedure medications given), and document a reassessment note in the anesthesia record. The Joint Commission mandates a preanesthetic evaluation on all patients receiving anesthesia and defines “immediately” as the moments just before the sedation is administered. Ensure that all anesthesia equipment, supplies, and medications are checked and immediately available should the patient status require a change in the anesthetic plan.

E Properly Prepare, Dispense, and Label All Medications to Be Used for the Patient

All medications drawn up prior to the case must be labeled with the drug name, strength (concentration), amount (if not apparent from the container), and expiration date (if not used within 24 hours), time, and initials of individual drawing up the medication. To

reduce the risk of infections the AANA, along with other health care organizations, now recommends the Centers for Disease Control and Prevention (CDC) guidelines for the use of single dose vials, single use needles, and single use syringes.

F Adhere to Appropriate Safety Precautions and Protocols as Established by the Institution, to Minimize the Risks to the Patient and Ancillary Staff

This standard is important for the patient, the anesthesia provider, and ancillary personnel for the prevention of accidents and injury related to fire, explosion, electrical shock, and equipment malfunction. These issues are also a consideration from a medicolegal perspective. The anesthesia provider is also an integral part of the team involved with protocols for preventing wrong site, wrong procedure, and wrong person surgery, also known as the *Universal Protocol* established by The Joint Commission.^{11,14,15} Anesthesia services must be consulted for scheduling consideration of patients in remote locations, as these therapeutic and diagnostic procedures are often complex when compared to anesthesia delivery in the operating room, and may require additional staffing resources.

G Monitor and Document the Patient's Physiologic Condition as Appropriate for the Type of Anesthesia and Specific Patient Needs^{6,7}

- *Perform a complete anesthesia equipment safety check daily and document in the patient's medical record.* An abbreviated check of all equipment is acceptable before each subsequent anesthetic is administered.
- *Monitor ventilation continuously.* Ventilation may be monitored in the patient undergoing mild, moderate, or deep sedation with a precordial stethoscope or by direct auscultation of the patient's ventilatory effort. Verify intubation of the trachea by auscultation, chest excursion, and confirmation of carbon dioxide in the expired

gas. In cases of moderate or deep sedation, the AANA and ASA mandate the measurement of end-tidal carbon dioxide (ETCO₂) unless the patient, procedure, or equipment interferes or precludes monitoring. Continuously monitor ETCO₂ during controlled, assisted, or spontaneous ventilation, including any anesthesia or sedation technique requiring artificial airway support. Use spirometry and ventilatory pressure monitors as indicated.⁹

- *Monitor oxygenation continuously* by clinical observation, pulse oximetry. Cerebral oximetry and/or arterial blood gas analysis may be indicated.
- *Monitor cardiovascular status continuously* via electrocardiography and heart sounds. Record blood pressure and heart rate at least every 5 minutes.
- *Monitor body temperature continuously* in all patients when clinically significant changes in body temperature are intended, anticipated, or suspected. Maintenance of normothermia must be an integral part of the anesthetic plan to preserve essential body functions and to prevent complications leading to patient morbidity and mortality. Temperature monitoring is a standard of care when delivering general anesthesia to the patient and optional while performing mild, moderate, or deep sedation.⁹
- *Monitor neuromuscular function and status* prior to the procedure and recovery when neuromuscular blocking agents are administered.
- *Monitor and assess patient positioning and protective measures* at frequent intervals. Periodic assessment of eye protection, skin, bony prominences, and extremities is mandatory.

H Precautions Shall Be Taken to Minimize the Risk of Infection to the Patient, the Operator, and Ancillary Personnel

Clean equipment regularly; maintain sterility of supplies until ready for use and assure that medications are not expired, opened, or tampered with before use. Protective eyewear for the anesthesia provider should be readily available in addition to an assortment of sterile and nonsterile gloves.

I There Must Be Complete, Accurate, and Time-Oriented Documentation of Pertinent Information on the Patient's Anesthesia Record

Document baseline patient vital signs before the anesthetic procedure and the therapeutic or diagnostic procedure have begun. Documentation must be made of all vital signs: heart rate, blood pressure, pulse oximeter readings, patient temperature, and the presence of ETCO₂. Documentation that includes names and quantities must be made of all fluids and medications administered. Compliance to institutionally-specific anesthesia documentation practices applies to remote locations in addition to the operating room.

J After the Anesthetic Treatment for Therapeutic or Diagnostic Procedures, Transfer the Responsibility for Care of the Patient to Other Qualified Personnel in a Manner That Ensures Continuity of Care and Patient Safety

Anesthesia care does not end with the completion of the therapeutic or diagnostic procedure. The patient may receive postanesthesia care at the site of the therapeutic or diagnostic procedure, or may be transported to a separate area for postanesthesia care by the anesthesia provider utilizing appropriate monitoring devices. A comprehensive report is given to the recovery personnel, and the transfer of care is documented including the receiving staff member. The patient's condition is evaluated continually in the recovery area and the patient may be discharged from the recovery area once discharge criteria are achieved.¹⁶ Table 58.1 lists a nonoperating room anesthesia safety checklist.

TABLE 58.1

Nonoperating Room Anesthesia Safety Checklist

Before Induction of Anesthesia	Before Procedure Start	Before Patient Leaves Procedure Room

K Summary

The standards listed in this section describe the minimum requirements for treatment and monitoring of any patient who requires anesthesia care. These guidelines are established to maintain patient safety and facilitate positive patient outcomes. The omission of any monitoring standard should be documented and the reason for such omission stated on the patient's anesthesia record. Any anesthetic procedure, including those performed in a remote location, should not begin until the anesthetist feels sufficiently comfortable, safe, and well prepared to deliver the anesthetic treatment required for the patient.

Guidelines for Sedation

Therapeutic and diagnostic procedures can be performed with various methods of sedation. Sedation is possible with enteral, rectal, parenteral (intravenous [IV]), and inhaled medications. It is important to remember that the depth of sedation in a patient is a continuum of progressive alterations in cognition, respirations, and protective reflexes. Many anesthetic agents are synergistic and potentiate the effects of one another when a multimodal approach is used, and consequently the patient may quickly progress from one level of sedation/anesthesia to another. It is essential that the anesthesia provider be able to respond to all depths of anesthesia, as well as have quick access to vital equipment, supplies, and trained and qualified ancillary personnel who are familiar with anesthesia delivery, emergencies, and monitoring.

Sedation exists as a continuum and it is not always possible to predict the individual responses of each patient to a particular level of anesthesia. Consequently the anesthesia provider must be able to intervene when the depth of anesthesia exceeds expectations. [Table 58.2](#) lists definitions of the four levels of sedation and physiologic responses associated with each category as described by the ASA. From these definitions, standards are provided to practitioners for the administration of safe and high-quality care to patients.¹⁷

TABLE 58.2

The Continuum of Depth of Sedation: Definition of General Anesthesia and Levels of Sedation/Analgesia

	Minimal Sedation Anxiolysis*	Moderate Sedation/Anxiolysis ("Conscious Sedation")**	Deep Sedation/Analgesia***	General Anesthesia****
Responsiveness	Normal response to verbal stimuli	Purposeful response to verbal or tactile stimulation	Purposeful response following repeated or painful stimulation	Unarousable even with painful stimulation
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous Ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular Function	Unaffected	Usually maintained	Usually maintained	May be impaired

* Minimal Sedation (formerly known as Anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive

function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

** Moderate Sedation/Analgesia (Formerly Known as Conscious Sedation) is a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained. (NOTE: Reflexive withdrawal from a painful stimulus is not considered a purposeful response.)

*** Deep Sedation/Analgesia is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

**** Anesthesia (General Anesthesia) consists of general anesthesia and spinal or major regional anesthesia. It does not include local anesthesia. General anesthesia is a drug-induced loss of consciousness during which patients are not aroused, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

Modified from American Society of Anesthesiologists: *Continuum of Depth of Sedation: Definition of General Anesthesia, and Levels of Sedation/Analgesia*. Accessed 2016 at the ASA website: <http://www.asahq.org/search?q=sedation>

Accepted standards for moderate sedation/analgesia and deep sedation/analgesia state the following^{10,17,18}:

1. The process from minimal sedation (anxiolysis) to general anesthesia is a continuum, and individuals vary in their responses to medications.
2. Qualified individuals with appropriate credentials (e.g., nurses, certified registered nurse anesthetists [CRNAs], anesthesiologists, and dentists) who are trained in professional standards and techniques do the following:
 - a. May administer pharmacologic agents to achieve a desired level of sedation.

- b. Must monitor patients carefully to maintain the patient's vital functions at the desired level of sedation. Appropriate equipment must be available for monitoring heart rate via ECG, respiratory rate and adequacy of pulmonary ventilation, oxygenation via pulse oximetry, and blood pressure measurement at regular intervals (at least every 5 minutes).
- c. Must be competent to evaluate the patient before performing the moderate sedation/analgesia and deep sedation/analgesia.
- d. Must be competent to support the patient's psychological functions and physical comfort.
- e. Must be competent in the administration of sedatives, analgesics, hypnotics, and other medications to produce and maintain moderate sedation/analgesia and deep sedation/analgesia.
- f. Must be competent to rescue the patient who unavoidably or unintentionally moves into a deeper than desired level of sedation and analgesia. In addition, for patients undergoing deep sedation/analgesia, one must also have competency to manage cardiovascular compromise.
- g. Must properly document the patient's response to

care.

- h. Must supervise recovery of the patient after the sedation postanesthesia recovery area or until transfer of care to another qualified health care provider.
 - i. Must discharge the patient once discharge criteria have been achieved and in conjunction with the proceduralist.
3. Adequate numbers of qualified and competent personnel must be present during the performance of moderate sedation/analgesia, deep sedation/analgesia, and general anesthesia to serve as a skilled second pair of hands if necessary. This should include not only qualified anesthesia providers as described earlier, but also nurses, assistants, technicians, and other office staff to meet the needs of the patient.^{17,18}

The Pediatric Patient

The pediatric population can pose complex challenges for the delivery of anesthesia. Pediatric patient behavior and degree of cooperation can range from very helpful to extremely anxious and even combative. Pediatric sedation and anesthesia improves the patient care experience by greatly reducing anxiety and eliminating movement while providing for safe patient outcomes for therapeutic or diagnostic procedures. The primary considerations in the practice of anesthesia are patient safety and guardianship of patient welfare. Children under the age of 5 years seem to be at the greatest risk for adverse events even with no underlying disease. Adverse events have occurred more commonly with the use of multiple drugs, especially sedative medications.¹⁹⁻²³ The problems encountered most often are respiratory events: respiratory depression, respiratory obstruction, and apnea.²⁰⁻²²

Adverse events can be reduced by proper adherence to patient

selection and a comprehensive preoperative assessment, proper dosage of medications to minimize unexpected responses, proper monitoring, skilled administration of anesthesia, and proper recovery time. The anesthesia provider must be prepared to alter anesthetic plans based on the patient response to anesthetic agents.²⁰⁻²³ Consideration must be made for the type of procedure to be performed, past medical history, past sedation/anesthesia history, current medication therapy, allergies, and respiratory or airway difficulties. Questions regarding the degree of patient stimulation expected throughout the procedure, amount of anticipated blood loss, ability to maintain normothermia, and ability to have close proximity in which to monitor the patient, are all questions the anesthesia provider is responsible for addressing. Length of procedure is critical information as adverse reactions are reduced with procedures that last less than 1 hour.²³ Clear communication with the adjunct medical staff is essential to clarify the requirements for the patient to be safe and properly anesthetized for the procedure.

The pediatric patient and the parent or legal guardian must be properly prepared for the planned therapeutic or diagnostic procedure. Clear explanation of the entire anesthetic process to the parent or guardian is based on the developed treatment plan and is offered in age-appropriate terms for the pediatric patient.¹⁹ Discussion with the parent/guardian about separation from the patient, where the parent/guardian will wait during the procedure and the ability to be reunited postprocedure will alleviate anxiety.

Box 58.4 identifies some relevant pediatric safety considerations and specific preprocedural assessments of the pediatric patient. It is particularly important to assess any recent upper respiratory infections, fever, cough, snoring, and sputum production, which could result in an airway compromise during sedation. Additional attention must be paid to the airway to assess for any loose dentition or anatomical aberrancies.

Aspects of Pediatric Anesthesia

Safety Considerations

Children of all ages should be NPO for clear liquids 2 hours before

undergoing sedation. Recommendations for duration of NPO for solid food and nonclear liquids (e.g., infant formula, milk) vary by age, as follows:

- < 6 months: 4–6 hours
- 6–36 months: 6 hours
- > 36 months: 6–8 hours

Preprocedural Evaluation

Important elements of the history are as follows:

- Past medical history, especially with respect to previous sedation or anesthesia
- Last solid and liquid oral intake
- Recent illness
- Medication or drug use
- Allergies or adverse reaction
- Pertinent family history
- Pregnancy status (for postmenarchal females)
- Upper respiratory infection (URI) symptoms; history of reactive airway disease

Elements of the physical examination are as follows:

- Age
- Weight
- Vital signs
- Airway examination (head, ears, eyes, nose, and throat [HEENT])

and pulmonary examination)

- Cardiovascular examination
- Neurologic/mental status
- Size and location of injury and neurologic status distal to it
- Airway examination for anatomic variations and presence of loose teeth

Modified from Chang, WT. *Pediatric sedation*. Accessed 2016 at <http://emedicine.medscape.com/article/804045-overview>.

Knowledge of the most common causes of adverse pediatric anesthesia events can help the anesthetist plan for and avoid these events (Box 58.5).^{20,21,23} Most adverse anesthesia events are caused when multiple anesthetic agents are used.²⁴

Most Common Causes of Pediatric Anesthesia Adverse Events for Therapeutic or Diagnostic Procedures

- Drug errors
- Nitrous oxide in combination with any other sedative medication
- Inability to rescue the patient from an adverse anesthetic event
- Unmet monitoring standards—especially respiration, oxygenation
- Respiratory depression/hypoventilation/apnea
- Airway obstruction
- Bradycardia secondary to hypoxia
- Laryngospasm/stridor
- Vomiting, aspiration, diarrhea

- Hypotension
- Inadequate sedation/paradoxical excitation (sustained irritability or combativeness)
- Prolonged sedation after the procedure

The Geriatric Patient

As a result of a number of factors, including better nutrition, more physical activity, less tobacco and alcohol use, and improved medical care and medical technologies, more Americans are living longer. In 2014 the US Census Bureau released population projections stating that the population of people within the United States currently over the age of 65 is 14.5% and will reach 98 million by 2060 with the continued increased life expectancy.²⁵ The increasing elderly population is placing, and will continue to place, many demands on the health care system. Medical technology is advancing and therefore more procedures requiring anesthesia will be performed on elderly patients. It is estimated that approximately 55% of anesthesia cases are being performed outside of the traditional operating room and that the elderly population account for a large percentage of those anesthetics.¹ Perioperative complications can increase with age and consequently special considerations related to the physiology of aging are necessary for the safe delivery of anesthesia.

Aging is associated with a progressive loss of functional reserve in all organ systems. However, there is considerable individual variability in the onset and extent of these changes. The elderly have a greater prevalence of comorbidities such as atherosclerosis, infections, autoimmune diseases, chronic disorders, and cancer. The immune system gradually and slowly diminishes in function with age. Therefore the ability to heal and fight foreign bacteria, viruses, and malignant cells diminishes. Additional components of the aging process include an increase in the ratio of adipose tissue to aqueous body tissue resulting in greater storage of lipid-soluble anesthetic agents. Basal metabolic rate along with liver and kidney functions all decrease with age causing a prolonged effect of anesthetic agents due to a decrease in metabolism and excretion.

Cerebral atrophy occurs with aging resulting in an overall loss of neurons in the neocortex, which suggests increased sensitivity to anesthetic medications. The elderly are at an increased risk for perioperative delirium and postoperative cognitive dysfunction. Therefore the dosage requirements for anesthetic drugs are usually decreased.²⁶

The geriatric patient's level of activity is one indicator of cardiovascular function and this generally decreases with age; this decrease in activity usually correlates with limited physiologic reserves. Patients may be restricted in their activity because of arthritis or other debilitation. Circulation time is decreased and skeletal muscle diminishes with a decline in physical activity, which decreases total oxygen consumption and blood-flow needs to the muscles, resulting in decreased cardiac output. The ability of the cardiovascular system to respond to the effects of anesthetic drugs, fluid administration, and the stresses of therapeutic and diagnostic procedures can cause decreased cardiac function, resulting in hemodynamic instability, and reduced circulation to vital organs.²⁶

Tissue oxygenation can decrease because of changes in ventilation ability and lung tissue. Lung compliance is decreased resulting in ventilation-perfusion mismatch. Aging itself brings on the increasing inability to respond to hypoxia and hypercapnia, especially when experiencing the effects of anesthesia. Therefore the anesthetist must always ensure and constantly monitor the supply of adequate amounts of oxygen to the elderly patient and be ready to offer ventilatory support. The ability to thermoregulate is also decreased with age.²⁶

Several EEG processing monitors are available that help in assessment of patient responses to anesthetic medications. These devices monitor anesthesia awareness, level of consciousness, depth of sedation, and response to anesthetic medications, which allows for more precise titration of anesthetic medications according to the patient's needs. Care must be taken to preserve body warmth and ensure the continual delivery of adequate warmth when necessary. Protection of the eyes, skin, and the extremities, both while moving the patient and during the procedure, by skin padding of bony prominences must also be assured.²⁶ All these variables are a component of the anesthetic plan when administering care to the

geriatric patient. Finally, consider verbal and written postoperative instructions to both the elderly patient and caregivers/significant others who will accompany the patient and be present to both monitor and care for the elderly patient after a therapeutic or diagnostic procedure.

Anesthesia for Specific Procedures in Remote Locations

Cardiology Procedures

Automatic Implantable Cardiac Defibrillator and Cardiac Pacemaker

See [Chapter 27](#) for a complete discussion of cardiac devices.

Cardioversion

Procedure Overview.

Cardioversion is the discharge of electrical energy, synchronized to the R wave of the QRS complex of the electrocardiogram, to convert hemodynamically unstable supraventricular rhythms such as atrial flutter, atrial fibrillation, or hemodynamically stable ventricular tachycardia (VT). These rhythms can be life threatening if left untreated. Atrial flutter and atrial fibrillation are associated with the development of congestive heart failure and with the formation of thromboemboli, which can lead to stroke. Cardioversion is usually a scheduled and planned procedure unless the patient's condition warrants otherwise. Patient optimization may not be possible if there is urgency for cardioversion as a result of hemodynamic instability. Much less electrical energy is required to synchronously cardiovert a patient when compared with asynchronous defibrillation.^{27,28} Defibrillation is an unplanned and usually emergent application of unsynchronized electrical energy. Cardioversion is believed to be therapeutic because it closes an excitable gap in the myocardium, which causes currents to reenter and excite the electrical system of the heart.²⁹

Anesthetic Considerations.

Because cardioversion is usually a nonemergent and planned procedure, patient conditions can usually be optimized. Proper nothing-by-mouth (*nil per os* [NPO]) status must be observed unless

the cardioversion is deemed urgent or emergent. Standard monitors are applied, with special attention paid to the ECG. A monitor of anesthesia awareness/level of consciousness/depth of sedation via EEG processing can be used to assess consciousness during cardioversion.³⁰ IV access is necessary. The energy required for cardioversion is measured in joules (watt-seconds). The cardiologist uses a cardioverter-manual monophasic or biphasic defibrillator for the procedure. The optimal shock dose for cardioversion of atrial flutter and other supraventricular tachycardias is 50 to 100 J.^{27,28,31-33} The operator applies cardioversion-defibrillator paddles with conduction gel or defibrillator pads to the patient's skin. One paddle or pad is placed parasternally over the second and third intercostal space. The other paddle or patch is placed over the area of the apex of the heart.^{27,28,31,32} The cardioverter-defibrillator is set to the synchronized (sync) mode. Visible synchronization marks are placed by the cardioverter atop the tallest R waves of the ECG. Energy shocks are delivered initially at 50 to 100 J, and are titrated progressively up to 360 J as necessary after observation of the effectiveness of the synchronized shock.^{27,28,33}

Midazolam may be administered as both a sedative and amnestic agent before cardioversion. Oxygen via nasal cannula or facemask is administered to the patient. Moderate sedation is often acceptable to counter the intense and brief pain of cardioversion. Because of the intense and brief pain of cardioversion, an ultra-short-acting general anesthetic such as propofol or etomidate is administered.³⁰ After the administration of anesthesia to the appropriate level, an "all-clear" signal is given by the operator. Then the synchronized shock or shocks are administered. Muscle relaxation is not necessary. As always, an assortment of oral airways, nasal airways, laryngeal mask airways (LMAs), endotracheal tubes, and laryngoscopes with blades and suction should be readily available in case complications occur. If cardioversion is required in a patient who has not fasted, general anesthesia with tracheal intubation is necessary to prevent aspiration of gastric contents.³³

Postanesthesia Care.

It is expected that the patient's heart is now beating in a desirable cardiac rhythm and that the patient's blood pressure is stable.

Spontaneous respirations return, along with swallowing and coughing reflexes. The patient is observed for any reactions to the anesthetic, and care is turned over to the nurse accompanying the patient, or who will be providing the postanesthesia care.

Radiofrequency Catheter Ablation

Procedure Overview.

Radiofrequency catheter ablation (RFCA) uses a catheter with an electrode at its tip, which is guided under fluoroscopy to an area of heart muscle that has demonstrated accessory electrical conductive pathways.³⁴⁻³⁶ RFCA has all but replaced arrhythmia surgery and is now considered the foremost therapy for the treatment of many arrhythmias in pediatric and adult patients.^{36,37} Supraventricular tachycardia is the most common tachyarrhythmia in children, and symptomatic supraventricular tachydysrhythmias are most often treated by RFCA.³⁴ Accessory electrical conductive pathways are distributed unevenly along the right and left atrioventricular valve annuli. Left-sided accessory pathways are most common, but both right- and left-sided accessory electrical pathways can be accessed and ablated.^{34,35} Other treatments possible with RFCA include modification of the sinus node or atrioventricular (AV) node, ablation of atrial flutter and atrial tachycardia, and ablation of focal atrial fibrillation and VT foci.³⁴⁻³⁶ Patients must undergo electrophysiologic studies to determine the origin and pathway of the arrhythmia, in addition to the mechanism of action, before RFCA can be chosen as a therapy.

Cryoablation is now being used prior to RFCA or in place of RFCA. Liquid nitrous oxide is circulated through the catheter tip to cause temperatures at the tip of -22°C to -75°C . At a higher temperature (-22°C or lower), tissue can be temporarily “ice mapped,” which is a trial to see whether this nonpermanent freezing of the tissue will successfully eliminate the dysrhythmia. If the ice mapping is successful, then the probe is further cooled, causing permanent destruction of the arrhythmogenic tissue. Cryoablation causes less discomfort and has been found to be safer to use in cases of dysrhythmias in the area of the AV node where iatrogenic complete AV heart block can be caused. Iatrogenic AV

block is relatively common and may require placement of a transvenous pacemaker.^{37,38}

RFCA is safe with success rates of 95% overall. Many patients no longer need their antiarrhythmic medications soon after therapy.^{33,34} RFCA is now being used as treatment for liver metastases from colorectal cancer. RFCA is providing a new treatment option for those patients with high risks for surgery but who would be at a lesser risk for the less-invasive RFCA.

Anesthetic Considerations.

Electrophysiologic studies conducted before RFCA are time-consuming procedures that may require moderate sedation in adults or general anesthesia in children. RFCA can be performed in the operating room, in a special cardiac procedure room, or in the cardiac catheterization suite by a cardiologist. The electrode catheter is guided via the femoral artery and vein to the area of the accessory electrical pathway, or an area of arrhythmogenic focus.^{34,37} The internal jugular vein also may be used. The electrode is then energized with radiofrequency energy, and cells within the path of the electrode are obliterated. The procedure can produce brief periods (less than 1 to 2 minutes) of mild to moderate retrosternal, angina-like pain.³⁷

RFCA is a short procedure where patients must remain perfectly still, except for respiratory movement, during the procedure.^{36,37,39} Many adults can be anesthetized with moderate sedation/analgesia along with a local anesthetic applied by the operator.³⁹ Children may be best treated with general anesthesia using either an LMA, or an endotracheal tube to secure the airway. If general endotracheal anesthesia is used, the patient may be held apneic for a short period of time while the catheter is accurately directed and the ablation procedure performed.³⁷ Full monitors and an IV catheter are necessary. Total IV anesthesia (TIVA) is often used because, during the cryoablation, 25% of cardiac output (CO) is transiently lost when the pulmonary artery is occluded. Patients can develop significant hemodynamic instability. Pulmonary artery occlusion also interferes with uptake and distribution of volatile anesthetics making TIVA technique ideal. TIVA with propofol and ondansetron has a much lower rate of nausea (postoperative nausea

and vomiting [PONV]) than does use of an inhaled anesthetic and an antiemetic. Careful attention must be paid to the ECG, because the patient must stop taking any antiarrhythmic drugs before the electrophysiologic study and RFCA are performed.^{34–37,39}

Possible thermal injury to the esophagus is a concern during RFCA of the left atrium resulting in esophageal ulcerations or an atrioesophageal fistula, which is an extremely rare but often fatal complication of RFCA. Insertion and use of an esophageal temperature probe during general anesthesia is essential, as is the position of the probe. The probe should be inserted so that it is alongside the esophageal tissues with no space in between. Constant monitoring and communication with the procedural team is a necessity for prevention, identification, and treatment of complication.⁴⁰ Electrophysiology procedures, anesthesia techniques, and estimated anesthesia times are listed in [Table 58.3](#).

TABLE 58.3

Electrophysiology Procedures, Anesthesia Techniques, and Estimated Anesthesia Times

Category	Procedure	Usual Anesthetic Technique	Time
MAC in recovery unit	Cardioversion	A short period of deep sedation usually using a bolus dose of propofol (or etomidate if the ejection fraction is low)	15 min
	TEE	Deeper sedation may be required for some patients undergoing TEE who are unable to tolerate the procedure with conscious sedation by the cardiology team	60 min
	NIPS	Deep sedation may be required for cardioversion or defibrillation	30–45 min
MAC in electrophysiology laboratory	Pacemaker placement or battery change	Fentanyl/midazolam or infusions of propofol/remifentanyl/midazolam	3–4 hr
	ICD or biventricular ICD placements or battery changes	Fentanyl/midazolam or infusions of propofol/remifentanyl/midazolam (defibrillator threshold testing will require a short period of deeper anesthesia similar to that in a cardioversion)	3–4 hr
	Loop recorder placement in superficial anterior chest wall	Fentanyl/midazolam or infusions of propofol/remifentanyl/midazolam	2–3 hr
	Atrial flutter radiofrequency ablation	Infusions of propofol/remifentanyl/midazolam	6–10 hr
	Ventricular tachycardia or ventricular fibrillation or premature ventricular contraction radiofrequency ablation	Usually infusions of remifentanyl only; discuss additional sedatives with cardiologist	6–10 hr

General anesthesia in electrophysiology laboratory	Atrial fibrillation radiofrequency ablation	General endotracheal anesthesia using jet ventilation and TIVA, which predominantly involves propofol and remifentanyl infusions Radial arterial lines commonly placed	6–10 hr
	Lead extraction (especially using laser)	General endotracheal anesthesia	3–4 hr
	Ventricular tachycardia or ventricular fibrillation radiofrequency ablation using an epicardial approach	General endotracheal anesthesia	6–10 hr

Postanesthesia Care.

Patients must be observed for possible RFCA procedural complications such as bleeding, ECG changes, cerebrovascular accidents, cardiac tamponade, or damage to the aortic valve.³⁴⁻³⁷

Percutaneous Coronary Intervention

Procedure Overview.

Percutaneous coronary intervention (PCI) encompasses a wide variety of procedures performed in the cardiac catheter laboratory (CCL). PCI is being performed on adults and is now more commonplace on younger and sicker patients. The CCL is generally located remotely from the operating rooms and the blood bank. It consists of a large procedural area with a small control room. PCI procedures use x-radiation/fluoroscopy doses “as low as reasonably achievable” (the ALARA principle), in addition to the use of IV radiocontrast media. The heart is commonly accessed via the femoral artery, although the brachial or radial artery can be used. The right side of the heart and pulmonary circulation are commonly accessed via the femoral vein.^{41,42}

Anesthetic Considerations.

PCI necessitates access to major blood vessels and the heart itself. [Box 58.6](#) lists possible PCI complications that affect the safety of the

anesthetic and may require interventions from the anesthetist. Consideration for rapid access to competent anesthesia assistance has to be prepared well in advance of PCI anesthesia. Anesthesia techniques can range from IV moderate sedation/analgesia, or deep sedation/analgesia, to general anesthesia, aided with local anesthetic infiltration at the insertion site and alongside the major **Box 58.6** for insertion of the PCI armamentaria.^{41,42}

PCI Complications that May Affect the Delivered Anesthetic and Require Anesthetist Intervention

- Supraventricular dysrhythmias
- Ventricular dysrhythmias
- Severe and rapid hemorrhage
- Pain
- Anaphylaxis related to administration of intravenous contrast media
- Vasovagal response
- Cardiac arrest
- Thromboembolic events
- Hypotension/hypertension
- Respiratory instability

PCI, Percutaneous coronary intervention.

Adapted from Buja LM, Schoen FJ. The pathology of cardiovascular interventions and devices for coronary artery disease, vascular disease, heart failure, and arrhythmias. In Butany J, Buja ML. *Cardiovascular Pathology*. 4th ed. London: Elsevier; 2016:577–610.

Postanesthesia Care.

Care of the patient undergoing PCI usually does not end with

completion of the PCI procedure. Arrangements can be made for observation and ongoing care of the patient in a telemetry environment or in the intensive care unit, depending on how critical the patient remains. Immediate postanesthesia concerns are continuing dysrhythmias, hypothermia, current fluid status, changes in fluid status, PONV, hemodynamic status related to hemorrhage, and analgesia.⁴²

Gastroenterology Procedures

Colonoscopy, EGD, and ERCP

Procedure Overview.

Endoscopy came into popular use in the early 1960s with the invention of a snare for retrieving intestinal polyps for biopsy. Endoscopy for gastrointestinal procedures is the use of a flexible fiberoptic endoscope that transmits brilliant, coherent, high-resolution, magnified, direct visual images to the operator. The operator may then examine, biopsy, dilate, or cauterize portions of the gastrointestinal tract. The endoscopist may pass accessory devices down the endoscope such as biopsy forceps, dilation devices, cytology brushes, measuring devices, needles for injection, Doppler probes, ultrasound probes, and probes to measure electrical activity and pH. Even foreign bodies may be removed with the aid of a snare passed through an endoscope. Endoscopes are available in different diameters for use in pediatric to adult patients.⁴³

An upper endoscopy, such as an esophagogastroduodenoscopy (EGD), is an accurate way for the operator to evaluate the mucosa of the esophagus, stomach, and duodenum. A colonoscopy allows total diagnostic visualization of the mucosa of the tortuous colon from the anus to the cecum. Endoscopic retrograde cholangiopancreatography (ERCP) is used for the diagnosis of obstructive, neoplastic, or inflammatory pancreatobiliary structures. The use of ERCP is decreasing because of the availability of less-invasive and noninvasive techniques. [Box 58.7](#) provides a brief list of indications for colonoscopy, EGD, and ERCP.⁴³ Use of endoscopic ultrasound (EUS) has been growing since its inception

in the 1980s and continues to broaden possibilities for the patient and practitioner. Once used solely for diagnostic and cancer staging purposes of the pancreas, periluminal structures, and biliary tract, it is now being used for therapeutic modalities such as cyst drainage, celiac plexus neurolysis for pain, and for fine-needle injection of therapeutic medication.^{44,45}

Indications for Colonoscopy, Esophagogastroduodenoscopy, and Endoscopic Retrograde Cholangiopancreatography, with Anesthetic Implications

Colonoscopy

- Routine screening
- Gastrointestinal bleeding and occult bleeding
- Evaluation of an abnormality on barium enema
- Polypectomy
- Unexplained iron deficiency anemia
- Significant diarrhea
- Chronic inflammatory bowel disease
- Malignancy
- Dilation of stenotic lesions
- Foreign body removal

Esophagogastroduodenoscopy

- Persistent and recurrent dyspepsia (heartburn)

- Persistent nausea or vomiting (PONV)
- Dysphagia (difficulty swallowing)
- Chest pain with a negative cardiac evaluation
- Iron deficiency anemia
- Suspected small bowel malabsorption
- Malignancy
- Stomach or esophageal ulcer
- Control of bleeding
- Ligation or sclerosis of varices
- Dilation of strictures
- Percutaneous gastrostomy
- Polypectomy
- Removal of foreign body

Endoscopic Retrograde Cholangiopancreatography (ERCP)

- Suspected biliary ductal disorder
- Suspected pancreatic ductal disorder
- Biliary drainage
- Pancreatic drainage
- Biopsy
- Bile or pancreatic juice collection

- Mapping of the pancreatic duct before intended surgery
- Manometry of the sphincter of Oddi or other ductal mapping

Data from Rubin PH, et al. Colonoscopy and flexible sigmoidoscopy. In Podolsky DK, et al. *Yamada's Textbook of Gastroenterology*. 8th ed. Wiley Blackwell; 2015; Arain MA, Freeman ML, Endoscopic retrograde cholangiopancreatography. In *Yamada's Textbook of Gastroenterology*. 8th ed. Hoboken, NJ: Wiley Blackwell; 2015; Stockland AH, Baron TH. Endoscopic and radiologic treatment of biliary disease. In Feldman M, et al, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 10th ed. Philadelphia: Elsevier; 2016:1201–1216.

Endoscopy for gastrointestinal procedures may be performed by a gastroenterologist, general surgeon, family practitioner, or proctologist. The endoscope is passed into the gastrointestinal tract with the aid of lubricant. The endoscope has controls to change the direction of the flexible tip, allow flushing with water, application of suction, or insufflation of air or carbon dioxide within the portion of the gastrointestinal tract being observed.⁴³

Anesthetic Considerations.

Endoscopic procedures often cause discomfort and require the patient to remain relatively motionless during the procedure. Consequently, anesthesia services have been utilized with more frequency to enhance the patient experience and improve patient outcomes. A proper preanesthetic assessment of the patient must be performed, focusing on the areas of age, ability to cooperate, level of anxiety, mental disability, allergies, fluid status, laboratory electrolyte values, cardiac history, hypertension, bleeding history, clotting status, respiratory status, obesity, drug and alcohol abuse, gastroesophageal reflux, and pregnancy.^{9,17}

Endoscopy has been safely performed in pregnant patients; however, elective procedures should be reconsidered and performed only after consultation with the patient's obstetrician. Urgent endoscopic procedures must be performed. None of the common sedative drugs such as propofol or the opioid fentanyl have been demonstrated to cause teratogenic changes in the fetus. Midazolam has also been shown to cross the placenta and cause neonatal central nervous system (CNS) depression.⁴⁶ Studies of the obstetric effect of anesthetic drugs are limited because of the

infrequent requirements for surgery during pregnancy and the ethical difficulties associated with performing controlled trials.

Patients must adhere to proper NPO guidelines, and these procedures have a greater risk of aspiration because of the pathology of the gastrointestinal tract and the introduction of the invasive endoscopy. Preemptive analgesia with gargled viscous lidocaine may help reduce the patient's gag reflex making an endoscopy of the upper gastrointestinal tract more feasible. Moderate sedation/analgesia is usually accomplished with short-acting sedatives like midazolam or propofol and analgesics such as remifentanyl, alfentanil, or fentanyl. Deep sedation can be achieved with titration of propofol until effective, along with an analgesic medication.⁴⁷⁻⁵⁰ Upper endoscopy may necessitate the use of an antisialagogue such as glycopyrrolate.^{48,49}

Colonoscopy requires thorough cleansing of the lumen of the colon to remove fecal material. The colon may be partly prepared with a cleansing enema. Full preparation of the colon is accomplished commonly with orally administered balanced electrolyte solutions in a volume of up to 4 L. Other types of solutions are also available.⁴³ Patients often find this preparation the most distressing portion of the procedure. The bowel preparation can lead to abdominal cramping, diarrhea, weakness, and nausea. Patients who arrive for the procedure require reassessment and the insertion of an IV catheter with IV fluid, usually lactated Ringer's solution, or normal saline. Conventional monitors, including pulse oximeter, noninvasive blood pressure monitor, and ECG are attached. The patient is supplied with oxygen through a disposable nasal cannula, or disposable facemask, ideally with ET_{CO}₂ monitoring as discussed previously. Patients are usually asked to assume a left lateral decubitus position and to remain on the transport stretcher for the procedure duration. It is optimal for the body to be flexed, the head and back bent downward toward the knees and for the patient's legs to be bent toward the abdomen to optimize visualization of the gastrointestinal tract. Patient anxiety, distention because of insufflation, and acute discomfort during the maneuvering of the endoscope usually necessitates the administration of deep sedation or a general anesthetic in some cases. The depth of sedation required may be titrated with the use

of an available monitor of anesthesia awareness/level of consciousness/depth of sedation via EEG processing.^{51,52} Strong vagal nerve stimulation can occur as a result of distention of the colon. This may cause hypotension, bradydysrhythmias, and ECG changes.^{43,51,52}

EGD and EUS require a patient assessment with special emphasis on any cardiac history, hypertension, bleeding disorders, nausea (PONV), dysphagia, and gastroesophageal reflux. The patient must be NPO according to guidelines. Occasionally patients require moderate sedation or deep sedation because topical anesthesia and even hypnosis have been less effective.⁴⁷⁻⁵⁰ An IV catheter is inserted, with fluids such as lactated Ringer's or normal saline attached. The patient is connected to standard monitors. Oxygen can be supplied through a disposable nasal cannula or a disposable facemask, preferably with ET_{CO}₂ monitoring. EGD is generally performed with the patient positioned supine or in a left lateral decubitus position. After the patient is adequately sedated, the operator inserts a hollow oral airway gently into the patient's mouth, and the endoscope is advanced through this airway, allowing direct visualization of the larynx, hypopharynx, esophagus, and stomach, and through the pylorus into the duodenal bulb.^{43,50}

ERCP requires thorough assessment of the patient, including a review of laboratory values of a complete blood count, serum liver chemistries, and amylase or lipase levels to evaluate liver function, and clotting studies. Patients also must be evaluated for anticoagulant medications, bleeding history, and prosthetic heart valves.^{43,53} Allergies must be evaluated, especially those to iodinated contrast media.⁵⁴ Patients who require ERCP are usually more ill than patients seen routinely for colonoscopy or EGD. The patient must be NPO according to AANA and ASA guidelines. IV access is obtained and fluid is administered. Standard monitors are applied, and oxygen is supplied to the patient via a disposable facemask or nasal cannula, or as appropriate for anesthesia plan. The procedure requires that the patient be in a prone, semi-prone, or slightly left lateral decubitus position. Often the extreme lateral patient position compromises airway access and prohibits airway rescue should the patient require ventilatory assistance. An appropriate anesthetic

plan should be discussed prior to positioning the patient to determine if general anesthesia with a protected airway is required; otherwise, deep sedation will be necessary to facilitate the procedure.⁵³⁻⁵⁶

Pediatric endoscopy has been performed with patients under deep IV sedation with agents such as propofol, midazolam, and alfentanil (when the patient will allow placement of the IV catheter), and under general endotracheal anesthesia.⁴⁹ Propofol provides anterograde amnesia during the procedure but little retrograde amnesia.^{48,49} The use of a eutectic mixture of local anesthetics lidocaine and prilocaine (EMLA cream) facilitates the placement of the IV catheter. EMLA must be applied to undamaged skin under an occlusive dressing for a period of 45 to 60 minutes before the IV catheter is inserted. When general anesthesia is administered, a secured endotracheal tube should be considered because of relative inaccessibility to the airway, the patient position required for pediatric colonoscopy or for EGD, and because of the shared airway with the proceduralist.⁴⁹

These procedures can cause vomiting, aspiration, laryngospasm, bleeding, severe bradycardia, hypotension, bowel rupture, or duct rupture. The anesthetist must be ready with immediate airway intervention, hemodynamic support as necessary, and monitored emergency transport to the operating room for surgical intervention if necessary.⁴³

Postanesthesia Care.

Postprocedure morbidity differs with each of the described procedures. All patients must be monitored in a postanesthesia care area until they have recovered from the sedation or general anesthetic and meet discharge criteria. Colonoscopy patients have intestinal distention, which is relieved with encouragement to pass flatus. Rectal bleeding, nausea, hypotension, dehydration, and vomiting may also be seen. Administration of a bolus of IV fluids along with an IV antiemetic agent may help alleviate some of the symptoms. EGD morbidity relates to bleeding, nausea, vomiting, aspiration, dysphagia, and hypotension. Treatments such as those used for colonoscopy may be indicated.^{57,58}

ERCP morbidity relates to possible reactions to iodinated contrast

media. Patient reactions can be mild (such as nausea, vomiting, pruritus, diaphoresis, flushing, or mild urticaria), moderate (such as faintness, severe vomiting, profound urticaria, mild bronchospasm, mild hypotension, mild tachycardia, or bradycardia), or severe (hypotensive shock, angioedema, respiratory arrest, cardiac arrest, convulsions, or death).⁵⁷ Postprocedure bleeding, pain, nausea, and vomiting (PONV) are possible and can be treated as described previously.

Gynecology Procedures

Assisted Reproductive Technologies

Procedure Overview.

Assisted reproductive technologies (ARTs) refer to all techniques used to retrieve and fertilize the human oocyte. In vitro fertilization (IVF) is the most common technique used to artificially fertilize the human oocyte. Research by reproductive endocrinologists has advanced technology since the first “test-tube baby” was born in 1978 and continues to result in new and more effective techniques. The CDC reports that approximately 15% of women over childbearing age within the United States have used some form of fertility aid in an attempt to become pregnant. In 2013, 163,209 ART cycles resulted in 54,323 live births (deliveries of one or more living infants), and 67,996 infants, and the numbers of ART procedures continues to grow.^{59,60} The procedure, which takes approximately 20 to 30 minutes to complete, is generally performed by a gynecologist who has had an advanced training fellowship in reproductive endocrinology and infertility.

The procedure is performed by initially stimulating maturation of the follicle with a gonadotropin-releasing hormone agonist, which induces pituitary-gland suppression and creates quiescent ovaries to prevent the production of a single dominant follicle. Follicle-stimulating hormone and human menopausal gonadotropin are then administered, which induces 10 to 15 ovarian follicles. The patient is then given human chorionic gonadotropin (hCG), which induces the follicle to mature and move into the follicular fluid. The oocyte is retrieved transvaginally, transabdominally, or via

laparoscopy with an ultrasonically guided probe 34 to 36 hours after hCG administration. All visible follicles are collected, washed, incubated for 4 to 6 hours in a culture medium, and examined microscopically. Most follicles contain only one oocyte.^{59,60} Fertilization occurs in the IVF laboratory. The oocyte is identified and has minimal exposure to ambient room temperature, room air, and especially any chemical odors. Sperm are washed and centrifuged. Fresh media is added next to the centrifuged sperm, and those sperm that swim to the media, which can number 50,000, are placed with the oocyte. Male factor infertility, which can affect up to 33% of couples seeking ART procedures, requires direct intracytoplasmic injection of sperm; 16 to 20 hours later, the oocytes are examined for evidence of fertilization. Within 3 to 5 days after fertilization is verified, the embryo (which has developed into 8 to 10 cells) is transferred into either the fallopian tube or (more commonly) the uterus. Timing must be coordinated with proper maturation of the uterine endometrium.⁵⁹⁻⁶¹ Assisted reproductive technologies increase the risk of multiple gestations. It has been reported that atypical implantations of the fertilized ovum or zygote, such as abdominal, cervical, ovarian, or tubal pregnancy, occur more frequently with ART.⁶¹ Common ART techniques are listed in [Table 58.4](#). IVF was first performed over 30 years ago and is accepted now because of increased success rates, up to 37.5% in 2013 depending on age. The CDC estimates that over 1% of all live births within the United States today occur as a result of ART.⁶⁰

TABLE 58.4
Common Assisted Reproductive Technology Techniques

Procedure	Description
In vitro fertilization (IVF)	Oocytes are removed, fertilization occurs in the laboratory, and the embryo is placed transcervically into the uterus or into the distal portion of the fallopian tube(s).
Gamete intrafallopian transfer (GIFT)	Oocytes and sperm are transferred into one or both fallopian tubes for fertilization. <i>Advantage:</i> Oocyte retrieval and gamete transfer occur with a single procedure. <i>Disadvantages:</i> Requires at least one patent fallopian tube and laparoscopic surgery. Fertilization cannot be confirmed.
Zygote intrafallopian transfer (ZIFT)	Fertilized embryos are placed into the fallopian tube. <i>Advantages:</i> Fertilization is confirmed. Laparoscopic surgery can be avoided if fertilization has not occurred. The embryos can be transferred at an appropriate developmental stage. <i>Disadvantage:</i> Requires a two-stage procedure, with added risks and costs. Requires at least one patent fallopian tube.
Tubal	Cleaving embryos are placed into the fallopian tube.

embryo transfer (TET)	
Peritoneal oocyte and sperm transfer (POST)	Oocytes and sperm are placed into the pelvic cavity.

Modified from Fritz MA, Speroff L. *Clinical Gynecologic Endocrinology and Infertility*. 8th ed. Baltimore: Lippincott Williams & Wilkins; 2011:1331–1382; Tsen LC. Anesthesia for assisted reproductive technologies. *Int Anesthesiol Clin*. 2007;45:99–113.

Patients are assessed for antibodies to human immunodeficiency virus types 1 and 2 (HIV-1, HIV-2), human T-cell lymphotropic virus type 1 (HTLV-1), hepatitis B antigen, and antibodies to hepatitis B and C. Patients are also tested for chlamydia, syphilis, gonorrhea, and cytomegalovirus. Smokers require twice as many attempts at successful IVF as nonsmokers; therefore smoking is actively discouraged.^{59–61}

Anesthetic Considerations.

IVF is generally performed on patients who are ASA class 1 or 2 in their third or fourth decade of life. Although IVF is a relatively simple procedure for the reproductive endocrinologist to perform, especially outside the operating room, IVF is an uncomfortable procedure and requires that patients do not move while the probe is guided for retrieval and later reimplantation. The vaginal wall must be pierced for the desired ovary to be accessed. In addition, major blood vessels are present in the proximity of the ovaries, and their injury could lead to complications.⁶²

Anesthesia requirements vary with the individual needs of the patient and the reproductive endocrinologist.^{59,62} Multiple ART procedures may need to be performed until one of them is successful; therefore, safe yet inexpensive anesthetic techniques are desirable.^{60,61} Minimal sedation, moderate sedation/analgesia, regional intrathecal anesthesia, paracervical block, or general anesthesia can be administered to assist in making the procedure as comfortable and successful as possible. Moderate sedation with analgesia is usually sufficient for most patients. None of the anesthetic techniques cause differences in reproductive outcomes.^{59,61,62} Techniques with quick onset and a short duration

are preferred. It should be noted that propofol, lidocaine, and alfentanil have been shown to accumulate in the follicular fluid. Although no deleterious effects of any anesthetics have been identified, this area continues to be studied.^{62,63} No data from human trials have ever condemned the use of local anesthetic agents for oocyte retrieval. Morphine has been shown to adversely affect fertilization of sea urchin eggs in vitro by allowing more than one sperm to enter the oocyte in 30% of cases; therefore, it is not used because of the existence of safe alternatives such as fentanyl, alfentanil, remifentanyl, and meperidine. Midazolam, when titrated in small doses to provide mild to moderate sedation and anxiolysis, is safe, with no accumulation in follicular fluid or indication of being a teratogen. Ketamine (0.75 mg/kg) with midazolam (0.06 mg/kg) used as moderate sedation/analgesia is safe as an alternative to general anesthesia with isoflurane. Sevoflurane and desflurane are avoided because of possible negative effects to ART outcomes.⁶³ Nonsteroidal antiinflammatory agents are avoided because of inhibition of prostaglandin synthesis and possible effects on embryo implantation.^{62,63} Droperidol and metoclopramide are known to induce rapid hyperprolactinemia and should be avoided. Low plasma prolactin levels are associated with higher incidences of pregnancy.⁶³ **Box 58.8** lists common anesthetic agents that could cause problems with ART.^{62,63}

Anesthetic Agents that May Cause Problems with Assisted Reproductive Technologies

- Morphine
- Sevoflurane
- Desflurane
- NSAIDs—ibuprofen, indomethacin, ketoprofen, ketorolac, meloxicam, naproxen, oxaprozin
- Droperidol

- Metoclopramide
- Postanesthesia care: As in all cases of anesthetic administration, the patient is assessed in a postanesthetic recovery area. Vital signs and pulse oximetry are assessed and must be stable. If intrathecal anesthesia was used, the patient must have a recovery of sensorium, be able to ambulate, and be able to void. All patients must be free of nausea.

NSAIDs, Nonsteroidal antiinflammatory drugs.

Hysteroscopy Sterilization

Procedure Overview.

Surgical sterilization continues to be a popular method of birth control in the United States second only to oral contraceptives. Traditional approaches to permanent sterilization required general anesthesia and were performed either laparoscopically or through an intraabdominal incision. Hysteroscopic sterilization as an alternative to these more invasive procedures has had a resurgence over the past few years and is associated with decreased postprocedural pain. Currently, the Essure microinsert system is the only method approved by the Food and Drug Administration (FDA) for hysteroscopic tubal sterilization in the United States. This method occludes the fallopian tubes by stimulating tissue fibrosis and subsequent scarring. Nearly 500,000 women have been sterilized using this method and its popularity continues to grow as this procedure can be safely performed in the office setting.⁶⁴

The Essure microinsert is 4 cm long and once deployed expands in diameter to anchor into the fallopian tube wall. The insert has a stainless steel inner coil and a nickel-titanium outer coil that anchors the implant in the proper location. Wound in and around the inner coil are polyethylene fibers that stimulate benign tissue growth that surrounds and infiltrates the device over time, resulting in fallopian tube occlusion and permanent sterilization.⁶⁴

Anesthetic Considerations.

Proper patient selection for hysteroscopic sterilization is highly

correlated to procedural success. The most common reasons for failure are pain, poor visualization of the tubal ostia, and cervical stenosis. Patient exclusion criteria for the Essure procedure are listed in [Box 58.9](#) and a negative pregnancy test must be obtained within 24 hours of the procedure. Pretreatment with a nonsteroidal antiinflammatory drug (NSAID) is recommended to reduce tubal spasm. A combination of preoperative anxiolytics and a low-dose oral narcotic may improve patient comfort and reduce anxiety. Paracervical local anesthetic blocks are often combined with IV sedation techniques, and in some instances a general anesthetic may be required to control pain, alleviate anxiety, and maintain [Box 58.9](#) [fertility](#) during the procedure.⁶⁴

Exclusion Criteria for the Essure Procedure

In General

- Patient unwilling to use a reliable method of pregnancy prevention for 3 months after the procedure
- Patient unwilling or unable to undergo hysterosalpingogram (e.g. severe contrast allergy)
- Patient uncertain about desire to end fertility
- Patient less than 6 week postpartum or postpregnancy termination
- Presence of active or recent pelvic infection
- Known uterine anomaly or anatomic variant that may preclude adequate visualization of the tubal ostia
- Patient is immune-compromised or currently receiving chemotherapy

In the Office Setting

- Patients who cannot tolerate basic gynecologic procedures

- Patients with high levels of anxiety
- Patients with known cervical stenosis
- Patients with significant medical comorbidities that would preclude safe office surgery

Adapted from Hodges K, Swaim L. Hysteroscopic sterilization in the office setting. *Obstet Gynecol Clin N Am.* 2013;40:671–685.

Postprocedure monitoring of the patient for a minimum of 30 to 60 minutes to assess for bleeding is recommended. Adverse events associated with Essure include abdominal cramping, pain, nausea or vomiting, dizziness, and bleeding or spotting. Return to normal activity is anticipated in 24 hours or less for most patients.⁶⁴

Office-Based Surgery

General Dental Procedures

Procedure Overview.

Anesthesia for dental procedures and dental surgery can present many challenges. The demand for dental care and visits from patients are increasing. Dentistry has changed from a role of therapeutic treatment of dental disease to a role of prevention. Historically, only 50% of the population ever visited a dentist and typically that intervention was for treatment of extreme pain or an emergency. The most recent demographic statistics show that this percentage has improved. More women see dentists annually than men, and, as employment status, income, and educational levels increase, so do the number of annual visits to the dentist. Children ages 6 or younger and adults ages 65 or older are seeing dentists more frequently than in the past.⁶⁵ These numbers are expected to increase as the United States government Healthy People Initiative has added oral health to the objectives for the current and coming years.⁶⁶

Dental procedures may be performed in an operating room, a specially equipped hospital suite, an ambulatory surgical center, or a dental office operatory (dental surgical area).⁶⁷ Anesthesia may be

required for dental procedures in the following areas of dentistry:⁶⁸

- *Pediatric dentistry*—an age-defined specialty that provides primary and comprehensive preventive and therapeutic oral health care for infants and children through adolescence, including those with special health care needs.
- *Oral and maxillofacial surgery*—the specialty that includes the diagnosis, surgical, and adjunctive treatment of diseases, injuries, and defects involving both the functional and esthetic aspects of the hard and soft tissues of the oral and maxillofacial region.
- *Periodontics*—the specialty that encompasses the prevention, diagnosis, and treatment of diseases of the supporting and surrounding tissues of the teeth, or their substitutes, and the maintenance of the health, function, and esthetics of these structures and tissues.
- *Endodontics*—the specialty that is concerned with the etiology, diagnosis, prevention, and treatment of diseases and injuries of the pulp and associated periradicular (concerning the root of the tooth) conditions.
- *Prosthodontics*—the dental specialty involved with the diagnosis, treatment planning, rehabilitation, and maintenance of oral functions, comfort, appearance, and patient health associated with clinical conditions of missing or deficient teeth, and/or oral and maxillofacial tissues along with biocompatible substitutes.
- *General dentistry*—encompasses the etiology, diagnosis, and treatment of conditions of oral, head, and neck tissues; the general dentist may perform procedures that encompass any or all of the dental specialty areas; this depends on the training, abilities, and experiences of the general dentist.
- *Dental hygienist*—a licensed oral health professional trained to treat patients by the removal of dental plaque and calculus (tartar) above or below the gingiva.^{67,68}

Anesthetic Considerations.

Important considerations that must be part of the anesthesia treatment plan for the dental setting are outlined in [Box 58.10](#). The patient may require minimal sedation, moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia

for dental surgery. The anesthesia required depends on the patient-related factors of fear, anxiety, age, medical condition, level of cooperation and behavior, gagging, ineffective local anesthesia in the past, mental impairment, and physical disability. A thorough, documented patient assessment along with appropriate laboratory studies and possible physician consultation regarding patient clearance for physically and/or psychologically stressful dental surgery are necessary.⁶⁹⁻⁷¹ In pediatric dentistry, a comprehensive and personalized discussion with the parent or guardian (with or without the patient present) of what the anesthetic procedure will entail, coupled with an opportunity for the parent or patient to engage in dialogue and ask questions, can alleviate the stress of the upcoming procedures for all parties.⁶⁹

Considerations Related to Anesthesia in the Dental Setting

- Anesthesia may be administered in an unfamiliar area. Carefully plan, equip, and set up the operatory so that it is as familiar and comfortable as in an operating room.
- The established airway will be shared with the dental surgeon.
- The potential exists for heavy bleeding because of the vast blood supply to the head and neck region.
- There could be the use of small instruments, burs (dental drill bits), files, implants, and filling materials in the mouth, with the potential of falling into the oropharynx, or being aspirated.
- Patients may be receiving dental prosthetic devices such as crowns, bridges, or full or partial dentures, which can also affect the airway.
- There exists the possibility of intense pain, transmitted primarily by the maxillary and mandibular divisions of the trigeminal nerve.
- Patients usually display a high level of anxiety, and adequate

time must be incorporated into the schedule to allow for safe anesthetic treatment.

The dental operator must be of adequate size for both access and egress of the patient and personnel. Proper considerations and advanced planning must be made to accommodate patients according to the Americans with Disabilities Act.^{72,73} The anesthetist must have full and rapid access to both the patient and all required equipment and supplies. Full monitors are necessary. Consider the use of the antisialagogue glycopyrrolate, as dental surgery can stimulate the flow of saliva. Excess salivation can lead to coughing, choking, laryngospasm, or aspiration in the sedated patient. Delivery of anesthesia in the dental operator should be as familiar as if it were in an operating room. Postoperative problems in dentistry are generally minimal but can involve pain, swelling, bleeding, nausea, vomiting, the vasovagal response, airway problems, hypoxemia, or hypothermia as a result of anesthetic procedures other than local anesthesia administered. Hypothermia can be addressed by the use of an electric blanket; forced-air warming may or may not be feasible for the dental operator.

General dentists and board-certified dental specialists are also trained to administer intraoral local anesthesia, which is a cardiac depressant and may cause either CNS depression or excitation. Local anesthesia for dentistry is commonly administered in conjunction with a vasoconstrictor to minimize bleeding. Dental specialists and specially trained general dentists can be licensed by state dental boards to administer the continuum of anesthesia, from minimal sedation to general anesthesia, while performing the dental surgery.⁷⁴⁻⁷⁶ Each dental specialty has particular anesthetic considerations, which are discussed in the following sections.

Pediatric Dentistry.

Pediatric dental patients can require the continuum of anesthesia from enteral minimal sedation to parenteral moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia if the patient is behaviorally uncooperative, immature, frightened, mentally disabled, or because of the necessity to perform all necessary dental surgery in one session. Pediatric dentists may have

a patient immobilization device available, commonly called a *papoose board*, to safely restrain the patient until anxiolytic anesthesia can be administered. Anesthetic choices such as oral or IV ketamine; a mixture of oral chloral hydrate, narcotics, midazolam; and propofol have been used with success. Premedication with orally administered midazolam dissolved in a small amount of the liquid forms of acetaminophen, ibuprofen, aspirin, or low-sugar clear juice is commonly used. For the liquid forms of acetaminophen, ibuprofen, or aspirin, the anesthesia provider should refer to the package insert for the proper dosing based on the patient's weight. Intranasal or rectal midazolam can be used alone or given before general endotracheal anesthesia and has proved as effective as nitrous oxide for sedation.^{74,76,77} After an inhaled mask or IV induction, endotracheal intubation via either the oral or nasal route can be performed to allow the pediatric dentist full access to the mouth. Pediatric dentists typically are, and should be, very cognizant of the importance of sharing the airway during surgery. Typical pediatric dental procedures include restorative dentistry, such as fillings of amalgam or composite, and placement of stainless steel crowns for posterior teeth, polycarbonate crowns, composite crowns, or stainless steel crowns with porcelain for anterior teeth, pulpotomies, tooth extractions, and space maintainers. Successful treatments can be provided along with stress reduction for the patient, parents, or guardians, and for the health care providers, with appropriate airway maintenance under deep sedation or general anesthesia.⁷⁴⁻⁷⁷

Oral and Maxillofacial Surgery.

Procedures performed within the specialty of oral and maxillofacial surgery (OMS) are among the most invasive in dentistry. Oral surgeons perform uncovering of teeth for orthodontic treatment; extraction of impacted, severely carious, and multiple teeth; insertion of dental implants; treatment of infections of the head and neck; surgical remodeling of maxillary and mandibular alveolar bone; facial cosmetics; and removal of soft-tissue or bony tumors, in addition to many other procedures. These procedures can produce both severe pain and heavy bleeding. Many OMS procedures are performed within the office setting. Oral and maxillofacial surgeons

receive 6 years of postdoctoral training and become licensed by the state dental board to perform the continuum from minimal sedation to anesthesia (general anesthesia) care. Patients can have challenging physical and mental conditions; therefore, a thorough preanesthetic assessment is necessary.⁷⁸ The patient's airway is shared with the oral surgeon; therefore, nasal intubation may be necessary. It may be possible to perform some oral surgical procedures while carefully working around an unsecured tube or with a standard or reinforced LMA. Local anesthesia in combination with IV sedation (propofol, midazolam), inhalation sedation (nitrous oxide), inhaled potent endotracheal anesthetics, and total IV general anesthesia are techniques available for office-based OMS.^{70,78} Remifentanyl has become a useful adjunct with the techniques listed to counteract the intense stimulation of OMS.⁷⁹ An anesthesia awareness/level of consciousness/depth of sedation monitor is also useful for careful anesthetic titration.⁷⁷

Periodontics.

Periodontal procedures can involve painful stimulation. Periodontists generally work in a particular quadrant of the patient's mouth and administer local anesthetic for the particular area of surgery. Periodontal treatment involves surgery of the teeth, gingiva, connective tissue, periodontal ligament, and alveolar bone, in addition to insertion and maintenance of dental implants. Local anesthetics are administered in conjunction with epinephrine concentrations that may be greater than normal concentrations to ensure hemostasis. Periodontal surgery can involve lengthy procedures with moderate amounts of hemorrhage and can be well managed with minimal sedation (both enteral or with inhalation sedation) or moderate sedation/analgesia.^{70,78} As with all procedures requiring monitored anesthesia care, use of standard monitoring is necessary. Midazolam with a propofol infusion helps achieve the goals of safety and comfort for periodontal surgical patients.⁷⁰

Endodontics.

Anesthesia for endodontic procedures is similar to that described for periodontal surgery. Local anesthesia provides adequate comfort, but in the presence of patient anxiety related to the length

of endodontic procedures, minimal sedation (both enteral or with inhalation sedation), or moderate sedation/analgesia can make the procedure tolerable and less anxiety producing for the patient. A dental dam is usually applied around the tooth and held in place with a special clamp to prevent aspiration of dental burs and endodontic files.

General Dentistry and Prosthodontics.

General dentistry can encompass all procedures from all of the dental specialties, depending on the interest and training of the general dentist. Anesthesia can be delivered along the continuum of care to ensure safety for the patient and to fill the requirements of the particular dental procedure.^{67,70,71}

Dental Hygiene.

Dental hygienists are also involved with providing dental care to patients who may require anesthesia along the continuum from minimal sedation/analgesia to deep sedation/analgesia with combinations of inhalation nitrous oxide/oxygen, local anesthesia, and IV medications. Thorough treatment can generate tooth or gingival sensitivity and pain. Even in the absence of pain, special populations such as pediatrics, the mentally handicapped, and those with severe anxiety disorders may require some degree of anesthesia for even routine dental care. Procedures range from routine hygiene to deep scaling and root planing of teeth with heavy dental accretions.

Postanesthesia Care.

Patients should be allowed to recover in a quiet, monitored environment. IV access allows the titration of additional analgesia or antiemetics as necessary. Fortunately, patient morbidity from general anesthesia for dental procedures is low.⁸⁰ Patients who receive inhaled sedation are less stressed postoperatively than those who receive general anesthesia, but TIVA procedures with proper airway maintenance and supplemental oxygen have also demonstrated significant success with good patient outcomes.^{69,71,80}

Invasive dental procedures can be a source of distress in children, which can lead to crying, nausea, vomiting (PONV), and bleeding

postoperatively. The addition of a potent long-acting opioid, ketorolac, or both greatly aids patient comfort in the postsurgical anesthesia recovery area. The use of oral minimal to moderate sedation in pediatric patients ages 2 to 34 months has been found to have no effect on behavior when the individual requires treatment later.^{69,76}

Psychiatric Procedures

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is the intentional inducement of a generalized seizure of the CNS for an adequate duration of time to treat patients with certain severe neuropsychiatric disorders.⁸¹⁻⁸⁴ The American Psychiatric Association continues to support ECT as a safe and evidence-based medical treatment when administered by trained, qualified personnel.⁸¹⁻⁸³ ECT in general, however, continues to be a topic of controversy. Research studies differ in the effectiveness of ECT. Most studies agree that the short-term effects of ECT are substantial; however, they argue about the long-term benefits, with current research supporting the effectiveness of maintenance ECT.^{85,86} Antidepressant medication administration, along with ECT, is well tolerated by patients, and both therapies can be beneficial. ECT may be performed as an inpatient or outpatient procedure. Acute patients receive three treatments per week and can undergo multiple treatment continuing on into maintenance ECT.⁸¹⁻⁸⁴ When clinical improvement is seen, it typically occurs within the first few treatments, and positive response to treatment is seen in 70% to 90% of patients, even those who had been treatment resistant.^{85,86} ECT is also used in certain patients who experience mania, catatonia, vegetative dysregulation, inanition, suicidal drive, and schizophrenia with affective disorders, and has begun to be used for patients with Parkinson disease.⁸¹⁻⁸⁶

ECT is one of the most controversial and invasive treatments in medicine. The first documented use of ECT was in 1938.^{81,82} Early ECT was performed without anesthesia resulting in the occurrence of many adverse effects such as bitten tongues, broken bones, and broken teeth. Treatment involves placement of electrodes with a

conducting gel, either right unilateral, bitemporal (bilateral), or bifrontal.⁸³ An alternating current of electricity is passed through the electrodes. Theories for the mechanism of ECT are related to profound changes in brain chemistry such as enhancement of dopaminergic, serotonergic, and adrenergic neurotransmission. Another theory postulates the release of hypothalamic or pituitary hormones, which have antidepressant effects. Finally, ECT produces anticonvulsant effects that raise the seizure threshold and decrease seizure duration exerting a positive effect on the brain.^{81,82} Some physiologic effects of electroconvulsive therapy are given in

Box 58.11

Possible Physiologic Effects of Electroconvulsive Therapy

Cardiovascular

Parasympathetic Response During Tonic Phase of Seizure

- Bradycardia
- Hypotension
- Bradydysrhythmias

Sympathetic Response During Clonic Phase of Seizure

- Tachycardia
- Hypertension
- Tachydysrhythmias

Cerebral

- Increased cerebral blood flow (increases of 100% to 400% above baseline are possible)

- Increased intracranial pressure

Other

- Increased intraocular pressure
- Increased intragastric pressure
- Hypoventilation

Adapted from Reti IM, et al. Safety considerations for outpatient electroconvulsive therapy. *J Psychiatr Pract.* 2012;18(2):130–136; Matsumoto N. Circulatory management, especially blood pressure and heart rate. In *Anesthesia Management for Electroconvulsive Therapy.* Japan: Springer; 2016:79–99.

Anesthetic Considerations.

Anesthesia for ECT involves the administration of an ultra-brief general anesthetic to provide lack of consciousness to the patient for the procedure (Table 58.5).

TABLE 58.5

Anesthetic Medications Used for Electroconvulsive Therapy

Drug	Dose
Anticholinergics	
Atropine	0.4–1 mg IV or IM
Glycopyrrolate	0.005 mg/kg IV or IM
Anesthetics	
Etomidate	0.15–0.3 mg/kg IV
Ketamine	0.5–1 mg/kg IV
Methohexital	0.5–1 mg/kg IV
Propofol	0.75–1.5 mg/kg IV
Muscle Relaxants	
Depolarizing	
Succinylcholine	0.5–1 mg/kg IV (onset 30–60 seconds)
Nondepolarizing	
Cisatracurium	0.15–0.25 mg/kg IV (onset 1–2 min)
Rocuronium	0.3–0.9 mg/kg IV (onset 1–2 min)

IM, Intramuscular; IV, intravenous.

Modified from Kadoi Y. Selection of anesthetics and muscle relaxants for electroconvulsive therapy. In Saito S. *Anesthesia Management for Electroconvulsive Therapy.* Japan: Springer; 2016:49–66; Mirzakhani H, et al. Neuromuscular blocking agents for electroconvulsive therapy: a systemic review. *Acta Anaesthesiol Scand.* 2012;56:3–6.

A thorough preanesthetic assessment must be performed, with consideration given to the possible critical physiologic hemodynamic responses generated by the induced seizure activity. [Box 58.11](#) lists possible physiologic effects as a result of ECT.

Few absolute and relative contraindications to ECT exist ([Box 58.12](#)).^{81,82,87,88} Patients may have results of laboratory studies, a pharmacologic regimen, and ECG readily available because of their psychiatric hospitalization. Informed consent is obtained whenever possible from the patient or legal guardian. An IV catheter is inserted in a peripheral vein. The patient is monitored with a pulse oximeter, ECG, noninvasive blood pressure monitor, temperature-monitoring device, and peripheral nerve stimulator. Use of ETCO₂ monitoring has been suggested because hypercarbia and hypoxia shorten seizure duration. Suction, oxygen, a positive-pressure Ambu bag and facemask, and rubber bite protectors must be present in addition to necessary airway and cardiovascular resuscitation equipment, medications, and supplies. ECT is usually performed in a dedicated psychiatric suite or special treatment

Box 58.12

Absolute and Relative Contraindications to Electroconvulsive Therapy

Absolute Contraindications to ECT

- Pheochromocytoma
- Recent myocardial infarction (less than 4–6 weeks ago)
- Recent cerebrovascular accident (3 months ago or less)
- Recent intracranial surgery (3 months ago or less)
- Intracranial mass lesion
- Unstable cervical spine

Relative Contraindications to ECT

- Angina
- Congestive heart failure
- Cardiac rhythm management device (pacemaker, automatic internal cardiac defibrillator [AICD])
- Severe pulmonary disease
- Major bone fracture
- Glaucoma
- Retinal detachment
- Thrombophlebitis
- Pregnancy

Modified from Reti IM, et al. Safety considerations for outpatient electroconvulsive therapy. *J Psychiatr Pract.* 2012;18(2):130–136; Yamahuchi S, Takasusuki T. Pre-procedural assessments and consideration. In *Anesthesia Management for Electroconvulsive Therapy.* Japan: Springer; 2016:1–16.

The patient is preoxygenated before induction. Anticholinergics may be administered as an antisialagogue or to prevent asystole.^{89,90} The induction agent is administered intravenously. Methohexital, propofol, or etomidate may be used without compromise of the therapy.^{87,89–93} Ketamine is used, although an enhanced hemodynamic response and increased intracranial pressure are possible after using ketamine. After loss of consciousness, positive-pressure ventilation is applied to the patient via the breathing bag and a facemask and is continued until after treatment is completed and spontaneous respirations resume. To assess the duration of the induced convulsion the psychiatrist usually applies a tourniquet, or manual blood pressure cuff inflated to slightly greater than the systolic blood pressure, above a lower extremity so that the muscle relaxant cannot reach the skeletal muscle in the extremity. A reusable rubber or disposable foam bite block is gently placed in the patient's mouth to prevent biting of the teeth, lips, and tongue, and a short-acting muscle relaxant is administered. Succinylcholine is

typically the muscle relaxant of choice for electroconvulsive therapy because of its rapid onset, short duration, and independent reversibility.⁹⁴⁻⁹⁷ Succinylcholine IV injection after the induction of anesthesia attenuates the potentially dangerous skeletal muscle contractions produced with seizure activity. Nondepolarizing agents can be used; however, induction dosage is typically adjusted to create a shorter duration of neuromuscular blockade.^{87,89,94} A nerve stimulator must be used and appropriate neuromuscular blockade reversal agents such as sugammadex should be administered as necessary. The electrodes are applied, the proper waveform and current level are selected, and the electroconvulsive seizure is induced. The seizure lasts from 30 to 90 seconds; the motor seizure is shorter than the seizure duration as seen on an EEG. Use of an anesthesia awareness/level of consciousness/depth of sedation monitor correlates with the EEG, and it can be a useful tool for the anesthetist and the psychiatrist. The level of sedation displayed by this monitor correlates with the proper point to induce seizure, the duration of seizure, and the potential for awareness during the ECT procedure.⁸⁸ At the end of the seizure spontaneous respirations resume, and the patient is transferred to a post anesthesia recovery area where vital signs are continually monitored until the patient is determined to be stable and able to be safely discharged.^{81,87,88} Certain anesthetic medications and techniques such as hyperventilation can affect seizure duration (Box **Box 58.13**)

Effects of Common Medications and Conditions on Seizure Duration

Medications That Can Prolong Seizure Duration

- Alfentanil with propofol
- Aminophylline
- Caffeine
- Clozapine

- Etomidate
- Ketamine (a proconvulsant)

Conditions That Can Prolong Seizure Duration

- Hyperventilation/hypocapnia

Medications That Can Shorten Seizure Duration

- Diltiazem
- Diazepam
- Fentanyl
- Lidocaine
- Lorazepam
- Midazolam
- Propofol
- Sevoflurane

Medications With No Apparent Effect on Seizure Duration

- Clonidine
- Dexmedetomidine
- Esmolol (may possibly shorten seizure duration)
- Labetalol (may possibly shorten seizure duration)
- Nicardipine
- Nifedipine

- Nitroglycerin
- Nitroprusside

Modified from Kadoi Y. Selection of anesthetics and muscle relaxants for electroconvulsive therapy. In Saito S. *Anesthesia Management for Electroconvulsive Therapy*. Japan: Springer; 2016:49–66; McTague A, Cross JH. Treatment of Epileptic Encephalopathies. *CNS Drugs*. 2013;27:175–184.

Adult patients about to undergo ECT should follow fasting guidelines of at least 6 hours for solids and 2 hours for liquids. Necessary bronchodilators may be taken. Oral medications, such as antihypertensives, cardiac medications, anticoagulants, and thyroid medications, may be taken with a sip of water up to 2 hours before the procedure.^{87,88} Rapid-sequence induction of general anesthesia with endotracheal intubation can be performed for patients at high risk for gastrointestinal reflux or hiatal hernia. One must take into consideration the total number of ECT treatments to be received weighed against the necessity for repeated intubations and the fact that most patients, even obese patients, have rarely been found to aspirate as a result of ECT.⁸⁷

Postanesthesia Care.

The intentional creation of CNS convulsions has profound effects on the patient's physiology. Patients usually experience multiple types of temporary cognitive and memory impairment after ECT. The first type of impairment that may be seen is postictal confusion, in which the patient is transiently restless, confused, and agitated immediately after the convulsive episode and for approximately 30 minutes following the treatment. The agitation can be difficult to manage for the recovery nurse and staff. Some patients require physical restraint or sedation with a benzodiazepine, antipsychotic medication, or propofol to treat postictal agitation.⁹⁵ One theory postulates that the postictal agitation or anxiety is a result of increased plasma lactate levels possibly caused by inadequate neuromuscular blockade, and that increasing the dose of muscle relaxant is necessary with the next treatment.⁹⁴ A second type of cognitive impairment that may be seen later is anterograde memory dysfunction, in which the patient may rapidly forget new

information. The patient may not remember things that he or she does or is told in the days after ECT. Anterograde amnesia usually subsides within a few days or weeks; however, it can be frightening to the patient. A third cognitive impairment is retrograde memory dysfunction, which is the loss of memories from several weeks to several months before the ECT treatment. No evidence suggests that ECT causes any brain damage nor does it impair the long-term ability for the patient to learn and retain new information. The cognitive effects described vary depending on the frequency and the number of ECT treatments the patient has received. The quantities of energy used to elicit the convulsions and the placement of the electrodes are also considered factors for cognitive dysfunction, in addition to the type of anesthetic drugs used.^{81,82}

Cardiovascular stimulation also occurs with ECT. The sympathetic and parasympathetic nervous systems are stimulated sequentially. Therefore, the patient may experience an increase in heart rate and blood pressure followed by a period of bradycardia or even asystole. This can lead to increases in myocardial oxygen demand, arrhythmias, and transient ischemic changes in susceptible individuals. Transient cardiac changes can be managed before ECT with anticholinergics, IV local anesthetics such as lidocaine, or IV narcotics such as remifentanyl.^{81,82,87-97} Changes after ECT can be managed with β -blockers such as esmolol, labetalol, calcium channel blockers, or other antihypertensives.⁹⁷

Finally, patients may also experience headache, muscle aches, or nausea as a result of ECT treatments. Symptoms of headache or muscle ache respond well to acetaminophen, aspirin, or nonsteroidal antiinflammatory agents such as IV or intramuscular ketorolac, or oral ibuprofen. Nausea can be caused by the stress and anxiety before the ECT treatment, the anesthetic agents used, the seizure itself, or air in the stomach from assisted ventilation. Nausea can be treated with agents such as ondansetron, dolasetron, granisetron, or metoclopramide.^{86,87}

New Therapies for Major Depressive Disorders

Two new therapies for severe major depressive disorders are now available, which often require anesthetic treatment: repetitive transcranial magnetic stimulation (rTMS), and vagus nerve

stimulation (VNS).^{98,99} Neuroanatomic studies have suggested that patients with major depressive disorder (MDD) have dysfunction within the frontal cortical-subcortical-brainstem neural network, specifically the dorsolateral prefrontal cortices. ECT and antidepressant medications do not act in these discrete areas of the brain, but new therapies stimulating these focal areas of the brain are now approved and in use in the United States.

Repetitive Transcranial Magnetic Stimulation and Magnetic Seizure Therapy.

rTMS uses electric current passing through an electromagnetic coil that has been placed on the scalp. The coil delivers brief, rapidly changing magnetic field pulses to specific areas of the brain. These bursts of pulses are called a *train* of stimuli. Multiple trains of rTMS may be delivered in one session. The scalp and skull are transparent to magnetic fields, an advantage over ECT, in which the scalp and skull are resistors to the electrical stimulation. To produce antidepressant effects, a convulsion must be initiated by trains of rTMS, because subconvulsive trains of rTMS are ineffective.^{98,100,101}

Convulsive magnetic energy levels are determined by the use of motor threshold (MT). MT is the point at which a single pulse of magnetic energy begins to elicit an electromyographic response, that is a twitch, usually of the abductor pollicis brevis muscle of the thumb or first dorsal interosseous muscle of the index finger.^{98,100} Treatment with rTMS is safe and well tolerated, with reduced cognitive side effects when compared to ECT. Patients are found to recover much more rapidly from rTMS or Magnetic Seizure Therapy (MST) compared to ECT.^{100,102}

MST uses a higher-intensity, more frequent, and longer-duration magnetic seizure-inducing dose when compared with the magnetic dose required for rTMS. MST can stimulate tonic-clonic seizures in more localized and focal regions of the prefrontal cerebral cortex when compared with ECT, and also generalized tonic-clonic seizures that resemble ECT.¹⁰²⁻¹⁰⁴ MST does not produce the rigid bilateral masseter muscle contractions noted during ECT but can produce elevations in blood pressure and heart rate similar to ECT.¹⁰⁰⁻¹⁰²

After rTMS some patients experience mild headache,

disorientation and inattention (although patients become reoriented much more quickly than with ECT), retrograde amnesia, some anterograde amnesia, transient auditory threshold increases as a result of the high-frequency clicking sound heard during coil discharge (which can be alleviated with the use of foam earplugs), and (rarely) generalized seizure.^{100,101} A single TMS treatment may be all that is necessary for treating certain severe MDD nonpsychotic patients along with their medications, although rTMS may be necessary.⁹⁸

The literature describes anesthesia requirements for rTMS or MST from none needed to ultra-brief general anesthesia as for ECT.^{98,100-102} A patent and secure IV catheter is established and full monitors are applied. Glycopyrrolate 0.004 mcg/kg is administered as an antisialagogue, along with ketorolac 0.4 mg/kg, 2 to 3 minutes prior to induction of ultrabrief general anesthesia. Methohexital 0.5 to 1 mg/kg may be used for induction in addition to propofol 1 to 2.5 mg/kg.⁸⁹ Succinylcholine 0.5 to 1 mg/kg can be used as the muscle relaxant after isolation of a lower extremity for observation of seizure duration.^{89,94} Use the smallest amount of muscle relaxant necessary to enable recovery from paralysis prior to the return of consciousness. The anesthetist can then manually hyperventilate the patient's lungs with a facemask to an ETCO₂ value of 30 to 34 torr. At this point, the magnetic stimulus may be applied.¹⁰⁰⁻¹⁰²

Vagus Nerve Stimulation.

VNS requires surgical implantation of a programmable battery-powered electrical stimulator that connects with the patient's left vagus nerve (cranial nerve X). The stimulator is usually implanted in the patient's chest with minimal sedation, moderate sedation/analgesia, deep sedation/analgesia, or under general anesthesia. Because of the delicacy of the surgery and its proximity to vital structures, no extraneous patient movement is permitted. Although originally approved for treatment-resistant epilepsy, the VNS is now approved for major depressive episodes that have not responded to four antidepressant medication trials.^{99,103,104}

Radiologic and Diagnostic Procedures

Medical science has been able to use the sciences of physics, chemistry, and computers to produce remarkably accurate images of the internal structure and function of the body to aid medical diagnosis. Energy is transmitted to the patient and interacts with patient tissues. This energy is then detected, processed, and displayed on a computer console, which allows images to be selected for further investigation and diagnosis. Some medical images are created in real time and allow observation of flow or changes in tissue resulting from treatment.

Procedure Overviews

Computed Tomography.

Computed tomography (CT) uses X-rays generated from a rotating anode X-ray generator. The patient is placed supine on a flat, wooden, wheeled platform and moved inside the scanning gantry. X-rays are then projected through the patient at different angles, penetrating tissues differently according to the atomic numbers of the atoms within the tissue. Dense tissue such as bone attenuates (reduces the energy of) the X-ray beam more than less dense tissue such as muscle, yielding high-resolution images of the scanned tissue. The patient images are then detected, and the computer acquires the image data. Finally, an image analyzer projects the analyzed data in the form of a tomogram or body section slice onto an operator console and a physician-viewing console. CT is excellent for imaging bone. The diagnostic quality of a CT scan is enhanced with the injection of IV contrast media (ICM). Contrast media containing iodine may be administered to the patient enterally or parenterally to further attenuate the X-ray beam to enhance the images for CT vascular or gastrointestinal studies.^{105,106}

Magnetic Resonance Imaging.

Magnetic resonance imaging (MRI) uses the dipole moment (i.e., the ability of the atomic nucleus to behave as a magnet) of the hydrogen atom. The patient is placed supine within the scanning gantry or bore of the magnet. The magnet used for MRI can be a permanent magnet or a powerful superconducting electromagnet cooled with liquid helium to 4°Kelvin. Magnetic strength is

measured in teslas (T); 1 T is equivalent to 10,000 gauss or oersted. MRI magnets can generate field strengths of 0.15 to 4 T, although MRI magnetic field strength generally ranges from 0.15 to 2 T. The quality of the MRI image is directly related to the strength of the magnetic field.^{105,107} The spin of the electron in hydrogen will align the hydrogen atoms parallel to this powerful magnetic field. The patient's water-containing tissues are then excited with variable radiofrequency pulses. After the proton in hydrogen receives this radiofrequency energy, it emits radiofrequency energy with three-dimensional-appearing spatial information. MRI technology now allows its use within the operating room with an open-bore, portable, 0.12-T, low-intensity magnet to assist the neurosurgeon with diagnostic decisions.^{105,108} Contrast media are also used in MRI studies to enhance the patient's tissues and allow the scan to provide further diagnostic information. MRI contrast is most commonly gadopentetate dimeglumine, which contains the element gadolinium bound as a chelated structure, and administered primarily parenterally, but rarely enterally.^{105,108,109}

The FDA classifies the MRI as a class II device. Class II devices require special labeling, mandatory performance standards, and postmarket surveillance by the FDA. The electromagnetic energy greatly drops off just outside the margins of the bore of the electromagnet. This is called the *fringe field*. There are no known reports of harmful physiologic effects from magnetic fields.^{105,106}

Because of the potential danger of the powerful electromagnetic attraction of ferromagnetic objects to both the patient and health care personnel, the American College of Radiology divides the MRI

Box 58.14 into four zones as noted in **Box 58.14**.¹¹⁰

Magnetic Resonance Suite Zones

Zone	Activity
Zone I	All areas freely accessible to the general public. This is the area through which personnel and patients access the MRI area.
Zone II	The area between the uncontrolled zone I and the strictly controlled zone III. This is the area where patients are greeted, histories obtained, and questions answered. Movement by non-MRI personnel and patients is under the supervision of MRI personnel.
Zone III	This is a restricted area. Movement in this area is strictly controlled by MRI personnel. Access to this area is only after screening for the presence of ferromagnetic material. Ferromagnetic objects may produce a serious hazard if brought into this area.
Zone IV	This is the MRI scanner room itself. By definition it is within zone III.

MRI, Magnetic resonance imaging.

Interventional Radiology (Vascular and Nonvascular), and Radiotherapy or Radiosurgery.

Interventional radiology (IR) involves minimally invasive procedures and therapies performed by radiologists, especially in patients at high medical risk.^{111,112} Major IR therapies include angiography, the embolization of blood vessels such as arteriovenous malformations or for epistaxis, the delivery of chemical or physical vascular occlusive devices, the removal of thrombi, ablation of aneurysms, and angioplasty of blood vessels with stent placement.^{111,113} **Box 58.15** lists indications for endovascular embolization procedures. See **Chapter 28** for a discussion of interventional vascular surgery and **Chapter 31** for **Box 58.15** interventional neuroradiology procedures.

Indications for Endovascular Embolization

- Arteriovenous malformation
- Arteriovenous fistula
- Intracranial aneurysm
- Recurrent epistaxis
- Hemoptysis
- Traumatic solid organ hemorrhage
- Preoperative major organ tumor embolization for blood loss reduction
- Gastrointestinal hemorrhage
- Uterine leiomyoma (fibroid)
- Uterine hemorrhage

- Pelvic fracture hemorrhage
- Postoperative hemorrhage after prosthetic hip or knee replacement
- Varicocele

Modified from Temple M, Marshalleck FE. *Pediatric Interventional Radiology: Handbook for Vascular and Non-vascular Interventions*. New York: Springer; 2014.

Radiation is a treatment itself for both benign tumors (e.g., low-grade astrocytoma, meningioma, pituitary adenoma, craniopharyngioma, schwannoma, pineocytoma, chemodectoma, and low-grade papillary neoplasms) and aggressive tumors (e.g., germinoma, primitive neuroectodermal tumor, chordoma, intermediate-grade pineal tumor, immature teratoma, undifferentiated sarcoma, anaplastic oligoastrocytoma, and metastatic tumors). Radiation surgery is the delivery of a single massive dose of radiation to the target tissue. Radiation therapy is the delivery of smaller doses of radiation over several sessions.¹¹⁴

Gamma radiation is used for radiotherapy and radiosurgery. The gamma radiation is introduced to the patient by the use of either a Gamma Knife or a CyberKnife. Each uses beams of gamma rays obtained from the radioactive decay of cobalt 60 or from a linear accelerator. The CyberKnife is used by first obtaining stereotactic three-dimensional images, which then allow computer-controlled robot arm guidance of the CyberKnife. The CyberKnife therapy delivers a sequence of many hundreds of gamma beams to the cancerous tumor from many different directions. Gamma Knife therapy delivers gamma radiation to the cancerous tumor simultaneously in a single dose.^{113,114}

Interventional Neuroradiology.

Interventional neuroradiology (INR) is the diagnosis and treatment of CNS diseases endovascularly to deliver therapeutic medications or devices. INR was first used in the early 1980s when digital subtraction angiography was developed. Digital subtraction angiography first uses an original angiograph of the blood vessels to be studied. Then a contrast medium is injected into the same

blood vessels, and opaque structures such as bone and tissues can be digitally subtracted or removed from the angiographic image, leaving a clear picture of the blood vessels.¹¹⁵

Improvements in vascular access techniques, new thin and flexible catheters and guidewires, and the development of innovative coils and therapeutic medications have made new treatments possible. Conditions that once required extensive surgery, with accompanying patient morbidity and mortality, can now be performed less invasively.^{111,115} Some major procedures performed with INR are mechanical or chemical removal of emboli or thrombi that cause stroke, the physical occlusion of malformed vascular structures such as arteriovenous malformations with chemicals or flow-directed balloons, dilation of stenotic blood vessels, and embolization (blocking blood flow) of cerebral vascular aneurysms using catheter-deployed coils.^{111,113,115}

Box 58.16 lists some current uses for each of the previously mentioned radiologic and diagnostic procedures. As technology advances, more uses will be seen.

Some Indications for Radiologic and Diagnostic Procedures

Computed Tomography

- Assessment of the airway with neck or thoracic tumors
- Assessment of bony trauma, especially the spine
- Assessment of head trauma
- Assessment of increased intracranial pressure
- Assessment of neoplasms
- Imaging of brain tumors
- Imaging of intracerebral hemorrhage

Magnetic Resonance Imaging

- Central nervous system imaging
- Imaging of the blood-brain barrier
- Kidney imaging
- Liver imaging
- Urinary bladder imaging

Interventional Radiology (Vascular and Nonvascular), Radiotherapy, and Radiosurgery

- Angiography
- Catheterization of ducts, and vascular lesions for drainage of cysts or hemangiomas (e.g., liver hydatid cyst, renal cyst, soft-tissue hemangiomas)
- Catheterization of tumors for delivery of chemotherapy directly to tumors (e.g., liver tumors)
- Embolization, embolectomy, or thrombofragmentation of vascular lesions and tumors (pulmonary thrombi or emboli)
- Radiosurgery
- Stereotactic radiosurgery
- Radiotherapy
- Transluminal dilation, angioplasty, and stent insertion for vascular stenosis, biliary stenosis, or tracheal malacia

Interventional Neuroradiology

- Angioplasty and stent placement for an atherosclerotic lesion
- Angioplasty or endovascular ablation of cerebral vasospasm from aneurysmal subarachnoid hematoma

- Balloon angioplasty of cerebral vasospasm
- Brain arteriovenous malformation embolization
- Carotid artery stenting
- Carotid cavernous fistula and vertebral fistula treatment
- Carotid test occlusion
- Dural arteriovenous malformation embolization
- Embolization of highly vascularized intracranial tumors
- Glomus tumor treatment
- Intracranial aneurysm ablation
- Juvenile nasopharyngeal angiofibroma treatment
- Meningioma treatment
- Sclerotherapy of venous angiomas
- Spinal cord lesion embolization
- Therapeutic carotid occlusion
- Thrombolysis of acute thromboembolic stroke
- Trigeminal nerve rhizotomy or glycerol injection
- Vein of Galen malformation treatment
- Vertebroplasty for back pain/vertebral body fractures

Anesthetic Considerations

Computed Tomography.

CT scans require that the patient remain as motionless as possible for several minutes to an hour. Patient motion can produce artifacts

in the diagnostic images to be read by the radiologist. Patients must lie on a flat, lightly padded wheeled platform, which is rolled into the short-bore scanning gantry of the CT scanner. Although the majority of patients are able to cooperate and tolerate CT, others may not be able because of extremes in age, concurrent medical conditions, or mental disability. The CT scan is neither physically invasive nor painful. Patients enter the CT scanner without precautions for ferromagnetic objects as for an MRI scan. CT is more rapidly performed than an MRI scan, especially if a spiral CT scanner is used.

The patient may require anesthesia anywhere along the continuum from minimal sedation to general anesthesia. Use of ferromagnetic anesthesia equipment and supplies around the CT scanner is not a concern. A standard anesthesia machine, laryngoscope and blades, and IV infusion pumps can be used as if in the operating room. An LMA is an appropriate alternative choice as a minimally invasive and secure airway in the patient without contraindications to its use. An LMA is contraindicated in patients with gastroesophageal reflux disease or a full stomach. Attention must be paid to securing the airway, and the anesthesia breathing circuit, the leads for the ECG, the noninvasive blood pressure cuff, the IV line, and the pulse oximeter must extend into the scanning gantry. The anesthetist must allow for extra lengths of anesthesia circuitry and electrical monitoring leads because of patient movement that will occur during intermittent repositioning of the mechanized table that positions the patient within the scanning gantry.^{88,106}

Sedation can be performed with a variety of agents, including midazolam or propofol. General anesthesia can be performed with TIVA, such as with IV propofol, or with potent inhaled agents.

All personnel must be aware of the use of ionizing radiation during the CT scan and should take precautions to be shielded from any exposure to the radiation. Radiation exposure is cumulative over a lifetime, and every precaution must be made to protect oneself from any unnecessary doses of radiation, which can cause genetic mutation and may lead to cancer. Protection can be accomplished with the use of a lead-glass barrier, a lead apron, a lead thyroid collar, and lead-glass safety glasses. Radiation dose

badges are available that attach to clothing. The badge monitors the dose of radiation received and is evaluated monthly. Federal technical information and guidelines for working in conjunction with radiation is available from the US Environmental Protection Agency.¹¹⁶

ICM can cause an unexpected allergic reaction in some patients, varying from itching with hives to severe, life-threatening anaphylactoid and anaphylactic reactions.^{109,117} Adverse reactions to ICM are more likely to develop in patients with asthma, a history of allergy or in patients with multiple morbidities. These reactions can be divided into renal or general, and subdivided into acute and delayed. Fatal reactions are rare. Contrast-media–induced renal impairment can be reduced with the use of low-osmolality contrast media and extracellular volume expansion.^{117,118} ICM also can cause local tissue sloughing and necrosis if the ICM extravasates from the vein into the surrounding tissue.^{110,117,118} Clinicians should be familiar with treatment protocols to minimize patient morbidity

Box 58.17).

Considerations and Treatment Protocols for Preventing Intravenous Contrast Medium Extravasation

Considerations

- Use intravenous catheters (as opposed to metal needles or butterfly needles).
- Avoid use of the same vein if the first attempt at intravenous catheterization was missed.
- Ensure the intravenous catheter is patent and is free flowing.

Treatments

- Attempt to aspirate as much ICM as possible.
- Elevate the affected limb.

- Apply ice packs for 20 to 60 minutes until swelling resolves.
- A heating pad may be necessary in place of ice for swelling.
- Observe the patient for possible tissue damage related to continual contact with ice or heat.
- Observe the patient for 2 to 4 hours before discharge; consider medical/surgical consultation if necessary.
- Follow up with patient assessing for residual pain, increased or decreased temperature, hardness, change in sensation, redness, or blistering.

ICM, Intravenous contrast medium.

Modified from American College of Radiology. Extravasation of contrast media. In *ACR Manual on Contrast Media*. version 10.1; 2015. Accessed 2016 at American College of Radiology website: <http://www.acr.org/Quality-Safety/Radiology-Safety/MR-Safety>; Reynolds PM, et al. Management of extravasation injuries: A focused evaluation of noncytotoxic medications. *Pharmacotherapy*. 2014;34(6):617–632.

ICM is typically a water-soluble, iodine-containing solution of two available types: media that can dissociate into ions in solution, and media that will remain in a neutral state in solution. ICM is also formulated as high-osmolar contrast media (HOCM), which contain few dissolved particles and iodine atoms, and low-osmolar contrast media (LOCM), which contain greater numbers of dissolved particles with iodine. A HOCM solution causes fluid shift from the cell to the vein with the ICM, whereas an LOCM solution is closely iso-osmolar, inducing less fluid shift from the cell. Nonionized LOCM is a more costly contrast medium for the patient. Some advocate that it should be the only contrast medium used for CT with dye studies.^{109,117}

Reactions are possible with either type of ICM solution, although fewer reactions occur with LOCM.^{116,117} Some reactions may occur anywhere from a half hour to a week after the administration of the ICM. Reactions to ICM are theorized to be caused by the ICM molecule's serving as an antigen and affixing itself to either mast cells or basophils. This causes release of mediators such as histamine and tryptase, which can inhibit coagulation, dilate blood

vessels, release complement, or even stimulate an IgE-modulated immune reaction.^{109,116,117} A new ICM using gold nanoparticles is available and undergoing tests prior to use in humans. It has many advantages over iodinated ICM, such as higher radiation absorption, yielding better images with lower X-ray dose, low allergenic response, and longer imaging times because of its nanoparticle size.^{118,119}

A thorough preanesthetic assessment for a patient about to undergo CT should include questions pertaining to asthma, allergies, and any previous reactions to contrast media. Diabetic patients taking metformin must withhold the medication because of the risk of lactic acidosis. This problem is mainly observed in patients with diabetic nephropathy. Other patients at risk for reactions to ICM are patients with multiple medical problems, especially those with cardiac disease or with preexisting azotemia, patients of advanced age, and patients being treated with nephrotoxic agents such as the aminoglycoside antimicrobials gentamicin, tobramycin, streptomycin, amikacin, kanamycin, and neomycin, or nonsteroidal antiinflammatory agents. ICM is contraindicated in pregnant patients.^{109,117}

Clinicians may use preventive measures in patients who may be at risk for a reaction to ICM. The radiologist should use the smallest amount of contrast agent necessary. To safeguard against the possibility of renal failure, the patient should be adequately hydrated beginning 1 hour before the procedure and continuing for another 24 hours. Patients who are at risk for possible anaphylactoid reactions should be pretreated with corticosteroids such as methylprednisolone, or prednisone administered by mouth or intravenously. In cases of moderate or severe previous ICM reactions, a histamine-1 (H_1) blocker such as diphenhydramine, and an H_2 -blocker such as cimetidine or ranitidine should be given together either intravenously or by mouth. ICM is probably the most frequently used agent that causes anaphylactoid reactions. Anaphylaxis recognition and treatment are outlined in [Chapter 46](#); as little as 1 mL of ICM can initiate these reactions.^{109,116,117}

Magnetic Resonance Imaging.

MRI can take up to an hour or longer. During this time, the patient

must remain extremely still to reduce motion artifacts. These artifacts can cause unfaithful representations of the tissues being studied. The motions of breathing, the heart, blood flow, swallowing, and even cerebral spinal fluid flow produce artifacts in a highly sensitive MRI scan. Patients must remain within the bore of the magnet for an MRI scan for longer periods of time than for a CT scan. During this time the MRI suite's ambient temperature is cold.

The patient is exposed to varying magnetic fields of up to 4 T, along with additional exposure to variable radiofrequency radiation. Blood flow is decreased by strong magnetic fields, and blood pressure compensates by rising. Patients have also reported symptoms of vertigo, nausea, headache, and visual sensations.^{107,108}

The MRI machine produces loud vibratory and knocking noises as coils are switched on and off during the course of the study. The size of the MRI magnet bore may preclude the morbidly obese or claustrophobic patient from MRI scanning, although a more open-bore MRI is available. Most patients are content with an explanation of what to expect during the procedure and with reassurance. Some patients need minimal or moderate sedation. Patients with claustrophobia or those who cannot, or will not remain motionless during the study, in addition to critically ill patients, may require deep sedation or general endotracheal anesthesia.^{105,107,108,110} MRI is not painful so opioids are not usually required. Sedation has been performed with oral and IV midazolam, ketamine, pentobarbital, or propofol.^{105-108,110} Minimal sedation requires full monitoring. Deep sedation or general anesthesia requires IV access and full monitoring. The LMA has served as an excellent, relatively noninvasive airway for MRI. Some anesthesia providers prefer general endotracheal intubation. Children, who cannot or will not cooperate, experience better MRI scans with general endotracheal anesthesia in shorter periods of time, despite longer recovery times when compared with sedation.^{111,113}

Because of the intense magnetic field always present in the MRI suite, anesthesia providers must be aware of every item on their persons and every item that is to be used in conjunction with anesthesia administered to the patient. Ferromagnetic (iron-

containing) substances are attracted at astonishing rates of speed into the bore of the magnet. Personal items such as pens, certain types of eyeglasses, jewelry, watches, pagers, personal computers, calculators, name badges, coins, audiotapes, videotapes, and credit cards are some of the items that should never enter the MRI suite, in addition to any ferromagnetic anesthesia equipment, medication vials, and supplies. If a patient were present within the bore of the MRI, injury or death could be possible from the missile created. As newer and more powerful 3-T MRI scanners become more prevalent, previously “safe” items could cause injury. Metals known to be safe within the proximity of the MRI bore are stainless steel, nonferrous alloys, nickel, and titanium. Materials and equipment constructed of plastic are safe.^{106,108}

Patients possessing certain medical therapeutic devices may be prohibited from an MRI scan. MRI lists devices or metal that patients may possess that could be affected by the MRI and cause patient morbidity or mortality (Box 58.18).¹⁰⁶⁻¹¹⁰ Further investigation by the anesthetist in concert with the radiologist or MRI technician regarding the metal content and MRI compatibility of these metal items is necessary.

Potentially Harmful Items When in Proximity to MRI

- Automatic implantable cardiac defibrillators (AICD)
- Cardiac pacemakers
- Certain mechanical heart valves
- Cochlear implants
- Deep brain neurostimulators
- Dorsal column stimulators
- Pacing wires
- Penile implants

- Permanent eyeliner or tattoos
- Prostheses (including dental prostheses)
- Implanted pumps (such as baclofen, narcotic, or insulin pumps)
- Internal plates, wires, or screws
- Metallic aneurysm clips (clips manufactured after 1995 and certified MRI compatible can be scanned)
- Certain metallic implants (history of recent orthopedic implants inserted within 3 months, dental implants)
- Metallic sutures
- Shrapnel and metal fragments (especially intraocular metal shrapnel)
- Tissue expanders with metallic ports

MRI, Magnetic resonance imaging.

Cardiac pacemakers may be affected several ways by the electromagnetic field: reprogramming may occur; the pacemaker may be inhibited; it may revert to an asynchronous mode; the reed switch may close; the pacemaker may become dislodged; or it may become heated by the magnetic field.^{107,108,110}

Manufacturers have developed a host of MRI-compatible anesthesia equipment and supplies ([Box 58.19](#)). This host of equipment and supplies allows performance of the anesthetic procedure directly within the MRI suite. Be aware that some equipment designated by the manufacturer as MRI compatible may not be compatible as magnet strengths increase.¹¹⁰

List of Available MRI-Compatible Equipment and Supplies

- MRI-compatible anesthesia machine

- Pulse oximeter
- Intravenous bag pole
- Liquid crystal temperature monitoring strip
- Thermocouple temperature probe with radiofrequency (RF) filter
- Respiratory rate monitor
- Noninvasive blood pressure monitor
- Pulse oximeter
- Electrocardiograph
- Electrocardiograph patches
- Electrocardiograph cable
- Capnograph
- Laryngoscope with lithium batteries and aluminum spacers
- Laryngoscope blades
- Nerve stimulator
- Intravenous infusion pump
- Oxygen tanks
- Precordial stethoscope
- Esophageal stethoscope
- Patient carts
- Tables and trays

MRI, Magnetic resonance imaging.

Facilities that cannot afford MRI-compatible equipment and supplies can provide anesthetic services to their patients by inducing anesthesia outside the MRI suite. The patient is placed on an MRI-compatible cart or a detachable MRI scanning table that fits within the bore of the electromagnet, where anesthesia may be then induced. With the aid of extra-long circuits, extension IV tubing, and properly insulated monitor cables, the anesthesia can be maintained with full monitors and a standard anesthetic machine outside the MRI suite. The patient is then carefully moved on a flat, relatively hard, wheeled platform into the bore of the electromagnet. Attention should be paid to isolate any monitor leads or IV tubing from touching the skin of the patient. Any monitor leads and IV tubing should be kept in straight alignment, because the intense magnetic fields in the MRI suite can induce current flow in coiled leads or tubing, and severely burn the patient. Flexible LMAs and endotracheal tubes that contain wire windings can also be sources of burns. The American College of Radiology recommends strong attention to and the elimination of induced current, which can be large tissue loops such as the loop created by the hand touching the hip or thigh, or the loop created when the feet or calves of the legs touch.¹¹⁰

Consideration must be given to the MRI contrast media administered to patients. Fortunately, the dyes used for MRI contrast are nonionic gadolinium chelates and have extremely low allergy rates.^{109,117,118} Nausea is a common side effect. Urticaria (hives) and anaphylactoid reactions occur in less than 1% of patients.^{111,117} The risk of a reaction to MRI dye is increased in patients with a history of asthma or other allergies or drug sensitivities, especially to iodinated contrast dyes.¹¹⁷ Proper equipment, medications, and supplies must be immediately available for management of a reaction if one occurs. Treatments for anaphylactoid and anaphylactic reactions are discussed in [Chapter 46](#).

Although MRI does not use ionizing radiation, patients and personnel are exposed to constant levels of magnetic force while in the MRI suite. Acute exposure to magnetic fields under 2.5 T has not been shown to have adverse effects in humans. All care providers must make their own determinations regarding how

much magnetic exposure they will accept during a patient's MRI scan. Doses both to the patient and to all personnel should be minimized.^{106,110} Pregnant anesthesia personnel have no restrictions on presence in the MRI scanner room during all of the required anesthesia preparations necessary to treat the patient, but the American College of Radiology recommends that personnel not be present in the MRI scanner room during the scan. Pregnant patients should discuss risks and benefits with their physician.¹¹⁰

If the anesthesia provider is away from the patient during the procedure, it should be ensured that all airway circuitry, monitoring leads, and IV connections are secure and tight. A respiratory monitoring apparatus (RMA) built into the anesthesia circuit reservoir bag will soon be available to monitor respiration with both visual and audible signals pertaining to movement of the RMA relative to the patient's respiratory rate and tidal volume.

When the environment could pose physical danger, anesthesiologists must be cognizant of their own safety and physical well-being while administering anesthesia for patients, especially during repeated exposures of radiation and/or chemicals. Therefore, a means for remote observation and monitoring either via a clear window, a camera, or telemetry must be available, although controversies regarding the traditional standards of physical presence during the conduct of anesthesia exist.^{106,110} In conjunction with recognized standards of safety, the anesthesiologist must use monitors with both audible and visual alarms and have a clear and continual view of the patient and the anesthesia monitors. Consideration must be made for safe and rapid access to the patient should the need exist.^{106,108,110}

The functional MRI (fMRI) is a tool used to better differentiate residual pathologic tissue from normal healthy tissue to perform higher-quality tumor resection. An fMRI scan requires the patient to remain motionless and cooperative to avoid artifact. It is known that anesthetic agents can alter cerebral blood flow and cerebral oxygen metabolism, which can affect the interpretation of the fMRI scan. Therefore, fMRI use for uncooperative or pediatric patients may preclude its use in this cohort of patients. Anesthesia research will provide the anesthesiologist tools to enable this population to receive both an anesthetic and needed fMRI.¹⁰⁸⁻¹¹⁰

Positron Emission Tomography Scan.

A positron emission tomography (PET) scan is used for the imaging and detection of malignant disease, neurologic function, and cardiovascular disease. The isotope fluorodeoxyglucose (FDG) is injected and is then absorbed into metabolically active cells. The absorbed isotope emits minute amounts of positron antimatter, which are detected and produce high-resolution images of diseased tissue. The patient must remain still for approximately an hour after the injection of FDG to minimize the amount of the muscle uptake of this glucose-like molecule. The patient must have fasted to minimize blood glucose levels. Any sedation medications containing sugar should also be avoided.¹²⁰⁻¹²²

Interventional Radiology (Vascular and Nonvascular), Radiotherapy, Stereotactic Radiosurgery, and Interventional Neuroradiology.

As skills, techniques, and technology progress, more procedures will be performed with radiation or under radiologic guidance.¹¹¹ These procedures all require the absolute immobility of the patient, with periods of controlled apnea, which assist in the viewing or treatment of the targeted area of the patient, especially during whole-body therapeutic radiation treatment.^{111,113-115} These procedures are also time consuming, taking up to several hours to complete. Procedures may be necessary in patients of various age groups from infants to geriatrics and in all states of health.^{113,115} A thorough preanesthetic assessment is imperative to ensure patient safety.

With the exceptions of angiography or radiotherapy, procedures for IR are painful, physically invasive to the patient, and may need to be accomplished over several treatment sessions. Treatment may be required electively or urgently.¹¹¹ Patients may require anesthesia along the continuum from minimal or moderate sedation/analgesia, local or regional anesthesia, with the trend moving toward general anesthesia because of the superior image quality obtained in a motionless patient, especially if the patient is held apneic for a brief period of time by the anesthetist.^{112,113} Studies have shown patients with acute ischemic strokes undergoing intraarterial therapy may have worse outcomes with

general anesthesia compared with conscious sedation.¹¹² Full monitors and IV access are required. Additional catheterization and monitoring of arterial pressure and central venous pressure may be necessary.^{113,115} Certain procedures require monitoring of the patient's neurophysiologic status for changes. The patient also may need to be assessed awake and then resedated at times during the procedure.¹¹⁷ Anesthetics that can be used are midazolam, propofol, ketamine, dexmedetomidine, and the other potent inhaled general anesthetics.^{111,113,114} Dexmedetomidine, a selective α_2 -adrenoreceptor agonist is being used for its reduction of intraoperative and postoperative anesthetic requirements.^{113,117} Rapid recovery from anesthesia to assess and monitor the patient's neurologic functioning at the end of the case is ideal.

It may be necessary to manipulate or manage normal systemic blood flow, normal cerebral blood flow, or other regional blood flow. The anesthetist may be called on to control deliberate hypertension or deliberate hypotension, manage anticoagulation, and manage unexpected procedural complications.¹¹³⁻¹¹⁵

Intraoperative radiation therapy (IORT) is the delivery of radiation to the patient via a linear accelerator, at times in conjunction with tumor surgery. If surgery is performed coincidental to the dose of radiation, normal tissues may be able to be moved away from the ionizing radiation beam. Normal tissues and organs can be shielded with lead beforehand. Some facilities use a dedicated IORT suite, whereas others use an operating room with transport of the patient to the radiation oncology suite. General anesthesia is performed if the surgical and radiation procedures are concurrent. All personnel must leave the room during IORT and stereotactically guided Gamma Knife or CyberKnife surgery so that high-dose radiation can be delivered to the patient while protecting personnel from the scattered radiation. The radiation oncology suite is heavily shielded and has a lead or iron door that can take from 30 to 60 seconds to open. The patient is monitored via closed-circuit video and hands-off anesthesia delivery during treatment.¹¹⁴

Complications can occur rapidly and be life threatening. Foremost is the possible complication of hemorrhage. A sedated patient experiencing hemorrhage may show sudden signs of

headache, nausea and vomiting, and vascular pain. A patient under general anesthesia may experience sudden bradycardia. The airway must be secured first if necessary, followed by support of the cardiovascular system, discontinuation of heparin, and administration of protamine (1 mg/100 units of total heparin dose administered). Other possible complications are radiocontrast reactions, embolization of particles or tissue, perforation of an aneurysm, and unintended obliteration of physiologically necessary arteries. Patient safety necessitates skilled and competent staff assistance in treatment of complications. Complications may necessitate the safe transfer of the patient to the operating room.¹¹³⁻¹¹⁵

Postanesthesia Care

Physiologic stability is the goal in any patient undergoing a radiologic or diagnostic procedure. The patient must be observed for possible reactions to dyes administered by the radiologist. The patient must be relieved of pain. Cardiovascular status must be stable. Hospital admission may be necessary for observation after any complication experienced by the patient or suspected to have occurred. One should always err on the side of patient safety and patient welfare.

Remote Anesthetic Monitoring Using Telecommunication Technology

Telecommunications technologies are being implemented to improve access and optimize care. First used in primary care over 30 years ago to gain specialty consultation from a distance, telecommunication technologies are now advancing throughout health care disciplines and specialties.¹²³ Communication technology, in conjunction with reliable and accurate electronic monitoring (telemonitoring), has made it possible to provide anesthetic monitoring and consultation with the anesthetist in one location while the therapeutic or diagnostic proceduralist is in another physically remote, geographically isolated, or environmentally extreme environment. The anesthetist may be involved with communication and monitoring through a variety of synchronous communication methods involving land-line telephone, cellular telephone, computer/monitor interlinks, and Internet audio-videoconferencing. The purposes of telemonitoring are the benefits to patients requiring therapeutic or diagnostic procedures with the added safety of available expert specialty care to assist the anesthetist in performing anesthesia in a challenging environment. Anesthetists can collaborate and use their combined skills during the entire anesthetic procedure, from preoperative planning to postprocedure care and eventual discharge.

Summary

New procedures and patient treatments are evolving and moving out of the traditional operating room and into nonoperating room anesthesia (NORA) environments. This demands evolution of anesthesia providers, equipment, and techniques for the provision of anesthesia services to patients in need of such services. Although anesthesia providers are required to be flexible in order to adapt to these dynamic changes in the health care world, this should never be at the cost of patient safety. The same standards of care that apply in the operating room setting should always be adhered to outside of the traditional operating suite. Clinicians must be absolutely comfortable that all required equipment, medications, and supplies are available, as would be true in a typical, fully equipped operating room. It is easier and safer to prepare beforehand than to gather the items needed for safe anesthesia delivery later, or go without them. Where cases of “minor” surgery or patient intervention may exist, cases of “minor” anesthesia do not.

Anesthesia Complications

M. Roseann Diehl, Kay K. Sanders

Every day health care professionals practice within enormously complex environments and unexpected patient outcomes or complications can occur at any time. Public interest regarding patient safety has increased significantly over the past decade, largely as a result of the staggering number of preventable deaths cited in the Institute of Medicine's 1999 landmark report.¹ The results of this report have led to implementation of a broad range of improvement efforts concentrating on the prevention and detection of errors in health care. Complications can arise as consequences of another concurrent disease or of mishap. Often these complications appear unexpectedly, and they have been experienced by well-intentioned health care professionals, who are surrounded by complex clinical conditions, poorly designed processes, and suboptimal communication patterns.^{2,3}

This chapter is more than a simple compilation and review of various types of anesthetic complications. The chapter goal is to provide more insight into common and emerging types of anesthetic complications, and to introduce organizational concepts that often surround complications in anesthesia. This chapter will discuss how to deal with complications systematically and examine the underlying human factors and lapses in communication involved in the development of these complications.

Mortality in Anesthesia

Risks related to anesthesia have declined over the past several decades. However, the exact cause of this decline is unclear.^{4,5} Anesthesia has had a tenfold decrease in mortality since the 1980s and is often cited as reaching a six-sigma defect rate (99.99966% of end-products are statistically free of defects, or 3.4 defects per million).^{4,6} Outcome measures studied related to the risk of anesthesia include mortality, morbidity, patient satisfaction, and quality of life.⁷ Perioperative risk related to anesthesia is multifactorial and depends on several interactions between anesthesia type, surgical procedure/location, and patient health.⁵ The dramatic improvement in anesthesia patient safety over the last 30 years was not initiated by electronic monitors. It was largely by a set of behaviors known as *safety monitoring* that were then made decidedly more effective by extending the human senses through electronic monitoring, for example, capnography and pulse oximetry.⁸

Death attributable to anesthesia is rare.⁹ Mortality data are difficult to use when extrapolating conclusions about anesthesia safety, because no standard definition of anesthesia mortality has been established. There is a lack of consensus related to the period postanesthesia that should define anesthesia-related mortality. In addition, significant morbidity involving patients who do not die has not been considered in regard to safety. Depending on which studies are referenced, this time frame can vary from 24 hours to 30 days postanesthesia.^{5,6,10}

Another issue that clouds morbidity and mortality outcome data is the fact that older patients with multimorbidities are now considered operable (e.g., less invasive procedures) resulting in skewed perioperative surgical and anesthetic risk.⁸ Actual data are difficult to analyze because most studies use coroner's registries, voluntary reports, surveys, and malpractice claims as primary data sources for perioperative death. As a result, prevalence data available for anesthesia-related mortality are approximate estimates as documented in [Table 59.1](#).

TABLE 59.1**Anesthesia-Related Deaths by Type of Complication (United States 1999–2005)**

Type of Complication	Number of Deaths	%
Complications of anesthesia during pregnancy, labor, and puerperium	79	3.6
Cardiac complications	60	2.7
Overdose of anesthetics	1030	46.6
Inhaled anesthetics	233	10.5
IV anesthetics	419	19.0
Other and unspecified general anesthetics	254	11.5
Local anesthetics	86	3.9
Unspecified anesthetics	38	1.7
Adverse effects of anesthetics in therapeutic use	940	42.5
Opioids and related analgesics	439	19.9
Benzodiazepines	42	1.9
Opioids and related analgesics	40	1.8

Adapted from Haller G, et al. Morbidity in anaesthesia: today and tomorrow, *Best Pract Res Clin Anaesthesiol.* 2011;25(2):123–132; Li G, et al. Epidemiology of anesthesia-related mortality in the United States, 1999–2005. *Anesthesiology.* 2009;110(4):759–765.

Anesthesia risk has evolved significantly as a result of improvements in drug efficacy, equipment safety, and operative/procedural setting. Over 60% of surgical procedures are now performed in an ambulatory setting. Procedures associated with greater perioperative risk are increasingly being performed on an outpatient basis, and the use of regional techniques has increased.¹¹ As a result, claim areas in which a reported mortality increase has occurred over the years include regional anesthesia (16% of all claims), chronic pain management (18% of all claims), and acute pain (9% of all claims).⁷ By contrast, claims related specifically to surgical anesthesia have declined from 80% during the 1980s to 65% as compared to all anesthesia malpractice claims since 2000.⁷

The American Society of Anesthesiologists (ASA) classifies patient physical status related to incidence of mortality on a scale of 1 to 5 based on comorbid conditions, 1 being the healthiest individual with no comorbidities, and 5 being the individual that

will likely die if surgery is not performed within 24 hours. The most current incidence of anesthesia mortality in a patient with an ASA physical status of 1 is 0.04 per 10,000 (0.0004%) anesthetics. Patients with comorbid conditions have higher risk. For example, an ASA physical status 2 risk is 0.5 per 10,000 (0.005%) anesthetics, an ASA physical status 3 risk is 2.7 per 10,000 (0.027%) anesthetics, and an ASA physical status 4 risk is 5.5 per 10,000 (0.055%) anesthetics.¹¹ Death still remains the leading outcome in the ASA Closed Claims Project database representing 26% of the most common complications from 1990 to 2007.⁷

Morbidity in Anesthesia

The term *morbidity* is indicative of disease, incorporating any complication, excluding death occurring during the perioperative period (Box 59.1). The most common events leading to injury in anesthesia claims included regional blocks (20% of claims), respiratory problems (17% of claims), cardiovascular events (13% of claims), and equipment problems (10% of claims)^{7,9} (Box 59.2).

Morbidity Classification

Minor morbidity: Moderate distress without prolonging hospital stay. No permanent complications (e.g., postoperative nausea and vomiting).

Intermediate morbidity: Serious distress prolonging hospital stay or both. No permanent complications (e.g., dental injury).

Major morbidity: Permanent disability or complication (e.g., spinal cord injury; anoxic brain injury).

From Haller G, et al. Morbidity in anaesthesia: today and tomorrow. *Best Pract Res Clin Anaesthesiol.* 2011;25(2):123–132.

Box 59.2

Complications of Anesthesia Identified by ASA Closed Claims Database

- Aspiration of gastric contents
- Failed intubation
- Esophageal intubation
- Other problems with the induction of general anesthesia
- Inadequate ventilation

- Airway obstruction
- Respiratory failure
- High spinal or massive epidural
- Neuraxial cardiac arrest
- Local anesthetic toxicity
- Drug reaction
- Anaphylaxis
- Overdose of sedatives
- Prolonged hypotension or hypertension
- Intraoperative cardiac arrest during anesthesia of undetermined etiology

ASA, American Society of Anesthetists.

From Metzner J, et al. Closed claims' analysis. *Best Pract Res Clin Anaesthesiol.* 2011;25:263–276.

Trends in anesthesia practice leading to morbidity claims have changed considerably over the last two decades. Acute pain claims have increased to 8% within the last decade, with no claims present 20 years ago. Chronic pain claims have also increased from less than 5% to 18% during the same time period. Monitored anesthesia care (MAC) claims have also increased from 2% to 10% over the decades. Obstetric claims trends have decreased, and regional anesthesia claims have remained steady at 20% to 25% over the last 20 years.⁷

The incidence of adverse outcomes with minor morbidity is quite high (18%–22%). For example, hoarseness has been cited to occur in 14% to 50% of patients and may accompany a traumatic lesion in the larynx or hypopharynx in 6.3% of patients. Drug errors (0.1%), equipment malfunction (0.23%), postoperative nausea and vomiting (10%–79%), accidental dural perforation (0.5–0.6%) are all fairly

common anesthesia-related morbidities. Therefore if morbidity is included in the definition of harm caused by anesthesia and linked to anesthesia safety within the framework of six sigma, then anesthesia remains far from being 99.99966% free of defects (Fig. 59.1).⁴

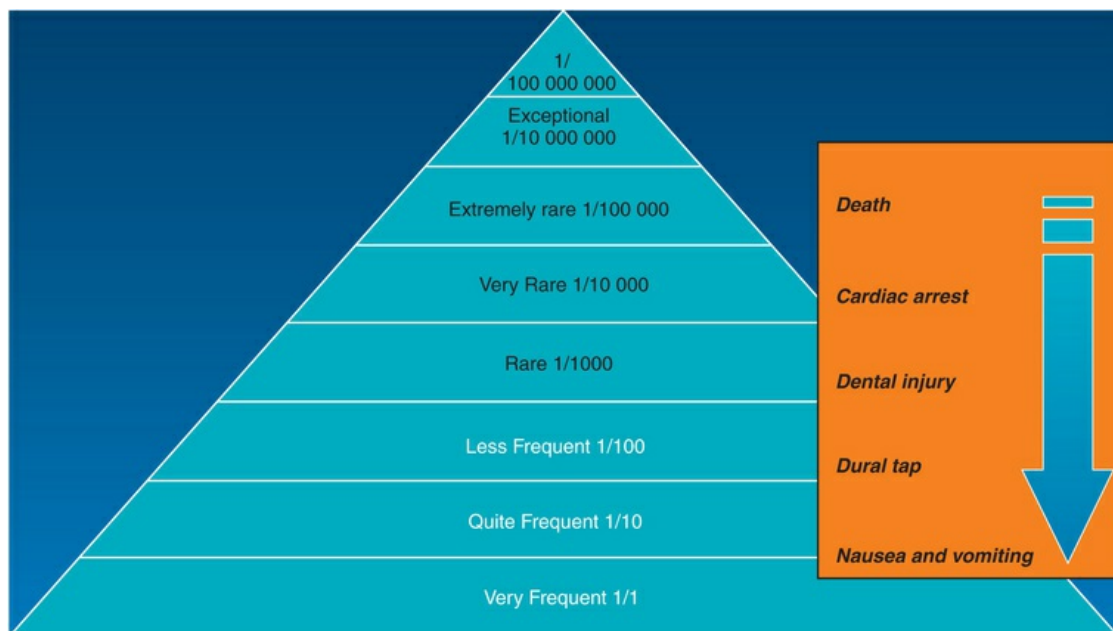

FIGURE 59.1 Anesthesia morbidity. (From Haller G, et al. Morbidity in anaesthesia: today and tomorrow. *Best Pract Res Clin Anaesthesiol.* 2011;25(2):123–132.)

Several areas within anesthesia continue to possess risk even today, including perioperative airway control during general anesthesia, perioperative management of hemorrhage, and circulatory perturbations associated with regional anesthesia. It is difficult to quantify human error related to morbidity, and more research should be conducted in this area.

Perioperative Mortality and Mortality Related to Human Error

Human error contribution to morbidity is a significant concern identified in 51% to 77% of anesthesia-related deaths.^{4,9} Teamwork and communication represent human factors that cause adverse outcomes, contributing to 43% to 65% of sentinel events occurring in the operating room (e.g., wrong side/site, transfusion error). Communication breakdown (oral 36%, written 20%) and absence of help (44% of failures) when needed also contribute to morbidity.⁴ Human factors related to complications is discussed in more detail later in this chapter.

Perioperative Mortality and Morbidity Related to Obstetrics

Anesthetic complications in the parturient are the seventh leading cause of pregnancy-related mortality in the United States, accounting for 1.6% of all pregnancy-related deaths. An 18-year retrospective study of maternal mortality was conducted in the state of Michigan, where all pregnancy-associated deaths within 1 year of the termination of pregnancy for any cause were reviewed. Eight anesthesia-related and seven anesthesia-contributing maternal deaths were cited, and the pattern of deaths illustrates three key points. First, all anesthesia-related deaths from airway obstruction or hypoventilation took place during emergence and recovery, not during induction of general anesthesia. Second, system errors contributed to the majority of deaths, for example, lapses in standard postoperative monitoring, missed diagnoses (e.g., cardiomyopathy, ischemic heart disease, sleep apnea). Third, obesity and African-American race are important risk factors associated with anesthesia-related maternal mortality.¹²

Perioperative Mortality and Morbidity Related to Pain

Future morbidity/mortality issues will likely include more acute and chronic pain issues, regional anesthesia, issues related to oversedation, and management of the difficult airway. Analysis of these rare events is imperative and can improve practice and ultimately patient safety. According to the Anesthesia Patient Safety Foundation (APSF), anesthesia-related mortality does not directly reflect patient safety during anesthesia. No patient should be harmed during anesthesia, but when a critical event does occur resulting in morbidity, the incident should be explored together with anesthesia-related mortality in order to assess the true level of patient safety during anesthesia.¹³

Perioperative Mortality and Morbidity Over 70 Years of Age

The population of older patients is growing in number, and increasingly these patients require surgery and anesthesia. Preventing, detecting, and managing morbidity and mortality is the greatest challenge facing anesthesia providers in this patient population. Several large studies using worldwide databases have recently been published with an attempt to identify patient risk factors that could predict postoperative mortality. The most important resource available to date related to exploring complications and mortality after surgery is the National Surgical Quality Improvement Program (NSQIP) database in the United States. The NSQIP was established in the early 1990s as part of the U.S. Veterans Health Administration, is now run by the American College of Surgeons, and contains data on millions of surgical patients. The database has been associated with hundreds of publications centered on perioperative risk.¹⁴

One such study from the NSQIP database extracted data on 25,000 patients aged 80 years or more and 550,000 patients aged less than 80 years, who had noncardiac surgery under general, spinal, or epidural anesthesia. In the cohort over 80 years of age, the top five variables associated with 30-day mortality were: (1) ASA physical status, (2) preoperative plasma albumin concentration, (3) emergency surgery, (4) preoperative functional status, and (5) preoperative renal impairment.^{14,15}

The Australian and New Zealand College of Anaesthetists Trials Group have published the Research into Elderly Patient Anaesthesia and Surgery Outcome Numbers study (REASON study), which is a prospective observational study of 4100 patients in 23 hospitals.^{15,16} Patients 70 years and older undergoing noncardiac surgery and expected to stay at least one night in the hospital were included. The major findings of this study are that 1 in 20 patients (5%) died within 30 days of surgery, and 1 in 5 (20%) had at least one major complication within 5 days of surgery. Four preoperative factors emerged predicting postoperative mortality

similar to the results of the NSQIP database study: age, ASA physical status, albumin, and those patients who had an accident and needed emergency surgery were at increased risk. A useful statistic from the REASON study is that patients aged 70 years, who were an ASA physical status 1 or 2, had a 30-day mortality of 1% for inpatient surgery. Patients 80 to 89 years had an odds ratio for 30-day mortality of 2.1, meaning that this age group is twice as likely to die when compared with healthy patients 10 years younger. Additionally, patients who were 90 years of age had an odds ratio for 30-day mortality of 4.0 or are 4 times as likely to have postoperative mortality when compared with healthy patients in their 70s (Table 59.2). The most important postoperative complications were systemic inflammation, acute renal impairment, and unplanned critical care admission.^{15,16}

TABLE 59.2

Factors Associated With Increased 30-Day Mortality

Factors	Odds Ratio Compared With Healthy 70-Year-Old Patients
Age 80–89	2.1
Age 90	4.0
ASA 3	3.1
ASA 4	12.4
Plasma albumin < 30 g/L	2.8
Emergent surgery	1.8
Thoracic surgery	2.6
Systemic inflammation	2.5
Acute renal impairment	3.3
Unplanned ICU admission	3.1

ASA, American Society of Anesthetists; ICU, intensive care unit.

From Story DA, et al. Complications and mortality in older surgical patients in Australia and New Zealand (the REASON study): a multicentre, prospective, observational study. *Anaesthesia*. 2010;65(10):1022–1030.

The National Confidential Inquiry into Patient Outcome and Death database in the United Kingdom reported on aspects of patient care and safety in 2010. This report explored remedial factors in the processes of care of patients aged 80 years and older who died within 30 days of a surgical procedure. Out of 1120 patients, 85% had an ASA physical classification of 3 or 4; most had nonelective surgery. Only one-third of the patients who died had acceptable perioperative care.¹⁶ The authors concluded that the

impact of comorbid conditions upon the frailty of a patient is underappreciated, and that increased vigilance in this patient population is warranted.

Until recently, the risk of surgery with accompanying anesthesia was viewed as the prime determinant of mortality. However, NSQIP data extracted from 8500 patients concluded that after accounting for age, ASA status, albumin, and emergency surgery, complexity was only important in approximately 5% of cases.¹⁶ This reinforced the fact that surgery itself was safe, and patient factors were more important than operative procedure factors.

One emerging area in the care of older patients is the attempt to define and quantify frailty and risk of postoperative complications. Five domains of frailty have been described as depicted in [Box 59.3](#). They include age, sex, comorbidities, physical status, and type of surgeries. Patients with 2 or 3 domains are considered to have intermediate frailty, and those having 4 to 5 domains are classified as frail. The odds ratio is 2.0 for postoperative complications in those who are considered to have intermediate frailty and 2.5 for [Box 59.3](#) patients.¹⁷

Domains of Frailty Measurements

1. Unintentional weight loss greater than 4 kg in the past year
2. Exhaustion measured by assessing effort and motivation
3. Decreased grip strength
4. Slowed walking speed
5. Low physical activity

From Makary MA, et al. Frailty as a predictor of surgical outcomes in older patients. *J American Coll Surg*. 2010;210(6):901-908.

Although age has often been the focus of perioperative concern, comorbidity, quantified with ASA physical status, is probably more important. Frailty is the new addition to this paradigm. Risk assessment should begin with patient factors that are more strongly associated with outcome than type of operation. Preoperative

albumin should be measured regularly in patients over 70 years of age.

Postoperative Cognitive Dysfunction

Postoperative cognitive changes after anesthesia have been reported in the elderly for over a century, and more recently in children displaying behavioral and developmental disorders after anesthesia.¹⁸ It has been postulated that anesthetic agents can produce neurotoxic effects leading to postoperative neurologic, developmental, and behavioral complications. Postoperative cognitive problems can be categorized as postoperative cognitive dysfunction (POCD), delirium, dementia, confusion, learning, and memory problems.

Advanced Age and Noncardiac Surgery

The two most common postoperative cognitive disorders in the elderly are delirium and POCD and both can be difficult to diagnose. A comparison of these two disorders can be found in [Table 59.3](#). Delirium is defined as a disturbance of consciousness that is accompanied by a change in cognition that cannot be attributed to a preexisting psychological state. Presenting symptoms of postoperative delirium are variable. Patients may exhibit hyper- or hypoactive cognitive or motor states.

Postoperative delirium usually occurs during the first postoperative days as an acute, fluctuating loss of orientation, and impairment of attention and memory. The incidence of delirium is approximately 20% in hospitalized elderly patients, and 80% in sedated intensive care unit (ICU) patients. Delirium is independently associated with increased hospital stay and mortality. Age and preexisting disease are important risk factors, in addition to medication side effects, electrolyte or fluid defects, and withdrawal symptoms.¹⁸ Delirium research has focused on identification and treatment of risk factors prior to surgery. Factors associated with an increased postoperative delirium include advancing age, sensory deprivation (visual or hearing impairment), sleep deprivation, social isolation, physical restraint, use of bladder catheter, polypharmacy, psychoactive drugs, comorbidities, severe illness, cognitive impairment, hyper-

/hypothermia, dehydration, malnutrition, and low serum albumin.¹⁹

TABLE 59.3

Characteristics of Postoperative Cognitive Problems in the Elderly

Postoperative Cognitive Problem	Onset	Symptoms	Anesthetic Issues
Delirium	Acute Hours/days	Decreased awareness of environment Fluctuating course Hyperactive state <ul style="list-style-type: none"> • Increased psychomotor activity • Rapid speech • Irritability • Restlessness • Disruptive to others Hypoactive state <ul style="list-style-type: none"> • Calm appearance • Inattention • Decreased mobility • Difficulty answering simple orientation questions • May be confused with depression/fatigue 	Avoid polypharmacy and long-acting sedatives (e.g., benzodiazepines) Use propofol, paracetamol, opioids as needed Regional techniques better Schedule surgery early after injury or illness Early geriatric consultation Effective pain management
POCD	Weeks/months (usually not detectable during first days after surgery)	Affects wide variety of cognitive domains <ul style="list-style-type: none"> • Memory • Information processing • Executive function Difficult to manage job Impaired attention Normal consciousness	Recognize risk factors Anesthetic issues undefined

POCD, Postoperative cognitive dysfunction.

Adapted from Monk TG, Price CC. Postoperative cognitive disorders. *Curr Opin Crit Care*. 2011;17(4): 376–381; Björkelund KB, et al. Reducing delirium in elderly patients with hip fracture: a multifactorial intervention study. *Acta Anaesthesiol Scand*. 2010;54(6): 678–688.

Recent randomized controlled trials (2016) suggest that pain management and depth of general anesthesia are important modifiable factors for postoperative delirium after hip fracture

surgery. Regional anesthesia with light propofol sedation compared with deep sedation was associated with a 50% decrease in postoperative delirium.¹⁹

Another study reported a 35% reduction in postoperative delirium after hip arthroplasty using a multifactorial approach. Perioperative interventions consisted of supplemental oxygen, systolic blood pressure greater than 90 mm Hg, transfusion for hemoglobin less than 10 g/dL, adequate pain relief, intravenous fluid supplementation, normothermia, avoidance of polypharmacy, spinal anesthesia, propofol sedation, and use of paracetamol (acetaminophen) in addition to opioids as needed.^{20,21} A Cochrane review concluded that there is no significant difference in mortality, pneumonia, myocardial infarction, cerebrovascular accident, acute confusional state, deep vein thrombosis, and return of the patient to their own home between regional anesthesia over general anesthesia²²

POCD presents as a subtle deterioration of memory, concentration, and information processing distinct from delirium and dementia, and it is not a formal psychiatric diagnosis. Neuropsychologic testing is necessary for detection and must show that an individual has new onset of deficits in at least two areas of cognitive function lasting for a period of at least 2 weeks, and diagnosis is made when all other neurocognitive disorders can be ruled out. These diagnostic criteria make it impossible to accurately identify POCD during hospital stay, and symptoms can persist for weeks or months postoperatively.

One of the first large prospective studies describing postoperative cognitive decline after noncardiac surgery described an incidence of 25% at 1 week and 10% at 3 months after surgery. Advancing age was the only significant predictor for POCD at 3 months after surgery. Other similarly designed studies report POCD in up to 40% of adult patients of all ages at hospital discharge.¹⁸

General anesthesia has been implicated as the cause of postoperative cognitive problems. However, the type of anesthesia may not impact long-term cognitive outcome. A study comparing coronary angiography with light sedation, total hip arthroplasty with general anesthesia, and coronary artery bypass graft surgery under general anesthesia found a 16% to 17% incidence of POCD at

3 months in all three groups. Therefore POCD may be independent of the type of anesthesia and surgical procedure.²³

The concept of cerebral oxygen reserve offers one hypothesis regarding the significant differences in the degree of cognitive symptoms. Patients with preoperative vascular risk factors may be at greater risk for POCD. Several other causes have been proposed, including brain hypoxia caused by arterial hypoxemia or low flow, residual concentrations of general anesthetics such as benzodiazepines, or long-lasting effects of general anesthetics on cholinergic or glutaminergic neurotransmission, in addition to psychological factors related to illness and environment during hospitalization.¹⁸

Advanced Age and Cardiac Surgery

The incidence of overall mortality after cardiac surgery has continued to decline and currently averages approximately 3%.²⁴ Delirium and POCD remain a major concern in patients undergoing cardiac procedures with a postoperative incidence ranging from 30% to 80%.²⁵ There is an assumption that the use of extracorporeal cardiopulmonary bypass is the primary culprit; however, large prospective randomized studies comparing on-pump versus off-pump bypass techniques have not shown any significant reduction in the incidence of postoperative neurologic injury.²⁶⁻²⁸ The causative factors could still involve the increased amount of atheromatous plaques and vascular disease in these patients, but this has yet to be clarified. Therefore efforts to reduce the incidence of postoperative neurologic injury have shifted focus towards patient risk factors (e.g., degree of aortic atherosclerosis, carotid arteries, and brain involvement).²⁵

Anesthetic Complications Related to the Growth and Development of Pediatric Brain

A great deal of concern has recently emerged regarding the safety of anesthesia in the pediatric population. Anesthetic agents have been implicated in pediatric developmental delays in patients who have undergone prolonged procedures and/or multiple procedures (Fig. 59.2).²⁹ A growing body of evidence in animals suggests that under certain circumstances, anesthetic drugs could adversely affect neurologic, cognitive, and social development of neonates and young children.^{29,30}

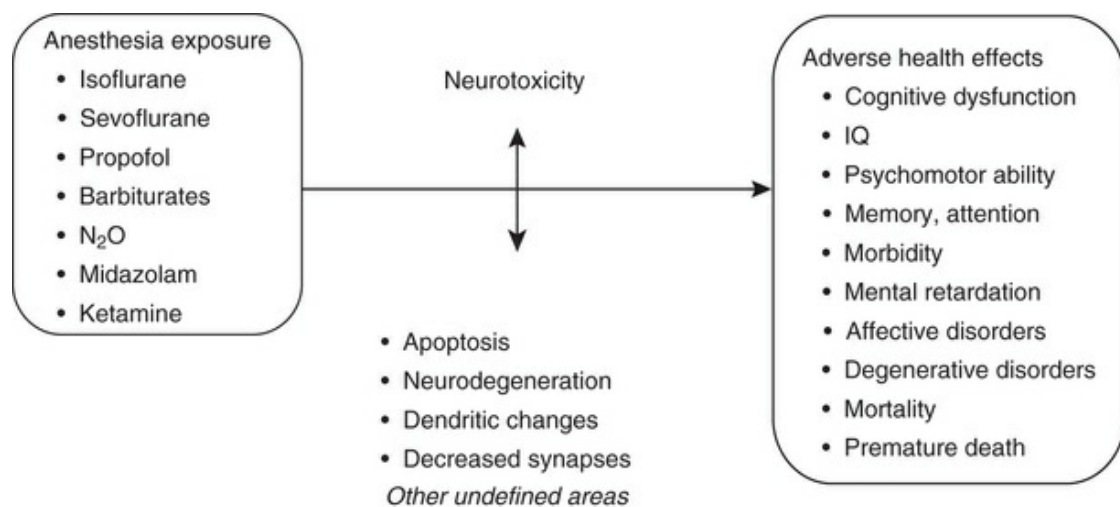

FIGURE 59.2 Conceptual framework for pediatric anesthetic neurotoxicity. N₂O, Nitrous oxide. (Adapted from Sun L, et al. Early childhood general anaesthesia exposure and neurocognitive development. *Br J Anaesth.* 2010; 105[(suppl 1):i61–i68.]

Exposure to certain anesthetic agents during sensitive periods of brain development in animal studies has been postulated to result in widespread neuronal apoptosis and functional deficits later in development. So far N-methyl-D-aspartate (NMDA) receptor antagonists and γ -aminobutyric acid (GABA) agonists have been implicated. However, no safe doses of these agents or safe duration of administration of these agents have been defined.^{29,31} For

example, 5-day-old nonhuman primates exposed to ketamine for either 9 or 24 hours experienced neuroapoptosis. A similar neurologic damaging effect was observed in the fetuses of pregnant rhesus monkeys (third trimester) exposed to ketamine for 24 hours. No effect was seen when ketamine exposure duration was 3 hours. Neuroapoptosis has also been demonstrated in primates given isoflurane on postnatal day 6.³⁰ The Food and Drug Administration and others are currently conducting more studies to address the neurocognitive and neurobehavioral aspects of anesthetic-induced apoptosis.

Studies in children have attempted to assess the effect of anesthetics on the developing human brain. A retrospective cohort analysis followed a birth cohort of 383 children who underwent inguinal hernia repair during the first 3 years of life, and compared them with 5050 children in a control sample who had undergone no hernia repair before the age of 3 years. The children who underwent hernia repair were twice as likely as those who did not to have a developmental delay or behavioral disorder.³⁰ Another study (2011) retrospectively examined children (younger than 4 years) who were exposed to a single anesthetic (n = 449), two anesthetics (n = 100), or more (n = 44) and how this related to the development of learning disabilities. No increased risk of learning disabilities was found with a single anesthetic. However, significant increased risk of learning disabilities was associated with two or more anesthetics and also increased with greater cumulative exposure to anesthesia.³¹

It appears that windows of anesthetic vulnerability exist that are dependent on the exposure time, amount, and type of anesthesia. However, no definitive conclusions can be drawn on the basis of these nonrandomized studies in humans because of the substantial potential for confounding and bias. Interpretation is difficult because of the retrospective nature of the studies, lack of precise information in terms of age, agent, duration, and dose of anesthetics, specific agents used, variable outcome end-points used, and the method outcomes that were assessed.²⁷ Although withholding anesthesia in children who need surgery is unreasonable, obtaining more information about safe use is imperative. If anesthetic agents are found to affect the developing

brain, strategies for mitigating and managing such risks can be implemented.²⁹⁻³¹ Anesthetic neurotoxicity is discussed further in [Chapter 8](#).

Perioperative Cardiopulmonary Complications

Intraoperative Cardiac Arrest

Currently cardiac arrest during anesthesia is usually a concomitant and not a causative factor. Incidence of intraoperative cardiac arrest has been cited as 0.2 to 1.1 per 10,000 adults and 1.4 to 2.9 per 10,000 children. Cardiac arrest during neuraxial anesthesia is less frequent compared to general anesthesia, with an incidence of 0.04 to 1.8 per 10,000 anesthetics. Causative factors can be grouped into categories: preoperative complications (65%), surgical procedures (24%), intraoperative pathologic events (9%), and those attributable to anesthetic management (2%).^{32,33} Excessive surgical bleeding can be identified in 70% of surgical procedure-related deaths, in addition to major causes of intraoperative pathologic events (e.g., myocardial ischemia, pulmonary embolism, and severe dysrhythmias). Fifty percent of anesthetic management–related events are caused by airway or ventilatory problems, followed by medication errors, and infusion/transfusion mishaps. Perioperative cardiac arrest is multifactorial in origin including factors such as patient comorbidities, inadequate risk estimation, inappropriate anesthetic management, and human error or misjudgment.^{32,33}

Sudden Cardiac Arrest

Sudden cardiac arrest (SCA) is a leading cause of death in the United States, accounting for an estimated 325,000 deaths each year. Approximately 6 cases per 100,000 individuals have been reported.³⁴ Ninety-five percent of victims die before ever reaching emergency assistance. The most common underlying substrate of SCA is ischemia and/or left ventricular dysfunction (Table 59.4).³⁵ Hypertrophic cardiomyopathy is the most common underlying cause of sudden cardiac death in young athletes.³⁴ However, there are also patients with preserved left ventricular function who are at risk for SCA. Many of these individuals are walking around with long QT syndrome (LQTS).³⁶ LQTS has gained increased attention

because of young athletes collapsing unexpectedly in SCA. It is an arrhythmogenic inherited or acquired cardiovascular disorder, with a prevalence of approximately 1 per 2500 to 10,000, which causes sudden death as a result of episodes of syncope, seizures, and ventricular tachycardia. Only approximately 60% of patients are symptomatic at the time of diagnosis. Induction of general anesthesia has provoked LQTS without any prior clinical diagnosis or preoperative abnormal clinical findings.³⁷ Sudden sympathetic stimulation during intubation may be a cause, or it could be QTc (interval corrected for heart rate) prolongation, and drugs that have positive adrenergic properties (e.g., ketamine, pancuronium). Careful anesthetic management should include treatment with β -blockers preoperatively. Heart rate should be maintained below 130 beats/minute. It is recommended that any pharmacologic agents that have the potential to further prolong the QT interval should be avoided (Table 59.5).³⁸ Episodes of torsades de pointes may be short lived and self-terminating, but magnesium sulfate is considered to be the treatment of choice. Temporary pacing is also an effective method for controlling torsades de pointes (Fig. 59.3).³⁷⁻³⁹

TABLE 59.4
Causes of Sudden Cardiac Death

Underlying Heart Disease	Incidence	Description
Ischemic heart disease	Greater than 50% luminal narrowing Less than 20 yr, 0% 20–29 yr, 24% 30–40 yr, 58%	Atherosclerotic coronary artery disease, generally with normal cardiac function
Sudden arrhythmic death syndrome	Brugada syndrome 5 : 10,000 (0.05%) Long QT syndrome 1 : 2500 (0.04%) Short QT syndrome Catecholaminergic polymorphic VT 1: 10,000 (0.01%) Wolff-Parkinson-White syndrome 0.9%–3%	Brugada syndrome—hereditary channelopathy with right ventricular conduction delay and ST elevation in right precordial leads (dome or cove-like) associated with incomplete or complete right bundle-branch block and ultimately VF Long QT syndrome—channelopathy with QT interval (greater than 480 msec) Short QT syndrome—channelopathy with QT interval (less than 340 msec) Catecholaminergic polymorphic VT—genetically mediated, cardiac channelopathy induced by exercise or emotional stress with structurally normal hearts Wolff-Parkinson-White syndrome—preexcitation syndrome with an accessory pathway (Bundle of Kent) causing atrioventricular reentrant tachycardia and/or VF with structurally normal hearts; shortened PR, delta waves, and widened QRS may be present

Hypertrophic cardiomyopathy (HCM)	1 : 500 (0.2%) of general population 36% of all sudden cardiac deaths (additional 10% of cases have unexplained increase in cardiac mass not meeting full criteria for HCM)	Inherited disease characterized by myocyte disarray, asymmetric hypertrophy of left ventricle (typically at the septum), occasional LV outflow tract obstruction, and predisposition for unstable ventricular arrhythmias
Arrhythmogenic right ventricular cardiomyopathy	1 : 5000 (0.02%) general population	Right ventricular wall-thinning and fibrofatty tissue infiltration
Congenital right ventricular cardiomyopathy	18% congenitally abnormal coronary arteries 12% anomalous coronary artery origins and hypoplastic anatomy	Also called <i>arrhythmogenic right ventricular dysplasia</i> (ARVD); rare form of cardiomyopathy in which the heart muscle of the right ventricle is replaced by fat and/or fibrous tissue
Commotio cordis	5% (nonspecific causes) 19.9% (athletic injury)	Blunt chest wall impact
Myocarditis	Less than 5%	Myocardial inflammation
Aortic disorder	3%–8%	Thoracic dissection/rupture

LV, Left ventricle; VF, ventricular fibrillation; VT, ventricular tachycardia.

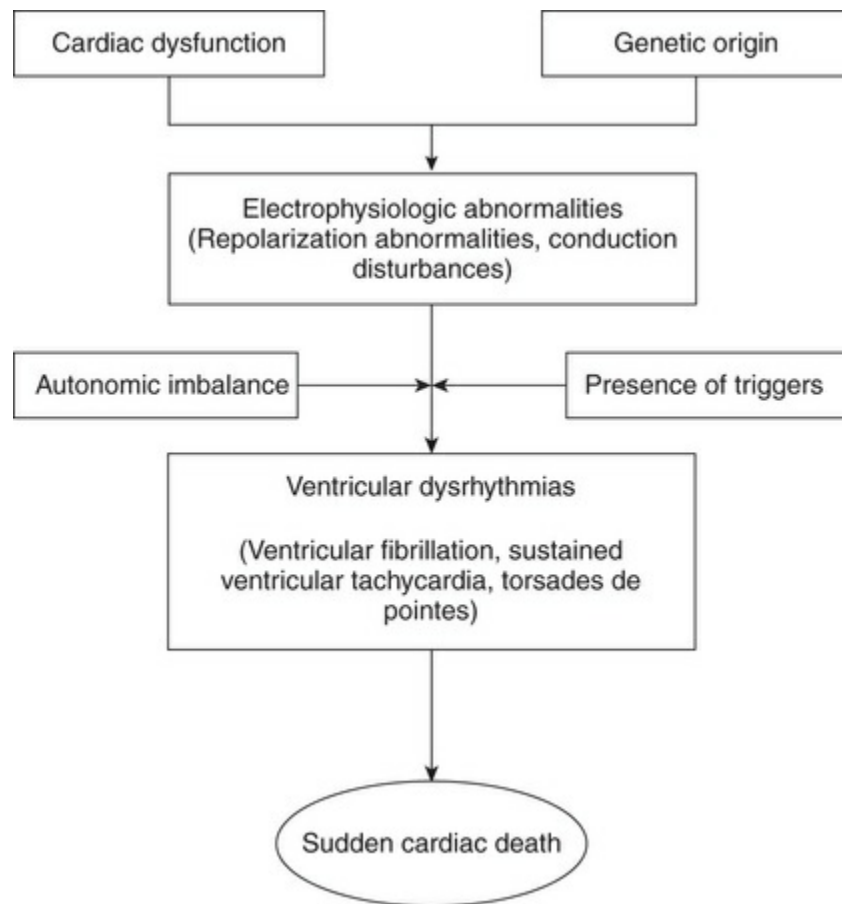

FIGURE 59.3 Mechanisms of sudden cardiac arrest. (From Ikeda T, et al. Risk stratification for sudden cardiac death. *Circ J.* 2007;71[suppl A]:A106–A114.)

Perioperative episodes of SCA in the pediatric population sparked the formation of the Pediatric Perioperative Cardiac Arrest Registry in 1994 to study the causes and outcomes from perioperative cardiac arrests in anesthetized children. Results from a recent examination of arrests, 1998 to 2005, indicate that cardiovascular causes of arrest accounted for the highest proportion of arrests (41%); among these the most common identifiable single

cause is hypovolemia related to underestimation of blood loss and inadequate peripheral IV access (Fig. 59.4).⁴⁰ Cardiac arrests resulting from medication errors were most common during the mid-1990s; this statistic has dropped significantly during more recent years. One explanation for this change is a decline in the incidence of cardiac depression resulting from the decreased use of halothane.⁴⁰

FIGURE 59.4 Causes of anesthesia-related cardiac arrests in children 1 to 18 years of age. (From Bhananker SM, et al. Anesthesia-related cardiac arrest in children: update from the Pediatric Perioperative Cardiac Arrest Registry. *Anesth Analg.* 2007;105[2]:344–350.)

Myocardial Infarction

The Perioperative Ischemic Evaluation (POISE) trial data using surgical data from 56 countries suggests that perioperative myocardial infarction (MI) is the most common cardiovascular complication after noncardiac surgery, with an incidence of 5% in patients 45 years or older with cardiovascular risk factors.⁴¹ Patients who suffer a perioperative MI have a 30-day mortality of between 11.6% and 21.6%.⁴⁰ Over 200 million noncardiac surgical procedures are performed annually worldwide, which equates to 10 million perioperative MIs and more than 1.1 million deaths. This is a

significant public burden considering that perioperative MIs are commonly undiagnosed and undertreated.⁴¹

Characteristics and short-term prognosis of perioperative MI have evolved over the past two decades. Fewer patients with nonoperative MI have ST-segment elevation, and more patients have non-ST segment elevation. Short-term mortality is decreasing. A large cohort study using POISE data extracted from over 8000 patients reported that most MIs occur within 48 hours of surgery (74.1%), and 65.5% are asymptomatic.⁴² Independent predictors of perioperative MI from this cohort are depicted in [Table 59.6](#).

TABLE 59.6

Independent Predictors of Perioperative Myocardial Infarction

Independent Predictor	Adjusted Odds Ratio (95% CI) for Association with Perioperative MI
Every 10-beats/min increase in baseline heart rate	1.29 (1.13–1.50)
History of stroke	2.24 (1.20–4.20)
Undergoing major vascular surgery	2.21 (1.15–4.25)
Preoperative serum creatinine level greater than 2.0 mg/dL	4.33 (2.32–8.09)
Age per decile increase	1.53 (1.20–1.95)
Emergency or urgent surgery	2.94 (1.65–5.26)
Serious bleeding, 2 units or more	3.62 (2.07–6.36)

CI, Confidence interval; MI, myocardial infarction.

From Devereaux PJ. Characteristics and short-term prognosis of perioperative myocardial infarction in patients undergoing noncardiac surgery: a cohort study. *Ann Intern Med.* 2011;154(8):523–528.

Perioperative Pulmonary Complications Associated With Supraglottic Devices and Endotracheal Intubation

Perioperative pulmonary complications are common, often equal to or outnumbering cardiac events. There is no unifying definition of what constitutes a postoperative pulmonary complication (POPC). Commonly cited POPCs are listed in [Box 59.4](#).⁴³ This discussion highlights the complications associated with manipulation and [management](#) of the airway.

Commonly Cited Postoperative Pulmonary Complications

- Laryngospasm
- Bronchospasm
- Airway obstruction
- Desaturation
- Pneumonia
- Pulmonary embolism
- Aspiration pneumonia
- Reintubation/mechanical ventilation without identifiable cause
- Severe coughing
- Stridor
- Pleural effusion
- Pneumothorax
- Respiratory infection not otherwise specified
- Aspiration pneumonitis

From Johnson DC, Kaplan LJ. Perioperative pulmonary complications. *Curr Opin Crit Care.* 2011;17(4):362–369.

Supraglottic Devices

Airway mortality does not happen because of failure to intubate. Airway mortality occurs as a result of failure to ventilate. A major challenge for any evidence-based evaluation of airway management techniques is the extremely low incidence of severe adverse events directly attributed to inadequate ventilation.

Incidence of difficult mask ventilation has been cited to be 1.4% to 5%.⁴⁴⁻⁴⁶ A 2009 study of 94,630 anesthetics reported impossible mask ventilation in 0.2% of patients, and within this group 25% were also difficult to intubate.⁴⁶ Combined difficult mask ventilation and difficult intubation was encountered 0.4% of the time. Finally the incidence of cannot ventilate–cannot intubate is a very small but devastating 0.008%.⁴⁷ Complications related to mask ventilation are underappreciated and underestimated and listed in **Box 59.5**

Airway Management Complications

Mask Ventilation

- Mucosal, skin irritation, conjunctivitis caused by cleansing agents
- Soft-tissue damage from excessive pressure
- Corneal abrasion, retinal artery occlusion, blindness
- Damage to mandibular branch of facial nerve causing transient facial nerve paralysis
- Damage to mental nerves causing lower lip numbness
- Broken teeth, mucosal tears
- Worsening obstruction from malposition of tongue
- Subluxation of the temporomandibular joint
- Gastric distention increasing risk for aspiration
- Gastric rupture
- Subcutaneous emphysema

Laryngeal Mask Airway

- Folding of epiglottis tip causing labored breathing, coughing, laryngospasm, and obstruction

- Excess lubricant that causes coughing or laryngospasm
- Lack of protection from aspiration of gastric contents
- Laryngospasm, coughing
- Sore throat
- Increased intracuff pressures with prolonged procedures using nitrous oxide and carbon dioxide
- Dysarthria
- Edema of epiglottis, uvula, posterior pharyngeal wall
- Hypoglossal nerve paralysis
- Postobstruction pulmonary edema
- Tongue cyanosis

Endotracheal Intubation

- Damage to teeth
- Mucosal injuries
- Lip injuries
- Swelling tongue
- Sore throat
- Trauma to larynx/vocal cords
- Arytenoid dislocation/subluxation
- Tracheobronchial trauma
- Barotrauma

- Nerve injury
- Cervical spine injury
- Vocal cord paralysis
- Temporomandibular joint injury
- Laryngospasm
- Bronchospasm
- Hemodynamic perturbations

Extubation

- Hemodynamic perturbations
- Laryngospasm
- Laryngeal edema
- Bronchospasm
- Negative-pressure pulmonary edema
- Aspiration
- Airway compromise
- Difficult/accidental extubation

From Hagberg C, et al. Complications of managing the airway. *Best Pract Res Clin Anesthesiol.* 2005;19(4):641–659.

Many airway devices exist today to assist with difficult or cannot ventilate and/or difficult to intubate situations. A considerable body of evidence (level 3b and 4) ([Table 59.7](#)),⁴⁸ over 300 publications (no greater than 3000), exists regarding successful use of the classic laryngeal mask airway (cLMA) in patients with difficult-to-manage airways. The intubating LMA has also been used successfully 97%

to 100% of the time for ventilation in both the anticipated and unanticipated difficult airway.^{49,50} Level 4 evidence of successful ventilation in patients with difficult airways was described for many other supraglottic devices in a 2011 review: LMA ProSeal, Supreme LMA, i-gel, Ambu Aura-I and air-Q intubating laryngeal airways, Cobra perilaryngeal airway, CobraPLUS, and Laryngeal Tube.^{49,50} However, even with current evidence of successful use of various supraglottic devices in difficult airways, there is still not enough evidence to judge one individual device superior.

TABLE 59.7

Levels of Evidence

Level of Evidence	Descriptor
1a	Systematic review of RCTs
1b	Single RCT
1c	All or none study (e.g., all individuals died before therapy was available, but some now survive on the therapy; or when some individuals die before the therapy became available, but now none die on the therapy)
2a	Systematic review of cohort studies
2b	Single cohort study or low-quality RCT
2c	Outcome studies investigating outcomes of health care practices using epidemiology to link outcomes (e.g., quality of care, quality of life)
3a	Systematic review of case-control or historical-control study
3b	Single case-control or historical-control study
4	Case report or case series
5	Expert opinion or ideas based on theory

RCT, Randomized controlled trial.

Adapted from Centre for Evidence-Based Medicine, 2011. Accessed 2016 at <http://www.cebm.net/>; Pandit JJ, et al. The difficult airway society ADEPT guidance on selecting airway devices: the basis of a strategy for equipment evaluation. *Anaesthesia*. 2011;66(8):726–737.

As useful as these devices are, they are not without complications. The LMA has been associated with inadequate seal, induced laryngospasm, and aspiration of gastric contents. Failed placement has been documented to occur in 1% to 5% of patients, although this decreases with operator experience.⁴⁷ Other supraglottic device complications tend to be similar to those found with the LMA and result from cuff overfilling, dislodgment, trauma during insertion, and insufficient anesthesia depth during insertion.⁴⁷

Endotracheal Intubation

The phrase “cannot intubate” represents an infrequent, but serious challenge for the provider, but also represents increased anesthetic risk to the patient. There is a close relationship between difficult intubation and traumatic intubation. Difficult intubation has been documented as a significant factor in 39% of all airway injury claims. Eighty-seven percent of these were temporary, and 8% resulted in death. In 21% of claims, the standard of care was not performed.⁴⁷ Airway management plans when dealing with difficult airways must have backup plans that require the same level of thought as the primary airway plan. All airway plans can fail. Early recognition by the anesthesia provider that the current plan is not working and good communication throughout the procedure are both crucial. This may seem obvious, but unless all plans have been thought out, the clinical situation can quickly deteriorate. To date, fiberoptic intubation of the spontaneously breathing patient is the gold standard for elective intubation in the anticipated difficult airway.⁵¹

Video laryngoscopy has emerged as an alternative for anticipated difficult airway cases and has become widely available.⁵² These devices may seem like a panacea for difficult airway management, but they have several limitations. Most devices are primarily designed for orotracheal intubation and require some mouth opening to allow the device to pass. Several case reports citing pharyngeal mucosal perforation and trauma while using the GlideScope have been published.^{53–55} This complication could be minimized by increased vigilance and visual observation when passing the rigid stylet because there is a potential blind spot in the oropharynx when attention is focused on the GlideScope monitor. Care should be taken to cautiously pass the endotracheal tube and not use unnecessary force during insertion or a too-large laryngoscope blade.

Complications of endotracheal intubation encompass both hemodynamic pathophysiologic effects in addition to associated anatomic injuries as depicted in [Box 59.5](#). Fifty percent of dental trauma occurs during laryngoscopy; sore throat occurs as often as 40%, and occurs greater than 65% when blood is noted on airway instruments. Trauma to the larynx, although not as common, has

been documented in 6.2% of cases, 4.5% of these developed vocal cord hematomas. Granulations of the laryngeal area can occur as a result of long-term intubation, and vocal cord paralysis can cause long-term hoarseness. Supraglottic complications induced by long-term intubation may be prevented by early tracheostomy.⁴⁷ For a more comprehensive list see [Box 59.5](#).

Intraoperative Awareness

Unintended awareness during the administration of anesthesia is a dreaded complication for the anesthesia provider and a significant source of fear for many patients. Awareness can occur during general anesthesia or monitored anesthesia care primarily as a result of underdosing of anesthesia relative to specific patient circumstances. An estimated 20,000 to 40,000 patients experience awareness during anesthesia annually in the United States alone, an incidence of approximately 0.1% to 0.4%.⁵⁶ The actual incidence of intraoperative awareness remains uncertain and likely is underestimated because of the limited nature of most postoperative interviews, which include the following: (1) no standardized or structured approach, and (2) single postoperative visitation by anesthesia personnel. As a result, many cases of awareness may not be elicited. The Brice Questionnaire developed in 1970 has been traditionally acknowledged as an accepted tool for detecting awareness postoperatively and has been modified over the years in recent studies (Box 59.6). A multicenter study in the United States estimated an incidence of awareness under general anesthesia with explicit recall (specific recollection of events) of approximately 0.023%, slightly lower than other large studies (0.13%).^{57,58} High-risk cases (e.g., trauma, obstetric, cardiovascular) possess 10 times the risk for awareness with an incidence of 1 case in 100.^{57,58} See [Box 59.6](#) list of risk factors for awareness.

Assessing Incidence of Awareness

Modified Brice Interview

- What was the last thing you remember before going to sleep?
- What is the first thing you remember after waking up?
- Do you remember anything between going to sleep and waking up?
- Did you dream during your procedure?

- What was the worst thing about your operation?

From Mashour GA, et al. Protocol for the Michigan Awareness Control Study: a prospective, randomized, controlled trial comparing electronic alerts based on bispectral index monitoring or minimum alveolar concentration for the prevention of intraoperative awareness. *BMC Anesthesiol.* 2009;9:7.

Box 59.7

Risk Factors for Awareness

- Female sex
- Age (younger adults, but not children),
- Obesity
- Clinician experience
- Previous awareness
- After normal hours operations
- Emergency procedures
- Type of surgery (obstetric, cardiac, thoracic)
- Use of nondepolarizing relaxants

From Pandit JJ. et al. 5th National Audit Project (NAP5) on accidental awareness during general anaesthesia: protocol, methods, and analysis of data. *Br J Anaesth.* 2014;113(4):540–548.

Episodes of awareness occur most often during maintenance of anesthesia, less during induction, and least during emergence. Patient movement has been cited in approximately 1 out of every 7 awareness case reports, and development of tachycardia and hypertension occurs in approximately 1 out of every 5 episodes of awareness.^{59,60}

Surprising cases of awareness have been cited by Mashour, et al,^{57,58} in a large study (n = 22,885) of patients who did not undergo general anesthesia, but received monitored anesthesia care 1 : 3269

(0.03%). This provocative finding indicated that awareness was not simply related to pain, but awareness itself was a source of distress. Several patients reported hearing unwanted conversations and remembered bright lights during their procedure inconsistent with their expectations, making them distraught. Therefore it might be prudent to spend more time preparing patients for such experiences in order to avoid disparities in expectations that could lead to complications of awareness discussed later in this section.

The concept of consciousness involves not simply brain arousal and recall, but also a subjective experience involving higher-order processes including memory. Explicit recall requires not only consciousness, but also involves memory. One of the most potent actions of general anesthetics is memory blockade or amnesia. Intravenous and inhalation anesthetics cause amnesia at doses considerably lower than those required for loss of consciousness and immobility. Propofol and midazolam cause greater memory blockade than fentanyl at equisedative doses. Retention of memory (studied after 24 hours) is also impaired by all anesthetics at relatively low concentrations (e.g., 0.2% isoflurane, 0.3% sevoflurane, 0.44% desflurane, 20% nitrous oxide). Finally, most anesthetics cause anterograde amnesia (i.e., loss of memory for a period after administration of the drug) but not reliable retrograde amnesia (i.e., loss of memory for events before administration of the drug). Intravenous anesthetics, including propofol and etomidate, cause anterograde amnesia and can also interfere with memory consolidation, or stabilization of memories after the initial acquisition.⁵⁸

Awareness is often associated with a high rate of posttraumatic stress disorder (PTSD), increases a patient's apprehension of future surgery, and enhances medicolegal risks associated with anesthesia. The B-Aware trial (2004), a randomized controlled trial studying awareness, reported a 71% incidence of postawareness PTSD.⁶¹ Not all patients who have documented intraoperative awareness develop PTSD, but initial emotional distress and the experience of paralysis have been cited as most predictive of developing PTSD. Postoperative sequelae reported related to PTSD include sleep disturbances (19%), nightmares (21%), fear of future anesthetics (20%), and daytime anxiety (17%).⁶⁰

Preventing intraoperative awareness may appear straightforward—give patients adequate anesthesia doses, keep them deep, and ensure that patients receive more-than-sufficient doses of intravenous and inhalational anesthetic agents. Unfortunately, there are no fail-safe methods for what constitutes sufficient dosing for each individual patient. It could be argued that routine administration of muscle relaxants is inhibiting observation of voluntary movement and should be minimized or avoided when possible. Nonetheless, patients who are distressed or in pain can be expected to manifest pain with sympathetic stimulation if anesthesia is light, thereby alerting the anesthesia provider to deepen the anesthetic. Vigilance is imperative.

Brain monitoring using bispectral index (BIS) values has become relatively common during general anesthesia to detect light anesthesia and decrease risk of awareness, although it does not ultimately prevent intraoperative awareness. BIS monitoring theoretically serves as an alert and helps to guide the titration of anesthesia along with other hemodynamic parameters. Currently all available brain-monitoring technologies have a nonlinear dose-response relationship, plateauing as doses reach higher levels. Therefore titration of anesthesia according to these devices may not be reliable. The risk of postoperative recall appears to be low if patients become light only briefly (less than 30 seconds), but increases if patients are awake for more than 30 seconds.⁵⁸

Studies hypothesizing that BIS monitoring protocols decrease intraoperative awareness have produced conflicting results. The B-Aware trial, involving 2500 patients, demonstrated that administration of anesthesia using a BIS monitoring protocol (maintaining BIS values between 40 and 60) compared with traditional anesthesia practice (end-tidal anesthetic concentrations) decreased intraoperative awareness by 0.74 percentage points in patients at high risk for awareness.⁶⁰ However, the B-Unaware trial (2008) demonstrated no reduction between a BIS monitoring protocol and using end-tidal anesthetic concentrations.⁵⁶ Both studies had lower than average incidences of awareness. A more recent trial (2009), the BIS or Anesthetic Gas to Reduce Explicit Recall (BAG-RECALL) trial, also demonstrated no significant differences in intraoperative awareness in high-risk populations

related to monitoring for awareness or not.⁶²

Incidence and consequences of pediatric intraoperative awareness data have been limited. Three studies evaluated awareness using semi-structured interviews modified for use in children with reported incidences between 0.6% and 2.7%.⁶³⁻⁶⁵ Forty-three percent of children reported feeling scared, and 21% reported hurting during their surgery. Psychological follow-up was deemed unnecessary in all cases, and none of the children or parents expressed concern. Additionally, 14% of children with possible/probable awareness stated they would feel worse if they had to undergo another anesthetic procedure in the future, which was similar to reports from children who did not experience awareness (15%). Data seem to suggest that children with awareness do not develop PTSD, but a child's report of intraoperative recall should not be readily dismissed and should be addressed with appropriate follow-up.⁶⁶

Complications Associated With Sedation and Anesthesia Outside of the Operating Room

Administration of sedation/anesthesia outside of the operating room is expanding with little outcome data regarding complications and adverse events. Some out of operating room locations, increasingly utilizing anesthesia services, include gastroenterology, and interventional radiology. Additionally, short, uncomfortable procedures (e.g., bone marrow biopsies, cardioversions), and procedures where the patient must lie still or can experience claustrophobia (magnetic resonance imaging, computed tomography scan) often require sedation and or general anesthesia.⁶⁷ A survey of 5000 gastroenterologists' sedation practices revealed that 79% of endoscopy patients had sedation performed by nurses under the supervision of a gastroenterologist, whereas an anesthesia provider only administered 29% of all sedation within the endoscopy suite.⁶⁸

Closed claims from anesthesia care outside of the operating room had a higher proportion of death that was primarily attributed to adverse respiratory events (44%). Respiratory depression secondary to oversedation and polypharmacy (propofol combined with other sedatives/analgesics) accounted for over one-third of the claims. Capnography was only employed in a minority of claims associated with oversedation (15%), and no respiratory monitoring was used in 15% of these claims.⁶⁷

Management of Complications

The aftermath of critical incidents and complications is equally as important as the incident itself, because incident investigation is a prerequisite for learning about the actions and events surrounding the critical incident and for prevention.^{69,70} It is important to view the critical incident from an organizational point of view after it has occurred. There are many documented systematic approaches for handling critical incidents. One approach is discussed in this chapter. It would be helpful for anesthesia providers to explore an individual institution's approach to handling critical incidents.

Organizational learning is an important strategy for improving patient safety. For quite some time, the focus on medicolegal risks has diverted attention from system-wide improvements with the potential to better meet the needs of patients, families, and health care providers. Patients, their families, supporting individuals, and health care professionals involved are all affected. Taking care of both the patient and their families is an important element of handling adverse events. Every health care organization should have a framework for handling critical events and complications embedded in effective communication between all parties involved, while also supporting the health care provider in the process.^{69,70}

Incident Reporting

Not all critical incidents lead to adverse outcomes or complications. Once a critical incident has occurred, it must be reported and investigated systematically. All critical incidents should be reported whether or not the outcome is negative.⁷¹ Any death occurring within 48 hours of an anesthetic should be evaluated for potential relevancy.¹¹ Effective risk management depends crucially on establishing a reporting culture.⁷⁰ Each hospital or health care institution should have a written, accessible policy to guide individuals how to best support patients and families, and also how to learn in a systematic way from the critical incident to minimize the likelihood of recurrence.

When a critical incident occurs, the anesthesia provider's first

obligation is to protect the patient from further harm, providing the care required, and mitigating further injury. Continuation of patient care by the same team, at least for a short period of time, is up to the individuals involved in the critical incident.^{69,70,72,73} After the critical incident is stabilized, actions to secure the area, brief the team, and analyze the incident should be taken. First, secure implicated drugs, equipment, and records for further investigation. Brief all members of the care team as soon as possible so all members are fully aware of the issues and all subsequent communications are consistent with the patient and family. Decide immediately who will have primary responsibility for communicating with the patient and family about the event. Determine the circumstances surrounding the adverse events and factors contributing to it as quickly as possible while memories of those involved are fresh. This information can be crucial to the immediate clinical treatment plan for the patient, as well as for analysis of the situation. Report the event to the appropriate institutional officer.⁷²

Root Cause Analysis

A retrospective analysis of the critical incident should ensue. One common example of this is called a *root cause analysis* (RCA). Root cause analysis is based on the premise that adverse events are caused, not by individual human errors, but by combinations of factors linked to organizational processes and structures, by which errors are missed and adverse events are not prevented.⁷⁴ The objective of an RCA is to systematically uncover multiple factors or causal chains that contribute to a critical incident, developing systems changes to make it less likely that the incident will recur. During this process, the importance of unbiased investigation and blame avoidance is important. The RCA process is organized in sequential steps including: (1) identifying the incidents/problem statement, (2) organizing a multidisciplinary team to conduct the RCA, (3) exploring processes involved, (4) collecting facts and written statements from all involved, (5) performing an evidence-based literature review, (6) identifying possible causes, (7) analyzing the data, (8) proposing possible actions, (9) writing a report, and (10) reevaluating actions taken.⁷⁵⁻⁷⁷ There is also broad

consensus that RCA represents a toolbox of approaches rather than a single method. A commitment to using some sort of systematic and disciplined approach should remain.⁷⁷

The first vital step in any RCA process is to identify the problem. Okes⁷⁶ has five components that should be answered when developing a problem statement, as shown in Table 59.8. The problem statement should represent cogent thinking and contain definitive, straightforward terminology that is well recognized and not misunderstood.

TABLE 59.8

Components of a Problem Statement When Conducting a Root Cause Analysis

What	What happened or should not have happened, or what change in performance is desired?
Where	Where specifically was the problem? This can be geographic, where in a process, and/or location on a piece of equipment.
Who	Who does this problem directly affect, either individual or group?
When	When was the problem first found or when did it begin?
How much	The frequency or magnitude of the problem: numbers provided should be absolute values plus percentages.

From Okes D. *Root Cause Analysis: The Core of Problem Solving and Corrective Action*. Milwaukee: American Society for Quality: Quality Press; 2009.

Step 2 calls for assembling a multidisciplinary group that will facilitate the process.

Step 3 seeks to understand the processes involved in and around the critical event. Why focus on process? Because everything individuals do on a daily basis is a process. Understanding the process is about stepping back and taking a broad view of the problem before jumping to possible causes. This step is especially important if the problem is thought to have been solved previously, but has recurred.⁷⁶ Keep the process boundaries internal to the organization, and limit them to those circumstances over which there is control. A flowchart diagram can be helpful for understanding the steps.

An example scenario would be a 48-year-old male undergoing a redo 3-level laminectomy, who awakened with bilateral blurry vision, only barely able to see shadows. It was concluded that that patient had developed postoperative vision loss. Previous medical

history included secondary hypertension and dyslipidemia. Vital signs included blood pressure 145/88 mm Hg, heart rate 78 beats/min, respiratory rate 14 breaths/min, and room air saturation 96%. Recent laboratory results included sodium 136 mEq/L, chloride 108 mEq/L, potassium 3.8 mEq/L, hemoglobin 14.3 g/dL, hematocrit 44%, and platelets 240 K/ μ L. The surgical procedure lasted 5.5 hours and the total anesthesia time was 6.2 hours. Estimated blood loss was 850 mL. Fig. 59.5 shows a sample flowchart diagram related to the postoperative visual loss.

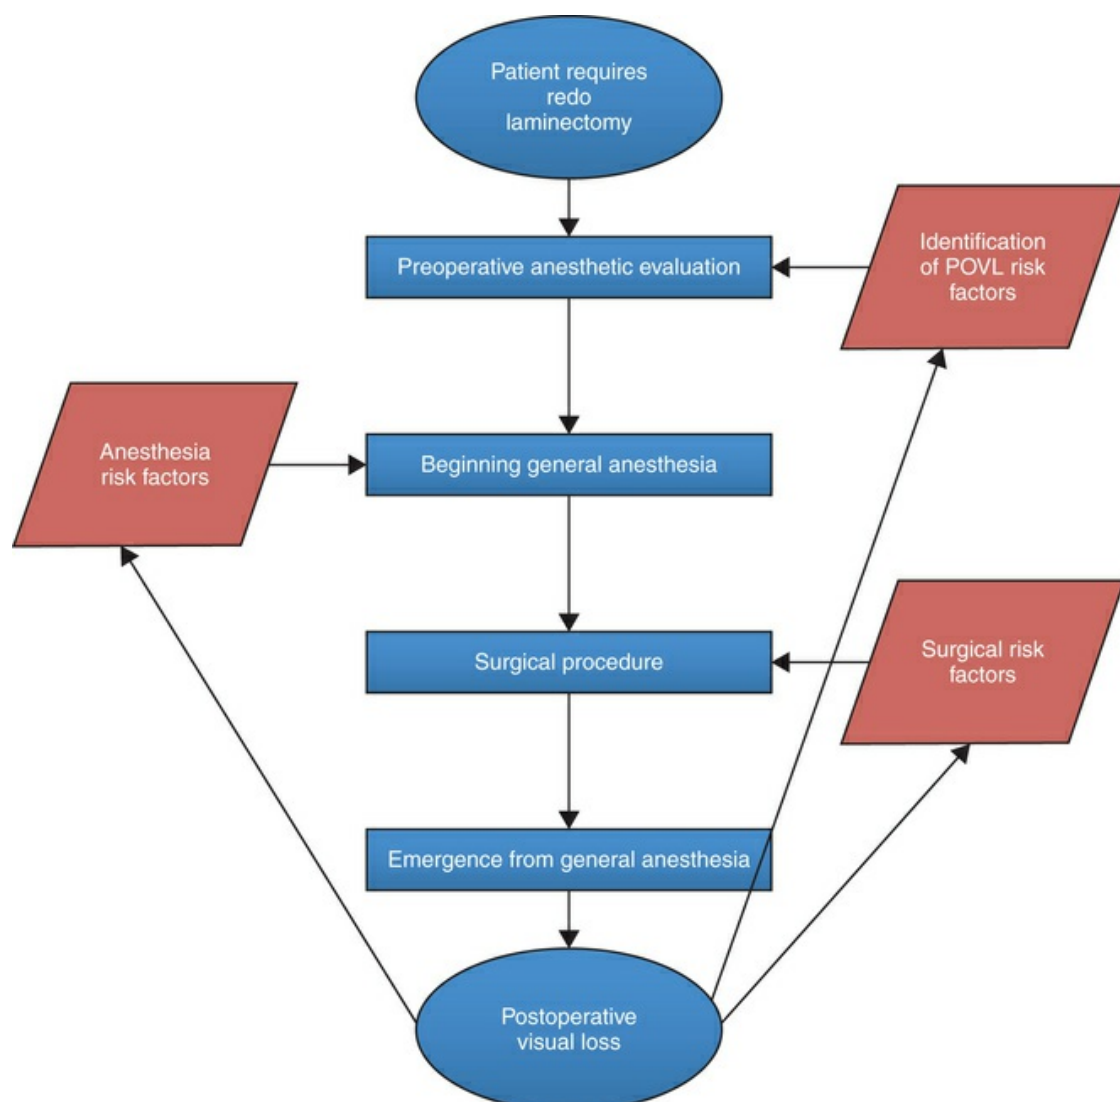

FIGURE 59.5 Sample flowchart diagram for Step 3, understanding the process, in a root cause analysis. *POVL*, Postoperative visual loss.

Step 4 entails collecting factual information and perspectives

from individuals involved. This should be performed by one individual and compiled for future use by the multidisciplinary group.

Step 5 involves developing a search strategy to locate meaningful, best-available evidence to support, refute, or reveal new information related to the critical event being studied. The essence of evidence-based decision making includes locating the latest and highest-quality information, combined with practitioner experience and skill, and incorporating the patient's desires as much as possible.⁷⁸ Locating needed information can be easily achieved by visiting the National Center for Biotechnology Information (NCBI) web-based database, which provides access to the National Library of Medicine and PubMed at <http://www.nlm.nih.gov>. The user should click on PubMed/MEDLINE and search using relevant terms. This website has multiple tools to help with searches. The Cochrane Database of Systematic Reviews and the Cumulative Index to Nursing and Allied Health Literature (CINAHL) databases are also helpful, quality web-based resources that can facilitate an evidence-based search. Other quality web-based resources exist, but the databases mentioned provide a solid, evidence-based foundation.

Once all pertinent data have been accumulated, brainstorming for all possible causes occurs in Step 6. Each brainstormed cause from the multidisciplinary group should ask the question “Why?” in order to form a connection to the critical event. A logic tree is helpful for depicting this thought process and for formulating relationships between each potential cause. An example of a logic tree related to the topic of postoperative visual loss in the scenario described earlier is shown in [Fig. 59.6](#).⁷⁶ Notice that the tree is hierarchical. The top level of the logic tree is the problem statement (or shorter description), and the next level lists potential causes across on the same level. Then each level below that should describe the causes. Each level of the tree is developed by asking “Why?” or how the previous step could have occurred. There is a recommendation to ask “Why” a minimum of 5 times in order to fully develop and ask the right question.⁷⁹

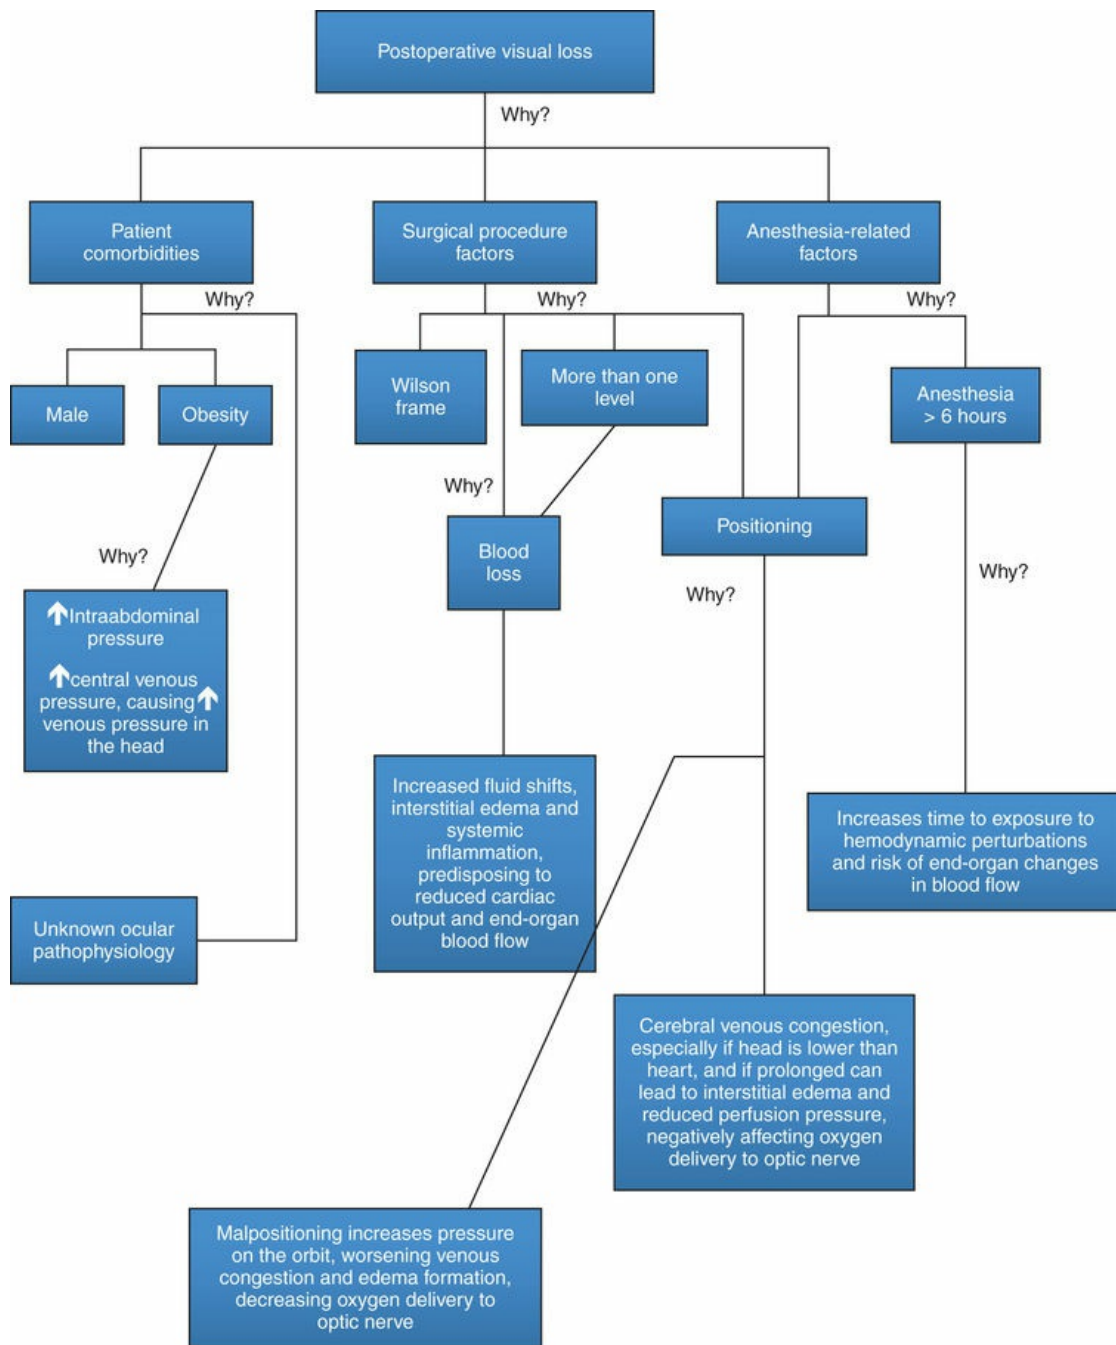

FIGURE 59.6 Sample logic tree diagram for Step 6, identifying potential cause, in a root cause analysis.

Step 7, data analysis, examines which of the causal theories appear plausible and which do not. Being clear about the theory (problem) to be tested and the data acquired to test for truth is important in analyzing each of the potential causes. Ask questions such as the following: What would the data look like if the theory (problem) were true? Do data collected support or deny the theory (problem) being tested? It is important to consider other conclusions the data might support, other ways to look at the same

data, and other data that might confirm or deny the same conclusions. This is where the multidisciplinary group becomes very helpful. There are many ways to analyze data using a variety of diagrams and tools that are beyond the scope of this chapter. Please consult the References section of this chapter to view excellent sources for a more detailed approach to data analysis.⁷⁶

Step 8 involves proposing possible actions related to the incident, event, or complication. This step should be embraced with caution as a tendency exists to formulate and accept only one idea or action that everyone thinks will work and then immediately implement it. Many tend to think that doing otherwise wastes time, but what is likely to happen is that the institution misses the opportunity to identify and implement breakthrough ideas. If a central idea has emerged, create a concept map expanding on that idea. The central idea is in the center of the diagram with lines connecting it to expanded or related concepts.^{76,78,80}

Writing a formal report related to the RCA process is vital for a successful Step 9. There are many methods for constructing a report, but primarily the report must be logical, cogent, and factual, **Box 59.8** and avoid of emotion or blame (**Box 59.8**).

Elements of a Root Cause Analysis Report

Executive Summary

- Incident description and consequences
- Preinvestigation risk assessment
- Background and context
- Terms of reference
- Members of the investigation team
- Scope and level of investigation
- Involvement and support of patient and relatives
- Involvement and support for staff involved

- Information and evidence gathered
- Chronology of events
- Detection of incident
- Notable practice
- Care and service delivery problems
- Contributory factors
- Root causes
- Lessons learned
- Recommendations
- Arrangements for shared learning
- Distribution

From Nicolini D, et al. Policy and practice in the use of root cause analysis to investigate clinical adverse events: mind the gap. *Soc Sci Med.* 2011;73(2):217–225.

Step 10 calls for reevaluation of actions taken within a certain predetermined time frame. Taking action without checking to see whether the process improvement worked is like shooting in the dark.⁷⁶

A vital aspect of RCA is that during discussions of adverse events, focus on the individual is removed. Therefore it is less likely that defensive behavior will occur and more likely that reflection on practice will occur openly. RCA can be used to reinforce good practice, support individuals involved in incidents so that they can come to terms with the event, and to explain to patients and families why care was suboptimal and what staff will do to prevent the event from recurring.⁷⁴

Disclosure

Open disclosure of a critical incident and timely communication

with patients and families is increasingly being emphasized and is largely responsible for decisions regarding legal action.^{69,70} Open disclosure includes accurate information about the critical incident, immediate consequences and remedial action, expression of regret, and other information about preventing such an incident from occurring again. A survey of 958 adults (31% reported experience with medical errors involving either themselves or another family member) revealed that not disclosing information was associated with lower patient satisfaction, less trust, and stronger negative emotional responses. Patients and families have interpreted health care provider silence as hiding information, covering up errors, or showing a lack of respect. Patients and families who take legal actions related to critical incidents do so in an effort to prevent that incident from ever happening again; they want an explanation and often feel abandoned. Patients and family members desire to make the physicians/health care providers realize what they have done.^{69,70} A recent interview study (n = 23) using open disclosure after a critical incident supported the positive aspects of open disclosure. All interviewees appreciated the opportunity to meet with staff to receive an explanation of the incident.⁸⁰ More research needs to be conducted in this area related to the full impact and techniques of open disclosure on patients, families, and health care providers. It is imperative that anesthesia providers comply with state law and/or institutional policies regarding disclosure and not **Box 59.9** disclosure as an individual endeavor (**Box 59.9**).

Process for Effective Disclosure

- Continuation of care
- Acknowledgement of incident and patient consequences
- Information on what happened and what to expect
- Apology (when appropriate)/expression of regret
- Advice about necessary treatment
- Information about preventing recurrence

- Tangible support regarding physical, psychological, social, and financial consequences

From Iedema R, et al. Practising Open Disclosure: clinical incident communication and systems improvement. *Sociol Health Illn.* 2009; 31(2):262–277.

The Second Victim

Complications, in the health care provider's eyes, have been described as the darkest hour of their professional career.⁸¹ Involvement of health care providers in critical incidents and the emotional turmoil that ensues is often regarded as taboo and to be avoided at all costs. No one wishes to be involved in the drama. Psychological stress and negative emotional responses can engulf the practitioner, creating serious health and performance deficits.^{69,70,81,82} This practitioner is called *the second victim*; a health care provider involved in an unanticipated adverse patient event who becomes victimized. The second victim is often traumatized by the critical/adverse event. Frequently these individuals feel personally responsible and believe they have failed their patients and begin second-guessing their clinical skills and knowledge.^{69,70,81} Some health care providers even report developing PTSD, sleep disturbances, and problems with irritability. As a result it becomes harder to work clinically and have job satisfaction. Published evidence addressing emotional and health-related effects of critical incidents on health care providers have looked only at short-term outcomes. However, a 2006 prospective longitudinal study examining medical errors by residents (n = 184) over a 3-year period found that self-perceived errors were common among trainees. These errors were associated with significant personal distress, burnout, loss of empathy, and increased risk of making another error.⁸³ Time to recovery from these symptoms lasted for several months.⁸²

Stages of Recovery

Health care providers who have been involved in a critical incident often develop their own unique way of coping. Six stages of recovery have been identified and are listed in [Box 59.10](#).⁸¹ The moment the critical incident occurs the involved clinician can usually describe chaotic and confusing scenarios of external and internal turmoil that ultimately lead to a realization about what happened. There is a period immediately after the incident of rapid

inquiry to verify exactly what happened. Additional clinicians are summoned to provide support. The victim is frequently distracted, immersed in self-reflection, while also trying to manage a patient in crisis. The second stage is characterized by haunted reenactments, often accompanied by feelings of internal inadequacy. The victim reevaluates the situation repeatedly with “what if” questions. Stage 3 is entered when the victim seeks support from a trusted individual, usually a colleague or supervisor, friend, or family member. One of the biggest challenges in this stage is an inability to move forward. Relentless introspection lingers related to “what will others think of me” and “will I ever be trusted again.” Then in Stage 4 the individual wonders what the ramifications from the institution will be and “will I ever practice again.” Second victims in Stage 5 seek out respected and safe colleagues again to confide in, often related to litigation issues. Stage 6 is a unique stage describing the second victim as moving on—dropping out, **Box 59.10** surviving or thriving.⁸¹

Stages of Second Victim Recovery

1. Chaos/accident response
2. Intrusive reflections
3. Restoring personal integrity
4. Enduring inquisition
5. Obtaining emotional first aid
6. Moving onward

From Scott SD, et al. Caring for our own: deploying a systemwide second victim rapid response team. *Jt Comm J Qual Patient Saf.* 2010; 36(5):233–240.

What do practitioners need emotionally and professionally after a critical incident involvement? Little evidence exists to address this issue, but four primary needs have been identified after a critical incident involvement: (1) talking to someone about what happened, (2) validation of decision-making process, (3) reaffirmation of

professional competence, and (4) personal reassurance.^{69,70} Colleagues and supervisors are perceived as being the most helpful people with whom to discuss the situation. However, evidence suggests that little support is obtained at an organizational level. This lack of support after a critical incident often causes the negative emotional responses and psychological stress to be sustained.⁸¹ Along with emotional needs, there are definite professional needs that should also be met. The anesthetist should consider speaking with the appropriate hospital administrators and possibly an attorney if there is litigation or expected litigation.⁸⁴

The Human Factor in Complications

Human Error

The term “human factors” describes human performance and behavior related to interaction with the environment.⁸⁵ Human factors have been identified in 51% to 77% of anesthesia-related deaths.¹⁰ Many cases are related to a lack of experience or competence observed in 89% of human failure–related deaths. Less frequently, errors of judgment or analysis have been detected in 11% of these deaths.⁴

The topic of human error is rich in myths such as error is intrinsically bad; bad people make bad errors; and errors are random and highly variable.⁷¹ Errors are not intrinsically bad, but instead are essential for coping with trial-and-error learning in novel situations. One of the basic rules of error management is that the best people can make the worst errors. Errors do not occur “out of the blue,” but can take on recurrent and predictable forms. Different errors occur in different situations. Errors can happen when individuals know what they are doing, but actions do not go as planned, taking the form of absent-minded slips and memory lapses. Errors also can happen when individuals think they know what they are doing, as in dealing with what appears to be a trained-for problem, but then misapply a normally good rule, apply a bad rule, or fail to apply a good rule. Errors are certain to occur when the individual is not sure what he or she is doing.⁷¹

Past concepts related to human error in health care have not embraced the statement that human error is inevitable, but tried to avoid or prevent human error, doing so without success.⁸⁶ It has been argued that judgments of human error should form the starting point of accident investigations, not be the explanation for the failure.^{86,87} Human involvement in complex systems is necessary and beneficial, because of our ability to adapt, our creativity, and our ability to be flexible.⁸⁶ This relevance of human factors in improving safety cannot be overstated. Even though we cannot change the human condition, we can change the conditions under which humans work.⁷¹

The aviation industry realized, embraced, and acted upon optimizing human factors to decrease human error more than 20 years ago. A systematic approach to safety at an organizational level is currently in practice in the aviation industry and recommended as an approach to dealing with human factors in anesthesia. This type of safety culture possesses certain features such as standard operating procedures, operations manuals, and checklists that could be incorporated into anesthetic practice; however, there is a certain amount of reluctance to embrace these tools, perhaps for fear of being constrained in exercising clinical judgment and critical thinking in addition to being forced to forego practical long-standing techniques.⁸⁶

A key concept related to human factors is the concept of resilience. Resilience is an everyday word synonymous with *buoyant*, *elastic*, and *flexible*, and it can describe an individual's ability to recover readily from illness, depression, or some other life adversity. The human factor perspective of resilience refers to the ability to understand how failure is avoided and how to learn from successes and error avoidance rather than simply conduct a reactive search for causes and remedies. It offers a systems-based approach to understanding how to stay safe proactively. Resilience is a positive human attribute that can be used to bounce back from errors made, learn from mistakes, and move forward. Resilience has the potential to provide significant advances in patient safety by shifting focus from an emphasis on human error and error counting, to preventing these errors from being repeated.⁸⁷⁻⁸⁹

Human factors that contribute to complications often include nontechnical skills and behaviors. Lack of communication and teamwork contribute to up to 80% of sentinel events occurring in the operating room (e.g., wrong side, transfusion error). The specialty of anesthesia has made huge strides in identifying human factors that lead to adverse events by examining the aviation industry. For example, poor flight team performance and a series of plane crashes in the 1980s became the trigger for the development of aviation's crew resource management (CRM).⁹⁰ Subsequently in the mid-1990s CRM was adapted to anesthesia practice in the form of anesthesia crisis resource management (ACRM) by David Gaba et al.⁹¹ Subsequently the development of a behavioral marker

system framework identifying and describing daily behaviors of good and poor anesthesia practice has been developed, called Anaesthetists' Non-Technical Skills (ANTS).⁹² An Anaesthetists' Non-Technical Skills rating tool also exists utilizing this ANTS framework (Fig. 59.7).⁹³

ANTS System –Observation and Rating Sheet	Consultant: _____ Trainee: _____ Date: _____
--	--

Categories	Elements	Observations	Element Rating	Debriefing notes and category rating
Task Management	Planning & preparing			
	Prioritising			
	Providing & maintaining standards			
	Identifying and utilising resources			
Team Working	Co-ordinating activities with team			
	Exchanging information			
	Using authority & assertiveness			
	Assessing capabilities			
	Supporting others			
Situation Awareness	Gathering information			
	Recognising & understanding			
	Anticipating			
Decision Making	Identifying options			
	Balancing risks & selecting options			
	Re-evaluating			

ANTS System –Observation and Rating Sheet
--

Additional Notes

Rating Options	Descriptor
4 – Good	Performance was of a consistently high standard, enhancing patient safety; it could be used as a positive example for others
3 – Acceptable	Performance was of a satisfactory standard but could be improved
2 – Marginal	Performance indicated cause for concern, considerable improvement is needed
1 – Poor	Performance endangered or potentially endangered patient safety, serious remediation is required
<i>Not observed</i>	Skill could not be observed in this scenario

Framework for Observing and Rating Anaesthetists' Non-Technical Skills. 2012. Available at <http://www.abdn.ac.uk/iprc/documents/ANTS%20Handbook%202012.pdf> Accessed 2017.)

Communication is fundamental in ACRM and ANTS to foster workplace efficiency and safety. Elements of good communication are not just verbal, but also nonverbal (Box 59.11). Good communication is a major part of good teamwork. Teamwork represents a distinguishable set of two or more people who interact dynamically, interdependently, and adaptively toward achieving a common goal, who have each been assigned specific roles or functions to perform, and who have a limited life span of membership (Box 59.12). Effective teamwork and communication do not happen alone, but must be developed through training. Training individuals working in a team is based upon developing competence, knowledge, skills, and attitude of individuals in addition to training objectives. Teams should develop identity, in which team members learn their own roles and tasks and understand those of other team members.^{71,92} Simulation provides a teaching and learning methodology that allows team members to practice ACRM and develop nontechnical skills and behaviors to improve teamwork and communication.⁴

Elements of Good Communication

- Send information clearly and concisely
- Include context and intent during information exchange
- Receive information, especially by listening
- Identify and address barriers to communication

From Flin R, et al. *Safety at the Sharp End: A Guide to Non-Technical Skills*. Burlington, VT: Ashgate Publishing Ltd; 2008.

Box 59.12

Elements of Team Working

- Supporting others
- Solving conflicts
- Exchanging information
- Coordinating activities

Fatigue

Fatigue is the largest identifiable and preventable cause of accidents. The aviation industry estimates that fatigue may involve 4% to 7% of civilian aviation accidents, and anywhere between 4% and 25% of military aviation accidents.^{92,94} Fatigue, anesthesia, and complications have not traditionally been discussed together, but are an expanding science of interest and a significant safety concern. Anesthesia care is a 24/7 profession, and consequently this can require long working hours, sustained vigilance, unpredictability of stressful situations, and production pressure.⁹² Currently no quantitative data exist regarding the incidence of complications in anesthesia related to the fatigued provider. Reducing work hours and allowing 24 hours of sleep time between shifts significantly impacted attentional failures (i.e., intrusion of slow rolling eye movements into confirmed episodes of wakefulness during work hours) in a small prospective study with interns.⁹⁴ The Joint Commission has published evidence-based actions that health care organizations can incorporate to help mitigate the risks of fatigue (Box 59.13).⁹⁵

The Joint Commission Action Suggestions for Health Care Provider Fatigue

1. Assess organizational fatigue-related risks (e.g., shift hours)
2. Assess patient handoff processes

3. Invite staff input for schedule design to promote less fatigue
4. Create and implement a fatigue management plan to help fight fatigue
 - a. Conversation
 - b. Strategic caffeination
 - c. Short naps (less than 45 minutes)
5. Educate staff about sleep hygiene and effects on patient safety
6. Provide opportunities for expressing concerns about fatigue
7. Encourage teamwork as a strategy to support staff working extended hours
8. Consider fatigue potentially contributing to adverse events

From Jeffcott SA, et al. Improving measurement in clinical handover. *Qual Saf Health Care*. 2009;18(4):272–277.

Stress

Every anesthesia provider knows what it feels like to be under stress, both professionally and personally. Stress can have both acute and chronic effects. Acute stress in humans can be related to the classic fight, flight, or freeze response.^{85,93} Chronic stress is related to conditions in the workplace and the individual's reaction to these over a period of time. Stress has been linked to safety outcomes, such as accident involvement. Because stress has been linked to accident involvement and safety outcomes, the ability to recognize and manage stress in self and others is an important nontechnical skill. Job demands, control over work activities, support, or lack thereof from managers or coworkers, poor relationships, uncertain work roles, uncertainty about change, and family-personal problems are all considered stressors. How each individual handles these with the resources available to them using

prior experience, training, personality, fitness, social support, and coping strategies will indicate whether the stress will have a positive or negative effect on the individual. The effects of stress on behavior are generally the most readily observable by work colleagues (Table 59.9). For example, a normally peaceful coworker becomes irritable, or a colleague who generally has a neat appearance begins to take less interest in how he or she looks.

TABLE 59.9
Indicators of Chronic Stress

Behavioral	Emotional	Somatic	Thinking	Organizational
<ul style="list-style-type: none"> • Absenteeism • Abuse of drugs • Hostile behavior • Apathy • Reduced productivity • Distracted • Careless errors 	<ul style="list-style-type: none"> • Anxiety • Hopelessness • Cynicism • Resentfulness • Depression • Irritability 	<ul style="list-style-type: none"> • Decline in physical appearance • Chronic fatigue • Frequent infections • Health complaints (e.g., headache, stomach) 	<ul style="list-style-type: none"> • Lack of concentration • Reduced attention • Difficulty in remembering • Impaired decision making • Failures in planning 	<ul style="list-style-type: none"> • High staff turnover • Absenteeism • Poor timekeeping • Decreased productivity • Increased client complaints • Increased employee compensation claims • More near-misses and accidents

Patient Handoff/Communication

Communication issues and breakdowns in communication have been estimated to contribute between 15% and 67% to the development of critical incidents.⁹⁶ In particular, communication at organizational interfaces (e.g., care transitions, shift changes) with changing responsibility for care is a key target for improvement.⁹⁷ A surgical patient undergoing elective surgery can have direct patient care change a minimum of at least four times (e.g., admission area, to surgery/anesthesia, to postanesthesia care area, to unit/floor).

A clinical handover/handoff or transfer of care is by definition “the transfer of professional responsibility and accountability for some or all aspects of care for a patient, groups of patients to another person or professional group on a temporary or permanent basis.”^{69,70,97,98} The Joint Commission defines handoffs as the real-

time process of passing patient-specific information from one caregiver to another or from one team of caregivers to another for the purpose of ensuring the continuity and safety of patient care.⁹⁹

Historically patient handover has not been studied systematically, which is in stark contrast to other high-risk industries where handovers have received considerable attention. Qualitative studies and surveys across different health care settings cite that handover processes are highly variable with widespread dissatisfaction among physicians and nurses.^{69,70,96} As a result, patient handover has been recognized as a safety initiative by the World Health Organization (WHO) Alliance for Patient Safety and the WHO Collaborating Center for Patient Safety and is listed as one of the National Patient Safety Goals by The Joint Commission.⁹⁹ There has been a substantial increase in research activity and literature reviews across health care disciplines focusing on a specific type of handover in a specific clinical setting (e.g., nursing, physicians, perioperative care area)^{96,100,101} (Fig. 59.8).

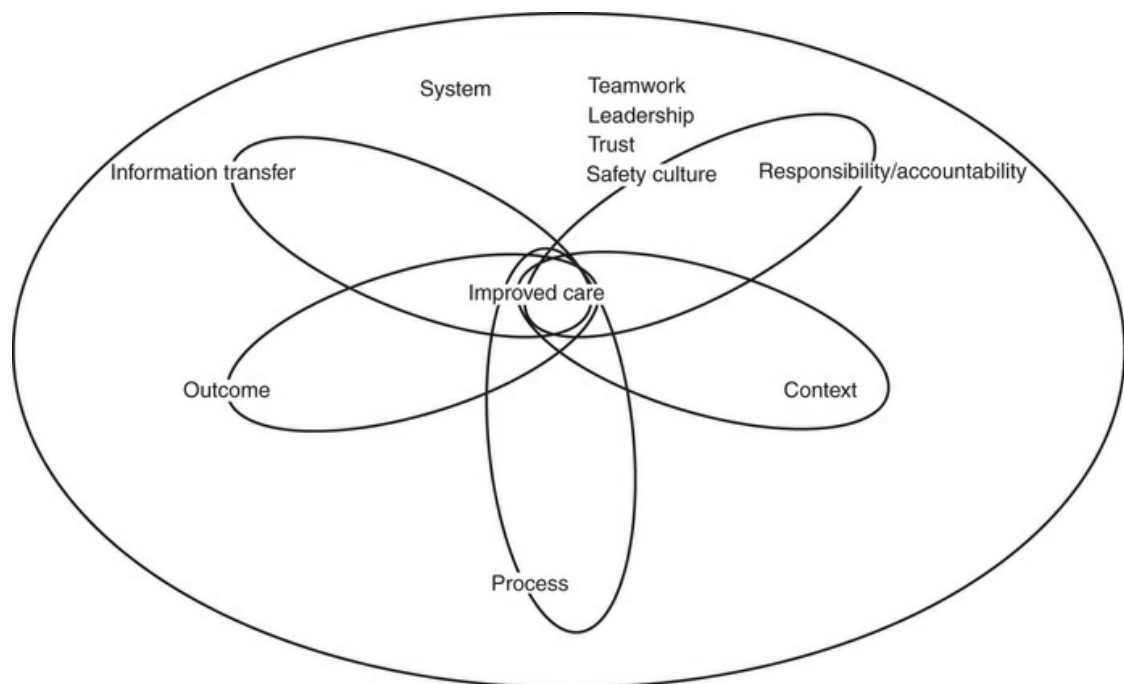

FIGURE 59.8 Conceptual model of handover elements.
(From Jeffcott SA, et al. Improving measurement in clinical handover. *Qual Saf Health Care*. 2009;18(4):272–277.)

Certain handoff attributes contribute to potential complications

such as truncated handoffs and omission of information resulting from work demands or time constraints, unfinished diagnostic and care activities, or a perceived lack of trust or familiarity with the participating individual.^{102,103} A self-reporting survey among 133 residents found that 31% had experienced an issue for which the handover had not prepared them.¹⁰⁴ Another study (2010) reviewing 2729 critical incidents found that the most frequent type of handover incident reported besides an incomplete handover (45.2%), was no handover at all (29.3%).¹⁰⁵

Information transfer and communication (ITC) across the entire surgical care pathway in patients undergoing major gastrointestinal procedures was assessed. Most ITC failures were observed during the preoperative phase (61.7%) and postoperative handover (52.4%). Seventy-five percent of patients had clinical incidents or adverse events because of ITC failures.

So what constitutes a handover that contributes to the quality and safety of patient care? Quality of the handover depends on the perception as to what is the primary function of the handover (e.g., information or responsibility transfer, shared decision making).^{69,70,97,98} Handover quality measures can be grouped into five areas: (1) information delivery or transfer, (2) responsibility/accountability, (3) context and environments, (4) the handover process, and (5) handover outcome.^{89,96} For a conceptual model of handover elements see [Fig. 59.8](#).

Measures of handover content appear to be straightforward, but which items should be included in a list for a quality handoff can vary depending on the clinical setting, timing, and individual perceptions and experience.^{69,70} The list can often become lengthy and generate heated discussions. Most handover content should concentrate on completeness and accuracy of information and related errors. Purely verbal handovers have been found to be the most incomplete when compared with information available in the patient record or located in a predefined protocol.^{97,98,102} A noisy operating room and an anesthetist that is in a hurry may not create the optimal handover process, leaving a gap for crucial information to be missed. The generation of evidence in this area is extremely limited, and there is still an open question regarding how various process measures translate into safe care.^{69,70,97,98}

Handover outcome measures usually include health care provider satisfaction. An observational study conducted in three different clinical settings (e.g., paramedic to emergency room, anesthetist to postanesthesia care unit (PACU), and PACU to floor/unit nurse) found that although information transfer was the key characteristic, overall handover quality was predicted by three factors: information transfer, shared understanding, and working atmosphere.^{69,70,97,98}

Professional organizations have published guidelines for handover communication, and standard approaches do exist that can improve handover communication. Study outcomes evaluating adherence to a protocol for handovers demonstrated statistically significant improvement in handover quality and improved teamwork.¹⁰⁶ Another approach focuses on general interaction structures and does not define actual content, but instead focuses on an order of topics to be covered. Both approaches have demonstrated improvements in teamwork and communication, which are factors that have translated into a significant reduction in morbidity and mortality in surgical patients.

An emerging area related to communication and handovers is incorporating a shared understanding among a health care team during a handover so that a handover is not a one-person–one-way process. An ideal patient handover conducted as a team-based activity would comprise an episode of shared cognition and understanding among health care providers and an opportunity for collaborative cross-checking. In this view, handovers represent a source of resilience for health care systems.

Standardized handovers in anesthesia have been proposed. One approach to handover content defines specific content to be included and also an order in which the information should be presented using a checklist-type format. A second approach focuses on the environment and general interaction structures without any defined content.^{69,70}

The electronic medical record (EMR) system has been proposed as one solution that provides a handover sheet that can easily be extracted to improve completeness of handover information. Arora, et al.^{97,98} systematically reviewed studies reporting interventions for improving patient handovers and found that technology solutions

were associated with a reduction in preventable adverse events and improved satisfaction with handoff quality, and also improved provider identification. Technology, however, ignores behavioral and cultural aspects of communication and does not necessarily improve communication.

Summary

Perioperative complications will occur. It is important not only to recognize and understand how and why complications arise, but also to be able to systematically deal with postcomplication issues. It is important to recognize the effect of local culture as a key underpinning for process improvement. A culture of blame is no longer acceptable and should not be supported.^{69,70} Learning from a critical incident can be both prospective (deliberating in advance of process changes and how they might affect safety) and retrospective (learning from events that have already transpired). It should be reinforced that errors are not always the cause of accidents, and blaming an individual may hinder uncovering a latent error or problem in the system. If reporting is safe and provides useful information from expert analysis, then it can measurably improve safety.

- Codeine metabolic pathway, [72f](#)
- Cognitive dysfunction, postoperative, in older adult, [1141](#), [1146](#)
- Cohen Flextip blocker, [634](#)
- Coherence, of laser beam, [984](#)
- Cold lasers, [988](#)
- Colitis
 - Crohn's, [734t](#)
 - ulcerative, [734–735](#), [734t](#)
- Collaboration, patient-centered care and, [21](#)
- Collagen
 - in blood vessel wall, [823](#)
 - laser absorption of, [986](#)
- Collagen vascular diseases, [616b](#)
- Collecting duct, renal, [685](#)
- Collimation, [984](#)
- Colloids, [350–351](#)
 - for abdominal aortic aneurysm repair, [544](#)
- Colon
 - anesthetic considerations in elective surgery of, [736](#)

carcinoma of, [736–737](#)

diverticulosis of, [735](#)

function of, [733](#)

ischemia of, [541](#)

volvulus of, [737](#)

Colonoscopy

anesthetic considerations for, [1203](#)

postanesthesia care in, [1203–1204](#)

procedure overview of, [1202–1203](#), [1202b](#)

Colony-stimulating factor, [959](#)

Colorimetric carbon dioxide sensor, [224](#)

Coma

barbiturates, [664](#)

scale, modified, for infants, [679t](#)

Combined spinal epidural (CSE) anesthesia, [1037–1040](#)

agents in, [1038](#)

for cesarean section, [1080–1081](#)

complications of, [1039–1040](#)

equipment and techniques for, [1038](#)

history and development of, [1037–1038](#)

for labor and delivery, [1077](#)

management of, [1038–1039](#)

sequential technique in, [1038](#)

single-level technique in, [1038](#)

specialized needles in, [1038](#)

two-level technique in, [1038](#)

Combitube, [425](#), [425f](#)

Common variable immune deficiency (CVID), [974](#)

Commotio cordis, in sudden cardiac death, [1221t](#)

Communication

in anesthesia complications, [1231–1234](#)

breakdown, that cause adverse outcomes, [1217](#)

elements of, [1231b](#)

Compartment models

central, [61–62](#)

drug distribution described with, [61–63](#)

one, [63f](#)

- peripheral, [61–62](#)
- three, [63f](#)
- two, [63f](#)

Compartment syndrome, [390, 848](#)

- abdominal, [736](#)

Complement cascade, [963f](#)

Complement system, [963](#)

Complete AV block, [185t–186t](#)

Complete blood count

- indications for, [342b](#)
- in pediatric patient, preoperative preparation of, [1123b](#)

Compound A, nephrotoxicity and, [689](#)

Compound A, soda lime degradation and, [254](#)

Compounds, [201](#)

- organic, [203–204](#)

Compressed Gas Association, cylinder regulations from, [235](#)

Compressed spectral array (CSA), [304](#)

Computed tomography (CT)

- anesthetic considerations in, [1211–1212](#)
- chest, for pulmonary embolism, [602t](#)
- for chronic pain, [1189](#)
- indications for, [1211b](#)
- procedure overview of, [1210](#)
- thoracic surgery preoperative evaluation with, [626](#)

Concentration, inhalation anesthetics and, [74–75](#)

Concentration effect, [74–75](#)

Concentric hypertrophy, hypertension associated with, [463](#)

Conducting zone, [566–567](#)

Conduction, [210](#)

Conductor, [218](#)

Congenital diaphragmatic hernia (CDH), neonatal anesthesia for, [1112](#)

Congenital heart defects, pathophysiology and clinical picture of, [1109t](#)

Congenital right ventricular cardiomyopathy, in sudden cardiac death, [1221t](#)

Congestive heart failure, [182–183](#)
cardiomyopathy associated with, [474–475](#)
differential diagnosis of, [584t](#)

Conjugate vaccines, [967](#)

Conjunctiva, of eye, [930](#)

Conn syndrome, [809](#)

Connective tissue, orbital, [930](#), [930f](#)

Consciousness, assessment of, during carotid endarterectomy, [556–557](#)

Consumer Assessment of Healthcare Providers and Systems (CAHPS), [21](#)

Contact activation factor, [826t](#)

Contact activation pathway, of clotting, [826](#)

Context-sensitive half-time, [66–68](#)
, Continuous opioid infusion, [135](#), [135b](#)

Continuous peripheral nerve blocks (CPNBs), for acute pain, [1175](#)

Continuous positive airway pressure (CPAP), [260](#), [403–404](#), [892](#)
for nonventilated lung, [640f](#)
for obstructive sleep apnea, [582](#)
one-lung ventilation and, [639–640](#)

for pediatric patient, [1128](#)

Continuous renal replacement therapy, [694](#)

Continuous spinal anesthesia, for labor and delivery, [1077](#)

Continuous wave (CW), of laser beam, [985](#)

Contractile force, grading, [766–768](#)

Contrast agents, for chronic pain, [1191](#)

Contrast media, IV, [1210](#)

- reactions to, [1212](#)
 - considerations and treatment protocols for, [1212b](#)

Conus arteriosus, [443](#)

Conus medullaris, infant, [1098f](#)

Convection, [210](#)

Convulsive disorders, outpatient surgery for, [892](#)

Cook airway exchange catheter, [426f](#), [436](#)

Coolant, gas embolism from, [991](#)

Coopdech blocker, [634](#)

Cor pulmonale, [598–600](#)

- anesthetic management for, [599–600](#)
- clinical features of, [599](#)
- definition of, [598](#)
- diagnosis of, [599](#)
- diagnostic testing for, [599](#)
- etiology of, [598–599](#)
- incidence and outcome of, [598](#)
- pathophysiology of, [599](#)
- in pulmonary hypertension of the newborn, [1093](#)
- signs of, [625](#)

- treatment of, 599
- Core temperature redistribution, 210
- Coreg, Carvedilol
- CoreValve, 514–515
- Corlopam, Fenoldopam
- Cormack and Lehane grading system, 406, 406*f*
- Cornea, 930
 - abrasion of, 944–945
- Cornua, 1015–1016
- Coronary artery bypass
 - minimally invasive, 514
 - total endoscopic, 514
- Coronary artery bypass graft, 501, 502*f*
 - anesthetic considerations in, 502*t*
 - off-pump, 503–504
 - on-pump, 501–503
- Coronary artery disease (CAD), 501–504
 - aortic stenosis and, 504–505
 - hypertension associated with, 463
 - management of, 464*t*
 - monitoring of, during anesthesia, 272
 - obesity and, 1001
 - in older adult, 1137
- Coronary blood flow, inhalation anesthetics effect on, 88
- Coronary filling, 451*t*
- Coronary heart disease, 184–187
- Coronary perfusion pressure, 451, 479–480

Coronary steal, [88](#), [451–452](#)

Coronary stent(s), [326](#)

acute stent thrombosis in, [838–839](#), [840b](#)

antiplatelet drugs and, [837–840](#)

outpatients requiring, [840–842](#)

perioperative considerations for, [841b](#)

perioperative management of, [327f](#)

stent restenosis of, [838–839](#)

types of, [839](#)

Coronary sulcus, [441](#)

Corpus callosum, [647](#)

Corpus striata, [658](#)

Corrected flow time, [357t](#)

Correlation coefficient

definition of, [35](#)

research goal and, [37t](#)

Cortical blindness, [754](#)

Cortical somatosensory evoked potentials, neurophysiologic monitoring of, [915t](#)

Corticospinal tract, [656f–657f](#), [657–658](#)

Corticosteroids

for asthma, [596t](#)

for chronic obstructive pulmonary disease, [587](#)

for chronic pain, [1176–1177](#), [1191](#)

for ENT procedures, [910](#)

in hypermetabolic/hyperhemodynamic phase, of burn injury, [849](#)

intracranial pressure and, [664](#)

- for sarcoidosis, [617](#)
- side effects of, [1176–1177](#)
- systemic effects of, [1177b](#)
- therapeutic uses of, [808b](#)

Corticosteroid therapy

- for myasthenia gravis, [770](#)
- perioperative, [322](#)

Corticotroph, [786](#)

Corticotropin, [785](#)

Corticotropin-releasing hormone, [786t](#), [805–806](#)

Cortisol, [805–806](#)

- actions of, [806](#)
- release of, surgery and, [978–979](#)
- secretion of, [805–806](#), [806f](#)

Cotransport, [684–685](#)

Cough

- asthma associated with, [592](#)
- chronic obstructive pulmonary disease and, [586t](#)
- as reflex mechanism, [581t](#)

Coulomb's law, [218](#)

Council for Public Interest in Anesthesia (CPIA), [16–17](#)

Electromagnetic spectrum, [983](#), [984f](#)

Electromagnetic waves, [217](#), [217f](#)

Electromyography, [141](#)

- intraoperative monitoring with, [664–665](#)
- motor-evoked potentials and, [306–307](#)
- for neurophysiologic monitoring, [667t](#)

Electronic medical records (EMRs)

- patient assessment and, [312](#)
- patient handoff with, [1234](#)

Electrons, [201](#)

- configuration of, [201](#)
- valence, [201](#)

Electrophysiology, cerebral, [652–653](#)

Electrostatic bonds, [202](#)

Electrosurgical cautery (EC), electromagnetic interference and, [532](#)

Electrotranslocation, of nerve, [1044](#)

Elements, [201](#)

Emancipation, informed consent and, [1073](#)

Emden-Meyerhof pathway, [796](#)

Embolism

- amniotic fluid, [1089](#)
- paradoxical air, [390, 670](#)

Emergence, inhalation anesthetics and, [76–77, 77b, 84–85](#)

Emergence agitation, pediatric patient and, [1119](#)

Emergence delirium, [86–87, 1156, 1157f](#)

- drugs associated with, [1156](#)
- pediatric patient and, [1119](#)

Emergence phenomenon, in children, [86–87, 86b](#)

Emergence reaction, ketamine associated with, [103](#)

Emergency Care Research Institute, [992](#)

Emergency transfusion, [373](#)

Emesis, following outpatient surgery, [901](#)

Empagliflozin, for type 2 diabetes, [801t](#)

Emphysema, [331](#)

- chronic obstructive pulmonary disease and, [584](#)
- cigarette smoking and, [586](#)
- definition of, [584–585](#)
- subcutaneous, [746b](#)

Enalapril

- dosage and effects of, [172t–173t](#)
- perioperative use of, [330](#)

Enantiomers, [64](#), [203](#)

Enbrel, [Etanercept](#)

Encephalopathy, hepatic, [717f](#), [719](#), [880](#)

End-diastolic pressure, [280f](#)

- left ventricular, [282](#)
- right ventricular, [280](#)

End-plate potential, [761–763](#), [763f](#)

End-stage kidney disease, [690](#)

End-stage liver disease, etiologies of, [877t](#)

End-stage renal disease (ESRD), [694](#), [695b](#), [701](#), [871–872](#)

- pathophysiology of, [871–872](#), [872t](#)
- renal transplantation for, [871](#)

End-tidal anesthetic concentration, [309–310](#)

End-tidal carbon dioxide capnography, [293–294](#), [293f–294f](#), [294b](#)

End-tidal carbon dioxide (ETCO₂)

- pneumoperitoneum effects on, [745](#)

steep Trendelenburg position and, [753–754](#)

End-tidal concentration, [83](#)

Endarterectomy *versus* Angioplasty with Symptomatic Severe Carotid Stenosis (EVA-3S) trial, [559](#)

Endoaortic balloon, [513](#)

Endobronchial intubation, [440](#)

Endobronchial tube, [632t](#)

- double-lumen, [624](#), [632–634](#), [633f](#)
 - advantages and disadvantages of, [632–633](#)
 - auscultation of breath sounds after placement of, [635b](#)
 - complications associated with, [633](#)
 - features of, [632](#)
 - insertion of, [633–634](#)
 - positioning of, [634f](#)
- single-lumen, [632](#)
- verification of placement of, [635f](#)

Endocarditis, infective

- risk of, [193b](#)
- valvular heart disease and, [504](#)

Endochondral bone, [397](#)

Endocrine disease, obesity and, [1004](#)

Endocrine function, [782](#)

Endocrine glands, [782](#)

Endocrine neoplasia, [813–814](#), [814t](#)

Endocrine system, [782–822](#)

- anesthesia and, [782–822](#)

- diabetes mellitus and, [798–805](#)
- dialysis and, [697](#)
- obesity and, [999b](#)
- opioids effect on, [134](#)
- pediatric medical history, anesthetic implication of, [1121t](#)
- physiology of, [782–784](#)
- preoperative evaluation of, [336–340](#)

Endodontics, [1206](#)

- anesthetic considerations in, [1207](#)

Endoleak, [549–551](#), [552f](#)

- classification of, [551t](#), [553f](#)

Endoneurium

- peripheral nerve structure and, [110](#)
- transverse section of, [111f](#)

Endorphin, opiate receptors and, [128](#)

Endoscopic retrograde cholangiopancreatography (ERCP), [711](#), [721–722](#)

- anesthetic considerations for, [1203](#)
- postanesthesia care in, [1204](#)
- procedure overview of, [1202–1203](#), [1202b](#)

Endoscopic ultrasound (EUS)

- anesthetic considerations for, [1203](#)
- procedure overview of, [1202–1203](#)

Endoscopy

- anesthetic considerations for, [1203](#)
- for ENT procedures, [912–913](#)
- procedure overview of, [1202](#)

spinal surgery with, [954](#)

Endothelin, imbalance in, cor pulmonale and, [599](#)

Endothelium-derived relaxing factor, [459](#)

Endotracheal tube (ETT)

- complications of, [440](#)
- displacement of, [391](#)
- for ENT procedures, [908–909](#), [909f](#)
- Fastrach LMA for, [424b](#)
- interincisor gap and, [405](#)
- laser-resistant, [995](#), [1127](#)
- lung transplantation and, [885–886](#)
- in outpatient surgery, [900](#)
- pediatric, [1126](#)
 - depth of, [1126](#)
 - sizing of, [1126](#)
 - specialized, [1127](#)
- PVC tube, [995](#)
- right angle, [1127](#)
- sizes, recommended, in neonate, [1105t](#)
- for supratentorial surgery, [668](#)
- surgical fires and, [993](#)
- for tracheoesophageal fistula, [1114f](#)

Endovascular aortic aneurysm repair, [549–551](#)

- complications associated with, [550b](#)
- potential complications associated with, [550b](#)
- procedure for, [549–551](#), [550f](#)
- short aortic neck and, [552f](#)

technique for, [560f](#)

Endovascular embolization, indications for, [1210](#), [1211b](#)

Endovascular graft, [550](#), [551f](#)

Endovascular stent grafting (EVSG), [549](#)

EndoWrist instruments, [752](#)

Energy, [209](#)

- bond, [203](#)
- dilution of, [213](#)
- external source of, [984](#)
- heat and, [210](#)
- kinetic, [205](#), [209](#)
- wavelength and, [983](#)

Energy balance, [796](#)

Energy concentration effect, [212–213](#)

Enhanced Recovery after Surgery (ERAS), [358](#), [358f](#)

- intraoperative fluid management in, [358–359](#)
- postoperative phase and, [359](#)
- preoperative fluid management in, [358](#)
- in robotic surgery, [755–756](#), [755b](#)

Enkephalin

- opiate receptors and, [128](#)
- for pain modulation, [1169–1170](#), [1170t](#)

Enophthalmos, [943](#)

Enteritis, radiation, [738](#)

Enterochromaffin cells, [740](#)

Enteroglucagon, effects and therapeutic uses of, [733t](#)

Enthalpy, [203](#)

FLAM score, [643](#)

Flammability, inhalation anesthetics and, 81

Flash visual-evoked potential, 309*f*

Flecainide, long QT syndrome and, 1222*t*

Fletcher factor, 826*t*

Flexibility, ventilators and, 260

Flomax, Tamsulosin

Flow

electrical, 218–219

fluid, 213–216

laminar, 213, 213*f*

transitional, 213, 213*f*

turbulent, 213, 213*f*

types of, 213

Flow-volume loops, 295, 295*f*, 582–583, 583*f*

after bronchodilator therapy, 589*f*

mediastinum mass and, 641

Flowmeter

anesthesia gas machine gases pathway through, 239–241, 240*f*

auxiliary oxygen, 241

care of, 240–241

common gas outlet, 240*f*, 241

components of, 240*b*, 240*f*

scavenging, 241

Fluid(s), 347–368, 348*f*

absorption of, prostate resection associated with, 704

antidiuretic hormone and, 789

balance of

- liver disease effects on, [718](#)
- in neonate, [1099](#), [1099t](#)
- flow of, [213–216](#)
- homeostasis, antidiuretic hormone and, [789](#)
- hourly requirements of, [1131t](#)
- hypovolemic shock and, [847](#)
- intravascular, restrictive pulmonary disease and, [604–605](#)
- intravenous
 - hemorrhagic shock and, [862](#)
 - as requirements, in newborn, [1103b](#)
- loss of, pancreatitis and, [728–729](#)
- maintenance calculation, in pediatric patient, [1131–1132](#)
- management of, [347](#)
 - during abdominal aortic aneurysm repair, [542–544](#)
 - historical approach to, [352–354](#), [353b–354b](#)
 - intravenous, [701](#)
 - neonatal, [1103–1105](#)
 - in pediatric patient, [1130–1133](#)
 - perioperative, [1163](#)
 - premature infant, [1104](#)
 - during supratentorial surgery, [667–668](#)
- physiologic distribution and regulation of, [347–349](#), [348f](#)
- postoperative assessment of, [1163](#)
- replacement, for burn injury, [852–853](#)
- requirements, assessing, [1103](#)
- resuscitation of, [848–849](#)
 - consensus formula for, [848b](#)

- criteria for, [848b](#)
- formulas, [848t](#)
- trauma and, [861–862](#)
- retention of, in chronic obstructive pulmonary disease, [586](#)

Fluid compartment

- pediatric, [1131](#)
- volumes, [1100t](#)

Fluid deficit, estimated, [353b](#)

Fluid mechanics, [213](#)

Fluid overload, prostate syndrome associated with, [703t](#)

Fluid therapy

- in outpatient surgery, [900](#)
- perioperative goal-directed, [354–359](#)

Flumazenil

- application of, [105t](#)
- cerebral physiology affected by, [660](#)

Fluorescence, [224](#)

Fluorescence quenching, [224](#), [224f](#)

Fluoride ion toxicity, [688–689](#)

Fluorodeoxyglucose (FDG), [1214](#)

Fluoroquinolones, administration of, [190–191](#)

Fluoroscopy, for chronic pain, [1189](#)

Fluoxetine, long QT syndrome and, [1222t](#)

Flurazepam, application of, [105t](#)

Fluticasone, for asthma, [596t](#)

Fluvastatin

- dosage of, [188t](#)

perioperative use of, [329](#)

Fogarty embolectomy catheter, [634](#)

Follicle-stimulating hormone (FSH), [785](#)
in vitro fertilization and, [1204](#)

Follicular thyroid cancer, [918](#)

Fondaparinux
neuraxial anesthesia for, [839t](#)
pharmacodynamic properties of, [838t](#)

Fontanelle, closure of, [1097](#)

Food consumption, obesity and, [1000](#)

Foot, surgery on, [957](#)
anesthetic management for, [957](#)

Foramen ovale, [1092](#)

Foraminectomy, [953](#)

Force, [206–207](#)

Forced air capacity, [583f](#)

Forced expiratory volume
chronic obstructive pulmonary disease and, [586–587](#)
thoracic surgery preoperative laboratory assessment with, [626–627](#)

Forearm
innervation of, [1046](#)
surgery for, [957–958](#)
anesthetic management in, [958](#)

Foreign-body aspiration, [913–914](#)

Formoterol
for asthma, [596t](#)

for chronic obstructive pulmonary disease, [589t](#)

Fosinopril, dosage and effects of, [172t–173t](#)

Fourier analysis, [304](#)

Fowler position, modified, for shoulder arthroscopy, [949](#)

Fractional tissue response (FTR), [53](#)

Frailty

- measurements of, [1219b](#)
- older adult and, [1142](#)

Frank-Starling law, [452](#)

Frank-Starling mechanism, [355–356](#), [355f](#)

Free fatty acid (FFA), [1000](#)

Frequency, of wave, [216](#)

Frequency bandwidth, electrocardiogram monitoring and, [278](#)

Frequency distribution, research described with, [34–35](#), [34t](#)

Frequency polygram, [34–35](#), [35f](#)

Fresh frozen plasma, [374–375](#)

- infusion guidelines for, [832](#), [832t](#)
- transfusion of, indications for, [376t](#)

Friction, [213](#)

Friedman curve, [1068](#), [1068f](#)

Friedman's statistic, [36t](#)

Fringe field, [1210](#)

Fuel cell, [222–223](#), [223f](#)

Full-thickness burns, [843](#)

Functional groups, [204](#)

Functional residual capacity (FRC), [404](#), [570–571](#), [1001](#), [1010–1011](#)

- neonatal, [1095](#)

in normal pulmonary function, in newborn and the adult, [1096t](#)
in older adult, [1139f](#)
during pregnancy, [1065–1066](#), [1066t](#)
surgical positioning effects on, [381](#)

Functional status, older adult and, [1143](#)

Functional status assessment proxy, [1143b](#)

Funnel chest, [620](#)

Furosemide, dosage and effects of, [172t–173t](#)

G

G protein-coupled receptors (GPCRs), [49](#), [50f](#), [129](#), [1173](#)

Gabapentin

- for chronic pain, [1176](#)
- for postdural puncture headache, [1029](#)

Gain setting, electrocardiogram monitoring and, [278](#), [278f](#)

Galanin, for chronic pain, [1185](#)

Galantamine

- Alzheimer's disease treated with, [149b](#)
- succinylcholine interaction with, [149](#)

Gallbladder, [720](#)

- bile released in, [711](#)
- blood supply to, [720–721](#)
- disease of, [722](#)

Gallstone

- acute pancreatitis associated with, [729](#)
- formation of, [720](#)
- obesity and, [1003–1004](#)

, Gamete intrafallopian transfer (GIFT), [1204t](#)

Gamma-aminobutyric acid (GABA), modulation of pain and, [1169–1170](#), [1170t](#)

Gamma (γ)-aminobutyric acid receptor

- potentiation of, [48](#)
- signal transduction of, [49](#)

Gamma (γ)-aminobutyric acid_A receptor, [49](#)

- signal transduction of, [49](#)

Gamma radiation, [1211](#)

Ganglia

- basal, [658](#)
- cervical, [651](#)
- paravertebral, [651](#)
- sympathetic, [650f](#)

Garde, John, [10](#), [10f](#)

Garlic

- effects of, [317t](#)
- hemostasis and, [1021t](#)

Gas, [201](#), [211](#)

- analysis of, [221–224](#)
- anesthetic

 - analysis of, [221–222](#), [221b](#)
 - exposure to, [265b](#)

- cross connection of, in pipeline supply, [233](#)
- decoupling, circle breathing system and, [262f](#)
- flow of, through anesthesia gas machine, [240](#), [240f](#), [251f](#), [253–254](#)
- pipeline supply of, [232](#)

- rapid expansion or compression of, [212](#)
- solubility of, [204](#)
- waste anesthetic, limiting exposure to, [265b](#)

Gas embolism, [748b](#)

- diagnosis of, [748](#)
- laparoscopic surgery, [748](#)
- laser safety from, [991](#)
- management of, [748](#)
- signs of, [748](#), [748b](#)
- symptoms of, [748](#)
- treatment of, [748b](#)

Gas lasers, [985](#)

Gas laws, [211–213](#), [211t](#)

Gas phase, [73–74](#)

Gastric banding, [1005–1006](#)

- procedure, outpatient, [892](#)

Gastric inhibitory polypeptide, effects and therapeutic uses of, [733t](#)

Gastric neoplastic disease, [726–727](#)

Gastric proton-pump inhibitors, [899](#)

Gastric ulcer disease, [726](#)

Gastrin, [725](#)

- effects and therapeutic uses of, [733t](#)

Gastrin-releasing peptide, [733t](#)

Gastrinoma, [731](#)

Gastritis, [725–726](#)

Gastroduodenostomy, [727](#)

Gastroesophageal reflux disease (GERD), [723](#)

- obesity and, [1003](#), [1009](#)
- Gastrointestinal disease/disorders
 - obesity and, [1003](#)
 - preoperative assessment, of pediatric patient, [1121](#)
- Gastrointestinal surgery, antimicrobial prophylaxis for, [193t–194t](#)
- Gastrointestinal system
 - acute pain effects on, [1171t](#)
 - burn injury effects on, [850–851](#)
 - dialysis and, [697](#)
 - dysfunction of, CPB causing, [489](#)
 - hemorrhage in, gastritis as cause of, [726](#)
 - obesity and, [999b](#)
 - opioids effect on, [134](#)
 - pediatric medical history, anesthetic implication of, [1121t](#)
 - during pregnancy, [1066](#)
 - preoperative evaluation of, [333](#)
- Gastrointestinal tract
 - carcinoid tumors in, [740](#)
 - ischemic injury to, [737](#)
- Gastrointestinal tract, spinal anesthesia in, [1028](#)
- Gastrojejunostomy, [727](#)
- Gastroschisis, neonatal anesthesia for, [1112–1113](#), [1112t](#)
- Gastrostomy, [727](#)
- Gate theory, [448](#)
- Gather, James, [1](#)
- Gating, nerve impulse and, [652](#)
- Gauge pressure, [208](#)

- radial arterial pressure, [287f](#)

right atrial pressure, [279–280](#), [279f](#)

right ventricular pressure, [280](#)

variables influencing, [282–283](#)

Hemodynamics, arterial, measurement of, [278–286](#)

Hemoglobin

concentration of, in blood loss, in pediatric patient, [1133](#)

fetal, [1094](#), [1104](#)

indications for testing of, [342b](#)

laser absorption and, [986](#)

level, renal failure and, [336](#)

oxygen bound to, [575](#)

oxygen saturation of, [296](#)

oxygenated, [224](#), [225f](#)

in pediatric patient, preoperative preparation of, [1123b](#)

in transfusion guidelines, [833](#)

value, in infant, [891](#)

Hemoglobinuria, burn injury and, [850](#)

Hemolysis, TURP syndrome and, [703t](#)

Hemophilia, [833–834](#), [834b](#)

Hemorrhage

burn injury and, [853](#)

carotid endarterectomy associated with, [558](#)

episcleral, [942](#)

intracranial, neonatal, [1098](#)

intraventricular, [1108–1109](#)

postpartum, [1086](#), [1087f](#)

retrobulbar, [942](#), [942b](#)

subarachnoid, [Subarachnoid hemorrhage](#)
trauma and, [856](#)

Hemorrhagic shock
blood volume and, [860–861](#)
fluid resuscitation and, [861–862](#)
intravenous fluid administration for, [862](#)
treatment of, [861–862](#)

Hemorrhoids, [737–738](#)

Hemostasis, [823](#)

Hemostatic disorders, possible causes and treatment of, [830t](#)

Hemothorax, [619](#), [619f](#)
blunt trauma and, [857](#)

Henderson, Florence, [2](#)

Henry's law, [205](#)

Heparin
for ACS, [490–491](#)
in anticoagulation, in CPB, [486](#)
for burn injury, [847](#)
concentration monitor for, [486](#)
pharmacodynamic properties of, [838t](#)
pulmonary embolism treated with, [1151](#)
resistance to, [486](#)
unfractionated, neuraxial anesthesia for, [839t](#)

Heparin-induced thrombocytopenia, [486–487](#), [836–837](#), [836b](#), [836f](#)

Heparin-platelet factor 4 (H-PH4) immune complexes, [836](#)

Hepatic artery buffer response (HABR), [709](#)

Hepatic encephalopathy, [719](#), [880](#)

Hepatic function, age-related changes in, [1140–1141](#)

Hepatic lobule, [709](#)

Hepatic system

- dysfunction of, [718–719](#)
- neonatal, [1099](#), [1108t](#)
- pediatric medical history, anesthetic implication of, [1121t](#)
- during pregnancy, [1066](#)
- succinylcholine effects on, [148](#), [148t](#)

Hepatitis

- acute, [714](#)
- alcohol use associated with, [335](#), [715](#)
- anesthetic management for patients with, [715](#), [716b](#)
- chronic, [715](#)
- drug-induced, [715](#)
- halothane, [713](#), [714b](#)
- liver disease surgery risk and, [714t](#)
- preoperative evaluation of, [333](#)
- viral, [715](#), [715t](#)

Hepatobiliary system

- physiologic functions of, [333b](#)
- preoperative evaluation of, [333–335](#)

Hepatocellular enzymes, [335](#)

Hepatopulmonary syndrome (HPS), [719](#), [879–880](#)

Hepatorenal syndrome (HRS), [716](#), [718](#), [718b](#), [880](#), [880t](#)

Hepcon, [486](#)

Herbal medicines, [317](#)

- affecting hemostasis, [1021t](#)

in central neuraxial blockade, 1020–1021
effects of, 317*t*

Herbal therapy, neuraxial anesthesia for, 839*t*

Hering-Breuer deflation reflex, 579, 581*t*

Hering-Breuer inflation reflex, 579, 581*t*, 1096

Hernia, pelvic procedure, spinal anesthesia for, 1026*t*

Heroin, 128
methadone for treatment of addiction to, 137

Hetastarches, 350–351

Hexane, 203–204, 204*f*

Hexastarches, 350–351

Hexene, 204, 204*f*

Hiatal hernia, 723, 723*f*

Hibernation, 481

High-efficiency particulate air (HEPA) filter, 991–992

High-molecular-weight kininogen (HMWK), 826, 826*t*

High-osmolar contrast media (HOCM), 1212

High-velocity wound, 858

Hilus, 682

Hips
arthroplasty for, 950–952
thromboprophylaxis in, 951–952
arthroscopy for, 948, 950*f*

Histamine, 969
carcinoid tumor and, 740, 740*t*
gastric acid secretion and, 725
morphine and release of, 137

- as neurotransmitter, [654](#)
- pain transmission and, [1169](#)

Mayo, Dr. W. W., [2](#)

Maze procedure, [508](#), [510](#)

McGrath video laryngoscope, [429–430](#), [430f](#)

McMechan, Francis Hoeffler, [4](#)

McNemar test, [36t](#)

McQuillen, Florence, [7](#)

Mealer, Annie, [5](#)

Mean

- dose response variability analysis and, [51](#), [51f](#)
- statistical, definition of, [35](#)

Mean arterial pressure (MAP), [286](#)

- coronary perfusion pressure with, [479–480](#)
- inhalation anesthetics effect on, [87](#), [87f](#)
- pneumoperitoneum effect on, [744](#), [753](#)
- regulation of, [460–461](#)
- steep Trendelenburg effect on, [753](#)

Measurement

- affective, [33](#)
- characteristics of categories of, [33t](#)
- cognitive, [33](#)

- interval level, [33](#)
- levels of, [33](#)
- nominal level, [33](#)
- ordinal level, [33](#)
- ratio level, [33](#)
- in research process, [32–34](#)
- of treatment effect, [33–34](#), [33t](#)

Mechanomyography, [141](#)

Medawar, Peter, [871](#)

Medial extraconal peribulbar block, [937–938](#), [937b](#), [937f](#)

Medial peribulbar area, [937](#)

Median

- dose response variability analysis and, [51](#), [51f](#)
- statistical, definition of, [35](#)

Median effective dose, [52f](#), [53](#)

Median nerve block

- at elbow, [1053–1054](#), [1054f](#)
- at wrist, [1055](#), [1055f](#)

Mediastinal masses, [641–642](#)

- flow-volume curve of, [641f](#)
- symptoms of, [641b](#)
- tumor in, [641](#), [641b](#)

Mediastinoscope, placement of, [642](#), [642f](#)

Mediastinoscopy, [642](#)

Mediastinum, [567](#)

- divisions of, [567t](#)

Medical history

- anesthetic, [313](#)
- asthma and, [332b](#)
- drug, [314](#)
- for outpatient surgery, [894](#)
- patient assessment and, [313](#)
- of pediatric patient, [1120–1121](#)
 - anesthetic implications of, [1121t](#)
 - surgical, [313](#)

Medical records, patient assessment and, [312](#)

Medicare

- certified registered nurse anesthetist reimbursement in, [8](#)
- certified registered nurse anesthetist supervision in, [11–12](#)
- fraud and abuse, [8](#)

Medications

- labels of, [1196](#)
- obesity and, [1007](#)
- ocular, [930](#), [932t](#)
- oral absorption of, [1118](#)
- outpatient surgery and patient use, [896–897](#)
 - , preoperative, for cardiac surgery, [490–491](#)
- rectal absorption of, [1118](#)

Medisorb, characteristics of, [254t](#)

Medulla, [647–648](#), [648f](#)

- renal, [682](#), [687](#)

Medullary respiratory centers, [579](#)

Meglitinides, [801](#), [801t](#)

Meissner plexus, [724](#), [731–732](#)

Melanin, laser absorption and, [986](#)

Melker Universal Emergency Cricothyrotomy Catheter Set, [432](#),
[432f](#)

Membrane potentials

- generation of, [447–448](#)
- resting, [447–448](#)

Membranes, diffusion through, [205](#)

Memory blockade, [1225](#)

Mendelson syndrome, [607](#)

Meninges, [648](#), [1017](#)

- cerebrospinal fluid and, flow of, [648f](#)

Meningitis

- aseptic, [1022](#)
- septic, [1021–1022](#)

Mental status

- postoperative assessment of, [1156–1158](#)
- preoperative evaluation of, [321](#)

Meperidine, [137](#)

- advanced renal disease and, [698](#)
- chemical structure of, [129f](#)
- doses of, [135t](#), [1036t](#)
- for labor and delivery, [1071](#)
- other opioids compared to, [136t](#)
- for patient-controlled analgesia, [1175](#)
- pharmacokinetics of, [131t](#)
- receptor sites of, [129t](#)
- for renal transplantation, [873–874](#)

Mepivacaine

- characteristics of, [116t](#)
- chemical structure of, [114f](#)
- clearance half-life of, [118t](#)
- dosage guidelines of, [121t](#)
- pharmacokinetics of, [118t](#)
- potency of, [115](#)

6-Mercaptopurine, Crohn's disease treated with, [734b](#)

Merocel Laser-Guard endotracheal tube wrap (Medtronic), [995](#)

Mesalamine, Crohn's disease treated with, [734b](#)

Mesenchyme, [397](#)

Mesenteric traction syndrome, [540](#)

Mesentery, [731](#)

Meta-analysis

- description of, [44–46](#), [45f–46f](#)
- steps in, [45b](#)

Metabolic disease, obesity and, [1004](#)

Metabolic equivalent

- in older adult, [1137](#)
- patient's functional capacity measured in, [323](#), [325t](#)

Metabolic syndrome

- definition of, [1004b](#)
- obesity and, [1004](#)
 - in children, [1005](#)
 - maternal, [1005](#)

Metabolic system

- clinical monitoring, [290–299](#)

pediatric medical history, anesthetic implication of, [1121t](#)

Metabolism

bilirubin, liver function and, [710b](#), [711](#)

carbohydrate, [710](#), [710b](#)

drug, [65–66](#), [66b](#)

in liver, [711–712](#), [711b](#)

inhalation anesthetics, [76](#), [76t](#)

neonatal, anesthetic pharmacologic considerations in, [1101](#)

phase I reaction in, [65–66](#)

phase II reaction in, [66](#)

protein, [710b](#), [711](#)

Metal vapor lasers, [988](#)

Metallic particles, in combined spinal epidural anesthesia, [1040](#)

Metered-dose inhalers, [214](#)

Metformin, for type 2 diabetes, [801](#), [801t](#)

Methacholine, [175](#)

Methadone, [137](#)

absorption of, [137](#)

for chronic pain, [1177–1178](#), [1187](#)

dosage of, [135t](#)

long QT syndrome and, [1222t](#)

metabolism of, [1177](#)

other opioids compared to, [136t](#)

pharmacokinetics of, [131t](#)

side effects of, [1177](#)

Methemoglobinemia, [124–125](#), [125b](#), [125f](#), [125t](#), [576](#)

Methimazole

for hyperthyroidism, [919t](#)
thyroid hormone and, [819](#)

Methohexital, in major depressive disorders, [1210](#)

Methotrexate

- Crohn's disease treated with, [734b](#)
- drug-induced pulmonary disease and, [615](#)
- for rheumatoid arthritis, [780](#)

Methoxyflurane, nephrotoxicity associated with, [689](#)

Methyl methacrylate (MMA), and total hip arthroplasty, [951](#)

Methyldopa, dosage and effects of, [172t–173t](#)

Methylprednisolone

- for asthma, [596t](#)
- cardiac transplantation and, [520–521](#)

α -Methyltyrosine, [815t](#)

Metipranolol, as ocular medications, [932t](#)

Metoclopramide

- in assisted reproductive technologies, [1204–1205](#)
- multimodal antiemetic therapy and, [197](#)

Metolazone, dosage and effects of, [172t–173t](#)

Metoprolol, [174–175](#)

- elevated blood pressure treated with, [1154–1155](#)
- for hyperthyroidism, [919t](#)

Metronidazole, Crohn's disease treated with, [734b](#)

Metyrapone, for Cushing syndrome, [810](#)

Metyrosine, [180](#)

Mevacor, [Lovastatin](#)

Mexiletine, for myotonic dystrophy, [778](#)

Meyer-Overton theory, [82](#)

Micardis, [Telmisartan](#)

Michaelis-Menten model, [66](#)

Microcirculation, [459](#)

- anatomy of, [459](#)

Microdialysis, brain monitoring with, [301t](#)

Microembolus, [611](#)

Microglia, functions of, [646t](#)

Microlaryngeal endotracheal tube (MLT), [912](#)

Microshock, [219](#), [219t](#)

Microzide, [Hydrochlorothiazide](#)

Midamor, [Amiloride](#)

Midazolam

- advanced renal disease and, [698](#)
- in assisted reproductive technologies, [1204–1205](#)
- chemical structure of, [94f](#)
- clearance rate of, [106](#)
- clinical application of, [105t](#)
- as commonly prescribed pediatric premedicants, [1124t](#)
- for dental restoration procedures, [921](#)
- endoscopy and, [1203](#)
- induction dose of, [99t](#)
- pediatric anesthetic neurotoxicity in, [1220f](#)
- pharmaceutical preparation of, [94t](#)
- as premedication for pediatric patient, [1123–1124](#)

Midbrain, [647–648](#)

- motor areas of, [658](#)

Middle ear

nitrous oxide used in surgery for, [915–916](#)

pressure in, [915–916](#)

surgical procedures for, [914–916](#)

Midgut volvulus, neonatal anesthesia for, [1114–1115](#)

Miglitol, for type 2 diabetes, [801t](#)

Military, certified registered nurse anesthetist, [13](#)

Milk-alkali syndrome, [726](#)

Mill-wheel murmur, [391](#)

Milnacipran, for chronic pain, [1176t](#)

Milrinone, [168](#)

cardiac effects of, [169t](#)

doses of, [170t](#)

for LV systolic failure, [499–500](#)

Mineralocorticoids, [808](#)

Mini-Cog scoring algorithm, [1142f](#)

Minimally invasive direct coronary artery bypass, [514](#)

Minimally invasive spine surgery, [953](#)

Minimum alveolar concentration (MAC), [73](#), [74b](#)

age on, effect of, [1101f](#)

drug response affected by, [51](#)

effects of age on, [1118f](#)

inhalation anesthetics and, [82–84](#), [83b](#), [83t](#)

for pediatric patient, [1118](#), [1118f](#)

neonatal, inhalation agents and, [1101](#)

Minipress, [Prazosin](#)

Minithoracotomy, [511–512](#), [511f](#)

Minor calyx, [682](#)
, Minoxidil, dosage and effects of, [172t–173t](#)
Minute volume, lung volume and, [570–571](#)
Miochol, [Acetylcholine](#)
Miosis, opioids as cause of, [133](#)
Miscarriage, maternal obesity and, [1005](#)
Mitotane, for Cushing syndrome, [810](#)
MitraClip, [516](#)
Mitral balloon valvotomy, [508](#)
Mitral insufficiency, [468–470](#), [508–510](#)
Mitral regurgitation, [468–470](#), [508–510](#)
 acute, [509](#)
 anesthetic considerations and surgical options for, [509–510](#), [509t](#)
 anesthetic considerations of, [470](#)
 effects of afterload reductions on, [469](#)
 hemodynamic waveform altered by, [281](#)
 pathophysiology associated with, [468–469](#), [469f](#)
 pulmonary vasculature and right ventricular function, [469](#)
Mitral stenosis, [467–468](#), [508](#)
 anesthetic considerations for, [468](#), [508](#), [509t](#)
 pathophysiology of, [467–468](#), [468f](#)
 pulmonary vascular changes in right ventricular function, [468](#)
 surgical options for, [508](#)
Mitral valve, [443](#)
 lesions on, [470t](#)
 repair of, [510f](#)
 percutaneous, [516](#)

- robotic-assisted, [512f](#)
- stenosis of, [467–468](#)
- systolic anterior motion of, [505](#)

Mitral valve procedures

- minimally invasive, [510–513](#)
 - anesthetic considerations for, [511–512](#)
- in robotic surgery, [757](#)

Mitral valve prolapse, [473–474](#)

- anesthetic management of, [474](#)
- description of, [473](#)
- etiology of, [473](#)
- management of, [473t](#)
- pathophysiology of, [473–474](#)
- pharmacology of, [474](#)
- unique problems in, [473–474](#)

Mivacurium, for renal failure, [700](#)

Mixed acidosis, [578](#)

Mixed connective tissue disease, pulmonary manifestations of, [616b](#)

Mixed-function oxidase system, [66](#)

Mobility, issues in, and robotic surgery, [753](#)

Mode, dose response variability analysis and, [51](#), [51f](#)

Model for End-Stage Liver Disease (MELD), [717](#), [717t](#)

Model for End-Stage Liver Disease score (MELD), [877–878](#), [878t](#)

Modified Mallampati airway classification, [405–406](#), [406f](#)

Moexipril, dosage and effects of, [172t–173t](#)

Molecular bond types, [201–203](#)

- covalent bonds, [201](#)

- double bond, [201](#)
- electrostatic bonds, [202](#)
- representations of, [203](#)
- single bond, [201](#)
- triple bond, [201](#)

Molecular modeling, [203](#)

Molecular size

- drug distribution affected by, [63](#)
- pharmacokinetic activity affected by, [57](#)

Mometasone, for asthma, [596t](#)

Monitoring

- for burn patient, [852](#)
- intraoperative, for liver disease, [719](#)
- issues in, [298–299](#)
- neonatal, during anesthesia, [1106](#)
- neurophysiologic, [664–666](#)
 - during surgery, [665b](#)
- obesity and, [1009](#)
- for procedures outside, of operating room, [298–299](#)
- systematic approach to, [291](#)
- of temperature, [297–298](#)
- during thoracic surgery, [628](#)
- during vascular surgery, [536](#)

Monitoring standards, from American Association of Nurse Anesthetists, [290](#)

Monoamine oxidase inhibitors

- as psychiatric drugs, [199–200](#)

Monoamines, as neurotransmitter, [654t](#)

Monoclonal antibodies, [968–969](#), [968f](#)

Monocular blindness, [553](#)

Monocyte, [960–962](#), [960t](#)

Mononuclear phagocyte system (MPS), [959](#)

Monopril, [Fosinopril](#)

Monro-Kelly doctrine, [661–662](#)

Montelukast, for asthma, [596t](#)

Morbid obesity, [404](#)

- airway management difficulty associated with, [404b](#)
- outpatient surgery for, [892](#)

Morbidity

- in anesthesia, [1216–1217](#), [1218f](#)
- classification of, [1217b](#)

Morphinans, opioids derived from, [129b](#)

Morphine, [136–137](#)

- for acute pain, [1173](#)
- advanced renal disease and, [698](#)
- in assisted reproductive technologies, [1204–1205](#)
- cerebral physiology affected by, [659t](#)
- chemical structure of, [129f](#)
- for chronic pain, [1187](#)
- doses of, [135t](#), [1036t](#)
- extended-release epidural, [1036](#)
- history of, [128](#)
- for labor analgesia, [1072](#), [1078](#)
- other opioids compared to, [136t](#)

- for patient-controlled analgesia, [1175](#), [1175t](#)
 - pediatric, [1181t](#)
- pharmacokinetics of, [131t](#)
- receptor sites of, [129t](#)

Morphine sulfate, for pediatric premedication, [1124t](#)

Mortality

- factors associated with, [1218t](#)
- pregnancy-related, [1217](#)

Morton, William T.G., [1](#)

Motilin, effects and therapeutic uses of, [733t](#)

Motion artifact, in pulse oximetry, [296](#)

Motor cortex, stimulation of, [306–307](#)

Motor end plate, [760–761](#)

Motor-evoked potentials, [306–307](#)

- brain monitoring with, [301t](#)
- intraoperative monitoring of, [664](#)
- neurologic monitoring with, [301b](#)
- neurophysiologic monitoring of, [915t](#)

Motor pathways, [657–658](#)

Motor threshold (MT), [1209](#)

Motor unit, [760](#), [761f](#)

Motor vehicle collision, trauma from, [855](#), [857](#)

Mouth

- anatomy of, [397](#)
- anomaly of, airway management and, [319b](#)

Mucopolysaccharidosis, [404b](#)

- airway management difficulty associated with, [404b](#)

Multi-minicore disease, [775](#)

Multiple ANOVA (MANOVA), [38](#)

Multiple myeloma, [978](#)

Multiple organ dysfunction syndrome, [488](#)

Multiple sclerosis, autoimmunity and, [972](#)

Murphy sign, [721](#)

Murphy's eye, [565–566](#)

Muscarinic receptor, [176t](#)

Muscle(s)

- in back, [1016](#)
- cardiac, [760](#)
 - cells, [447](#)
 - contraction of, [446f–447f](#)
- contraction of, [141](#)
 - isometric, [765](#)
 - isotonic, [765](#)
 - process of, [760](#)
- depolarization of, [141](#)
- extraocular, [925](#), [926f](#)
- eyelid, [925](#)
- inferior oblique, [925](#)
- inferior rectus, [925](#)
- of larynx, [565b](#)
- levator, [925](#)
- motor pathways and, [657](#)
- orbicular, [925](#), [927f](#)
- orbital, [926t](#)

- papillary, [443](#)
- physiology of, [765–768](#), [765f](#)
- rigidity of, opioids associated with, [133–134](#)
- scalene, brachial plexus block and, [1047f](#)
- skeletal, [760](#)
- slow *versus* fast, [768](#)
- smooth, [760](#)
- superior oblique, [925](#)
- superior rectus, [925](#)
- transversus abdominis, [1057–1058](#)
- ulnar flexor, [1054–1055](#), [1055f](#)

Muscle cramping, dialysis and, [695](#)

, Muscle fibers, [760](#)

- structural arrangement of, [765f](#)

Muscle pain, succinylcholine associated with, [151–153](#)

Muscle reflexes, preoperative evaluation of, [321](#)

Muscle relaxants

- in cardiac surgery, [494](#)
- for chronic pain, [1188](#)

Musculoskeletal system, [760–781](#)

- disorders of, [321](#)
- evaluation of, [319–321](#)
- preoperative evaluation of, [321](#)

Myalgia, succinylcholine associated with, [151–153](#)

Myasthenia gravis, [768–771](#)

- anesthetic implications for, [770–771](#), [771b](#)
- clinical manifestations of, [769–770](#)

- epidemiology of, [768](#)
- pathophysiology of, [768–769](#), [769f](#), [770t](#)
- treatment of, [770](#)

Mydriatics, as ocular medications, [932t](#)

Myelin, [645–646](#)

Myelinated axon, [111f](#)

Myelinolysis, [360](#)

Myelomeningocele, neonatal anesthesia for, [1115–1116](#), [1116f](#)

Myocardial cell, [446](#), [446f](#)

Myocardial infarction

- abdominal aortic aneurysm and, [543](#)
- after cardiac surgery, [479–480](#)
- clinical classifications of, [326t](#)
- heart failure from, [482](#)
- monitoring for, [272](#)
- perioperative, [1222](#)
 - independent predictors of, [1223t](#)

Myocardial oxygen balance, perioperative management of, [480t](#)

Myocardial oxygen consumption, [451](#), [451t](#)

Myocardial oxygen supply and demand, [479–480](#), [480f](#)

Myocardial revascularization, [501–504](#)

- minimally invasive, [513–514](#), [514f](#)

Myocardial sarcomere, [446–447](#), [446f](#)

Myocarditis, [770](#)

- in sudden cardiac death, [1221t](#)

Myocardium, [443](#)

- contractility of, [452](#)

- of newborn, [1093](#)
- in older adult, [1137](#)

Myoclonia

- etomidate associated with, [99](#)
- propofol associated with, [95–96](#)

Myofibrils, [765](#)

Myoglobinemia

- burn injury and, [844](#)
- pneumatic tourniquet associated with, [946](#)

Myoglobinuria

- burn injury and, [850](#)
- pneumatic tourniquet associated with, [946](#)

Myoneural junction, [760](#)

Myopic (nearsighted) eye, [930](#)

Myoplasm, [765](#)

Myosin, cardiac muscle contraction and, [446–447](#), [446f–447f](#)

Myosin filament, [765f](#)

Myositis, rheumatoid, [780](#)

Myotonias, [777](#)

Myotonic dystrophy, [777–779](#)

- anesthetic implications for, [778–779](#), [779b](#)
- incidence of, [778](#)
- pathophysiology of, [778](#)
- treatment of, [778](#)

Myringotomy, [916](#)

Myxedema, hypothyroidism and, [821](#)

Myxedema coma, [822](#)

N

N-acetylcysteine, for burn injury, [847](#)

N-methyl-D-aspartate amino acid receptor, [101](#), [102f](#)

N-methyl-D-aspartate antagonists, for acute pain, [1173–1174](#)

N-methyl-D-aspartate (NMDA), in growth and development, of pediatric brain, [1220](#)

N-methyl-D-aspartate (NMDA) receptors, in chronic pain, [1188](#)

Nadbath eyelid block, [938](#), [944b](#)

Nalbuphine, [138](#)

chemical structure of, [129f](#)

for labor and delivery, [1072](#)

other opioids compared to, [136t](#)

pharmacokinetics of, [131t](#)

receptor sites of, [129t](#)

Nalmefene, [138–139](#)

other opioids compared to, [136t](#)

receptor sites of, [129t](#)

Naloxone, [138](#)

cerebral physiology affected by, [660](#)

chemical structure of, [129f](#)

other opioids compared to, [136t](#)

receptor sites of, [129t](#)

Naltrexone, [139](#)

other opioids compared to, [136t](#)

receptor sites of, [129t](#)

Naratriptan, long QT syndrome and, [1222t](#)

Narcotic, definition of, [128](#)

Narkomed 6000 ventilator, [262–263](#)

Nasal cavities, [563](#), [904](#)

Nasal conchae, [563](#)

Nasal procedures, [921](#)

Nasal RAE tubes, for ENT procedures, [908](#)

Nasal septum, [563](#), [904](#)

Nasoendotracheal tube, [904–905](#)

Nasolacrimal duct, [930](#)

Nasopharyngitis, infectious, [333](#)

Nasopharynx

- anatomy of, [398](#)
- pathologic conditions of, in pediatric patient, [1130b](#)

Natalizumab, Crohn's disease treated with, [734b](#)

Nateglinide, for type 2 diabetes, [801t](#)

National Association of Nurse Anesthetists (NANA), [5](#)

National Board of Certification and Recertification for Nurse Anesthetists (NBCRNA), [16–17](#)

National Certification Examination (NCE), [15](#)

National Confidential Inquiry into Patient Outcome and Death, [1218](#)

National Fire Protection Association, cylinder regulations from, [235](#)

National Institute for Health and Clinical Excellence (NICE), antibiotic prophylaxis and, [192](#)

Partial-thickness burns, [843](#)

Participation, patient-centered care and, [21](#)

Pascal, [207–208](#)

Passive immunity, [966f](#), [967–968](#), [968f](#)

Pathogen-associated molecular patterns (PAMPs), [959](#)

Patient Blood Management (PBM), [370–371](#), [371b](#), [371t](#)

Patient-centered care, [20–24](#)

- benefits of, [22](#)
- concept of, [20–21](#)

- cultural competence and, [22–23](#), [24t](#)
- decision making and, in anesthesia, [24](#)
- as dimension of safety and health care quality, [24](#)
- measurement of health care quality in anesthesia, [24–25](#)

Patient-controlled analgesia

- for acute pain, [1175](#), [1175t](#)
- epidural, [1035–1036](#), [1076](#)
- fentanyl for, [137](#)
- for pediatrics, [1180–1181](#), [1181t](#)
- postoperative pain management with, [1158](#)

Patient engagement, [21–22](#)

- shared decision-making, [22](#)

Patient-intervention-comparison-outcome (PICO) approach, [41–42](#)

Patient-level variables, racial and ethnic disparities, [22](#)

Patient Protection and Affordable Care Act, [23](#), [25](#)

Patient refusal, regional anesthesia contraindicated by, [1042](#)

Patient-specific plan, for anesthesia care, [1196](#)

Patients

- alcohol intake by, [315–316](#)
- anesthetic history of, [313](#)
- applying evidence to, [46–47](#), [46b](#), [47f](#)
- assessment of, timing of, [311](#)
- drug history of, [314](#)
- education, of, objectives of, [313b](#)
- elderly
 - hemodynamic changes in, [745](#)
 - pain in, [1179–1180](#), [1180t](#)

perioperative mortality and morbidity in, [1217–1220](#)
postoperative cognitive dysfunction in, [1219](#), [1219t](#)
postoperative hypothermia in, [1159–1160](#)
evaluation for, outpatient surgery, [894–898](#)
fasting interval for, [343](#)
handoff, [1231–1234](#)
health history of, [313](#)
heat loss from, [211f](#)
illicit drug use by, [316](#)
interview of, preoperative, [312–317](#)
intoxicated, management of, [716b](#)
mechanical ventilation of, [214](#)
medical history of, [313](#)
monitoring of, during anesthesia, [272](#), [299](#)
optimization of, thoracic surgery preoperative evaluation and, [627–628](#)
pediatric, anesthesia for, [1117–1135](#)
physiologic response of, anesthesia and, [1196](#)
positioning of
 for arthroscopy, [949](#), [949f–950f](#)
 for elbow arthroplasty, [953](#)
 for hip arthroplasty, [951](#)
 for orthopedic procedures, [948](#), [948f–949f](#)
 for shoulder arthroplasty, [952](#)
 for spinal surgery, [955](#), [955f](#)
postanesthesia recovery of, [1147](#)
preexisting conditions of, nerve injury and, [383](#)

- pregnant, nonobstetric procedure for, 1090*b*
- preoperative evaluation of, 311–345
- preparation for, 311–345
 - outpatient surgery, 894–898
- recovery after, outpatient surgery, 903
- satisfaction with, outpatient surgery, 889
- screening for, outpatient surgery, 894
- selection for, outpatient surgery, 890–893
- social history of, 314–317
- surgical history of, 313
- surgical positioning for, 380
- tobacco use of, 314–315

Peak inspiratory pressure, ventilation and, 258

Peak plasma level, as local anesthetic additives, 116–117

Pectus carinatum, 620

Pectus excavatum, 620

Pediatric anesthesia, 1117–1135

- agents for, 1118–1120
- anatomy and physiology in, 1117
- anesthetic management in, 1124–1133, 1124*b*, 1127*t*, 1128*b*–1130*b*, 1129*f*, 1131*t*–1132*t*
- cardiac arrest associated with, 1134–1135, 1134*f*
- difficult airway in, 1130, 1130*b*
- drug administration in, 1118
- emergence from, 1130
- extubation in, 1130
- fluid management in, 1130–1133

induction of, [1125–1126](#)
inhalation (mask) induction for, [1125](#)
intramuscular induction for, [1126](#)
intravenous induction for, [1125](#)
morbidity and mortality in, [1134–1135](#), [1134f](#)
outpatient, [1134](#)
parent presence during induction of, [1124](#)
pharmacologic considerations in, [1117–1120](#), [1118f](#), [1118t](#)
postoperative care after, [1133–1134](#)
preoperative preparation for, [1120–1124](#), [1121t](#), [1122b–1123b](#),
[1124t](#)
regional, [1134](#)

Pediatric Anesthesia and NeuroDevelopment Assessment
(PANDA) study, [86](#)

Pediatric anesthetic neurotoxicity, [1220f](#)

Pediatric brain, growth and development of, anesthetic
complications related to, [1220–1221](#)

Pediatric dentistry, [1205](#)
anesthetic considerations in, [1206](#)

Pediatric Perioperative Cardiac Arrest Registry, [1134–1135](#)

Pelvic procedure, hernia, spinal anesthesia for, [1026t](#)

Pelvis, venous circulation of, [459](#)

Penbutolol, dosage and effects of, [172t–173t](#)

Penicillin, allergy, [191–192](#)

Pentazocine, other opioids compared to, [136t](#)

Pepsinogen, [725](#)

Peptic ulcer disease, [725](#)

Peptide hormones, [782](#)

Peptide YY, effects and therapeutic uses of, [733t](#)

Percentage of glottic opening, [406](#)

Perception, of pain, [1169](#)

Percutaneous coronary intervention (PCI), [1202](#), [1202b](#)

Percutaneous endoscopic lumbar discectomy, [953](#)

Percutaneous mitral valve repair, [516](#)

Percutaneous transtracheal jet ventilation (PTJV), [431](#)

Perfusion, surgical positioning effect on, [381](#)

Perianesthesia patient care, [1147](#)

Peribulbar block, [932](#), [933f](#)

Peribulbar extraconal techniques, [936–937](#), [936f](#)

Pericardial cavity, [441](#)

Pericardial disease, [464–467](#)

Pericardial tamponade, blunt trauma and, [857](#)

Pericardiocentesis, [466](#), [501](#)

Pericarditis

- acute, [464–465](#)
- chronic constrictive, [465](#)

Pericardium, [441](#), [442f](#)

Perijunctional area, [763](#)

Perinatal period, terminology used during, [1093b](#)

Perindopril, dosage and effects of, [172t–173t](#)

Perineurium

- peripheral nerve structure and, [110](#)
- transverse section of, [111f](#)

Period, of wave, [216](#)

Periodontics, [1205–1206](#)

anesthetic considerations in, [1207](#)

Perioperative fluid management, and enhanced recovery after surgery, [755](#)

Perioperative goal-directed fluid therapy (PGDT), [354–359](#), [355b](#)
hemodynamic monitoring and, [355–357](#), [355f](#)
, Perioperative Ischemic Evaluation (POISE) trial, [1222](#)

PeriOperative ISchemic Evaluation trial (POISE-2), [839–840](#)

Perioperative medications, recommended dosing for, [1144t](#)

Perioperative nausea and vomiting, [192–197](#)

Perioperative neuropathies, [383–386](#)

Perioperative pulmonary complications, [1222–1225](#)

Peripheral airways disease, [584](#)

Peripheral nerve blockade, complications of, [1043](#)

Peripheral nerve blocks
for acute pain, [1175](#)
continuous, for acute pain, [1175](#)
in outpatient surgery, [901](#)
for pediatric patient, [1181](#), [1181t](#)

Peripheral neuropathies, central neuraxial blockade with, [1020](#)

Peripheral vascular disease, [535–537](#)
preoperative evaluation of, [535–536](#)
treatment of, [535](#)

Peritoneal oocyte and sperm transfer (POST), [1204t](#)

Peritubular capillary bed, [682–683](#)

Persistent pain, [1183](#)

Persistent pulmonary hypertension of the newborn (PPHN), [1092–1093](#)

pH

- drug ionization and, [57–58](#)
- local anesthetics action, [115](#)
- neonatal, [1096](#)
- normal balance of, [577](#)
- select body fluids, [59b](#)
- urinary, drug elimination affected by, [69](#)

Phagocyte, [959](#)

- cells of, [964f](#)

Phagocytosis, [959](#)

Phagosome, [962f](#)

Pharmacodynamics

- anesthetics and, [48–56](#)
- concepts, [56b](#)

Pharmacodynamics, in neonate, [1101](#)

Pharmacogenetics, [50–51](#)

- definition of, [70](#)
- history of, [70–71](#)
- opiates and, [132b](#)
- pharmacogenomics and, [70–71](#)

Pharmacogenomics

- definition of, [70](#)
- pharmacogenetics and, [70–71](#)

Pharmacokinetics, [57–72](#)

- age influence on, [69](#)
- definition of, [57](#)
- disease state influence on, [69–70](#)
- gender influence on, [69](#)

in neonate, [1100–1101](#)
properties that influence, [57–69](#)
summary of principles, [70b](#)
temperature influence on, [69](#)

Pharmacology

autonomic, [165–189](#)
cardiac, [165–189](#)
definition of, [48](#)

Pharmacotherapy

for asthma, [332](#), [332t](#)
cardioprotective, [329–330](#)

Pharyngeal arch, [397](#)

Pharynx, [905](#)

airway management and, [319b](#)
airway obstruction and, [398](#)
anatomy of, [397](#), [564](#)
obesity and, [1001–1002](#)
patency of, [1127–1128](#)
pathologic conditions of, in pediatric patient, [1130b](#)
view of, [399f](#)

Phase II block, [153–154](#), [153b](#)

Phenanthrene, [128](#)

opioids derived from, [129b](#)

Phenols, [204](#), [204f](#)

Phenoxybenzamine, [170–171](#)

adrenergic receptor blockade with, [814–815](#)
for pheochromocytoma, [815t](#)

Phentolamine, [171](#)

doses of, [170t](#)

for pheochromocytoma, [816t](#)

Phenylephrine, [168](#)

cardiac effects of, [169t](#)

doses of, [170t](#)

for maternal hypotension, [1079](#)

as ocular medication, [932t](#)

Phenylethanolamine-N-methyltransferase (PNMT), [812](#)

Phenylpiperidine, [128](#)

opioids derived from, [129b](#)

Phenytoin

for myotonic dystrophy, [778](#)

protein binding of, [59–60](#)

Pheochromocytoma, [812–816](#)

anesthetic management of, [815–816](#)

clinical manifestations of, [814](#), [814t](#)

diabetes associated with, [799](#)

incidence and associated disease in, [813–814](#), [814t](#)

intraoperative management of, [816t](#)

postoperative management of, [816](#)

preoperative management of, [814–815](#), [815t](#)

surgery for, [814–815](#)

Phonomyography, [141](#)

Phosphate

balance, disorders of, [367–368](#), [368t](#)

metabolism of, parathyroid hormone and, [791](#)

Phosphate buffer, renal regulation and, [686–687](#)

Phosphocreatine-creatine system, [768](#)

Phosphodiesterase inhibitors, [168](#)

Phosphoinositides, [49t](#)

Photoacoustic gas analyzer, [222](#)

Photodynamic therapy (PDT), [983](#), [988](#)

Photon, [220](#)

- definition of, [983](#)
- energy of, [983](#)
- interaction of, with electron, [984f](#)

Physical examination

- in central neuraxial blockade, [1020](#)
- patient assessment with, for outpatient surgery, [894](#)
- for thoracic surgery, [624–625](#)

Physician, opposition of, to nurse anesthetist, [4](#)

Physician Quality Reporting System (PQRS) Program, [25](#)

Physics, of anesthesia, [201–227](#)

- Newtonian, [206–208](#)
- quantum, [220–227](#)

Pia mater, [648](#), [648f](#), [1017](#)

Pickwickian syndrome, [1002–1003](#)

PICO approach, [41–42](#)

Pierre Robin syndrome, [404](#), [1130b](#)

- airway management difficulty associated with, [404b](#)

Piezoelectric crystals, [288](#)

Piezoelectric effect, [216](#)

Piezoelectric gas analysis, [222](#)

Piggyback technique, for liver transplantation, [882](#)

Pilocarpine, as ocular medications, [932t](#)

Pilot study, description of, [34](#)

Pimozide, long QT syndrome and, [1222t](#)

Pin index safety system (PISS), [234](#), [234f](#)

Pin position, anesthesia gas machine cylinder and, [234](#)

Pindolol, dosage and effects of, [172t–173t](#)

Pinocytosis, [685](#)

Pioglitazone, for type 2 diabetes, [801t](#)

Pipeline

- to anesthesia gas machine, [232f](#)
- connections in, diameter index safety system and, [232f](#)
- gas supplied through, [232–233](#), [232f](#)
- oxygen pressure loss in, [233b](#)
- supply of gases by, problems with, [232](#)

Piperidine, opioids derived from, [129b](#)

Pitavostatin, dosage of, [188t](#)

Pitocin, [1079](#)

Pitressin, [Vasopressin](#)

Pituitary gland, [784–790](#)

- anterior pituitary lobe, [785–788](#)
 - disorders of, [786–787](#)
 - hypersecretion of, [787](#)
 - hyopsecretion of, [787](#)
- hormone secretion, control of, [786](#), [786f](#), [786t](#)
- hypothalamus and, [784–785](#)
- location of, [785f](#)

- posterior pituitary lobe, [788–790](#), [789f](#)
 - tumors in, [786–787](#)
- Pituitary hormones
 - secretion of, control of, [786](#)
 - target sites for, [785f](#)
- Pituitary stalk, [784–785](#)
- Pituitary surgery, [672–673](#)
 - transsphenoidal approach to, [673](#)
- pKa, [Dissociation constant \(pKa\)](#)
- Placebo analgesia, chronic pain and, [1186](#)
- , Placenta
 - abnormal implantation of, [1088–1089](#)
 - abruption of, [1088–1089](#)
 - drugs, transfer and fetal effects of, [1067–1068](#)
 - in fetal circulation, [1092](#)
- Placenta accreta, [1088](#), [1089f](#)
- Placenta increta, [1089f](#)
- Placenta percreta, [1089f](#)
- Placenta previa, [1088](#), [1089f](#)
- Placental barrier, opioids crossing, [130](#)
- Placental villi, [1067](#)
- Planck's constant, [220](#)
- Plantar fasciotomy, [957](#)
- Plasma, [201](#)
 - concentration of drug in, [63](#)
 - fresh frozen, [374–375](#)
 - glucose removal from, [796](#)

osmolarity, [789](#)
osmotic threshold of, [789](#)
oxygen dissolved in, [575](#)
volume of, during pregnancy, [1064](#), [1066t](#)

Plasma concentration curve, [64–65](#)

Plasma oncotic pressure, [347](#)

Plasma protein

- binding, hormone and, [782](#)
- propofol binding to, [95](#)

Plasma thromboplastin antecedent, [826t](#)

Plasmalyte-A, [349t](#), [350](#)

Plasmapheresis, for myasthenia gravis, [770](#)

Plasmin, [828](#)

Plasminogen, [828](#)

Plateau pressure, [568–569](#)

Platelet(s), [375–376](#), [961f](#)

- abnormalities during perioperative period, [377t](#)

- adhesion and aggregation, [826f](#)

- attachment of, [823](#)

- components of, [823](#)

- function of, hypothermia and, [863](#)

- hemostasis and, [375–376](#)

- infusion guidelines of, [831–832](#)

- membrane surface of, [823](#)

- metamorphosis of, [824–825](#)

- minimum counts before invasive procedures, [376b](#)

- during pregnancy, [1066t](#)

- receptors, glycoproteins, and common inhibitor of, [838f](#)

- replacements of, [832t](#)

- transfusion guidelines for, [376b](#)

Platelet count, [830–831](#), [830t](#)

- test for, in pediatric patient, preoperative preparation of, [1123b](#)

Platelet-derived growth factor, [400](#)

Plendil, [Felodipine](#)

Plethysmography variability index, [357t](#)

Pleura

- anatomy of, [567](#)

- drug-induced adverse effects on, [614](#)

- parietal, [567](#)

- visceral, [567](#)

Pleural cavity, [567](#)

- blood in, [619](#)
- Pleural effusion, [620](#)
- Pleural pressure, [570f](#)
- Pleural space, [567](#)
 - conditions that affect, [567t](#)
 - fluid in, [620](#)
- Plume, [911](#)
- Pneumatic system, low-pressure
 - components in, [231b](#)
- Pneumatic tourniquet, [946](#)
- Pneumocephalus, [394](#)
- Pneumomediastinum, pneumoperitoneum associated with, [749](#)
- Pneumonitis
 - aspiration, [Aspiration pneumonitis](#)
 - chronic, drug-induced, [615](#)
- Pneumopericardium, pneumoperitoneum associated with, [749](#)
- Pneumoperitoneum, [758–759](#)
 - cardiovascular effects of, [744–745](#)
 - creation of, [743](#)
 - hemodynamic changes in, [745](#)
 - hepatic and splanchnic effects, [747](#)
 - immunologic effects of, [747](#)
 - physiologic effects of, [743–747](#)
 - pressure effects, [745b](#)
 - pulmonary function changes associated with, [746b](#)
 - renal effects of, [747](#)
 - respiratory effects of, [745–747](#)

Pneumothorax, [567](#), [618–619](#)
 blunt trauma and, [857](#)
 closed, [618f](#)
 communicating, [618](#), [618f](#)
 intercostal nerve blocks and, [1056](#)
 nitrous oxide and, [619](#)
 pneumoperitoneum associated with, [749](#)
 simple, [567](#), [618](#), [618f](#)
 tension, [Tension pneumothorax](#)

Podiatry
 anesthesia for, [946–958](#)
 patient positioning in, [948](#), [948f–949f](#)

Poiseuille's law, [213–214](#), [460](#)
 resistance to breathing and, [570](#)

Polarographic electrode, [223](#), [223f](#)

Polycystic ovary syndrome, diabetes associated with, [799](#)

Polymorphisms, [71](#)

Polymyositis, pulmonary manifestations of, [616b](#)

Polyneuropathy, peripheral, in central neuraxial blockade, [1020](#)

Polypharmacy
 older adult and, [1143](#)
 in pain management, [1188](#)

Polysomnography, [320–321](#), [581](#)

Polyuria
 diabetes insipidus with, [790](#)
 hyperglycemia and, [799](#)
 postoperative, [1164](#)

Pons, [647–648](#), [648f](#)
 apneustic center in, [579](#)
 location of, [580f](#)

Popliteal fossa, transverse view of, [1062f](#)

Popliteal nerve block, [1061f](#)

Pores of Kohn, [566](#), [569](#)

Porphyria, etomidate associated with, [101](#)

Port-access coronary artery bypass (PA-CABG), [514](#)

Portocaval shunt, [334–335](#)

Portopulmonary hypertension, [879](#)

Positioning
 airway management and, [403f](#)
 for caudal anesthesia, [1040](#)
 for epidural anesthesia, [1032](#)
 extreme, physiologic changes associated with, [753–754](#), [754b](#)
 for obese parturient, for laryngoscopy, [1082f](#)
 ramping of patient, [402–403](#), [404f](#)
 remote location monitoring of, [1197](#)
 for spinal anesthesia, [1023](#), [1026–1027](#)
 surgical, [380–396](#)
 airway complications of, [391](#)
 injuries associated with, [384t](#), [385b](#), [390t](#)
 physiologic effects of, [380–382](#)
 spinal cord injury associated with, [387](#)
 for venous air embolus, [671–672](#), [672f](#)

Positioning device
 brachial plexus injury associated with, [387](#)

nerve injury caused by, [383](#), [383b](#)

Positive end-expiratory pressure (PEEP)

- automatic, [638–639](#)
- cardiovascular pressures affected by, [282–283](#), [283f](#)
- electronic selection of, [261](#)
- intrinsic, [590–591](#), [590f](#)
 - one-lung ventilation and, [639](#)
 - optimal pressure for, [590f](#)
 - ventilator and, [259f](#)

Positive feedback, hormone secretion and, [784](#)

Positive-pressure device, [939](#)

Positron emission tomography (PET), [1214](#)

Post-gastric bypass anastomotic leaks, [1014](#), [1014b](#)

Post reperfusion syndrome, [882](#), [883t](#)

Post tonsillectomy hemorrhage (PTH), [917](#)

Post transfusion purpura, [378](#)

Postanesthesia care unit, [1147](#)

- admission, [1147](#)
- Aldrete scoring system, [1148](#)
- assessment in, initial, [1147–1149](#), [1149b](#)
- discharge from, [1164–1165](#), [1164b](#)
- pain management, [1158–1159](#)

Postanesthesia Discharge Scoring, [1164](#), [1164b](#)

Postanesthesia recovery, [1147–1166](#)

- score for, [1149b](#)
 - street fitness, [1165t](#)

Postdischarge nausea and vomiting (PDNV), [192](#), [1160](#)

incidence of, [1162t](#)
risk factors for, [195b](#)

Postdural puncture headache (PDPH), [1028–1029](#), [1084–1085](#)
in central neuraxial blockade, [1020](#)
in combined spinal epidural anesthesia, [1040](#)
, in epidural anesthesia, [1037](#)
needles for, [1023](#)
treatment of, [1084–1085](#)

Posterior fossa surgery, [670–672](#)
postoperative consideration with, [672b](#)
surgical positioning for, [671–672](#), [672f](#)

Posterior ischemic optic neuropathy (PION), [754](#)

Postganglionic axons, [650–651](#)

Postgestational age, at surgery, [1106](#)

Postjunctional end plate, [761–763](#)

Postoperative cognitive dysfunction (POCD), [86](#), [1146](#), [1219](#)
characteristics of, [1219t](#)
prevention of, [1146](#)
risk factors for, [1146](#)

Postoperative delirium, [1141](#), [1145–1146](#), [1156](#)

Postoperative nausea and vomiting (PONV), [192](#), [755–756](#), [1160](#)
incidence of, [1162t](#)
laparoscopy and, [750](#)
management of, [1162](#), [1162f](#)
nonpharmacologic interventions for, [1162–1163](#)
primary risk factors, [1160b](#)
prophylaxis for

obesity and, [1009–1010](#)
risk factors of, [195b](#)

Postoperative pulmonary complications, risk factors for, [1140b](#)

Postoperative urinary retention (POUR), [1030](#)

Postoperative visual loss, [387–389](#), [956–957](#), [957b](#)
robotic surgery and, [754](#)

Postpartum hemorrhage, [1086](#), [1087f](#)

Posttetanic count, neuromuscular blockade testing with, [143–145](#),
[143t](#), [145b](#)

Posttraumatic stress disorder (PTSD), in intraoperative awareness,
[1225](#)

Potassium

- absorption of, in colon, [734](#)
- balance, disorders of, [361–364](#)
- in crystalloid solutions, [1132t](#)
- imbalance of, dialysis and, [698](#)
- indications for testing of, [342b](#)
- in newborn, requirements for, [1103b](#)
- in pediatric patient, preoperative preparation of, [1123b](#)

Potassium channel, nerve impulse and, [652–653](#)

Potassium ion, [111f](#)
equilibrium potential of, [448t](#)
nerve impulse and, [652](#)

Potassium-sparing diuretics, [172t–173t](#)

Potassium-titanyl-phosphate laser, [984](#), [988](#)

Potential, drug interaction terminology, [55t](#)

Pouches, [397](#)

Power, research sensitivity and, [37–38](#)

PR segment, [272](#), [273f](#)

Prasugrel

coronary stent and, [326](#)

pharmacodynamic properties of, [838t](#)

Pravachol, [Pravastatin](#)

Pravastatin

dosage of, [188t](#)

perioperative use of, [329](#)

Prazosin, [171](#)

adrenergic receptor blockade with, [815](#)

dosage and effects of, [172t–173t](#)

for pheochromocytoma, [815t](#)

Preanesthesia assessment, standards for remote location anesthesia and, [1194–1195](#)

Preanesthesia assessment clinic, [311](#)

Preanesthesia checkout, [266–267](#), [267b](#)

procedures, recommendations for, [268b–270b](#)

Preanesthesia questionnaire, [312](#)

Preanesthetic evaluation, for obesity, [1007–1009](#)

Preanhepatic phase, of liver transplantation, [881–882](#)

Precardiopulmonary bypass period, [494–497](#)

Precordial Doppler, for detection of venous air embolism, [671t](#)

Prednisolone, for asthma, [596t](#)

Prednisone, for asthma, [596t](#)

Preeclampsia, [1086–1088](#)

anesthetic implications of, [1088](#)

description of, [1086–1087](#)

obstetric management of, [1087](#)
pathophysiology of, [1087](#)
placental insufficiency and, [1067](#)

Pregabalin

for chronic pain, [1176](#)
for neuropathic pain, [1187–1188](#)

Pregnancy

acute kidney injury and, [692](#)
anatomic and physiologic changes during, [1064–1068](#)
anesthesia during, number of deaths in, [1217t](#)
antihypertensive drugs during, [184](#), [187t](#)
asthma and, [595–597](#)
cardiac arrest in, [1085](#)
cardiovascular changes in, [1064–1065](#)
complications of, [1086–1089](#)
gastrointestinal changes in, [1066](#)
hematologic changes in, [1065](#)
hepatic changes in, [1066](#)
inhalation anesthetics and, [77](#), [91](#)
local anesthetic drugs use during, [119](#)
myasthenia gravis and, [769](#)
myotonic dystrophy and, [779](#)
nervous system changes in, [1066](#)
obesity and, [1005](#)
outpatient surgery postponed by, [895](#), [895t–896t](#), [898](#)
in pediatric patient, preoperative preparation of, [1123b](#)
physiologic changes in, [1066t](#), [1067b](#)

- propofol use during, [95](#)
- renal changes in, [1066](#)
- respiratory changes in, [1065–1066](#)
- testing for, [341](#)
 - indications for, [342b](#)
- Prejunctional receptors, [764](#)
- Premature Infant Pain Profile (PIPP), [1180](#)
- Premature infants, outpatient surgery for, [891b](#)
- Premature ventricular contraction, hemodynamic waveform altered by, [281](#)
- Premedication
 - delayed awakening associated with, [1157](#)
 - emergence delirium associated with, [1156](#)
 - pediatric, [1123–1124](#), [1123b](#), [1124t](#)
- Preoperative autologous donation (PAD), [372](#)
- Preoperative considerations, in diabetes mellitus, [800–802](#)
- Preoperative evaluation/assessment, [317–340](#)
 - for abdominal aortic aneurysm repair, [543](#)
 - for asthma, [594–597](#)
 - benefits of, [312b](#)
 - for cardiac surgery, [489–491](#)
 - of carotid endarterectomy, [553–554](#)
 - for chronic obstructive pulmonary disease, [588–589](#)
 - for hypertension, [462–463](#)
 - for liver disease, [716–718](#)
 - in neonate, [1106–1111](#)
 - for older adult patient, [1136](#)

- of patient, [311–345](#)
- for pediatric patient, [1120](#)
- for peripheral vascular disease, [535–536](#)
- for pituitary surgery, [673](#)
- for scoliosis, [621–622](#)
- for subarachnoid hemorrhage, [676](#)
- for supratentorial surgery, [666](#)
- for thoracic and thoracoabdominal aneurysms, [547–548](#)
- for thoracic surgery, [624–628](#), [626b](#)

Preoperative history, in central neuraxial blockade, [1020](#)

Preoperative interview

- objectives of, [313b](#)
- of patient, [312–317](#)

Preoxygenation, trauma and, [859](#)

Pressure

- absolute, [208](#)
- atmospheric, [208](#)
- Dalton's law of, [212](#)
- gauge, [208](#)
- measurement of, [208](#)
- pathways for, [656](#)
- vapor, [210–211](#)

Pressure-controlled ventilation, [258–259](#), [259f](#)

Pressure-volume diagram, [454f](#)

Pressure-volume loops, [295](#), [295f](#)

Pressure waves, [216–217](#)

Presynaptic α_2 -agonism, [171f](#)

Presystemic elimination, drug absorption and, 60

, Prilocaine

chemical structure of, 114*f*

clearance half-life of, 118*t*

clearance half-life of, 118*t*

dosage guidelines of, 121*t*

intercostal nerve block with, 1057

potency of, 115

Procardia XL, Nifedipine

Procoagulant

in endothelium, 825*f*

mediators of, 824*t*

Proconvertin, 825–826, 826*t*

Prodynorphin, opiate receptors and, [128](#)

Progressive systemic sclerosis, pulmonary manifestations of, [616b](#)

Prolactin, [786](#)

Prolactin-inhibitory factor, [786t](#)

Prolonged QT syndrome, conditions at risk for, [196b](#)

Prone position, [395f](#)

- respiratory dynamics affected by, [954](#)
- for spinal surgery, [954–955](#), [955f](#)

Propensity score, description of, [38](#)

Propofol, [93–98](#)

- for advanced renal disease, [699](#)
- allergies and use of, [97–98](#)
- for asthma, [595](#)
- binding in, [96f](#), [106](#)
- carcinoid syndrome treated with, [741](#)
- cardiac and respiratory systems affected by, [97t](#)
- cardiovascular effects of, [96–97](#)
- central nervous system affected by, [97t](#)
- cerebral metabolism affected by, [555](#)
- cerebral physiology affected by, [659t](#), [660](#)
- cesarean section, general anesthesia and, [1081](#)
- chemical structure of, [93](#), [94f](#)
- contraindications for, [97](#)
- deliberate controlled hypotension with, [911t](#)
- electroencephalogram affected by, [303](#)
- elimination half-life of, [93](#)
- induction dose of, [99t](#)

- key points for, [98b](#)
- kinetics, [95f](#)
- mechanism of action, [95](#)
- metabolism of, [93](#)
- obstetric use of, [97](#)
- pediatric anesthetic neurotoxicity in, [1220f](#)
- for pediatric patient, [1119](#)
- pH of, [93](#)
- pharmaceutic preparation of, [94t](#)
- pharmaceutics of, [93](#)
- pharmacodynamics of, [95–97](#)
- pharmacokinetics of, [93–95](#)
- protein binding of, [59–60](#)
- reformulations of, [93](#)
- respiratory system affected by, [97](#)

Propofol infusion syndrome, [98](#), [98b](#), [1119](#)

Proportioning system, in anesthesia gas machine, [242](#)

Propranolol

- for hyperthyroidism, [919t](#)
- for pheochromocytoma, [815t](#)
- protein binding of, [59–60](#)

Proprioception, pathways for, [655f](#), [656–657](#)

Propylthiouracil (PTU)

- for hyperthyroidism, [919t](#)
- thyroid hormone and, [819](#)

ProSeal LMA, [422f](#)

Prospective payment system (PPS), nurse anesthetist

reimbursement and, 8

Prostacyclin, production of, 823

Prostaglandins

- for acute pain, 1172
- as ocular medications, 932*t*
- pain transmission and, 1169
- renal function and, 686
- for uterine contractions, 1086

Prostanoid biosynthesis pathway, 1172*f*

Prostate, transurethral resection of, 703–706

Prostatic disease, acute kidney injury as complication of, 692

Prosthodontics, 1206

- anesthetic considerations in, 1207

Protamine, administration of, during cardiac surgery, 499

Protamine sulfate, 832*t*

Protein

- cardiac function regulated with, 446–447
- insulin deficiency on, effects of, 799
- metabolism of
 - glucocorticoids and, 806
 - insulin and, 795–797
 - in liver, 710*b*, 711
- plasma, drugs binding to, 59*b*

Protein binding

- drug distribution affected by, 63
- drug ionization and, 59–60
- factors altering, 95*t*

neonatal, anesthetic pharmacologic considerations in, [1100–1101](#)
in pediatric patient, [1117–1118](#)

Protein hormones, [782](#)

Protein synthesis, liver function and, [710](#), [710b](#)

Proteinuria, [692](#), [695](#)

Prothrombin, [826t](#)

Prothrombin time test, [830t](#), [831](#)
in pediatric patient, preoperative preparation of, [1123b](#)

Renal dysfunction, after cardiopulmonary bypass, [489](#)

Renal failure

- aortic cross-clamping as cause of, [540, 545](#)
- chronic, [336, 693–695, 693b](#)
- dialysis for, [694–695](#)
- pneumatic tourniquet associated with, [946](#)
- preoperative assessment of patient with, [695–698](#)
- systemic abnormalities and, [696–698](#)

Renal fraction, [683](#)

Renal function

- age-related changes in, [1140](#)
- anesthesia effects on, [687–688](#)
- hormones and, [685–686](#)
- laboratory tests for, [695–696](#)
- perioperative, [701](#)

Renal insufficiency, [701](#)

Renal replacement therapy, [694b](#)

- continuous, [694](#)

Renal system

- anatomy of, [682–708](#)
- anesthesia management for, [682–708](#)
- anesthetic drugs effect on, [688–689](#)

- blood supply to, [682–684](#)
- burn injury effects on, [850](#)
- filtration in, [683f](#)
- function tests for, [336t](#)
- hormones in, [685–686](#)
- liver disease on, [718](#)
- neonatal, [1098–1099](#), [1108t](#)
- pathophysiology of, [682–708](#)
- physiology of, [682–708](#)
 - during pregnancy, [1066](#)
- preoperative evaluation of, [335–336](#)
- reabsorption in, [686f](#)
- secretion in, [685](#), [686f](#)
- succinylcholine effect on, [149](#)
- tubular reabsorption and secretion in, [684–685](#)

Renal transplantation, [707](#), [871–875](#)

- indications for, [871–872](#)
- intraoperative considerations for, [873–874](#), [873f](#), [874b](#)
- postoperative considerations for, [874](#), [875b](#)
- postoperative pain control for, [875](#)
- preoperative considerations for, [872–873](#), [873b](#)

Renin, [179](#), [808](#)

- glomerular filtration and, [684](#)
- renal function and, [685](#)

Renin-angiotensin level, renal function and, [688](#)

Renin inhibitor, [172t–173t](#)

Repaglinide, for type 2 diabetes, [801t](#)

Reperfusion injury, during lung transplantation, [886](#)

Reperfusion injury salvage kinase (RISK) pathway, [88](#)

Reperfusion pulmonary edema, [604](#)

Reperfusion syndrome, [736](#)

Repetitive transcranial magnetic stimulation (rTMS), for major depressive disorders, [1209–1210](#)

Research, [27–47](#)

- applied, [29](#)
- basic, [29](#)
- characteristics of, [27](#)
- classification of, by method, [30t](#)
- definition of, [27](#)
- descriptive, [30t](#)
- dissemination of findings of, [38–39](#)
- evaluation of, [39–40](#), [40b](#)
- ex post facto, [30t](#)
- experimental, [30t](#), [31](#)
- historical, [30t](#)
- nature of, [27](#), [28b](#)
- qualitative, [30t](#), [32](#)
- quasi-experimental, [31–32](#)

Research into Elderly Patient Anaesthesia and Surgery Outcome Numbers study (REASON study), [1218](#)

Research method

- classification of, [30t](#)
- classifying research on basis of, [30–32](#), [30t–31t](#)
- description of, [29–30](#)
- descriptive, [30t](#)

Research plan, execution of, [34](#)
, Research process
 blinding in, [29](#)
 hypothesis in, [29](#)
 instrumentation in, [32–34](#)
 literature review in, [28–29](#)
 masking in, [29](#)
 measurement in, [32–34](#)
 problem identification in, [28](#), [28b](#)
 stages in, [27–40](#)

Research report, evaluation of, [39–40](#), [40b](#)

Reserpine, [180](#)

Residual neuromuscular blockade, [161b](#), [436](#)

Residual paralysis, avoiding, [161b](#)

Residual volume, [570–571](#)
 in normal pulmonary function, in newborn and the adult, [1096t](#)
 in older adult, [1137–1139](#), [1139f](#)

Resilience, [1230](#)

Resistance, [218](#), [460](#)
 in series and parallel systems, [460f](#)
 of systems, [460](#)

Respect, patient-centered care and, [20–21](#)

Respiration
 paradoxical, [631](#), [631f](#)
 quiet, diaphragm and, [567–568](#)
 spontaneous, [567](#)

Respiratory arrest, optic nerve sheath trauma and, [943](#)

“Respiratory burst”, [975](#)

Respiratory centers, [579](#)

Respiratory control, reflex mechanism of, [581t](#)

Respiratory depression

- neonatal, [1096](#)
- postoperative, [1152](#)

Respiratory distress syndrome, [569](#)

- infantile, [1094–1095](#)
- neonatal anesthesia and, [1107](#)

Respiratory dysfunction, scoliosis and, [620](#)

Respiratory evaluation, obesity and, [1008](#)

Respiratory function, postoperative, assessment of, [1149–1152](#)

Respiratory membrane, [574](#)

Respiratory monitoring apparatus (RMA), [1214](#)

Respiratory patterns, head trauma and, [679t](#)

Respiratory quotient, [572](#)

Respiratory rate

- in normal pulmonary function, in newborn and the adult, [1096t](#)
- during pregnancy, [1066t](#)
- ventilation and, [258](#)

Respiratory system

- age-related changes in, [1137–1140](#)
- anatomy and physiology of, [563–579](#)
- clinical monitoring of, [290–299](#)
- compensatory mechanisms in, [578–579](#)
- depression of, opioids as cause of, [132–133](#)
- dexmedetomidine effects on, [108](#)

dialysis and, [697](#)
etomidate effects on, [100](#)
inhalation anesthetics effect on, [89](#)
ketamine effects on, [104](#)
liver disease effects on, [719](#)
neonatal, [1094–1096](#), [1095f](#), [1108t](#)
 abnormalities in, [1107](#)
obesity and, [999b](#), [1001](#)
pain and, [1170](#)
pathology of, [580–623](#)
pediatric medical history, anesthetic implication of, [1121t](#)
 during pregnancy, [1065–1066](#)
preoperative evaluation of, [330–333](#)
propofol effects on, [97](#)
spinal anesthesia in, [1027](#)
surgical positioning effect on, [381–382](#)

Respiratory tract
 compression, [641](#)
 infection, upper, outpatient surgery postponed by, [898](#), [899f](#)
 lower, [399–400](#)
 upper, [397–399](#)

Respiratory zone, [566–567](#)

Resting membrane potentials, [110](#), [447–448](#), [652](#)

Restrictive cardiomyopathy, [475t](#), [477](#)

Restrictive pulmonary disease, [604–607](#), [605t](#)

Reticuloendothelial system, [959](#)

Retina, [930](#)

Retinopathy, diabetic, [800](#)

Retrobulbar block, [933](#), [933f–934f](#)

Retrobulbar hemorrhage, [942](#), [942b](#)

Retroglottic tubes, [425](#)

Retrograde autologous priming (RAP), [488](#)

Retrograde cerebral perfusion, [524](#)

Retrograde intubation, [433–434](#)

Reverse Trendelenburg position, [391](#)

Review of medications, older adult and, [1143](#)

Revised cardiac risk index (RCRI), [322–323](#), [324t](#)

Rewarming

- hypothermia treated with, [1160](#)
- of patient, cardiopulmonary bypass and, [524](#)

Reynolds number, [214](#), [460](#), [570](#)

Rhabdomyolysis

- anesthesia-induced, [773](#)
- lateral decubitus position and, [394](#)
- succinylcholine associated with, [149–150](#)
- surgical procedure as cause of, [383](#)

Rhesus (Rh) blood group, [971](#)

Rheumatic heart disease (RHD), [504](#)

Rheumatoid arthritis, [321](#), [404b](#), [779–781](#)

- airway management difficulty associated with, [404b](#)
- anesthetic management for, [780–781](#), [781b](#)
- autoimmunity and, [972–973](#)
- cervical spine and, [779](#), [780f](#)
- clinical manifestations of, [779–780](#)

- etiology of, [779](#)
- incidence of, [779](#)
- orthopedic surgery and, [958](#)
- pericarditis caused by, [464–465](#)
- pulmonary manifestations of, [616b](#)
- treatment of, [780](#)

Rheumatoid factor, [779](#)

Rheumatoid spondylitis, [622](#)

Rhinitis, upper respiratory infection and, [1122](#)

Rhinorrhea

- ambulatory surgery for patient with, [897–898](#)
- differential diagnosis of, [898b](#)

Rhythmicity, [653](#)

Rickets, [791](#)

RIFL, [428](#)

RIFLE classification of acute kidney injury, [690](#), [691t](#)

Right bundle branch block, [185t–186t](#)

Right to left shunt, inhalation anesthetics and, [78](#)

Right ventricular dysfunction

- acute respiratory distress syndrome and, [611](#)
- echocardiogram for assessment of, [626](#)

Right ventricular failure, [670](#)

Right ventricular hypertrophy, cor pulmonale and, [598](#)

Right ventricular stroke work index, [493t](#)

Risk management

- anesthesia, [265–271](#)
- definition of, [265–266](#)

- department-level aspects, [265–266](#)
- individual, [266](#)

Risperidone, long QT syndrome and, [1222t](#)

Rituxan, [Rituximab](#)

Rituximab

- for cancer, [968–969](#)
- for rheumatoid arthritis, [780](#)

Rivaroxaban

- neuraxial anesthesia for, [839t](#)
- pharmacodynamic properties of, [838t](#)

Rivastigmine

- Alzheimer's disease treated with, [149b](#)
- succinylcholine interaction with, [149](#)

Robb, Isabel Adams Hampton, [3](#)

Robinul, [Glycopyrrolate](#)

RoboDoc, [752](#)

Robotic-assisted surgical system, laparoscopic surgery and, [751](#)

Robotic surgery

- anesthesia for, [752–759](#)
- cardiac procedures in, [756–757](#)
- enhanced recovery after surgery (ERAS) in, [755–756](#), [755b](#)
- extreme positioning and, physiologic changes associated with, [753–754](#), [754b](#)
- general anesthetic considerations for, [753–756](#)
- general surgical procedures in, [757–758](#)
- gynecologic procedures and, [758](#)
- head and neck procedures and, [759](#)

- history of, [752](#)
- mitral valve procedures in, [757](#)
- orthopedic procedures and, [759](#)
- postoperative visual loss and, [754](#)
- robotic systems in, [752–753](#)
- surgical subspecialties, considerations for, [756–759](#)
- surgical time, spatial restrictions, and mobility issues in, [753](#)
, thoracic procedures in, [757](#)
- urologic procedures and, [758–759](#)

Robotic urologic surgery, [706–707](#), [707b](#)

Robotic video-assisted thoracic surgery (RVATS), [757](#), [758f](#)

Robotically-assisted laparoscopic prostatectomy (RALP), [758](#)

Rockwell Laser Industries, [990](#)

Rocuronium

- dosage of, [1102t](#)
- hypersensitivity to, [969–970](#)
- for liver transplantation, [880–881](#)
- for renal failure, [701](#)
- for renal transplantation, [873](#)
- for trauma, [859](#)

Rocuronium bromide, [154–160](#)

- chemical structure of, [155f](#)
- duration of, [154](#)
- elimination of, [154](#)
 - mechanism of, [147t](#)
- onset, [154](#)
- pharmacokinetics of, [154–156](#)

properties of, [157t](#)
renal system affected by, [159](#)

Root cause analysis

in anesthesia complications, [1226–1227](#)
flowchart for, [1228f](#)
problem statement in, components of, [1227t](#)
report, elements of, [1228b](#)

Root sleeve, [1017](#)

Ropivacaine

characteristics of, [116t](#)
chemical structure of, [114f](#)
clearance half-life of, [118t](#)
dosage guidelines of, [121t](#)
as local anesthetic, for labor and delivery, [1074](#)
pharmacokinetics of, [118t](#)
potency of, [115](#)

Rosiglitazone, for type 2 diabetes, [801t](#)

Ross procedure, [505](#), [506f](#), [506t](#)

Rosuvastatin

dosage of, [188t](#)
perioperative use of, [329](#)

Roux-en-Y gastric bypass (RYGB), [1006](#)

Ruby laser, [983](#), [988](#)

“Rule of Nines”, [843](#)

Ryanodine receptor, [766](#)

S

S/5 Entropy Module, [309](#)

Sacral hiatus, [1015–1016](#)

Sacroiliac joint, [1191](#)

Sacrum, [1015–1016](#), [1016f](#)

Saddle block, [1025–1026](#)

Safe Anesthesia For Every Tot (SAFETOTS) initiative, [86](#)

Safety

- in anesthesia gas machine use, [229](#)
- electrical, [219](#)
- magnetic resonance imaging and, [218](#)
- in patient, in prone or jackknifed position, [1019](#)
- for spinal or epidural anesthesia, [1019](#)
- systematic approach to, [1230](#)
- ventilators, [258](#)

Safety margin, drug dose response and, [52–53](#)

Salmeterol

- for asthma, [596t](#)
- for chronic obstructive pulmonary disease, [589t](#)

Saltatory conduction, [110](#)

Sample

- convenience, [32](#)
- random, [32](#)

Sample size, research validity and, [37–38](#)

Sampling

- description of, [32](#)
- probability, [32](#)

Saphenous vein graft (SVG), [503](#)

SAPIEN Transcatheter Heart Valve, [514](#)

SAPPHIRE trial, [559](#)

Sarcoidosis, [616–617](#)

Sarcolemma, [765](#)

Sarcomere, [765](#), [765f](#)
 diagram of, [765f](#)

Sarcoplasmic reticulum, [766](#)

Saxagliptin, for type 2 diabetes, [801t](#)

Scarring, in reconstructive phase, for burn patient, [854](#)

Scattergram, [35](#)

Scavenging system
 in anesthesia gas machine, [264–265](#), [264f](#)

Sellick maneuver, [420](#), [858–859](#)

Semiconductor laser, [985](#)

Semirigid fiberoptic stylets, [428](#)

Sensitive oxygen ratio controller (S-ORC), [242](#)

Sensitization, [89](#)

Sensory pathways, [655–657](#)

Sensory system, preoperative evaluation of, [321](#)

Septic meningitis, [1021–1022](#)

Septic shock, etomidate and, [100](#)

Serotonin
carcinoid tumor and, [740](#), [740t](#)
modulation of pain and, [1170t](#)
as neurotransmitter, [654](#)
pain transmission and, [1169](#), [1170t](#)

Serotonin norepinephrine reuptake inhibitors (SNRIs)
for chronic pain, [1187](#)

- as psychiatric drugs, [200](#)
- Serotonin syndrome, [198–199](#), [198t–199t](#), [199b](#), [1176](#)
 - postoperative, [1157–1158](#)
 - treatment of, [1158](#)
- Sertraline, long QT syndrome and, [1222t](#)
- Serum
 - calcium in, [791](#), [791f](#)
 - osmolarity, [789](#)
- Serum albumin, concentration of, [712](#)
- Serum chemistry
 - indications for testing of, [342b](#)
 - in pediatric patient, preoperative preparation of, [1123b](#)
- Serum creatinine, renal function and, [696](#)
- Serum potassium level, [336](#), [341](#)
- Serum transferase, [712](#)
- Seventh cervical vertebra, [921–922](#)
- , Severe combined immunodeficiency (SCID), [975](#)
- Severinghaus PCO₂ electrode, [224](#), [225f](#)
- Sevoflurane, [80](#)
 - advantages and disadvantages of, [92t](#)
 - in assisted reproductive technologies, [1204–1205](#)
 - cerebral physiology affected by, [659t](#)
 - characteristics of, [81t](#)
 - chemical structure of, [81f](#)
 - effects of, on heart rate, [88f](#)
 - electroencephalogram affected by, [303t](#)
 - evoked potentials and, [84](#)

hepatic blood flow affected by, [710t](#)
liver affected by, [713](#)
long QT syndrome and, [1222t](#)
low fresh gas flow and, [247](#)
MAC values of, [83t](#)
malignant hyperthermia due to, [774](#)
mean arterial pressure (MAP) affected by, [87f](#)
metabolism of, [76t](#)
oil/gas partition coefficient of, [74t](#)
pediatric anesthetic neurotoxicity in, [1220f](#)
for pediatric patient, [1119](#), [1125](#)
receptor bonding of, [49](#)
renal function affected by, [689](#)
soda lime degradation of, [254](#)
vapor pressure of, [211](#)

Shared decision-making, [22](#)

Sheath of brachial plexus, [1046](#), [1049f](#)

Shikani optical stylet, [428](#), [428f](#)

Shivering

- oxygen consumption increased by, [1141](#), [1160](#)
- postoperative, [1160](#)

Shock

- in central neuraxial blockade, [1022](#)
- classification of, [861t](#)
- irreversible, acute, [861](#)
- nonprogressive, [861](#)
- progressive, [861](#)

spinal, [866](#)
trauma and, [863–864](#)

Shoemaker, Kenneth, [7f](#)

SHORT, [409](#)

Shoulder

- arthroplasty for, [952](#)
 - anesthetic management of, [952–953](#)
- arthroscopy for, [948](#)
 - patient positioning in, [949](#), [949f](#)
 - position-related complications during, [953t](#)
 - prevention of complications during, [953t](#)

Shunt equation, [576–577](#)

Shunt flow, hypoxic pulmonary vasoconstriction and, [637–638](#)

Shunts, inhalation anesthetics and, [78](#)

Sickle cell disease, [835–836](#), [836b](#)

- outpatient surgery for, [893](#)

Sickle cell trait, [835](#)

Signal transduction, drug receptor and, [49](#)

Significance, description of, [35–36](#)

Silastic silo, [1113](#)

Sildenafil, [168](#), [598t](#)

Silodosin, [171](#)

Simulation, nurse anesthesia education and, [16](#)

Simultaneous kidney and pancreas transplant, [876f](#)

Simvastatin

- dosage of, [188t](#)
- perioperative use of, [329](#)

Single-blind design, research and, [29](#)

Single bond, [201](#)

Single twitch, neuromuscular blockade testing with, [142](#), [143t](#)

Sinoatrial node, [445](#)

- action potential of, [449](#), [449f](#)

Sinus, procedures for, [921](#)

Sinus bradycardia, [185t–186t](#)

Sinus rhythm, [185t–186t](#)

Sinus tachycardia, [185t–186t](#)

Sinuses of Valsalva, [521–522](#), [522f](#)

Sitagliptin, for type 2 diabetes, [801t](#)

Sitting position, [394](#)

- complications associated with, [394](#)
- example of, [394f](#)

Sjögren syndrome, pulmonary manifestations of, [616b](#)

Skeletal diagram, of molecular bonding, [203](#), [203f](#)

Skeletal disorders, pulmonary function and, [620–623](#)

Skeletal muscle, [760](#)

- contractile force of, [766](#), [768f](#)
- energy sources for, [768](#)
- relaxation of, [767b](#)

Skeletal structure, pathologic conditions of, in pediatric patient, [1130b](#)

Skin

- color of, in respiratory monitoring, [292](#)
- laser effects on, [990t](#)

Skin grafts, for burn injury, [851](#)

Sleep, pain management and, [1188](#)

Sleep apnea

acromegaly and, [788](#)

airway obstruction associated with, [404b](#)

obstructive, [1150](#)

Sliding filament mechanism, [765–766](#), [766f–767f](#)

Sliding filament theory, [446–447](#), [447f](#)

Small airways disease, [584](#)

Small for gestational age (SGA), [1106](#), [1107b](#)

Smoke inhalation injury, low gas flow avoided for, [253](#)

Smoke plume, [991](#)

SNAP II monitor, [309](#)

Sneeze, as reflex mechanism, [581t](#)

Snoring, mask ventilation difficulty associated with, [403–404](#)

Social history, of patient, [314–317](#)

Soda lime

carbon dioxide absorption in, [254–255](#), [254b](#)

chemistry of, [254](#)

Sodasorb, characteristics of, [254t](#)

Sodium

absorption of, in colon, [733–734](#)

balance, disorders of, [359–361](#), [360t](#)

in crystalloid solutions, [1132t](#)

in newborn, requirements for, [1103b](#)

restriction of, in hypertension, [809](#)

Sodium bicarbonate

cesarean section, epidural anesthesia and, [1080](#)

- as local anesthetic additive, [116](#), [127](#)
- Sodium channels, nerve impulse and, [652](#), [652f](#)
- Sodium chloride solutions, [349](#), [349t](#)
- Sodium-glucose co-transporter-2 (SGLT2) inhibitors, [801](#), [801t](#)
- Sodium ion
 - changes in conductance, [111f](#)
 - equilibrium potential of, [448t](#)
 - glomerular filtration and, [684](#)
 - nerve impulse and, [652](#)
- Sodium nitroprusside, [177–178](#)
 - deliberate controlled hypotension with, [911t](#)
 - doses of, [170t](#)
 - onset and duration of, [177t](#)
- Sodium pentothal, [93](#)

Stomach
 anatomy of, [723–725](#)
 blood supply to, [724](#), [724f](#)
 diseases of, [723–727](#)
 position of, [724f](#)

STOP-Bang questionnaire, [321b](#), [892–893](#)

STOP-Bang Scoring Model, for obstructive sleep apnea, [1002b](#)

STOP questionnaire, [581](#)

ST point
 J point, [272](#)
 ST-segment deviation and, [272](#)

Strain, [213](#)

Strategic vision/plan, patient-centered care and, [21](#)

Stray capacitance, [218–219](#)

Streptokinase, pharmacodynamic properties of, [838t](#)

Stress, [213](#)

- in anesthesia complications, [1231](#)
- indicators of, [1233t](#)

Stress testing, [329](#)

- for liver transplantation, [878–879](#)

Stridor, [403](#)

Stroke

- acute ischemic, blood pressure management in, [679t](#)
- carotid artery stent and, [560](#)
- causes of, [551](#)
- ipsilateral, [551–553](#)

Stroke index, [493t](#)

Stroke volume, [493t](#)

- normal values for, [357t](#)
- in older adult, [1137](#)
- pneumoperitoneum and, [745](#)
- during pregnancy, [1066t](#)

STS score, [490](#)

Stuart-Prower factor, [826t](#)

Stunning, ischemia and, [481](#)

Sub-tenon block, [931–932](#)

Subarachnoid block, failure to obtain, in combined spinal epidural anesthesia, [1039](#)

Subarachnoid blockade, peripheral, for postoperative pain, [1175](#)

Subarachnoid hemorrhage, [673](#)

- blood pressure management in, [679t](#)

- diagnosis of, [674](#)
- preoperative evaluation for, [676](#)
- timing of surgery for, [675–676](#)
- vasospasm and, [675](#)

Subarachnoid space, [1017](#)

- spinal needle in, [1024f](#)

Subcortical motor areas, [658](#)

Subcutaneous implantable cardioverter defibrillators (S-ICDs), [530](#)

Subcutaneous tissue, burn injury to, [843](#)

Subdural hematoma, [678f](#), [679–680](#)

Subdural space, [648](#)

- epidural catheter, accidental subdural injection, [1085](#)

Substance abuse

- outpatient surgery and, [890](#)
- signs of, [316b](#)

Substance P

- chronic pain and, [1179](#)
- modulation of pain and, [1170t](#)
- as neurotransmitter, [654](#)
- pain transduction and, [1167](#)

Succinylcholine

- for airway obstruction, [1129](#)
- cesarean section and, [1081](#)
- dosage of, [1102t](#)
- hypersensitivity to, [969–970](#)
- in major depressive disorders, [1210](#)
- malignant hyperthermia due to, [774](#), [776b](#)

- for myasthenia gravis, [771](#)
- open-eye injury and, [941–942](#)
- for pediatric patient, [1120](#)
- for renal failure, [700](#)
- for renal transplantation, [873](#)

Succinylcholine chloride, [145–154](#)

- chemical structure of, [155f](#)
- contraindications to, [151b](#)
- duration of, [146–147](#)
- in elderly patient, [159](#)
- elimination, [147](#)
 - mechanism of, [147t](#)
- hyperkalemia associated with, [151b](#)
- laryngospasm treated with, [1150](#)
- metabolism of, [147f](#)
- in obese patients, [159](#)
- onset, [146](#)
- in pediatrics, [159–160](#)
- pharmacokinetics of, [146–147](#)
- properties of, [157t](#)

Sudden arrhythmic death syndrome, in sudden cardiac death, [1221t](#)

Sudden cardiac arrest (SCA), [1221–1222](#)

- causes of, [1221t](#)

- for postdural puncture headache, [1029](#)

Therapeutic index, [53](#)

Therapeutic window, [56b](#)

Thermal burns, [844](#)

Thermal diffusion flowmetry, brain monitoring with, [301t](#)

Thermal injury, [843–854](#), [Burn injury](#)

Thermal trauma, from laser, [989–990](#)

Thermistor, [298](#)

Thermodilution cardiac output (TDCO), [284](#), [285t](#)

- calculation of, [284](#)

Thermodynamics, [209–220](#)

Thermoregulation, [297–298](#), [1141](#)

Thiazide-type diuretics, [172t–173t](#)

Thiazolidinediones, [801](#), [801t](#)

Thionamides, for hyperthyroidism, [919t](#)

Thioridazine, long QT syndrome and, [1222t](#)

Third space

- losses, in neonate, [1104](#)
- in pediatric patient, [1132t](#)

Thirst threshold, [789](#)

Thoracic aortic aneurysms, [545–547](#)

- classification of, [546](#)

diagnosis of, [546](#)

etiology of, [546](#)

treatment for, [546–547](#)

Thoracic procedures, in robotic surgery, [757](#)

Thoracic surgery

analgesia for, [638](#)

anesthesia for, [624–644](#)

antimicrobial prophylaxis for, [193t–194t](#)

complications after, [643–644](#)

diagnostic data for, [625–627](#)

lateral decubitus position, [628–631](#)

monitoring plan, [628](#)

postoperative complications in, preoperative factors predicting, [625b](#)

preoperative preparation, [624–628](#), [626b](#)

history and physical examination in, [624–625](#)

Thoracoabdominal aortic aneurysm

Crawford classification of, [546f](#)

endovascular aortic aneurysm repair for, [549–551](#)

etiology of, [547b](#)

repair of, complications following, [548b](#)

Thoracoscopy, [642–643](#)

video-assisted, [642f](#)

indications for, [643t](#)

Thoracotomy, complications following, [643–644](#)

Thoratec, [519t](#)

Thorax

- blunt trauma and, [857](#)
- venous circulation of, [459](#)

Thorpe tube, [240](#)

Three-in-one block, [1059](#)

Threshold potential, [652](#)

Thrombin, [826–827](#)

- cell-based theory of coagulation and, [827–828](#)
- in fibrinolytic system, [828](#)
- hypothermia and, [863](#)
- platelet production of, [823](#)

Thrombin time, [830t](#), [831](#)

Thrombocytopenia

- abdominal aortic aneurysm rupture associated with, [545](#)
- heparin-induced, [486–487](#), [836–837](#), [836b](#), [836f](#)
- liver disease associated with, [718–719](#)

Thromboelastogram (TEG), [830t](#), [831](#), [831f](#), [881–882](#)

Thromboembolism

- carotid artery stent and, [560](#)
- venous
 - arthroplasty associated with, [951–952](#)
 - risk for, [840–842](#), [840t–841t](#)

Thromboendarterectomy, [603](#)

Thrombolytics, neuraxial anesthesia for, [839t](#)

Thrombophlebitis, etomidate use associated with, [100](#)

Thromboplastin, [826t](#)

Thrombosis

- acute stent, [838–839](#), [840b](#)

- ocular ischemia and, 943–944
- in postoperative patient, 1151

Thromboxanes, pain transmission and, 1169

Thymus gland, excision of, 770

Thyroid cartilage, 398, 564

Thyroid gland, 816–822, 917–918, 918*f*

- disorders of, 338–340, 818–822

Thyroid hormones, 782

- formation of, 817
- functions of, 817–818, 817*f*
- secretion, regulation of, 818, 818*f*
- synthesis of, 817

Thyroid isthmus, 917–918

Thyroid receptor antibodies, 972

Thyroid-stimulating hormone, 785

- in thyroid hormone formation, 817

Thyroid stimulating immunoglobulins (TSI), 972

Thyroid storm, 820–821, 820*b*

Thyroid surgery, 917–920

- intraoperative anesthetic management of, 919
- pathophysiology and, 918
- postoperative management for, 919–920, 920*b*
- preoperative assessment and preparation for, 918–919

Thyroidectomy, 819

Thyromental distance, 318, 406–407, 407*f*

Thyromental space, 406–407

Thyrotoxicosis, 818–821, 918

signs and symptoms of, [818–819](#)
treatment of, [819](#)

Thyrotroph, [786](#)

Thyrotropin-releasing hormone, [786t](#)

Thyroxine, [817](#)

Tiazac, [172t–173t](#)

Ticagrelor, coronary stent and, [326](#)

Ticlopidine, pharmacodynamic properties of, [838t](#)

Tidal volume (V_T)

- accuracy of
 - breathing circuits and, [258](#)
 - ventilator and, [258, 260–261](#)
- atelectasis and, [620](#)
- fresh gas decoupling *versus*, [261](#)
- inhalation anesthetics for pediatric patient and, [1118](#)
- lung volume and, [570–571](#)
- in normal pulmonary function, in newborn and the adult, [1096t](#)
- during pregnancy, [1066t](#)
- ventilation and, [258](#)
- volume-controlled ventilation and, [258](#)

Tight chest, opioids associated with, [133–134](#)

Time, surgical, and robotic surgery, [753](#)

Timolol, as ocular medications, [932t](#)

Tiotropium, [176, 587, 589t](#)

Tirofiban, pharmacodynamic properties of, [838t](#)

Tissue

- adipose, [999–1000](#)

- groups based on perfusion, [63t](#)
 - subcutaneous, burn injury to, [843](#)
- Tissue factor pathway inhibitor (TFPI), [827](#)
- Tissue factor (TF), [823–824](#), [826t](#)
- Tissue oxygenation, PGDT and, [357](#)
- Tissue plasminogen activator, pharmacodynamic properties of, [838t](#)
- Tissue-related, inhalation anesthetics and, [75–76](#)
- Tissue response
 - drug action and, [49](#)
 - fractional, [53](#)
- Tissue toxicity, local anesthetics associated with, [125–126](#)
- Tobacco smoking, effects of, [315t](#)
- Tobacco use, of patient, [314–315](#)
- Tocilizumab, for rheumatoid arthritis, [780](#)
- Tolerance, [56b](#), [1178](#)
 - pain management and, [1188](#)
- Tongue, [398](#)
 - anomaly of, airway management and, [319b](#)
 - hypopharyngeal, [407](#)
 - pathologic conditions of, in pediatric patient, [1130b](#)
 - postoperative airway obstruction caused by, [1149](#)
- Tonicity, definition of, [1132](#)
- Tonsillectomy, [916–917](#), [917f](#)
- Tonsils, [905](#)
 - bleeding of, [917](#)
- Topical anesthesia, [126](#), [126t](#)
- Torseamide, dosage and effects of, [172t–173t](#)

, Total body surface area (TBSA), burn injury and, 843, 849

Total body water, 347

- neonatal, 1100
- pediatric, 1117

Total disc replacement, 954

Total hip arthroplasty (THA), 950

- direct anterior approach for, 950–951
- positioning for, 951
- thromboprophylaxis for, 951–952

Total intravenous anesthesia (TIVA), 755–756

- for radiofrequency catheter ablation, 1201

Total knee arthroplasty (TKA), 952

Total lung capacity (TLC), 567, 571

- in normal pulmonary function, in newborn and the adult, 1096*t*
- obesity and, 1001

Total parenteral nutrition (TPN), 735, 1104

Total spinal block, 1085

Totally endoscopic coronary artery bypass (TECAB) surgery, 514, 756

- contraindications to, 756*b*
- robotically assisted, 756–757, 756*b*

Touch, pathways for, 655*f*, 656

Tourniquet

- for intravenous regional anesthesia, 1055
- pain caused by, 947–948
- physiologic changes caused by, 947*b*
- pneumatic, 946

- postoperative paresthesias, [948](#)
 - safety measures for, [947b](#)
- Toxic megacolon, [735](#)
- Toxoid vaccines, [967](#)
- Trachea, [400](#)
 - airway management and, [319b](#)
 - airway obstruction and, [404b](#)
 - anatomy of, [565–566](#)
 - burn injury to, [845](#)
 - features of, [400f](#)
 - injuries of, blunt trauma and, [857](#)
 - thermal injury to, [846](#)
 - total disruption of, [857](#)
 - view of, [399f](#)
- Tracheal extubation, [434–438](#)
 - algorithm, [437f](#)
 - complications of, [435b](#), [436–438](#)
 - criteria for, [435b](#)
 - difficult airway, [435–436](#), [438t](#)
 - for infant, [1128](#)
 - for pediatric patient, [1128](#)
 - risk factors for difficult, [436b](#)
 - techniques, [435](#), [435t](#)
- Tracheal intubation, [411f](#)
 - assessment of, [405–408](#)
 - difficulty with, [401](#)
 - for hypertensive patient, [463–464](#)

indications for, [410t](#)
methods, [436](#)
obesity, [401](#)

Tracheobronchitis, [616](#)

Tracheoesophageal fistula (TEF), neonatal anesthesia for, [1113–1114](#), [1113f–1114f](#)

Tracheotomy, [434](#)

Trachlite lighted stylet, [425–426](#), [426f](#)

Tract of Lissauer, pain transmission and, [1169](#)

Tractus solitarius, [579](#)

Traditional anesthesia ventilators, [262–263](#)

Train-of-four, neuromuscular blockade testing with, [142–143](#), [143t](#), [144f](#), [153f](#)

Train-of-four ratio, [142–143](#)

Tramadol, [138](#)
 other opioids compared to, [136t](#)

Trandate Normodyne, [Labetalol](#)

Trandolapril, dosage and effects of, [172t–173t](#)

Tranexamic acid (TXA)
 cardiopulmonary bypass and, [487](#)
 total hip arthroplasty and, [951](#)

Transcatheter aortic valve implantation (TAVI), [514](#), [515f](#)

Transcranial Doppler sonography
 brain monitoring with, [301t](#)
 neurologic monitoring with, [301b](#)

Transcranial Doppler (TCD) velocity, monitoring of, during carotid endarterectomy, [555](#)

Transcranial Doppler ultrasonography, [304–305](#)

Transcranial motor evoked potentials, for neurophysiologic monitoring, [667t](#)

Transcutaneous carbon dioxide monitoring, [294](#)

Transcutaneous electrical nerve stimulator (TENS) ,for chronic pain, [1191](#)

Transcutaneous pacing pads, pacemakers, [526](#), [527f](#)

Transdermal scopolamine, multimodal antiemetic therapy and, [196](#)

Transduction, of pain, [1167](#)

Transesophageal echocardiography (TEE), [287–289](#), [288f](#)

- for abdominal aortic aneurysm repair, [539](#)
- cardiac surgery and, [493–494](#)
- for detection of venous air embolism, [671t](#)
- for lung transplantation, [885–886](#)

Transfer of care, after anesthetic treatment, [1197](#)

Transforaminal epidural steroid injection (TESI), for chronic pain, [1190](#)

Transformer, [219](#)

Transfusion

- guidelines for, [833](#)
- preoperative discussion on, [829](#)

Transfusion reactions, [971](#)

Transfusion-related acute lung injury, [612](#)

Transfusion-related circulatory overload, [613](#)

Transfusion-related immunomodulation (TRIM), [378](#), [979](#)

Transfusion-related pulmonary disease, [612–614](#)

Transfusion therapy

- autologous, [372](#)
- compatibility of, [372–373](#), [373t](#)

type, crossmatch and, [373](#)
type, screen and, [373](#)
complications of, [377–378](#)
thresholds and indications for, [369–370](#), [370b](#)

Transfusion trigger, [369](#), [1133](#)

Transient ischemic attack (TIA), [551](#)

Transient neonatal disease, [971](#)

Transient neurologic syndrome, [1026–1027](#)

Transitional circulation, [1092–1093](#)

Transitional flow, [213](#), [213f](#)

Transitional zone, [566–567](#)

Transmission, pain, [1169](#), [1169f](#)
modulation of, [1169–1170](#)

Transmural pressure, [674f](#)

Transnasal hypophysectomy, [672f](#)

Transport, renal, mechanism of, [684–685](#)

Transport protein, [782](#)

Transporter
adenosine triphosphate binding cassette, [57](#)
drug, [57](#)
P-glycoprotein, [60–61](#)
solute carrier, [57](#)

Transpulmonary pressure, [569–570](#), [570f](#)

Transtracheal block, [420](#)

Transtracheal injection, [420f](#)

Transtracheal jet ventilation system, [431f](#)

Transurethral resection of prostate syndrome, [703](#)

- anesthesia for, [705–706](#)
- prevention of, [705](#)
- treatment of, [705](#)

Transurethral resection of prostate (TURP), [703–706](#)

- anesthesia for, [704b](#)
- complications of, [704–706](#)
- spinal anesthesia for, [1019](#)

Transverse processes, [1016f](#)

Transverse tubules, [766](#)

Transverse waves, [216](#)

Transversus abdominis plane block, [1057–1058](#), [1057f](#)

Trauma, [404b](#)

- abdominal, [858](#)
- acidosis and, [863](#)
- airway management for, [859–860](#)
 - difficulty associated with, [404b](#)
- anesthesia, [855–870](#)
- blunt, [856–858](#)
 - cardiac rupture and, [857](#)
 - massive hemothorax and, [857](#)
 - pericardial tamponade and, [857](#)
 - tension pneumothorax and, [857](#)
 - tracheal injuries and, [857](#)
 - traumatic aortic rupture and, [857](#)
- breathing for, [860](#)
- care, levels of, [856f](#)
- cervical spine injuries, airway management for, [860](#), [860f](#)

circulation and, [860–864](#)
coagulopathy and, [862–864](#)
continuum of care for, [869–870](#)
damage control surgery for, [858](#)
direct laryngoscopy for, [859–860](#)
endotracheal intubation for, [858](#)
etiology of, [855](#)
evaluation of, [855–856](#)
head injury from, [864–865](#)
hypothermia and, [863](#)
injury from, [855](#)
, injury patterns, [855–856](#)
management of care for, [855](#)
massive transfusion protocols (MTP) and, [373](#)
orthopedic injury and, [869](#)
penetrating, [858](#)
prehospital management of, [856](#)
primary survey of, [856](#)
secondary survey of, [856](#)
spinal cord injury from, [865–869](#)
to spleen, [739](#)
thoracic, [857](#)
in thyroid surgery, [921–922](#)
ventilation for, [860](#)

Trauma center, efficacy of, [855](#)

Trauma-induced coagulopathy, [862–863](#)

Trauma system

efficacy of, 855
organization of, 855

Traumatic brain injury, 677–681
blood pressure management for, 679t
management of, 863

Travoprost, as ocular medications, 932t

Treacher Collins syndrome, 404b, 1130b
airway management difficulty associated with, 404b

Trendelenburg position, 391
complications associated with, 394
example of, 386f
pneumoperitoneum and, 746
steep, in robotic surgery, 753, 754b

Treprostinil, for pulmonary hypertension, 598t

Triamterene, dosage and effects of, 172t–173t

Triazolam, application of, 105t

Tricuspid regurgitation, hemodynamic waveform altered by, 281

Tricyclic antidepressants (TCAs)
for chronic pain, 1176, 1176t
as psychiatric drugs, 199

Trigeminal nerve palsy, in spinal anesthesia, 1030

Trigger window, ventilation and, 259, 260f

Triglyceride, 797

Trigone, fibrous, 441–442

Triiodothyronine, 817

Triple bond, 201

Triple therapy, for congestive heart failure, 183

Trismus, [777](#)

Trochlea, [925](#)
