previously for PVR also hold true for SVR, although perhaps to a lesser extent, because the systemic vasculature has lower compliance. In general, supporting afterload via vasoconstrictors should be deferred until maximization of preload or the use of positive inotropes has proven to be ineffective.

Determination of CO assists critical care specialists in providing rational hemodynamic therapy, evaluating the response to therapy, and determining the adequacy of tissue perfusion, which is linked to maintenance of arterial BP, delivery of oxygen, and removal of wastes. It also permits the calculation of other hemodynamic indices (e.g., PVR and SVR). A “normal” CO value can be qualified by taking into account age differences, metabolic activity (as it declines with anesthesia and increases with hyperthermia), and patient size. This last factor may be adjusted for by converting CO to CI, which attempts to normalize CO for the large number of values found in the general population. However, CI adjusts only for the variables of height and weight; it does not address the lack of uniformity of predicted basal oxygen consumption and metabolic rates resulting from differences in sex and age. In addition, the relationship between body surface area (BSA) and blood flow is indistinct.⁵⁹ CI is calculated by dividing CO by BSA. The plotting of height and weight on a body surface chart estimates the BSA in square meters (Fig. 17.20). Commonly quoted normal values are 5 to 6 L/min for CO and 2.8 to 3.6 L/min • m² for CI.

FIGURE 17.20 Chart used to calculate body surface area. In this example, a height of 6 feet and a weight of 155 lb translates into a surface area of approximately 1.9 m².

The most commonly used technique for determining CO is thermodilution, whereby an analog computer calculates the CO using the modified Stewart-Hamilton equation. This method was first used by Fegler in 1954.⁶⁰ It entails the injection of a known quantity of an indicator solution (most commonly 5% dextrose in water, although 0.9% normal saline has a similar density factor) through the proximal port of a thermodilution PAC.⁶¹

The injected solution is considered a thermal indicator because it is cold relative to body temperature. It rapidly mixes with the incoming blood and is carried through the RV until it is detected by the thermistor near the end of the catheter in the PA. The computer plots a time-temperature curve, with the area under the curve being inversely proportional to the CO; therefore, larger curves are not desired. Variables that can influence recorded values include the

computation constant (which varies with catheter size, injectate volume, and temperature), temperature of the injectate (desired range of 0°C to 24°C),⁶² volume of injection,⁶² speed of injection (which should take 4 seconds or less),⁶³ and the timing of injection (it should be consistent, i.e., administered at the same time during each respiratory cycle).⁶⁴ Iced injectates have not been shown to offer any significant advantage over room temperature injectates.⁶² In fact, cold indicator solutions injected rapidly into the right atrium have been shown to produce arrhythmias,⁶⁵ including sinus bradycardia.⁶⁶ Research that has examined the impact of valvular or septal defects on thermodilution CO (TDCO) values has produced conflicting results.⁶⁷⁻⁶⁹ A list of variables that can skew CO measurements is provided in [Table 17.9](#).

PAC, Pulmonary artery catheter.

The accuracy for TDCO (including when performed in patients in the lateral position) is $\pm 10\%$, and the reliability is $\pm 5\%$.⁷⁰ These values are lower in the pediatric population,⁷¹ in patients who have low CO,⁷² and for measurements taken in the OR.⁷³ Anesthetists should be careful not to overinterpret small changes (e.g., 5% to 10%) and should never express values beyond one decimal point. The common practice of averaging three CO output values has also been shown to improve accuracy.⁷⁴

A further advancement in CO technology has been achieved via the placement of thermal filaments within the RV portion of the PAC and near the tip of the thermistor (e.g., the Vigilance system [Edwards Lifesciences Corporation] and the OptiQue system [Abbott Labs]). A sophisticated computer algorithm permits for

analysis of a thermal signal created by small quantities of heat being emitted from the PAC—a pulsed warm thermodilution continuous cardiac output (TDCCO) technique. This heat signal is eventually transmitted by the blood to the distal thermistor, which permits for continuous CO (CCO) assessment.⁷⁵ An adequate signal-to-noise ratio is necessary to produce accurate and reliable CCO measurements. Research has shown a low ratio (derived from a core body temperature > 38.5°C) can result in inaccurate CCO values.⁷⁶ One advantage of a CCO catheter is the elimination of the time-consuming administration of a thermal injectate through the proximal port of the PAC. It also reduces the number of discrepancies in thermodilution CO values that can occur with inconsistent injectate administration relative to the respiratory cycle.

A drawback to the CCO device is the hysteresis in recording hemodynamic information. Although the monitor displays updated CO figures every 30 seconds, they nonetheless do not represent real-time data. Instead, the CCO values depict the average CO from the prior 3 to 6 minutes.⁷⁷ This can be a significant limitation in patients who develop acute hemodynamic changes occurring in response to hemorrhage and resuscitation.⁷⁸ In this setting, a standard bolus thermodilution technique is preferable.

Manufacturers of TDCCO monitors have attempted to circumvent this limitation by developing “Fast-Filter” and “Urgent” modes to supplement the “Normal” mode of data processing. One investigation found a significant decline in the precision of CO measurements when the Fast-Filter and Urgent modes were used.⁷⁹ The reliability and accuracy of the device in intensive care and surgical patients have been established with recordings taken in the supine position^{76,80} and with the backrest elevated up to 45 degrees.⁸¹ Nevertheless, some investigators have found the TDCCO technique to be less precise than bolus thermodilution.^{82,83}

Other investigators have examined a variation of the TDCCO PAC, specifically a PAC (truCATH) that measures the amount of energy required to maintain a fixed blood temperature gradient between two distal thermistors. Researchers have found the truCATH PAC and TruCCOMS monitor to overestimate low CO and underestimate high CO, and have suggested an improvement

in the calibration scheme that may obviate this problem.^{84,85}

Although the truCATH provides ultrafast data, it demonstrates problems with reliability.

In spite of reports in the literature of a positive clinical outcome based on the use of TDCCO,^{86,87} future studies will be required to establish whether CCO measurements (as well as other monitoring modalities such as Doppler techniques⁸⁸ and transpulmonary thermodilution⁸⁹) reduce the length of hospitalization and improve morbidity and mortality rates.⁹⁰

Mixed Venous and Central Venous Oxygen Saturation

Since its introduction in 1981, measuring SvO₂ has been described as a means to indirectly monitor oxygen delivery. This is based on the fact that SvO₂ is determined by pulmonary function, cardiac function, oxygen delivery, tissue perfusion, oxygen consumption, and hemoglobin concentration. During the course of an anesthetic (excluding cases of major trauma or hemorrhagic shock), it is not unusual for pulmonary function, hemoglobin content, and oxygen consumption to remain relatively stable. Therefore, proponents of SvO₂ monitoring state that it is reasonable to assume that a decrease in SvO₂ reflects a change in oxygen delivery, presumably via a reduction in CO.^{91,92} In contrast, some researchers have found a poor correlation between SvO₂ and CO.^{93,94}

Continuous mixed venous oximetry is measured by fiberoptic reflectance spectrophotometry through two fiberoptics housed in the PAC. One fiberoptic transmits narrow wavelengths of light to the distal catheter. The extent of light absorption and reflection is a function of the quantity of oxyhemoglobin and deoxyhemoglobin present in the PA.⁹⁵ The receiving fiberoptic transports the reflected light to a microprocessor that interprets the signal and displays an SvO₂ value; the normal range of SvO₂ is 65% to 77%. Factors that increase SvO₂ values include left-to-right shunts, hypothermia, sepsis, cyanide toxicity, a wedged PAC, and an increase in CO. SvO₂ decreases with hyperthermia, shivering, seizures, reduced pulmonary transport of oxygen, hemorrhage, and decreased CO.

Sustained low values (e.g., 50%) merit investigation followed by appropriate intervention(s). It has also been demonstrated that some SvO₂ monitoring systems adapt well to acute changes in hematocrit.⁹⁶ In addition, research with two-wavelength and three-wavelength SvO₂ oximetry catheters has shown the systems to be comparable in accuracy.⁹⁷

Central venous oxygen saturation (ScvO₂) monitoring has been advocated as a surrogate for SvO₂ when a less invasive form of hemodynamic monitoring is indicated. Modified central venous catheters (CVC) that contain a fiberoptic lumen can measure ScvO₂ when positioned at the junction of the superior vena cava and right atrium. A major difference between SvO₂ and ScvO₂ measurements is that the latter is considered a regional indicator of venous oxygen saturation; it measures venous O₂ saturation from the upper body and head. In contrast, SvO₂ measurements depend on blood flow from the superior vena cava, inferior vena cava, and coronary sinus (which has an O₂ content of approximately 7 mL/dL [venous O₂ saturation of 35%]). Also, the mixed venous O₂ content is greater in the inferior vena cava than in the superior vena cava.^{98,99} The net effect of these differences is that, under normal conditions (e.g., in unanesthetized subjects),⁹⁹ the ScvO₂ is approximately 2% to 3% less than the SvO₂.⁹⁸⁻¹⁰¹ However, the literature also reports the opposite relationship.¹⁰²

From a monitoring perspective, research indicates that the use of ScvO₂ as a substitute for SvO₂ is both advocated^{93,102,103} and discouraged.^{100,104-106} Numerous clinical investigations in different practice settings with patients having diverse pathological states have been conducted. In spite of the diverse opinions, some professional healthcare societies have established guidelines that recommend ScvO₂ be used as a clinical tool to guide therapy for improving morbidity and mortality. For example, the 2012 Surviving Sepsis Campaign: International Guidelines For Management Of Severe Sepsis strongly suggested using an ScvO₂ goal of 70% or greater (or SvO₂ ≥ 65%) in the first 6 hours of resuscitation. Concurrent hemodynamic/clinical recommendations included achieving a CVP of 8 to 12 mm Hg, a MAP of 65 mm Hg

or greater, and a urine output of 0.5 mL/kg per hr or higher, and administering intravenous (IV) antibiotics within the first hour of recognizing severe sepsis and septic shock.¹⁰⁷

In conclusion, the cost-benefit ratio of using PACs that provide TDCO, TDCCO, or SvO₂ measurements, or even CVCs with ScvO₂-monitoring capabilities, remains controversial. As with any physiologic monitor, the potential to promote health or cause harm is determined by the clinician's ability to interpret and apply data.¹⁰⁸ A similar analogy can be made for computerized ST segment analysis, whereby failing to account for numerous variables when interpreting ST segment shifts can potentially lead to iatrogenic injury. Therapeutic strategies should be guided by a knowledge of the patient's underlying pathophysiology and the limitations of the respective hemodynamic monitoring device.

Arterial Pressure Monitoring

As with ECG monitoring, professional societies have designated the routine assessment of arterial BP to be essential for the safe conduct of any anesthetic; at minimum, BP should be recorded at least once every 5 minutes.¹ This frequency of assessment should be increased for patients noted to have any systemic disease that limits physiologic reserve, such as CAD or valvular heart defects (e.g., aortic stenosis). This author advocates BP assessment at 1-min intervals during the induction period of most anesthetics, the rationale being that many commonly administered induction agents are associated with cardiac depressant effects. The concomitant disruption or gross activation of homeostatic reflexes can lead to substantive changes in hemodynamics, even in relatively healthy patients. It is also known that the hemodynamic response to many drugs used during induction of anesthesia can be unpredictable, owing to differences in pharmacokinetics and pharmacodynamics among patients.

BP monitoring can be accomplished through both noninvasive and invasive techniques. Each recording modality will be reviewed, with an emphasis on clinical relevance. Other resources provide a comprehensive description of the theoretical underpinnings for the calculation of noninvasive and invasive arterial BP data. In today's modern OR environment, noninvasive blood pressure (NIBP) monitoring is most often recorded by automated BP cuffs that can be configured to measure systolic blood pressure (SBP), diastolic blood pressure (DBP), and mean arterial blood pressure (MAP) in a standard mode, stat mode, at varied frequencies of assessment, and adjusted for patient age and habitus. The literature recommends that BP cuffs have a bladder dimension of approximately 40% the circumference of the extremity.¹⁰⁹ Bladders that are not properly sized and cuffs that are not applied firmly to the extremity can lead to inaccurate recordings. For example, cuffs that are applied loosely to the extremity, positioned below the level of the heart, or are too small can produce arterial BP values that are falsely elevated.¹¹⁰

The physics associated with auscultation of BP relates to the audible discernment of Korotkoff sounds through a stethoscope.

These sounds are produced by turbulent blood flow within an artery during cuff deflation. A second mechanism for BP assessment is via an oscillometric technique (Fig. 17.21). The inflation and deflation cycles of NIBP devices are controlled by a microprocessor. During deflation of the cuff, oscillations are sampled over the span of several cardiac cycles. Any oscillations sensed by the pressure transducer are then processed numerically. If none are sensed, a stepwise reduction in cuff pressure followed by sustained measurement for oscillations occurs. This process is repeated until SBP, DBP, and MAP are derived. MAP can also be estimated by $[SBP + (DBP \times 2)]/3$. For example, a BP of 120/80 has a calculated MAP of 93 mm Hg $(120 + 80 + 80) \div 3 = 93$ mm Hg). This formula accounts for diastole, comprising approximately two-thirds of a normal cardiac cycle.

FIGURE 17.21 Arterial blood pressure, comparing

Korotkoff sounds, oscillations with a blood pressure cuff, and radial artery palpation. Note correlation between onset of the first Korotkoff sound, onset of oscillations in the cuff pressure, and radial pulse wave. (From Saidman LJ, Smith NT, eds. *Monitoring in Anesthesia*. New York: Wiley & Sons; 1978.)

Generally speaking, the benefits outweigh the risks of taking frequent NIBP recordings during an anesthetic. Nevertheless, injury and harm can occur with automatic NIBP measurements, and may include damage to peripheral nerves (e.g., ulnar), development of a compartment syndrome, or interference with delivery of drugs through an IV line. For example, propofol sequestered in a forearm during BP-cuff inflation can cause intense pain. This can be avoided by routinely placing the BP cuff on the extremity without the peripheral IV. In circumstances in which the scheduled surgery involves an upper extremity, the BP cuff and IV can be placed on the contralateral arm (brachium or antebrachium), with the caveat that the NIBP must be configured so BP measurements are recorded in the manual mode to prevent unexpected disruption of the delivery of IV induction drugs. Alternatively, a lower extremity (thigh or calf) can be used for BP measurements.

In morbidly obese patients, it is not unusual to have to relocate a BP cuff from the upper arm because of the cone shape of the extremity. An alternative BP monitoring site is the forearm. However, NIBP measurements taken in the forearm with the patient in supine or sitting position, or with the head of the bed elevated 45 degrees, can overestimate the more proximal brachial BP.^{111,112} Formulas have been proposed to correct for such discrepancies. For example, in an obese patient with a diastolic forearm pressure of 80 mm Hg and an arm circumference between 32 and 44 cm, the adjusted DBP would equal 72.4 mm Hg. This is derived from the following equation:

$$\text{Brachial DBP} = 25.2 + 0.59 \times \text{Forearm DBP}$$

This formula was proposed based on a study of 129 subjects with an average body mass index of $40 \pm 7 \text{ kg/m}^2$.¹¹¹ Discrepancies in BP measurements have also been noted between upper and lower extremities and between arms. In study participants up to 16 years

of age, SBP has been shown to be greater in the thigh and calf than in the arm. In contrast, DBP and MAP are lower in the calf and thigh than in the arm.¹¹³ Patients most likely to exhibit interarm BP differences are those who are obese and who have a higher HR and SBP.¹¹⁴ Concerns about accuracy also arise when measuring BP noninvasively versus invasively. One group of investigators found NIBP taken in the upper arm in patients with septic shock to correlate poorly with arterial line pressure measurements, specifically causing an overestimation of MAP with the noninvasive technique.¹¹⁵

It is apparent that a substantive change has occurred in recent years in the number of adults and children in the United States who are classified as obese. Consistent with this change are the findings that mean mid-arm circumference has increased across the country, with the greatest increase occurring in 20- to 39-year-olds. This change should cause anesthesia providers to be more attentive to the daily task of selecting properly sized BP cuffs. In fact, research has shown that up to 39% of all hypertensive patients and 47% of self-reported diabetic patients should not have their BP measured with the standard adult-size cuff.¹¹⁶ Inattentiveness to this basic and essential monitoring need could cause the anesthetist to process inaccurate hemodynamic data (e.g., overestimated BP recordings) and ultimately contribute to a poor surgical outcome.

Direct measurement of arterial BP is considered by many to be the gold standard for recording BP. Many anatomic locations can be used for direct BP measurement, with the most common being the radial artery. Other, less commonly used arteries are the ulnar, brachial, axillary, femoral, and dorsalis pedis arteries. Risks associated with placement of an intraarterial catheter include infection (localized and systemic), thrombus formation, hematoma, vasospasm, embolization, injury to adjacent nerves and veins, ischemia to extremities or digits, loss of a limb secondary to poor collateral circulation, iatrogenic injuries (air embolization, intraarterial injection of drugs meant to be administered by IV), and acute blood loss due to an unexpected disruption of the transducing system (e.g., cracked or disconnected stopcock). A displaced transducer (no longer level with the phlebostatic axis) can show a false increase in arterial BP if positioned substantially below the

level of the heart. Assessment of an abnormal BP recording should include an understanding of problems inherent to a fluid-pressure monitoring system. To mitigate the ongoing risks of direct arterial BP monitoring, constant vigilance on the part of the anesthetist is paramount.

Monitoring BP directly offers several distinct advantages, including beat-to-beat assessment of BP, limited hysteresis in measured values, and easy access for arterial sampling of blood for any number of laboratory tests (e.g., arterial blood gases, serum electrolytes, glucose, hemoglobin levels). Indications for direct arterial BP monitoring include surgical procedures in which there is potential for acute and/or gross changes in hemodynamics. This would include operations such as repair of aortic aneurysms, carotid endarterectomy, and craniotomies. Even with lower risk surgical procedures, direct arterial BP monitoring may be indicated, particularly if preoperative BP is poorly controlled (labile), or when intraoperative monitoring of somatosensory-evoked potentials produces frequent gross movement of the upper extremities, which can mitigate the effectiveness of providing noninvasive BP recordings. Patients with comorbidities may be at substantial risk for a stroke or heart attack during periods of acute stress (e.g., laryngoscopy or emergence from an anesthetic) if BP is not directly monitored.

Risks associated with placement of a radial artery catheter can be minimized if precautionary measures are taken. This would include positioning of the hand and wrist on an arm board. A roll should be placed beneath the wrist, and the fingers and thumb should be taped securely across the board. This position keeps the hand from interfering with manipulation and placement of the needle-catheter system; it also facilitates palpation of the radial artery. Commonly, a 20-gauge nontapered catheter is used (a 22-gauge is optional) to penetrate an area of skin that has been prepped with antiseptic solution and infiltrated with local anesthetic. The needle, bevel pointing upward, is directed at a 45-degree angle toward the palpated pulse. If bone is encountered with the tip of the needle during advancement, the complete catheter system (catheter and needle) is slowly withdrawn while observing for the free flow of arterial blood; sometimes the artery can be pierced without a “flash

back” (unintentional transfixion-withdrawal method). If no blood is seen during catheter withdrawal, the needle system is directed slightly laterally (in either direction) and readvanced. Once arterial blood is seen in the lumen of the catheter, the angle of the needle is reduced to approximately 30 degrees, then advanced slightly (a few millimeters). The catheter is subsequently threaded off the needle. “Fatigue” at a puncture site may occur, at which time a new artery may be chosen to cannulate, or a “fresh set of hands” (perhaps another anesthesia provider or member of the surgical team) may be used to repeat the attempt at arterial puncture. After verifying correct placement of the catheter within the lumen of the artery (free flow of blood through the rigid tubing when vented to air), it is important to securely fasten the arterial catheter to the skin and apply a sterile dressing on top of the puncture site.

The transducing system should be zeroed to atmospheric pressure (with the stopcock vented to air) and referenced at the level of the left atrium. In patients with poor vascular compliance, the arterial tracing can produce an “overshoot” or “ringing” phenomenon. If not recognized, BP recordings will overestimate SBP and MAP values. In contrast, a dampened waveform, which can develop with a flexed wrist or low pressure in the continuous-flush device, can lead to an underestimation of BP recordings (Fig. 17.22). Direct arterial pressure measurements, although very accurate in many clinical circumstances, can still produce BP recordings that are significantly skewed and lead to inappropriate interventions (e.g., preload augmentation, indiscriminate use of vasoactive drugs).

Normal morphology; **B**, overshoot; **C**, dampened. With waveform **B**, the overshoot should be ignored regarding the displayed systolic blood pressure. The dicrotic notch reflects the closure of the aortic valve.

Transesophageal Echocardiography Monitoring

Transesophageal echocardiography (TEE) has been established as a safe, noninvasive diagnostic tool for monitoring numerous cardiac parameters to guide medical, surgical, and nursing care.

Identification of systolic wall motion abnormalities (SWMA) and vascular aneurysms, calculation of ejection fraction and ventricular preload, and measurement of blood flow within heart chambers and across valves are a few ultrasound imaging utilities that are applied during TEE. Guidelines for indications and training proficiency have been advocated by medical professional societies.¹¹⁷

The use of sound waves to define anatomic structures in the human body was first described by Dussik et al. in 1947. These investigators attempted to outline the cerebral ventricles by driving sound waves across the skull.¹¹⁸ In 1971, C.D. Side and R.G. Gosling were the first to report the assessment of cardiac function via transesophageal techniques.¹¹⁹ Forty-five years later, substantial advancements in the medical application of ultrasound have occurred, leading, in some circumstances, to an improvement in surgical outcomes.¹²⁰ Fundamental to the interpretation of data obtained by TEE is an understanding of the physics of ultrasound. Ultrasound waves are inaudible to the human ear, having a frequency greater than 20,000 Hz. Piezoelectric crystals are known to produce ultrasound waves by vibrating when exposed to an electric current. The opposite also occurs, in that they produce voltage in response to an ultrasound echo or when pressed (i.e., subjected to mechanical stress) or released. The electric current produced has been shown to be of sufficient magnitude to temporarily illuminate a small bulb. Thus, piezoelectric crystals function as both generators and receivers of ultrasound waves and electric currents.

Within the esophagus, ultrasound waves emitted by piezoelectric elements are absorbed, reflected, or scattered. When reflected by an organ (e.g., heart), the ultrasound echo produced is received by the

piezoelectric elements housed within the TEE probe. These elements then generate an electrical impulse that is processed, amplified, and subsequently displayed as an image on the echograph machine. Manufacturers can place as many as 32 linearly arranged piezoelectric elements within a probe (Fig. 17.23). The frequency of the piezoelectric crystals in TEE probes ranges from 3.7 to 7 MHz. This frequency range allows for greater detail in displayed images. Unfortunately, the tradeoff for clearer images is lower tissue penetration. Thus, smaller frequency values (e.g., 2.5 MHz) are required in transthoracic echocardiographic probes due to the greater distances between the elements and distal anatomic structures.

FIGURE 17.23 A 170-cm transesophageal echocardiography probe with cm markings. Examination depth is approximately 35 to 40 cm from teeth. The positioning-holding mechanisms are located on control knobs, allowing for manipulation of the probe in the anterior, posterior, and lateral planes. *2D TEE*, Two-dimensional transesophageal echocardiography.

Clinically, three primary ultrasound imaging techniques are used: the M-mode, 2-dimensional (2-D) imaging, and the Doppler exam. The M-mode provides high picture resolution, with 1000 images per second. It is commonly described as unidimensional,

and produces a well-focused, narrow ultrasound beam. It is sometimes referred to as an *ice-pick view*. With the 2-D scan, the ultrasound beam is electronically steered across a target field. The intermittent ultrasound pulses are produced by varying the firing sequence (phasing) of individual piezoelectric crystals. The monitor subsequently displays an image that is somewhat triangular or appears as a “slice” of pie. This produces excellent spatial orientation; however, at 30 images per second, the pictures are less well defined. The Doppler exam incorporates the concept of frequency shift, which was first described in 1842 by Austrian physicist Christian Doppler. The clinical application of this concept involves viewing red blood cells (RBCs) as moving reflectors of ultrasound. As ultrasound reflects off the moving RBCs, echoes are produced, which are then recorded by the TEE transducer. With the flow of RBCs toward the TEE probe, the distance between the sound source and its reception changes. This phenomenon is referred to as a *frequency shift*. It is analogous to the change in pitch of a train whistle as the locomotive approaches the station: sound waves are compressed, and the pitch increases (i.e., the frequency shifts). In contrast to RBCs, body fluids (in this case, plasma) only minimally reflect ultrasound. Spectral and color-flow Doppler exams performed with echographs incorporate this concept by assigning different colors to RBCs that move toward and away from the source of ultrasound. This permits easy visualization of retrograde flow of blood across incompetent heart valves, as may occur with MR. For example, the retrograde flow of blood from the LV into the left atria during MR is seen distinctly as a mosaic pattern of color. Doppler exams are recognized as being beneficial in determining the etiology of regurgitation and the adequacy of valve repair, as well as influencing surgical management, such as the use or nonuse of cardiopulmonary bypass.^{120,121}

Fundamental elements of the TEE exam include positioning the TEE probe in the esophagus, either under sedation or after induction of the anesthetic (Fig. 17.24). During the examination, cardiac anatomy can be assessed, myocardial ischemia can be diagnosed via the presence of SWMA, and blood flow through heart chambers and across valves can be seen. By convention, the posterior structures are displayed at the top of the screen (apex of

the sector) and anterior structures at the bottom. The first image displayed in a standard exam is the short-axis view of the aortic valve. At a depth of approximately 35 to 40 cm from the teeth, the aortic valve leaflets and coronary arteries are seen. Rotation and angulation of the probe can allow a long-axis view of the right and left atria, tricuspid and mitral valves, pulmonic and aortic valves, and right and left ventricles. This view is useful for assessing stenotic valves, identifying masses within the atria or ventricles, and observing the overall size of each heart chamber. A short-axis view of the LV can be obtained with further advancement of the probe and angling of the tip. This position is also referred to as the *standard monitoring view*, which allows the echocardiographer to assess for SWMA. Normal ventricular wall motion (which is not entirely uniform) increases during systole, and the endocardial surface moves inward. Approximately 87% of the normal stroke volume is derived from shortening in the short axis of the ventricle, with little contribution from the long axis.

FIGURE 17.24 Transesophageal echocardiography probe. Distal tip contains thermistor and piezoelectric elements.

Abnormal wall motion can be described by three terms: hypokinesia, akinesia, and dyskinesia. *Hypokinesia* represents contraction that is less vigorous than normal; wall thickening is decreased. *Akinesia* depicts the absence of wall motion and can be associated with MI. *Dyskinesia* correlates with paradoxical movement (i.e., outward motion during systole) and is a hallmark

of MI and ventricular aneurysm (Fig. 17.25). Not all wall motion abnormalities are diagnostic of an imbalance between myocardial oxygen supply and demand. Abnormal loading conditions, asynchronous ventricular depolarization (e.g., left bundle branch block), echo dropout due to haphazard reflection of ultrasound off myocardial walls in lateral fields of the sector arc, or improper use of the gain controls of the TEE probe can lead to an erroneous diagnosis of SWMA. In addition, the duration of SWMA can persist well after coronary reperfusion has been restored (e.g., 6 hours), indicating a stunned myocardium.¹²² In canine research, a 50% decline in coronary blood flow has been shown to serve as a threshold for hypokinesia. In contrast, a 75% reduction in coronary blood flow commonly produces ST segment deviation. Thus there is greater hysteresis and less sensitivity with ischemia-induced ECG changes than with ischemia-induced SWMA.^{123,124} This finding is consistent with classic research done by Tennant and Wiggers in 1935.¹²⁵

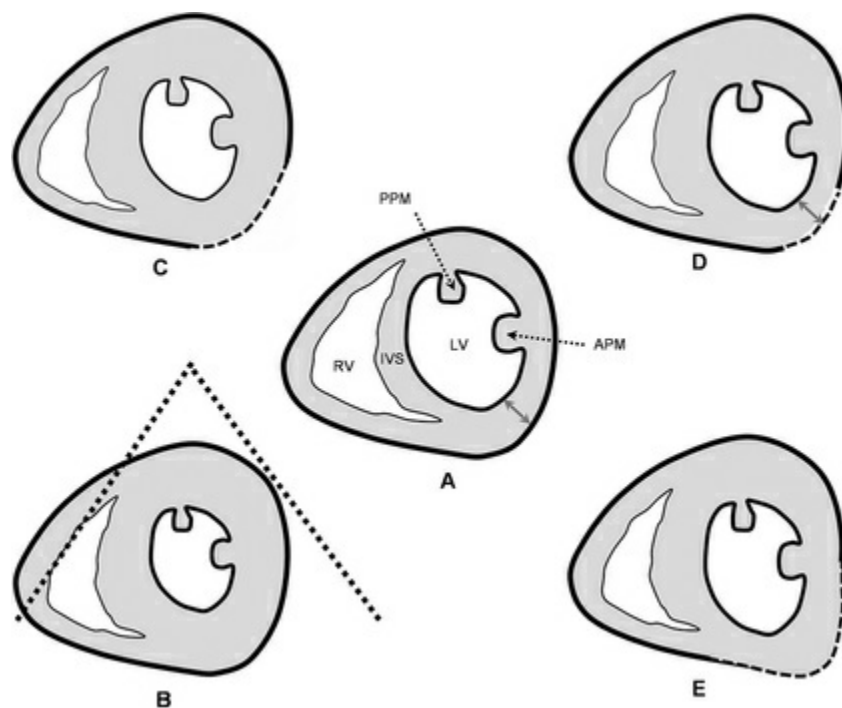

FIGURE 17.25 Midpapillary muscle level short-axis view of the heart (A) during diastole, (B) during systole, with normal wall thickening and inward movement of the endocardial surface, (C) systole with an area of hypokinesia (decreased wall thickening), (D) systole with

an area of akinesia (no change in wall thickness), and **(E)** systole with an area of dyskinesia (paradoxical movement).

APM, Anterior papillary muscle; *IVS*, interventricular septum; *LV*, left ventricle; *PPM*, posterior papillary muscle
RV, right ventricle.

To summarize, the best single view for routine monitoring for SWMA (myocardial ischemia) is the short axis at the midpapillary muscle level (see [Fig. 17.25](#)), followed by the apical segment in the same axis. The midpapillary muscle level includes segments of the myocardium that are perfused by all three coronary arteries. This level is created by dividing the long axis of the LV into three parts (i.e., the basal, mid-, and apical regions). The mid-region extends from the tips to the bases of the papillary muscles. Interestingly, the skills required of anesthesiologists, residents, and CRNAs (compared with those trained in echocardiography to recognize gross SWMA) can be acquired with little training. One study group successfully identified 95% of regional wall motion abnormalities.¹²⁶

Newer imaging techniques introduced with TEE include contrast echocardiography, selected three-dimensional techniques, parametric imaging modes, and harmonic imaging modalities. Continued research with these echocardiographic diagnostic tools will help elucidate what patient populations may benefit most from their application. Recent investigations have shown that live/real-time, three-dimensional echocardiography is a feasible way to estimate the area of the aortic valve orifice in patients with stenotic lesions, to evaluate patients with suspected CAD for myocardial wall motion and perfusion abnormalities, and to better visualize/detect cardiac lymphomas.¹²⁷⁻¹²⁹ Also of interest is porcine research that showed intracardiac transvenous echocardiography to be superior to precordial Doppler and TEE techniques in diagnosing venous air embolism and retrieving as little as 0.05 to 1 mL of air.¹³⁰

Summary

With continued advancements in technology and improved clinical databases derived from research, future monitoring techniques offer promise for continued improvement in anesthesia care. The development of specialized task forces comprising multiple professional societies also contributes substantively to professional practice. Understandably, anesthesia providers should continue to maintain a healthy skepticism of reported advancements in monitoring modalities. The decision to change practice routines should occur only after critiquing the reported merits of any research findings. Ultimately, this clinical paradigm will allow patients to benefit from medical and nursing care derived from evidence-based practice.

Clinical Monitoring II

Respiratory and Metabolic Systems

Gregory Bozimowski

The monitoring of ventilatory status in an anesthesia context epitomizes the contract between the nurse anesthetist and the patient receiving anesthesia care. Clinical monitoring in the perioperative setting or remote location is the process of observing physiologic responses to surgery, procedure, and anesthesia, and is the essence of what the Certified Registered Nurse Anesthetist (CRNA) does to ensure an optimal, safe anesthetic outcome. The CRNA needs to embrace this part of their role with an obsessive, nearly compulsive, approach.

It is important to consider the monitoring modalities utilized for their value in reducing patient morbidity and mortality. Research provides rationale to support the standardization of minimal monitoring modalities. Standards are available to the anesthesia provider from both the American Association of Nurse Anesthetists (AANA) and the American Society of Anesthesiologists (ASA). It is a matter of clinical judgment by the anesthetist that determines what modalities beyond those minimally required will provide useful information when added to the anesthetic plan of care. It is through this evidence-based approach that best practices are developed.

Above all, human vigilance must be maintained and considered primary in assessing patient responses to anesthesia and surgical procedures. Human error is always possible and may be associated with adverse outcomes. Monitoring alone cannot prevent adverse outcomes, but a timely response to warnings can have a positive impact. It cannot be emphasized enough that reliance on technology must never be allowed to lull the clinician into

complacency. Although accuracy and reliability of monitors continue to improve, the potential for machine malfunction and artifact is ever present. Timely human response to intraoperative events remains the key to predicting, avoiding, and managing untoward responses to anesthesia and surgery. As such, the use of technology in combination with human vigilance remains the patients' best defense against preventable respiratory critical events. The basic human senses of sight, hearing, touch, and even smell remain crucial tools in clinical monitoring because the patient is the primary source of assessment data.

This chapter reviews the relevant standards for respiratory and temperature monitoring outlined by the AANA. Because systematic processes can provide consistency, a practical systems approach to monitoring is presented. Respiratory monitoring is reviewed as it relates to the ongoing assessment of airway and breathing using not only the human senses but also technologic tools used by nurse anesthetists. The modalities to be discussed in this chapter include the precordial stethoscope, carbon dioxide detection devices, and pulse oximetry. Thermoregulation is significantly altered under anesthesia, therefore temperature monitoring modalities are also reviewed in this chapter. Finally, implications for the education of nurse anesthetists and the future of clinical monitoring are visited.

Monitoring Standards

Monitoring standards are published and reviewed by anesthesia professional associations so that minimal standards in the provision and monitoring of care can be recommended. Such standards are intended to lend guidance to anesthesia providers and health care facilities in evaluating quality of care and developing and improving the safety of practice while educating the public regarding patient rights and expectations. The AANA *Scope of Anesthesia Practice* states that “CRNAs are accountable and responsible for their services and actions, and for maintaining their individual clinical competence.” In this regard, the CRNA is accountable for their practice and responsible for being aware of and adhering to the standards of care set forth. Standard V of the AANA *Standards for Nurse Anesthesia Practice* outlines specific monitoring requirements necessary for compliance ([Table 18.1](#)).¹

TABLE 18.1

Scope and Standards for Nurse Anesthesia Practice

Standard V	
Monitor the patient's physiologic condition as appropriate for the type of anesthesia and specific patient needs	
Parameter	Modifier
Monitor ventilation continuously	Verify intubation of the trachea by auscultation, chest excursion, and confirmation of carbon dioxide in the expired gas; continuously monitor end-tidal carbon dioxide during controlled or assisted ventilation including any anesthesia or sedation technique requiring artificial airway support; use spirometry and ventilatory pressure monitors as indicated
Monitor oxygenation continuously	By clinical observation, pulse oximetry, and if indicated, arterial blood gas analysis
Monitor cardiovascular status continuously	Via electrocardiogram and heart sounds; record blood pressure and heart rate at least every 5 minutes
Monitor body temperature continuously	On all pediatric patients receiving general anesthesia and when indicated, on all other patients
Monitor neuromuscular function and status	When neuromuscular blocking agents are administered
Monitor and assess the patient	Assess and institute protective measures

Adapted from the American Association of Nurse Anesthetists. *Scope and Standards for Nurse Anesthesia Practice*; 2016. Available at <http://www.aana.com>.

Similarly, in the *ASA Standards for Basic Anesthetic Monitoring, standard 2*, it is stated, "During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated." Throughout the course of care, these standards emphasize continuous monitoring by the anesthesia provider and, additionally, it is specifically written that during moderate or deep sedation, continuous monitoring of end tidal carbon dioxide (ETCO₂) shall be utilized to evaluate the adequacy of ventilation. The ASA standards also explicitly state that the use of ETCO₂ monitoring should be utilized when propofol is administered during endoscopy procedures.²

These standards acknowledge and emphasize the importance of vigilant monitoring as the basis of safety in anesthesia practice. In addition, the standards point out that the CRNA must constantly be in attendance of the patient until the responsibility for care can be safely transferred to another qualified health care provider. They further point out that these are intended to be minimum requirements and should be exceeded as deemed necessary in the judgment of the anesthetist. In most cases, when certain monitoring modalities are not used, they must be at least immediately available. Whereas it may seem obvious that standards should be followed, a closed-claims study revealed that nearly half of the time standards were not followed and, in particular, standards III, IV and V were those most often breached.³

Alarm Fatigue

The AANA Practice Standard V specifically indicates that alarm limit parameters and audible warning systems should be used, and a specific statement is made recommending the use of variable pitch alarms and that threshold alarms should be activated. The value of variable pitch commonly used in pulse oximetry equipment has been widely appreciated for its ability to provide information regarding subtle changes in oxygen saturation using the sense of hearing, prior to visualizing the monitor. Alarms are designed to protect the patient by alerting the practitioner that the individual is at increased risk and needs immediate assistance.

An area of concern related to electronic monitoring devices is a phenomenon referred to as *alarm fatigue*. Alarm fatigue is a form of human error occurring when a practitioner is desensitized to alarms or alerts.⁴ The ideal alarm would be easy to localize and recognize. It would be evident despite other noises and alarms, yet would allow for effective communication between care providers. The ideal monitoring device would also elicit a minimal number of false alarms. Alarms in many medical devices fall short of the ideal and as a result are subject to being ignored or even disabled by the practitioner. It has been demonstrated that many alarms generated during the course of an anesthetic are clinically irrelevant, with only a small incidence indicating a critical event.⁵ As a result, it is not surprising that little progress has been made in combating alarm fatigue.⁶

Systematic Approach to Monitoring

A systematic process shown to be effective in reducing anesthetic morbidity and mortality should be the goal when planning appropriate monitoring to be used. As monitoring standards guide practice by prescribing minimums to be adhered to, other processes can be helpful in defining how monitoring should occur and which modalities should be used. In addition, a systematic approach to problem solving for cause of alarms or adverse patient responses can speed the anesthetist to provide remedy. Closed-claim studies can provide valuable insight into monitoring techniques and habits that could be useful in preventing future anesthesia mishaps. Whereas overall respiratory closed claims events have decreased, they still remain a concern. The incidence of esophageal intubation was drastically reduced with the advent of ETCO₂ monitoring, demonstrating the value of technologic advances.⁷ Incident monitoring systems and practices can be used to collect data for practitioners to use to develop safer processes, as in the often referenced analogies made to the aviation industry.⁸ The vigilance needed for effective clinical monitoring can be thought of as a means to avoid critical incidents. A multitude of external factors can have an impact on the human capability to be vigilant. Anyone entering an operating room or other location where anesthesia is provided could easily identify several distractors. Environmental factors such as noise, music, temperature, and human interaction can be disruptive. Factors such as fatigue, boredom, sleep deprivation, and circadian disruption from extended work hours have been implicated in human error at one time or another.⁹

The act of administering anesthesia results in a physiologic response to the pharmacodynamics and pharmacokinetics of each substance given. The insult of the surgical or diagnostic procedure performed also results in a physiologic response. As such, observation of the human systems response is the monitoring of the pharmacology of the agents used and the physiology of the human system. As the science and process for quality assurance and improvement have evolved, much has been learned and written about the value of a systematic approach to the analysis of critical

incidents and crisis management. The concepts used in quality assurance management can be applied to anesthesia monitoring because a primary function of the nurse anesthetist is to prevent or respond to critical incidents to assure a quality anesthetic in terms of safety and efficacy.

Many algorithms and protocols have been written to guide the practitioner through the monitoring process and to ensure thorough, vigilant observation. Simple, systematic approaches to crisis management are often focused on or derived from the common algorithm “ABC,” representing airway, breathing, and circulation. There is enormous value in developing a systematic approach to monitoring. The habit sometimes referred to as *sweeping* the anesthesia field to visualize the patient, with the eyes following a path to the anesthesia machine via the airway and breathing circuit and progressing to the monitoring modalities used, has long been taught as a means of increasing vigilance and attention to detail. The well-known mantra of the ABCs—observing the Airway, Breathing (respiration), and Circulation—remains foremost and critical in anesthesia clinical monitoring. The addition of D for evaluating drug effects completes the basic monitoring approach in anesthesia. The expanded use of checklists in health care have gained popularity and have been aptly applied to assuring equipment function. But the use in clinical monitoring and troubleshooting application has been met with mixed reviews. Some evidence suggests that checklists do provide an effective means of identifying causes of failure and incidents.¹⁰ In an anesthesia context, additional foci for monitoring can include (1) Color (i.e., cyanosis), (2) Oxygen and oxygen analyzers, (3) Ventilation, vaporizer, or pump settings and status, (4) Endotracheal tube (ETT) patency and placement, and (5) Review of monitors, equipment, and drug effects, thereby expanding the crises response algorithm to COVERABCD (Table 18.2).¹¹

TABLE 18.2

Crisis Management Algorithm

Algorithm	Descriptor
C—Circulation, Color	Determine adequacy of circulation, check pulse, blood pressure; ECG notes oxygenation through assessment and oximetry

O —Oxygen, Oxygen analyzer	Check oxygen delivery system, hypoxic guard
V —Ventilation, Vaporizer	Ventilate by hand to assess breathing circuit and airway patency, assess chest excursion and auscultation; assess $ETCO_2$; check vaporizer function
E —Endotracheal tube	Systematic assessment of ETT if used, including patency, seal, etc
R —Review monitors, Review equipment	Review all monitors in use, assure appropriate calibration and maintenance, review any and all equipment in contact with the patient
A —Airway	Check patency of the unintubated airway, assess for laryngospasm, foreign body, etc
B —Breathing	Assess pattern, rate, and depth of respirations; examine, auscultate, and review $ETCO_2$ and pulse oximeter monitors
C —Circulation	Repeat assessment of circulation
D —Drugs	Review drugs given; consider needed pharmacologic intervention; consider possibility of medication administration error

Review of critical incidents has provided insight into how clinicians can enhance safety and prevent mishaps through their use of monitors with alarms. Equipment malfunctions, as well as a lack of familiarity with equipment or user error, have all been shown to contribute to incidents.¹² The ever increasing practice of providing anesthesia care in remote areas (outside of the operating room), where the use of fewer or less familiar monitors may be employed has been implicated in an increase in the number and severity of liability claims.^{13,14} It behooves the anesthetist to be aware of the differences in equipment and availability of all resources when providing care away from their more familiar settings.

Airway Monitoring

Monitoring the airway includes the observance of gas exchange from the upper to lower airways. Assessment of airway patency is performed in very subtle yet essential ways. Ventilatory movement of the chest must be observed and the presence of any sign of airway obstruction such as retractions, or seesaw motion of the chest and abdomen, is noted. Seeing the presence of condensation in an airway device or clear mask can serve to indicate the presence, although not adequacy, of gas exchange. The sense of touch can also be helpful to perceive subtle movement of air exchange felt on the hand of the anesthetist. The sense of smell can be the first aid in detecting a disconnected circuit or airway device when volatile agents are being used. Listening for the presence of abnormal airway sounds such as stridor is crucial in noting airway obstruction. The precordial stethoscope is a valuable tool in auscultating the presence or absence of airway exchange during all phases of the anesthetic, regardless of the type administered.¹⁵ Ensuring adequacy of ventilation, whether an ETT or laryngeal mask airway is in use, must include verification of placement by assessing breath sounds and chest expansion, as well as verification of the presence of carbon dioxide (CO₂) in the expired gas.² Whereas failure to successfully intubate is problematic, failure to recognize misplacement is catastrophic.

Respiratory Monitoring: Ventilation

Merely assuring the presence of airway movement does not assure adequate gas exchange. Monitoring respiratory parameters is aimed at evaluating both ventilation and oxygenation. The patient must be observed for adequate minute ventilation throughout the anesthetic course. At the most basic level, this is accomplished through visualization of chest excursion and auscultation of breath sounds. The value of the precordial or esophageal stethoscope is twofold: it provides continuous assurance that ventilation is occurring and can be used to detect changes in breath sounds.¹⁵ With the reliance on electronic devices, the use of a simple monaural stethoscope has

diminished and its use may at times represent a divide between anesthesiologists educated during a simpler time and those who were initiated since the standard use of electronic ventilation monitoring. A novel device that has been shown to accurately measure respiratory rate through the use of acoustic monitoring transducers may serve to bridge that gap. This device senses turbulent air flow through a sensor placed on the upper airway. The monitor provides a readout of respiratory rate and has been shown to be well tolerated by patients. Whereas acoustic respiratory monitoring does not identify stridor or other adventitious sounds, it can alert the anesthesiologist to apnea. In addition, it offers the added benefits of being effective despite the presence of large body habitus or extraneous room noises which limit the value of a traditional precordial stethoscope. This method of detecting apnea has shown promise in the post anesthesia care unit (PACU) and was shown to be more reliable than the more frequently used thoracic impedance technology which relies on movement of electrocardiographic electrode leads.^{16,17} Assessing the respiratory rate and tidal volume is crucial to ensuring adequacy of minute ventilation, as well as interpreting patient response to pharmacologic agents and surgical stimuli.

Skin and nail bed color should be observed as part of the whole patient-assessment picture; however, skin color changes alone are not a reliable measure of whether ventilation and oxygenation are adequate. Cyanosis is a late sign of anemia or hypoxia and can be difficult to assess accurately, given such variables as differences in lighting during certain procedures and lack of controls in comparisons of patients' coloring throughout the perioperative period. In addition to physical assessment skills, monitoring the adequacy of ventilation must be done throughout the perioperative period, using multiple parameters. Several themes are evident that relate to safety and vigilance in monitoring when reviewing closed-claims studies for anesthesia incidents. The most prominent of these is the value of certain specific monitors and their alarms. These include pulse oximetry, ETCO₂ measurement, oxygen analyzers, and disconnect alarms. Of equal importance is the users' ability to assure the proper function of these prior to administering an anesthetic.¹⁴

Carbon Dioxide Monitoring

The measurement of arterial blood gases to determine the level of carbon dioxide provides direct measurement of ventilation and metabolic status, and the necessity of this action may be indicated at times. The means of measuring the carbon dioxide tension in the blood (PaCO_2) is based on hydrogen ion concentration, because CO_2 reacts with water to produce hydrogen ions through a reversible reaction. This reaction yields carbonic acid, which dissociates to yield hydrogen and bicarbonate ions,¹⁸ as shown in the following equation:

The production of carbonic acid also allows for the qualitative—and to a limited extent, quantitative—detection of the presence of CO_2 through the use of disposable ETCO_2 detector devices. These colorimetric devices react to changes in pH and display it as a color change. They are widely used in emergency settings to verify proper placement of an ETT.¹⁹ These devices are sensitive enough to detect carbon dioxide quickly; however, in most cases a minimum of six breaths has been suggested to avoid misinterpretation. With advances in newer technologies, colorimetric devices may become even more rapid and reliable.²⁰ False positives may result from the detection of CO_2 from air forced into the stomach during mask ventilation or the presence of carbonated beverages or antacids in the stomach.²¹

The means to measure CO_2 level must be based on the patient's condition, the type of anesthetic administered, and the complexity of the surgical procedure. The continuous measurement of CO_2 in expired gas provides a practical, noninvasive, and accurate reflection of arterial blood carbon dioxide and is the most common means of monitoring carbon dioxide levels in the anesthesia setting. As previously mentioned, it is also a monitoring standard of care during general anesthesia for the patient being ventilated or whose ventilations are being assisted, as well as during moderate or deep sedation, unless precluded or invalidated by the nature of the

patient, procedure, or equipment.²

Accuracy of ETCO_2 as a correlation with arterial carbon dioxide has been well documented. ETCO_2 is said to be approximately 2 to 5 torr lower than arterial CO_2 in patients who have no cardiac or pulmonary abnormalities.²¹ Pathologies that result in an increased dead-space, as well as significant alterations in hemodynamic stability, will increase the variance seen between ETCO_2 and arterial measurements.²² An in-depth discussion of CO_2 dissociation and O_2 - CO_2 exchange is presented elsewhere in this text.

Capnometry is a term that encompasses all means of measuring carbon dioxide, whereas *capnography* refers to the recording of the measurement. The term *capnogram* is used to describe a continuous display of CO_2 during the phases of ventilation. The continuous measurement of ETCO_2 is accomplished through the use of infrared analysis. When a gas mixture containing more than one substance, (e.g., an exhaled gas sample) is analyzed, a quantitative measurement can be made to determine the proportional contents. Each gas in the mixture absorbs infrared radiation at a different wavelength. The amount of CO_2 is measured by detecting its absorbance at specific wavelengths and filtering the absorbance related to other component gases.

Sampling of ETCO_2 can be accomplished through either a nondiverting (also known as *mainstream*) or diverting (also known as *sidestream*) monitor. A nondiverting monitor measures gas directly within the breathing system. Gas passes through a wide-chambered sensor that fits over a connector between the anesthesia circuit and mask adapter. The sensor is connected to the monitor by a cable. Nondiverting monitors offer several advantages. They have minimal sampling-time delays, use few disposable items, and do not require scavenging because gas is not removed from the system. Disadvantages include the inability to measure gases other than CO_2 and nitrous oxide, an increase in circuit deadspace by the adapter, and greater risk of interference by condensation and secretions. In addition, because the sensor and cable are attached in proximity to the patient, the added weight may cause traction on the tube, increase the risk of circuit disconnect, and make sampling in a nonintubated patient difficult.²¹

The other, more commonly used, CO₂ monitor type is the diverting monitor. The diverting monitor extracts gas from sample tubing attached near the patient end of the circuit and pumps it to the monitor. Disadvantages include the need for scavenging of sampled gases because they are removed from the circuit, and some risk of contamination by condensation or secretions also exists. Advantages of the diverting system include minimal increase in deadspace and versatility in gas analysis because the sample can also be sent to anesthetic agent monitors. In addition, the small, lightweight tubing can be adapted to sample awake, spontaneously breathing patients through the mouth, nares, or simple mask.²¹

It has become common to adapt the sampling line of a diverting ETCO₂ monitor to trace a capnogram in awake or sedated, spontaneously breathing patients receiving O₂ via simple mask or nasal cannula. Whereas there is a possibility of air or oxygen entering the sample line and resulting in a lowered ETCO₂ value due to dilution, the use of ETCO₂ monitoring as a warning of hypoventilation or excess sedation has gained attention outside of the anesthesia setting. For example, ETCO₂ monitoring has been shown to be a more sensitive indicator of hypoventilation than clinical observation or pulse oximetry when used during sedation in the emergency department setting.²³ Other studies note the value of ETCO₂ monitoring during sedation, as well and note the advantage over pulse oximetry alone in detecting hypoventilation in patients receiving supplemental O₂. It has been suggested that, like pulse oximetry, ETCO₂ monitoring should be considered a standard of care for patients receiving sedation outside the operating room.²⁴

End-Tidal Carbon Dioxide Capnography.

Capnography can record CO₂ as a component of expired lung volume or as a measure of CO₂ alone throughout the phases of respiration plotted against time. Time capnography is most commonly used in the perioperative setting. Basic interpretation of the ETCO₂ capnogram is a necessary skill. The capnogram can differentiate between normal and abnormal patterns of ventilation that result from patient pathologies, anesthesia system problems, or

unexpected patient responses during anesthesia.

The normal time capnogram can be recorded at varying speeds. A fast speed setting of approximately 12.5 mm/second allows interpretation of individual respiratory components and short-term changes, whereas a slow speed of approximately 25 mm/minute displays long-term changes.²⁵ Although no standard descriptions exist for the components of the capnogram, it is typically described as encompassing four basic phases (Fig. 18.1). These phases are often displayed in a classic waveform shape best recorded during mechanical ventilation in an intubated patient. It is important to note that the basic shape of the wave form will vary depending on the mode of airway management used (e.g., ETT, laryngeal mask airway, simple mask, nasal cannula, etc.) as well as in comparison to the spontaneously breathing patient.

FIGURE 18.1 The four phases of a normal capnogram. A-B represents baseline; B-C represents expiratory upstroke; C-D represents expiratory plateau; D represents end-tidal concentration; and D-E represents descent to original baseline. (Courtesy Repironics, Inc., Murrysville, PA.)

Although the shapes may vary, the represented phases apply universally. The first phase is the end of inspiration and very beginning of expiration. Gas sampled at this point identifies the baseline. This sample comes from the anatomic deadspace and contains no CO₂. This portion in a normal capnogram should approximate zero. The second phase is the expiratory upstroke. Gas sampled represents a mix of deadspace and alveolar gas and thus records measurable CO₂. This phase represents the rapid passing of initial expired gas through the upper airways. The third phase represents the plateau and records alveolar emptying of CO₂. In the normal pulmonary measurement, the plateau is very nearly flat. This phase represents the longest duration of the measurement.

ETCO₂ is measured at the end of the plateau just prior to the beginning of phase four. The fourth phase is displayed as the rapid decrease in CO₂ concentration of sampled gas as a result of inspiration of air or O₂. This downstroke returns the recorded CO₂ measurement to or very near to zero. Variations in the capnography tracing can be very subtle and represent specific alterations in the ventilatory process. Some common deviations are worth noting. In the process of evaluating the capnogram, the anesthetist should note the respiratory rate, whether ventilation is spontaneous or mechanical, the value of measured end-expired CO₂, the shape of the recorded waveform, and the presence of additional respiratory efforts. Deviations from what is normally a close approximation of arterial CO₂ can occur. ETCO₂ measurements may be inaccurate in the presence of significant ventilation and perfusion mismatching. When ventilation-to-perfusion ratio is large, the resultant increase in deadspace causes a low concentration of ETCO₂ overall.^{19,22,26} In addition, small tidal volumes, reflecting inadequate alveolar ventilation, may produce ETCO₂ recordings that significantly underestimate arterial CO₂ levels.

After esophageal intubation, an initial, slight upstroke of carbon dioxide may be seen in those rare circumstances when carbon dioxide may be sampled from the stomach as mentioned previously in reference to disposable ETCO₂ detector devices. These CO₂ measurements are the result of excess air blown into the stomach, possibly during overzealous ventilation or a partially obstructed airway. Such a waveform will display for a very brief period and be followed by a measurement of zero.

A waveform that fails to return to baseline during phases one and four indicates that rebreathing of carbon dioxide is occurring. This can be the result of inadequate fresh gas flow in the non-rebreathing system or a depleted or ineffective carbon dioxide absorber (Fig. 18.2). Although this may be detected over time, it can be difficult to distinguish.

FIGURE 18.2 Elevation of the baseline indicates rebreathing. (Courtesy Repironics, Inc., Murrysville, PA.)

Sloping of the plateau phase represents a progressive prolongation of expiration. It is typically the result of either an obstruction of expired gas flow at some point along the airway or ventilation-perfusion mismatch (Fig. 18.3). It also can be indicative of chronic obstructive lung disease, because CO₂ is exhaled more slowly from diseased portions of the lungs (with more significant airway narrowing) than from areas with less severe narrowing. Plateau-phase sloping can also occur with kinking of the ETT or any aspect of the circuit tubing. Changes in the waveform from baseline normal should always be evaluated to determine the cause and necessary interventions.

FIGURE 18.3 Inspiratory flow waveform demonstrating the effect of impedance on decay of flow. In a patient with stiff lungs (e.g., acute respiratory distress syndrome) and a fast time constant, flow decay is rapid. In the patient with normal compliance and high airway resistance (e.g., chronic obstructive pulmonary disease), the flow decay is prolonged. In these two breaths with the same peak flow, 10% of the fast-time constant is equivalent to 50% of the slow-time constant. (From Branson RD. Functional principles of positive pressure ventilators: implications for patient-ventilator interaction.

Respir Care Clin N Am. 2005;11(2):119–145.)

Regular, saw-tooth waves within the expiratory phase at a rate equal to the heart are likely the result of cardiac oscillations (Fig. 18.4). This is the result of the contraction of the heart and great vessels forcing gas in and out of the lungs. This is a common occurrence in pediatric patients owing to the relative size of the heart to the thorax.

FIGURE 18.4 Cardiac oscillations occur as a result of contractions of the heart and great vessels. (From Miller RD. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015.)

During mechanical ventilation in an anesthetized and/or paralyzed patient, spontaneous respiratory effort may be seen if the anesthetic depth is insufficient to prevent respiration or when inadequate muscle relaxation is present. The resultant capnogram is often referred to as *curare cleft* (Fig. 18.5). This irregular asynchronous waveform may occur within the mechanically ventilated wave or separate from it. Causes of increased or decreased ETCO_2 levels are noted in Box 18.1.

FIGURE 18.5 Clefs displayed as a spontaneous inspiration asynchronous with controlled ventilation. (Courtesy Repironics, Inc., Murrysville, PA.)

Box 18.1

Causes of High and Low End-Tidal Carbon Dioxide

Increased $P_{et}CO_2$

Increased CO_2 Delivery/Production

Malignant hyperthermia, fever, sepsis, seizures, increased metabolic rate or skeletal muscle activity, bicarbonate administration/medication side effect, laparoscopic surgery, clamp/tourniquet release

Hypoventilation

COPD, neuromuscular paralysis or dysfunction, CNS depression, metabolic alkalosis (if spontaneously breathing), medication side effect

Equipment Problems

CO_2 absorbent exhaustion, ventilator leak, rebreathing, malfunctioning inspiratory or expiratory valve

Decreased $P_{et}CO_2$

Decreased CO_2 Delivery/Production

Hypothermia, hypometabolism, pulmonary hypoperfusion, low cardiac output or arrest, pulmonary artery embolism, hemorrhage, hypotension, hypovolemia, V/Q mismatch or shunt, auto-PEEP, medication side effect

Hyperventilation

Pain/anxiety, awareness/ "light" anesthesia, metabolic acidosis (if spontaneously breathing), medication side effect

Equipment Problems

Ventilator disconnection, esophageal intubation, bronchial intubation, complete airway obstruction or apnea, sample line problems (kinks), endotracheal tube or laryngeal mask airway leaks

CNS, Central nervous system; CO_2 , carbon dioxide; *COPD*, chronic obstructive pulmonary disease; $P_{et}CO_2$, end-tidal carbon dioxide; *V/Q*, ventilation perfusion.

Adapted from Newmark JL, Sandberg WS. Noninvasive physiologic monitors. In

Transcutaneous Carbon Dioxide Monitoring.

Accurate analysis of ETCO_2 reflects adequacy of ventilation. Transcutaneous CO_2 monitoring does not provide immediate, breath by breath verification of ETT placement nor the presence of respirations; therefore its use is not common in the anesthesia care realm. Nonetheless, it is a reliable, noninvasive means of CO_2 measurement and can be useful in detecting hypoventilation. Transcutaneous CO_2 measurement is a noninvasive measure of PaCO_2 . It can either estimate PaCO_2 or determine trends in the measurement. Transcutaneous CO_2 monitoring can be accomplished using the same technology that is commonly used for measurement of oxygen saturation through pulse oximetry. The electrode used provides a measurement of CO_2 through measurement of H^+ ion change. Transcutaneous CO_2 monitors have gained notice for their value in analyzing analysis during circumstances in which ETCO_2 measurement may be inaccurate, as in the case of ventilation-perfusion mismatching. In such cases as severe obesity, which may affect ventilation-perfusion ratios as a result of reduced functional residual capacity, transcutaneous CO_2 monitoring may provide a more accurate estimate of arterial carbon dioxide than ETCO_2 . In addition, transcutaneous CO_2 monitoring has been shown to accurately approximate arterial blood gas (ABG) analysis in critical care patients.^{27,28} An added benefit of transcutaneous CO_2 measurement may be seen in monitoring the awake patient at risk of hypoventilation in whom ETCO_2 monitoring is impractical.

Flow, Volume, and Pressure Monitoring of Ventilation

Many modern anesthesia machines offer the ability to monitor spirometry loops. Observation of spirometry loops can provide rapid evaluation of changes in lung compliance and resistance. A spirometry loop is a graphic representation of a dynamic

relationship between two respiratory variables: flow and volume or pressure and volume. Pressure-volume loops provide insight into lung compliance and show volume on a vertical axis and airway pressure on the horizontal axis (Fig. 18.6). Flow-volume loops provide information on pulmonary resistance and show flow on the vertical axis and volume on the horizontal axis (Fig. 18.7).

FIGURE 18.6 P-V loop showing the peak inspiratory pressure (PIP), pressure at the airway opening (P_{awo}), alveolar pressure (P_A), and transairway pressure (P_{TA}).
(From Cairo JM. *Pilbeam's Mechanical Ventilation: Physiological and Clinical Applications*. 6th ed. St. Louis: Elsevier; 2016.)

FIGURE 18.7 Flow-volume loop showing curves for normal (A), obstructive (B), and restrictive (C) lung disease. (From Rakel RE, Rakel DP. *Textbook of Family Medicine*. 9th ed. Philadelphia: Elsevier; 2016.)

The forces that oppose lung expansion determine the compliance of the lung. In states of high compliance, minimal force is needed for expansion, and conversely, when compliance is low, higher force (pressure) is needed for lung expansion. Compliance is shown by a pressure-volume loop in Fig. 18.6. The more upright, solid loop shows increased compliance in that greater volumes are achieved at lower pressures, as compared to the dotted loop showing decreased compliance, so that more pressure is needed to deliver the same tidal volume. Decreases in compliance will also be apparent on a flow-volume loop as an increase in flow during exhalation and will have a higher peak and steep slope.²¹ Decreases in compliance can occur as a result of pulmonary embolism, bronchoconstriction, pneumothorax, insufflation of the abdomen for laparoscopic surgery, or even inadequate muscle relaxation, to name a few causes. Compliance may be increased in emphysema, positive end-expiratory pressure (PEEP), or simply by resolving those factors that decrease compliance.²⁹

Changes in resistance can also be detected by loop spirometry. An increase in resistance may occur when an ETT is kinked or blocked, when there is an airway obstruction, and when bronchoconstriction is seen. Mild bronchospasm may cause slight changes in the flow-volume loop, but, as the spasm progresses, a decreased flow throughout exhalation can be seen. In a pressure-volume loop, increased resistance manifests as an increased

pressure needed to deliver the same volume as that prior to the added resistance.²⁹

Respiratory Monitoring: Oxygenation

It is obvious that ensuring adequate oxygen delivery to the tissues is of paramount importance in the safe delivery of anesthesia. Monitoring of oxygenation follows the course of oxygen delivery from the source to the patient until distribution within the body. The anesthetist must evaluate the adequacy of the gas machine's delivery of O₂ and the efficiency of its delivery to the alveoli during ventilation. Oxygenation monitoring by itself only constitutes a part of the whole picture when considering the respiratory process. Hypoventilation, hypercapnia, and impending respiratory arrest can occur despite adequate oxygenation, particularly during the administration of supplemental O₂.³⁰

Like ventilation monitoring, the means to ensure oxygenation uses multiple senses and technologies. Monitoring oxygenation starts with O₂ delivery analysis and is covered in depth elsewhere in the text. It is crucial to note that ensuring delivery of O₂ from the source does not ensure adequate uptake and distribution of O₂ on the part of the patient.

To assess the major aspects of acid-base balance and respiratory function, including oxygenation, ABG analysis is most helpful. Although the need for frequent sampling and analysis of ABG is dictated by the patient's physiologic status or surgical procedure, noninvasive, continuous monitoring of oxygenation through clinical observation and pulse oximetry is the standard of care¹ (see [Table 18.1](#)). Clinical observation parameters also include an assessment of skin color and temperature, nail-bed perfusion signs, assessment of depth and rate of respirations, auscultation of breath sounds, and assessment of upper airway patency.

Pulse Oximetry

The use of pulse oximetry is commonplace in many health care settings, and has proven valuable in detecting hypoxemia. Pulse oximetry measures heart rate and percent of oxygen saturation

(SaO₂) of hemoglobin (Hgb) continuously and noninvasively. The technology involved in providing the transcutaneous measurement uses a spectrophotometer to determine SaO₂. Oxygenated Hgb absorbs light at a different wavelength than unoxygenated Hgb. At a red wavelength between 650 nm and 750 nm, reduced oxygen hemoglobin absorbs more light than oxyhemoglobin does. In the infrared wavelengths of 900 nm to 1000 nm, the opposite occurs.³¹ A light signal is emitted from one diode and transmitted through tissue, most commonly a finger, to an oppositely placed photosensitive diode that measures the amount of unabsorbed red light. This method is sometimes referred to as transmittance technology. Pulse oximeters can distinguish arterial from venous blood by measuring the change in transmitted light during pulsatile flow. The pulse oximeter converts the detected light to a plethysmographic signal that measures the drop in light intensity with each beat.³²

Oxygen Saturation Physiology.

To understand the measurement and significance of monitoring oxygen saturation via pulse oximetry, it is important to understand the physiology of oxygen transport and the factors that influence the binding to, and release from, Hgb. This is expressed in the following equation:

The reversibility of the reaction allows for the release of O₂ to the tissues. Oxygen is transported throughout the body and is either physically dissolved in the blood or chemically combined with Hgb. The vast majority is carried bound to Hgb. As a result, the oxygen-carrying capacity is mainly dependent on the amount of Hgb. If varying concentrations of O₂ are added to a volume of blood, after allowing the mixture to equilibrate, the oxygen tension (PO₂) of the gas can be measured. Because it is known that 0.003 mL of O₂ will dissolve in 100 mL of blood (at a PO₂ of 100 mm Hg), the remaining O₂ bound to Hgb can be determined. In short, the PO₂ of

the plasma determines the amount of O₂ that binds to Hgb. Like oxygen-carrying capacity, this is expressed in milliliters (mL) per 100 mL of blood.^{33,34}

The proportion of Hgb bound to O₂ is expressed as percent saturation and excludes that amount dissolved in the blood. The relationship between oxygen tension and percent of oxygen saturation is illustrated in the oxyhemoglobin dissociation curve (Fig. 18.8). It shows how the availability of O₂ (PO₂ in plasma) can affect the reversible reaction between O₂ and Hgb. The curve demonstrates that the amount of O₂ carried by Hgb (percent saturated) increases rapidly to a PO₂ of approximately 50 and slows thereafter, as displayed by a flattening of the curve. As blood travels to the systemic capillaries, the oxygenated Hgb releases O₂ to tissue with lower oxygen tension. In the 10 to 40 mm Hg range, the curve is very steep. This demonstrates that small decreases in PO₂ can result in significant dissociation of O₂ for use by the tissue. For example, at a PO₂ of 40 mm Hg, Hgb is approximately 75% saturated with O₂, whereas at 20 mm Hg, only 32% is saturated. This relationship can be altered by a variety of physiologic changes. The result is a shift in the curve either to the right, indicating a more ready release of O₂ from Hgb at the tissue level, or to the left, indicating a greater attachment of O₂ to Hgb, thereby decreasing release to tissues (Table 18.3).^{33,34}

FIGURE 18.8 Oxyhemoglobin dissociation curve. (From Roberts JR, et al. *Clinical Procedures in Emergency Medicine*. 6th ed. Philadelphia: Elsevier; 2014.)

TABLE 18.3

Factors Influencing the Oxyhemoglobin Dissociation Curve

Curve Shift to the Right	Curve Shift to the Left
Elevated CO ₂	Decreased CO ₂
Elevated temperature	Decreased temperature
Elevated levels of 2, 3-DPG	Decreased levels of 2, 3-DPG
Decreased pH, acidosis (elevated H ⁺ ions)	Elevated pH, alkalosis (decreased H ⁺ ions)

2,3-DPG, 2,3-Diphosphoglycerate; H⁺, hydrogen.

Clinical Use of Pulse Oximetry.

Although many studies regarding the use of pulse oximetry show conflicting impact on outcome, it should be intuitive that early detection and warning of hypoxemia, followed by appropriate interventions, will improve care. Pederson et al.^{35,36} reviewed more than 21,000 perioperative patients and reported that the incidence of hypoxemia ranged from 1.5 to 3 times less in patients monitored with pulse oximetry. Perhaps one of the greatest benefits of pulse oximetry is in its simplicity. The pulse oximeter is calibrated by the manufacturer and needs little or no further maintenance. It is basic to apply, and ongoing product development has made the device quite portable and durable. Its efficiency in measuring O₂ saturation has been shown to be accurate within 2% when oxygen saturation is between 80% to 100% and approximately 5% when saturation falls below 80%.³⁷

Despite the qualities of pulse oximetry, it is essential to understand the optimal use and limitations. Pulse oximeters can use a variety of sensor types applied to the body. The finger probe is the most commonly used and is available as a reusable clip-on device or disposable stick-on probe. The finger probe is often used successfully on the toe as well, particularly in the pediatric population. Although monitors continually improve, motion

artifact can still be problematic. Using alternative sites can be helpful. Forehead, ear, or nose probes can be used with comparable accuracy and reliability.³¹ The site of application of the pulse oximeter probe should be assessed at reasonable intervals during particularly long periods of use and changed as needed to avoid skin irritation or ischemia because prolonged application of a clip-on probe could potentially compromise perfusion. Another common problem associated with inaccurate measurement or sensor difficulties with pulse oximeter monitoring is the vasoconstriction state that results from cold temperatures or inadequate circulation. During such circumstances, measurement may be improved by using oximeter sites closer to the central circulation and away from the periphery, such as the forehead, nose, or ear.^{38,39}

Pulse oximeters utilizing reflectance technology has shown promise in reducing inaccuracies in pulse oximetry related to vasoconstriction or other limiting factors associated with transmittance technology. In reflectance pulse oximetry the light emitter is adjacent to the detector, rather than across from it and thus measures the backscatter of light. The sensor is typically placed on a forehead but could be placed elsewhere. These oximeters have been shown to provide accurate and in some cases more reliable measurement of perfusion than typical sensors and have even been employed to monitor tissue perfusion of surgical flaps.⁴⁰⁻⁴²

Whereas discussion surrounding the impact of the presence of nail polish on pulse oximeter measurement may arise, studies suggest that improved monitor sensitivity has virtually eliminated any effect nail polish might once have had on pulse oximetry readings.⁴³ A less commonly occurring but still problematic issue is the presence of abnormal hemoglobin. For example, methemoglobin absorbs light equally to oxyhemoglobin. As a result, pulse oximeter measurements are falsely underestimated when oxygen saturation is above 85% and overestimated when oxygen saturation is below 85%. Likewise, abnormally high levels of carboxyhemoglobin can cause the oximeter to overestimate oxygen saturation. Sickle cell anemia and other rarer forms of anemia may also impact the accuracy of pulse oximeter

measurements. Injectable dyes for diagnostic use, such as methylene blue or indigo carmine, will result in a significant, but transient, decrease in the measured oxygen saturation by pulse oximetry. This is because the presence of the dye alters the absorption of infrared light. Technology available on some pulse oximeters enables the monitor to distinguish between normal Hgb and carboxyhemoglobin or methemoglobin and quantitatively measure amounts of these variant forms of hemoglobin.^{44,45}

Cerebral Oximetry.

Monitoring for adequacy of oxygenation specific to the brain has been demonstrated through the use of near infrared spectroscopy (NIRS) in monitoring, which is referred to as cerebral oximetry. Cerebral oximeters utilize emitter/sensor pads similar to reflectance pads applied to the forehead which measure light attenuation from the emitting light source. As opposed to pulse oximetry, which utilizes plethysmography to differentiate pulsatile flow, cerebral oximeters provide measurements of oxygen supply versus demand within a region. Nonquantitative cerebral oximeters use wavelengths of 730 and 810 nm and measure the ratio of oxygenated Hgb to total Hgb within a region. The ratio is expressed as a percentage value and may be abbreviated as rSO₂. Quantitative cerebral oximeters utilize wavelengths of 775, 825, 850 and 904 nm. They also measure tissue oxygen index as a ratio of oxygenated Hgb to total Hgb.⁴⁶

This technology has been employed during cardiac bypass surgery but is also being implemented for other procedures and situations when cerebral perfusion may be compromised, as well as in research to determine best practices to maintain cerebral perfusion.^{47,48}

Temperature Monitoring

The standards of care from both the AANA and the ASA support the notion that the ability to monitor the patients' body temperature is essential.^{1,2} Temperature monitoring alerts the anesthetist to hyperthermia, and, as is more commonly the case, hypothermia. The American Society of Perianesthesia Nurses (ASPN) defines

hypothermia as a core temperature of less than 36°C (96.8°F). It has been reported that approximately 70% of postoperative patients experience some degree of hypothermia, whereas other estimates indicate as much as 90% of surgical patients experience some adverse effect of hypothermia.^{49,50} Risks of hypothermia include wound infection and delayed healing, increased O₂ consumption through shivering, increased risk of cardiovascular incidents and myocardial infarction, and increased rate of sickling in sickle cell patients.^{50,51} Hypothermia has also been shown to result in a prolonged stay in PACU, thus increasing the cost of care during the perioperative period.⁴⁹

Appropriate and aggressive means of maintaining normothermia intraoperatively should be instituted, and key to this is temperature monitoring. National quality improvement initiatives supported by the Centers for Medicare and Medicaid Services (CMS) have partnered with health care organizations and accrediting bodies to promote best practices aimed at improving surgical care. These initiatives have identified essential factors in preventing postoperative complications. Not the least of these identified areas of care is centered on maintenance of normothermia.⁵² An understanding of the potential causes of variations in core body temperature is valuable in appreciating the importance of temperature monitoring.

Thermoregulation

Body temperature is tightly regulated through a process termed *thermoregulation*. Thermoregulation occurs through a three-phase process: afferent thermal sensing, central regulation or control, and efferent responses. Peripheral sensors send thermal information via tracts in the anterior spinal cord, such as the spinothalamic tract, to various regions of the brain, including the hypothalamus.

Behavioral responses to changes in temperature (i.e., layering clothing, seeking warmth) are the most important aspect of thermoregulation in persons who are awake; however, anesthesia prevents patients from responding accordingly. As a result, they must rely on autonomic efferent responses such as shivering, vasoconstriction, and sweating. General anesthetics do not have

significant effects on sweating but do reduce shivering and vasoconstriction thresholds. Neuraxial anesthesia also affects thermoregulatory control, resulting in hypothermia.⁵³

Normothermia can be defined as a body temperature of 37°C. It is important to note that there is typically a variance between core and peripheral temperatures. This is key to appreciating the value of core versus peripheral temperature measurement.⁴⁹

Hyperthermia, or core temperatures exceeding 38°C, can be seen intraoperatively. The genetic predisposition to drug-induced malignant hyperthermia is one well known, if not common cause and the possibility alone warrants the use of intraoperative temperature monitoring during general anesthesia.⁵⁴ Other causes of fever may include infection or hypermetabolic states. Certain recreational drugs such as amphetamines, ecstasy, or cocaine can raise the body temperature through an increased rate of metabolism.⁵⁵ Drugs such as atropine can inhibit the sweating response, resulting in impaired regulatory response and a rise in the core temperature. In the anesthesia setting, these effects are typically overshadowed by the multiple factors in place that serve to lower core temperature.

Hypothermia, or core temperature below 36°C, occurs for multiple reasons. The ambient room temperature is one obvious cause of hypothermia. Reports suggest that the greatest amount of heat loss occurs during the first hour in the perioperative setting and that patients in rooms at a temperature of 21°C will all develop hypothermia. Radiant heat loss, or that transfer of body heat into a cooler environment, accounts for the majority of heat loss in the patient undergoing surgery. This is followed by evaporative loss from liquids on the skin, such as from cleansing or perspiration or through the expiration of warm, moist air. In addition, convective heat loss (through moving cool air) and conductive heat loss (through contact with a cooler object such as an operating room table) contribute. Redistribution of lower-temperature blood from the vasodilated, anesthetized periphery to the central compartment also accounts for significant heat loss.^{49,56} General and regional anesthesia inhibit thermoregulation and cause significant vasodilation such that temperature monitoring is warranted. During local anesthesia or sedation, temperature monitoring should

be considered under circumstances in which the patient is at risk of hypothermia and should always be immediately available. It is important to note that normal core body temperature can vary between individuals, as well as within individuals at different points within their circadian rhythms. As a result, monitoring the patients' temperature is most beneficial when done continuously rather than intermittently and is most valuable when evaluated for trends.⁵⁵

Temperature Monitoring Modalities.

Temperature is an important parameter in the complete monitoring of homeostasis in the perioperative period. The AANA and ASA practice standards allow for some discretion on the part of the anesthesia provider in deciding under what circumstances temperature monitoring should occur. The ASA states that body temperature monitoring should occur whenever significant changes in temperature are “intended, anticipated, or suspected.” The AANA states that temperature should be monitored “on all pediatric patients receiving general anesthesia and when indicated, on all other patients.”^{1,2}

To ensure monitoring is done and active warming strategies employed, it is essential that the anesthetist be well aware of the factors that place patients at risk for perioperative hypothermia. Some of these risk factors include high ASA status, lengthy or involved surgical procedures, combined epidural and general anesthesia, surgery of long duration, elderly patients, and those with lean body mass. Interestingly, another identified risk factor for hypothermia is failure to monitor temperature. Protective factors of increased body weight, higher preoperative temperature, and warmer rooms were noted to help maintain normothermia.^{53,57,58}

Technology used for temperature monitoring varies often by site measured. Thermistor, thermocouple, and platinum wire devices are frequently used with electronic monitors and have been shown to be accurate and reliable. Liquid crystal temperature monitors have been employed for skin temperature monitoring; however, although these are noninvasive and convenient, they lack specific accuracy both in measurement and in interpretation between readings by separate observers.²¹

There has been some debate as far as how best to measure temperature, and indeed, each site has certain advantages and disadvantages (Table 18.4). Skin temperature measurement is convenient and noninvasive; however, its accuracy as a reflection of core body temperature is unreliable. Temporal artery temperature measurements use infrared technology to measure blood temperature close to the surface with a device swiped across the forehead and down along the temporal artery. Some studies suggest this approximates oral and axillary temperatures to a reasonably close degree; however, others question their accuracy.^{53,59}

TABLE 18.4
Comparisons of Body Temperature Monitoring Sites

Monitoring Site	Advantages	Disadvantages
Bladder	Reflects core temperature Correlates accurately with other core sites	Invasive—requires urinary catheter placement Risk of UTI
Pulmonary artery	Reflects core temperature Correlates accurately with other core sites	Invasive—requires PA catheter Not reliable during open chest procedures
Esophageal	Considered by most authors to reflect core temperature Ease of insertion	Slight potential for oral or esophageal trauma, bleeding Not useful in awake patients Inaccurate if placed too close to the stomach
Nasopharynx	Considered by most authors to reflect core temperature Ease of insertion	Potential for nasopharyngeal trauma, bleeding Less useful in awake patients Inaccurate if breathing through nares
Tympanic	Considered by most authors to reflect core temperature Accurate if contact probe is used Ease of insertion Possible for awake patients	Slight potential for tympanic membrane trauma Possible to push ear wax from canal to membrane Infrared device less accurate
Axillary	Safe, noninvasive, ease of placement Reasonable correlation with core in adducted arm when placed close to axillary artery	Not a direct measurement of core temperature Influenced by IV fluids Easily dislodged

PA, Pulmonary artery; UTI, urinary tract infection.

Noninvasive temperature monitoring in postanesthesia care units. *Anesthesiology*. 2009;111(1):90–96; Sessler DI. Temperature monitoring and perioperative thermoregulation. *Anesthesiology*. 2008;109(2):318–338;

Lenhardt R. Monitoring and thermal management. *Best Pract Res Clin Anaesthesiol.* 2003;17(4):569–581.

Core temperature monitoring is believed to be the most reflective of thermal status in humans. This includes temperature monitoring at the tympanic membrane, distal esophagus, nasopharynx, or pulmonary artery.⁵³ The type of surgery may play an important role in determining the optimal location for temperature monitoring. For example, in liver transplantation, bladder temperature has been shown to closely approximate pulmonary artery temperature measurements. Esophageal monitoring may be less reflective of core temperature during open heart surgery because of the exposed thoracic cavity. For many surgeries, the tympanic membrane may be considered an ideal site, particularly because of its close proximity to the brain, therefore providing an accurate reflection of brain temperature. It should be noted, however, that tympanic membrane temperature measurement using aural probes with thermocouples provides this reliable assessment as opposed to the popular but less accurate use of infrared technology.⁶⁰

Additional Monitoring Issues

Monitoring for Procedures Outside of the Operating Room

It has become common to administer all forms of anesthesia in areas outside of the traditional operating room setting. Multiple factors could be anticipated to increase anesthesia risk outside of an operating room. These include decreased availability of anesthesia personnel, less adjunct equipment, and unfamiliarity with supportive staff and settings. Procedures and settings often involve risk of allergic reactions to radiologic dyes, sharing of access to airway, and (in general) support staff with less experience with the anesthetized patient.

There is a growing need for studies of anesthesia morbidity and mortality as they relate to setting. A review of the ASA closed-claims database was done by Robbertze et al.¹³ to assess for trends and look for insight into how to best provide anesthesia in these remote settings. Reviewers noted that anesthesia claims in these settings had a higher severity of injury and more often demonstrated that anesthesia was administered below the accepted standard level of care. The most common mechanism of injury was inadequate oxygenation or ventilation. Close review of these cases emphasizes that monitoring standards during anesthesia administered outside of the operating room must never be lower than what one would otherwise use and in fact, the circumstances may necessitate even closer vigilance. Focused attention and pressure is being applied in many areas to recognize and prevent the dangerous effects of potent opioids and other sedative drugs given for pain and procedural sedation. Emphasis should be placed on ensuring adequate ventilation and oxygenation through close visualization, monitoring of ETCO_2 , and pulse oximetry.³⁰

Education, training, and certification are crucial for nonanesthesia nurses, physicians, or other providers involved in the administration of sedation in the absence of a nurse anesthetist or anesthesiologist. Strict policies should be in place to guide monitoring and sedation practices and such policies should be

reviewed by anesthesia providers.

Anesthesia Education and Patient Monitoring

Teaching clinical monitoring begins in the classroom and is reinforced and emphasized in the clinical learning environment. As with all aspects of anesthesia education, teaching the art and science of clinical monitoring of the patient must be well thought out. Many educational programs and anesthesia departments use some form of simulation-based education as a supplement to clinical experience. Simulation learning is designed to give additional interactive practice and can also serve to review critical incidents and adverse events.⁶¹ The use of simulated clinical experience can assist in developing critical decision-making skills through repetition.

A part of vigilance in monitoring lies in developing habits that promote frequent, almost ritualistic, patterns of assessment and visualization. Many students have a tendency to first focus on the electronic devices while forgetting the ongoing physical assessment of the patient. It is the role of the instructor to promote affective routines by explaining the underlying rationale, as well as by example. Another important part of learning to closely monitor the patient is training the senses to notice changes in the clinical picture. Every anesthetist should be able to discern when the changing audible tones of the pulsatile measurement of the pulse oximeter monitor indicate decreasing oxygen saturation. One should rapidly recognize the subtle development of abnormal airway sounds heard through a precordial stethoscope. These are only several of the basic clinical skills essential to anesthesia practice, and the anesthesia student requires time, experience, and appropriate habits to hone them.

Beyond learning the use and interpretation of monitoring methods, the student must also learn to appreciate the potential artifacts that can occur during electronic measurement. Because artifacts can result in false alarms, there exists the potential to ignore important alarms if their validity is uncertain. The student and experienced provider must learn to assimilate all data to make

the right interpretation.⁶²

Summary

Whereas technology advances the anesthetists ability to monitor important physiologic functions in ways previously unheard of, the importance of the human factor in anesthesia delivery and monitoring does not appear to be replaceable any time soon. Clinical monitoring is a human skill that uses all of the senses. The importance of maintaining adequate ventilation and oxygenation has been underscored in reviews of closed-claim studies, thereby emphasizing the need for vigilant, continuous monitoring of these parameters in the patient receiving anesthesia. A systematic approach to monitoring can be useful in keeping the anesthetist vigilant. Of all monitoring modalities, ETCO₂ and pulse oximetry have been shown to be of particular value and improvements in technology have brought more accurate and dependable means of evaluation. Hypothermia is an all too common occurrence under anesthesia, and management must center on prudent temperature monitoring. Clinical standards of care, as developed by the recognized professional anesthesia organization, must be adhered to continuously and reevaluated frequently. Outcome studies are warranted to justify the use of monitoring modalities, and the potential benefits must outweigh the potential risks.

Clinical Monitoring III

Neurologic System

Michelle Matthews

The practice of anesthesia requires constant vigilance and evaluation of the patient. Historically, early anesthetists such as John Snow and Arthur Guedel proposed the use of clinical and neurologic signs to evaluate and determine the depth of anesthesia. Snow described the “five stages of narcotism” in response to anesthesia using chloroform.¹ Guedel further refined these signs by developing a set of physical criteria for the “clinical signs and stages of anesthesia” that are based on the autonomic nervous system responses to anesthesia.² He used neurologic signs, such as respiratory rate and rhythm, ocular movement, pupillary size, and reflexes to evaluate the depth of ether anesthesia.^{1,2}

Today, the practice of anesthesia incorporates sophisticated technology for neurologic monitoring in addition to the classic neurologic signs as determined by Guedel and Snow. Due to the significant pharmacodynamic effects of anesthetic medications on the cardiovascular system, it is impractical to depend solely on clinical signs for assessing anesthetic levels or neurologic functioning. Furthermore, the adult brain comprises approximately 2% to 3% of body weight but requires 15% to 20% of cardiac output. This fact substantiates the enormous metabolic activity of neurologic tissue. Monitoring the neurologic status of a patient demands a thorough knowledge of the modern devices used and the skills needed to navigate a rapidly changing clinical environment. The most important goal of clinical monitoring of the central nervous system (CNS) is to identify and rapidly treat possible CNS ischemia. Specific tenets of neurologic monitoring during anesthesia include:

1. Possessing a thorough knowledge of the monitors and modalities available for neurologic monitoring.
2. Selecting appropriate neurologic monitor(s) for data acquisition and patient management.
3. Understanding the various pathologic disease states that increase the potential for cerebral ischemia during a period of increased or decreased blood flow.
4. Choosing anesthetic medications and doses that best preserve cerebral blood flow (CBF).
5. Identifying and intervening if deleterious neurologic changes occur during the perioperative period.

The neurophysiological parameters that can be monitored during anesthesia and surgery include cerebral electrical activity, CBF, cerebral oxygen content, intracranial pressure (ICP), and cerebral metabolic rate of oxygen consumption (CMRO₂). Monitoring of the CNS electrical activity is performed by means of electroencephalography (EEG) and brainstem auditory-, sensory-, and motor-evoked potentials (EPs). Monitoring CBF velocity is achieved by transcranial Doppler (TCD) ultrasonography. ICP can be determined by the use of intraventricular catheters and fiberoptic intraparenchymal microtransducers. Near infrared spectrometry (NIRS) is a measure of cerebral oxygen content. Lastly, CMRO₂ can be measured through invasive techniques such as placement of intracerebral partial pressure of oxygen (PO₂) electrodes and jugular venous oximetry.³ Select methods for monitoring neurologic functions are presented in [Box 19.1](#).

Specialized Methods of Neurologic Monitoring

- EEG—electroencephalogram
- SSEP—somatosensory-evoked potential

- MEP—motor-evoked potential
- VEP—visual-evoked potential
- BAEP—brainstem auditory–evoked potential
- BIS—bispectral index
- NIRS—near-infrared spectroscopy
- TCD—transcranial Doppler ultrasonography
- ICP—intracranial pressure

This chapter examines the monitors currently used in clinical practice, the effects that anesthetic medications exert on CNS monitoring modalities, and preservation of neurologic function during the perianesthetic period. A thorough discussion of neurophysiology and the principles that regulate cerebral vascular autoregulation, CBF, and cerebral perfusion pressure is presented in [Chapter 31](#). Methods that can be used to assess CNS integrity and their indications, advantages, and disadvantages are noted in [Table 19.1](#).

TABLE 19.1
Brain Monitoring Methods

Method	Spatial Resolution	Temporal Resolution	Purpose	Advantages	Disadvantages
ICP	Global	Continuous	Measure intracranial pressure	Reliable Quantitative Allows monitoring of CPP and calculation of secondary indices	Invasive Risk of infection Risk of hemorrhage
Jugular oximetry (SjvO ₂)	Global	Continuous	Measure adequacy of hemispheric oxygenation	Quantitative Allows monitoring of AVDO ₂ and O ₂ ER	Susceptible to artifacts Local complications (e.g., infection, thrombosis)
EEG	Global	Continuous	Monitoring electrical brain activity Detection of seizures	Technique well standardized Only method to diagnose nonconvulsive	Qualitative Relatively insensitive to secondary insults

				seizures	
SSEP	Global	Continuous	Monitoring integrity of sensory pathways	Technique well standardized Simple	Qualitative Fairly insensitive to secondary insults
Bedside Xe-133 CBF	Regional	Discontinuous	Measure hemispheric CBF	Quantitative	Only accurate if radiotracer injected into carotid artery Radioactivity
Laser Doppler flowmetry	Local	Continuous	Measure cortical CBF	Accurate Dynamic information	Qualitative Invasive Susceptible to artifacts Only monitors 1–2 mm ³ of tissue
Thermal diffusion flowmetry	Local	Continuous	Measure cortical CBF	Simple Dynamic information	Qualitative Invasive Monitors small volume of tissue
TCD	Regional	Continuous	Measure CBF velocities	Simple Noninvasive Allows measuring PI, VMR	Qualitative and indirect assessment of CBF Difficult to keep probes in place
Brain tissue PO ₂	Local	Continuous	Measure cerebral oxygenation	Quantitative Sensitive Probes also measure brain temperature	Invasive Susceptible to artifacts Monitors small volume of tissue
NIRS	Local	Continuous	Measure cerebral oxygenation	Noninvasive	Measures only relative changes Susceptible to artifacts
Microdialysis	Local	Discontinuous	Measure cerebral metabolism	Sensitive Quantitative	Invasive Complicated technique Labor intensive Unclear which is the best parameter to monitor

AVDO₂, Arteriovenous oxygen difference; *CBF*, cerebral blood flow; *CPP*, cerebral perfusion pressure; *EEG*, electroencephalogram; *ICP*, intracranial pressure; *NIRS*, near-infrared spectroscopy; *O₂ER*, oxygen extraction rate; *PI*, pulsatility index; *PO₂*, partial pressure of oxygen; *TCD*, transcranial Doppler; *SSEP*, somatosensory evoked potentials; *VMR*, vasomotor reactivity.

Electroencephalogram

EEG Fundamentals

The brain is an electrochemical organ that generates electrical impulses in specific patterns. The voltage from the ionic current generated between neurons in the brain can be recorded. The electrical activity from the surface of the brain that can be observed through an EEG is called *electrical brainwaves*. The brain does not emit electrical waves; rather, the EEG is a sensitive monitor that measures the differences in electrical potentials in groups of neurons between brain regions.⁴ Electrodes used to produce the EEG are placed on the patient in a standardized sequential configuration that examines known electrical potentials, or EPs. Auditory, visual, and tactile stimuli cause the neurologic EP response to occur. Sensory-evoked responses are elicited by somatosensory-evoked potentials (SSEPs), visual-evoked potentials (VEPs), and brainstem auditory–evoked potentials (BAEPs). Specific alterations in the EP signal can help diagnose a host of conditions, including systemic hypoxia, brain trauma, and ischemic and hemorrhagic stroke. The information gained from EEG can also be used to assess and guide the depth of anesthesia during neurosurgical procedures.

The basic components of the EEG waveform include frequency, amplitude, and the overall morphology (shape). *Frequency* refers to the rate of or duration between impulses. *Amplitude* is defined as the peak to peak measurements in a vertical plane and is measured in microvolts. Lastly, the *morphology* or shape is comprised of the wave amplitude and the frequency at which the waves occur. The ability to detect significant changes in EEG waveforms is a complex process that requires specialized training. There are four common types of brainwaves that comprise the EEG; alpha, beta, delta, and theta waves (Table 19.2). There are also several variants or subgroups of waves noted during specific activities. Some of these waveform variants are gamma and mu waves. Gamma waves are typically seen with high-order activity such as problem solving and analytic thinking, and represent the activity of groups of neurons.

Mu waves represent synchronous firing of neurons during rest.^{5,6} Depending on the situation, it can be difficult to distinguish artifact from normal variations of EEG patterns, especially as the majority of anesthetic agents inhibit neuronal activity.⁷⁻⁹ An example of an EEG recording is presented in Fig. 19.1.

TABLE 19.2
Comparison of EEG Waveform Types

Waveform and Frequency (Hz)	Characteristics
Alpha (7.5–14)	Occurs with eyes closed during deep relaxation
Beta (14–40)	Normal awake consciousness, alertness, logic, and critical thinking
Theta (4–7.5)	Light sleep
Gamma (> 40)	High-level information processing
Delta (0.5–4)	High amplitude, associated with deep sleep

FIGURE 19.1 Samples of normal electrographic recordings from two patients. (From Daroff RB, et al. *Bradley's neurology in clinical practice*. 7th ed. St. Louis: Elsevier; 2016.)

The head and much of the scalp may be inaccessible during intracranial surgical procedures, so the standard 21-channel EEG used to detect generalized neuronal activity is rarely used. Intraoperative monitoring during craniotomy is usually accomplished with a 2- to 4-channel recording with computer processing to simplify the interpretation. Depression of and characteristic changes in EEG activity can be seen with reductions in CBF, oxygen, or glucose delivery. During an awake state, the high-frequency and low-amplitude beta waves are most prominent. There is a transient increase in the beta waves with the onset of ischemia or hypoxia, with eventual development of increased-amplitude theta and delta waves. With the increase in ischemia or hypoxia, beta waves begin to disappear, and there is an appearance of low-amplitude delta waves. This progresses to electrical activity suppression with occasional bursts of activity. The onset of irreversible damage can be determined when there is complete electrical silence, as seen with an isoelectric or flat EEG pattern.

Monitoring the EEG intraoperatively for the development of delta waves allows for the recognition of an increased risk of ischemic damage to the brain. After the induction of anesthesia and prior to the start of surgery, an EEG tracing will be established to determine a baseline pattern. To allow for reliable EEG interpretation during the administration of anesthesia, the type and amount of medication given should be titrated to inhibit the sympathetic nervous system without obliterating the EEG waveform. Changes in the depth of anesthesia should be immediately communicated to the EEG technician so that false-positive ECG patterns suggestive of ischemia can be disregarded. The EEG can only provide information about the integrity of the brain's cerebral cortical structures. Therefore, neuronal ischemia and infarction are possible in the subcortical regions, spinal cord, or cranial and peripheral nerves.^{3,10,11}

Anesthetic Effects on EEG

Considerations for Inhalation Anesthetics and EEG Interpretation

Interpreting the EEG in the presence of anesthetic medication administration can be confounding because the majority of anesthetic agents inhibit neuronal activity and depress EEG waveforms. Instead, generalized assumptions are made that brain function is adequate or inadequate during anesthetic management based on trends. There are two major reasons why the EEG tracing is difficult to correlate with patient outcomes. First, dose-related cerebral inhibition occurs with inhalation and intravenous agents, as they increase frequency and decrease amplitude of the EEG waveforms (Table 19.3 and Table 19.4).¹²⁻¹⁷ The second variable involves environmental factors (e.g., artifact) and manipulation of the brain, which adds to the complexity of interpretation.

TABLE 19.3

Effects of Inhalation Anesthetics on EEG

Inhalation	Low-Dose Inhalation	Moderate-Dose Inhalation	High-Dose Inhalation	EEG	Dose for Burst Suppression
------------	---------------------	--------------------------	----------------------	-----	----------------------------

	Anesthesia	Anesthesia	Anesthesia		Suppression
Desflurane	< Alpha waves > Beta waves	> Beta waves	Diffuse delta and theta	↑ Low dose ↑ Anesthetic dose ↑ or 0 High dose	> 1.2 MAC
Isoflurane	< Alpha waves > Beta waves	> Beta waves	Diffuse delta and theta	↑ Low dose ↑ Anesthetic dose ↑ or 0 High dose	> 1.5 MAC
Sevoflurane	< Alpha waves > Beta waves	> Beta waves	Diffuse delta and theta	↑ Low dose ↑ Anesthetic dose ↑ or 0 High dose	> 1.2 MAC
Nitrous oxide (alone)	> Beta waves	> Beta waves	> Beta waves	↑ Low dose ↑ Anesthetic dose ↑ High dose	Not seen in clinical concentrations

↑, Increase; 0, no effect; EEG, electroencephalogram; MAC, minimum alveolar concentration.

TABLE 19.4

Intravenous Anesthetic Medications and Their Effect on the EEG

Medication	Effect: EEG Frequency	Effect: EEG Amplitude	Burst Suppression
<i>Etomidate</i>			
<i>Low Dose</i>	Fast frontal beta activity		Yes with high doses
<i>Moderate dose</i>	Fast frontal frequency spindles		
<i>High dose</i>	Diffuse delta→burst suppression→silence	↓, 0	
Propofol			
<i>Low Dose</i>	Loss of alpha; frontal beta		Yes with high doses
<i>Moderate dose</i>	Frontal delta; waxing/waning alpha		
<i>High dose</i>	Diffuse delta→burst suppression→silence	↓, 0	
Ketamine			

<i>Low Dose</i>	Loss of alpha, variability	↓	No
<i>Moderate dose</i>	Frontal rhythmic delta		
<i>High dose</i>	Polymorphic delta; some beta	Low amplitude beta	
Benzodiazepines			
<i>Low Dose</i>	Loss of alpha; increased frontal beta activity	0	No
<i>High dose</i>	Frontally dominant delta and theta		
Opioids			
<i>Low Dose</i>	Loss of beta; alpha slowing		
<i>Moderate dose</i>	Diffuse theta; some delta		
<i>High dose</i>	Delta, often synchronized		
Dexmedetomidine	Moderate slowing, prominent spindles	↓, 0	No

Alpha = 8–13 Hz frequency; Beta \geq 13 Hz frequency; Delta \leq 4 Hz frequency; Theta = 4–7 Hz frequency.

↓, Decrease; 0, no effect; *EEG*, electroencephalogram.

Inhalation agents depress CMRO₂ in a dose-dependent manner, resulting in decreased regional tissue oxygen consumption and vascular constriction. As a result, these medications have a global effect of decreasing CBF. However, the net effect of a volatile agent's influence on CBF is dependent on the direct vasodilatory properties of the individual drug and the vasoconstricting effects associated with catecholamine release. Older adults and those patients with baseline slowing of the EEG are more sensitive to the effects associated with isoflurane and desflurane.¹⁸

When administered in “approximate” doses, inhalation agents induce a significantly greater depression of EEG activity as compared to intravenous anesthetic agents.¹⁹

Induction Agents

Induction doses of etomidate and propofol have similar effects on the EEG by increasing the frequency and decreasing the amplitude of beta waves. This beta-rhythm EEG activity correlates with the patient losing consciousness after drug administration; a time-/dose-related neuronal depression is seen with anesthetic drugs.^{20,21} One difference between these two drugs is that myoclonus, which can occur with the use of etomidate, is not reflected on EEG signals.²² Coincidentally, the EEG frequency decreases as the serum levels of etomidate rise, thereby leading to burst suppression. Burst suppression can be achieved with both of these induction agents in

higher dosage ranges. *Burst suppression* is a term used to describe an EEG pattern associated with alternating high-voltage, mixed frequency, slow wave activity, along with periods of electrical suppression that last several seconds (Fig. 19.2). This type of electrical activity is unpredictable, and the duration is variable. Burst suppression is also typically seen with a decrease in cerebral circulation and oxygenation, as well as with hypothermia, particularly during cardiopulmonary bypass surgery. Burst suppression may be desirable during manipulation of brain tissues as it decreases $CMRO_2$, which is neuroprotective.^{23–25} Burst suppression can be achieved during anesthesia using a variety of anesthetic agents. These agents include etomidate, propofol, dexmedetomidine, and inhalation agents, which all provide varying levels of suppression of electrical activity in a dose-dependent manner.^{20,22,26} Propofol enables a deeper state of unconsciousness as compared to dexmedetomidine by inducing large-amplitude slow oscillations that produce prolonged burst suppression states.²⁷ Unilateral burst suppression is indicative of ischemia or injury to the brain. Forethought should be given to the use of sevoflurane in patients with known epileptiform EEG activity; the activity may be accentuated by these inhalation agents in lower concentrations.^{21,28,29}

FIGURE 19.2 Burst suppression pattern on the electroencephalogram of a 53-year-old woman with anoxic encephalopathy following cardiorespiratory arrest. The patient died several days later. (From Daroff RB, et al. *Bradley's Neurology in Clinical Practice*. 7th ed. St. Louis: Elsevier; 2016.)

A summary of the effects of intravenous anesthetic medications on EEG recordings is shown in [Table 19.4](#). There is a synergistic depressant effect on EEG sensory-evoked responses when various intravenous agents are administered concomitantly.

Processed EEG Waveforms

The interpretation of a raw EEG is often difficult, and can depend on the waveform quality, lead placement, artifact or electrical interference, and the skill level of the clinicians in interpreting the waveforms. To further analyze the EEG, multiple methods are used, including compressed spectral array (CSA) and density spectral array (DSA). The CSA and DSA are obtained, calculated, and displayed by collecting, assessing, and providing a summary of each of the waves (alpha, beta, theta, delta) over a period of time. A mathematical description for the timeframe, using the amplitude and frequency of the waves, is accomplished by using a fast Fourier transform (FFT) algorithm. Applying an FFT algorithm is typically thought of as breaking down a signal into a variety of components and then reconstructing the useful information into an analysis of the complex signals. The Fourier analysis also results in a compressed view of EEG waveforms. The compressed data are presented in a two- or three-dimensional graph. Depending on the display used, these data appear as either a CSA or a dot matrix called a *DSA*.

The processed information collected and displayed for the CSA and DSA is analyzed for the waveform relationships using the amplitude and frequency and illustrated in two- or three-dimensional graphs. These relationships are expressed as the spectral edge frequency (SEF), median frequency, and relative delta power. Most commonly, the SEF is used and represented by the EEG frequency and power activity, which falls below 90% (SEF90).^{30,31} As frequency declines below a predetermined power, the spectral edge changes. In the presence of general anesthesia or cerebral injury, frequency and power decline, thereby causing a change in the spectral edge. The modern EEG calculates the computerized spectral array, which is then used during anesthesia to determine the depth of anesthesia or unilateral injury, based on the processed results. General anesthesia produces a reduction in high-frequency waves and an increase in low-frequency amplitudes.

Monitors for Assessing Central Nervous System Blood Flow and Oxygenation

Cerebral Oximetry via Near-Infrared Spectroscopy

Cerebral oximetry uses NIRS to assess cerebral oxygen saturation. This noninvasive monitor allows the practitioner to detect decreases in CBF in relation to $CMRO_2$. Regional oxygen saturation is determined by the difference in intensity between transmitted and received light delivered at specific wavelengths (as described by the Beer-Lambert law), as with pulse oximetry. The light source is applied to the patient's forehead and it is then transmitted through tissue and bone. NIRS can better penetrate deep into thick tissues, allowing physiologic interpretation of oxygenation by evaluating, in real time, the transmission and absorption of infrared light by hemoglobin in brain tissue. The near-infrared spectrum of electromagnetic waves range from approximately 600 to 2500 nm. The localized volume of cerebral blood (of which 70% is venous) is analyzed. The near-infrared wavelengths used in commercial devices are between 700 and 850 nm, where the absorption spectra of oxygenated and deoxygenated hemoglobin are maximally distinguishable.

As in any monitoring modality, there are conditions that can decrease the accuracy of the information obtained. Changes in blood pressure, partial pressure of carbon dioxide in arterial blood ($PaCO_2$), regional blood volume, hemoglobin concentration, and individual variability (e.g., differences in extracranial tissue) all effect NIRS readings. Contamination of the signal occurs with increased levels of hypoxia in the tissues on the scalp, leading to distorted signals and brain oxygenation readings. When using the NIRS monitor, the anesthetist must be careful to consider peripheral oxygenation of the scalp, as the NIRS value may not be fully reflective of cerebral oxygenation.^{32,33} For these reasons, definitive values that would be suggestive of cerebral ischemia do

not exist. However, measuring NIRS values prior to induction allows for its use as a trend monitor throughout the intraoperative course.

Currently, the most frequent uses of NIRS are in neonatology, during cardiac surgery, and during carotid endarterectomy. The goal of supportive intervention is to maintain the NIRS value at a minimum of 75% of the baseline reading. Avoiding cerebral desaturation during these procedures is believed to reduce complications relating to cerebral ischemia. A systematic review of patients undergoing shoulder arthroscopy in the beach chair position or internal carotid artery cross clamping during carotid endarterectomy showed that the majority of these patients experienced periods of significant cerebral desaturation. A greater than 20% reduction in cerebral oxygen saturation is correlated with regional and global ischemia during carotid endarterectomy. Following thoracic surgery, major orthopedic surgery, and abdominal surgery, the occurrence of postoperative cognitive dysfunction might be related to intraoperative cerebral desaturation.³⁴ Currently, there is a lack of evidence to define what specific cerebral oxygen saturation value, as assessed by NIRS, correlates with an “abnormal” level suggestive of cerebral ischemia. In addition, scientific data do not indicate that patients monitored via NIRS have a lower rate of mortality as compared to those who are not monitored.³⁵

Transcranial Doppler Ultrasonography

Transcranial Doppler ultrasonography is accomplished by the use of a probe positioned on the temporal bone that emits ultrasound waves. This noninvasive monitoring modality allows for the anesthetist to monitor blood flow velocity within the large arteries of the brain and detect instances of hyperperfusion and hypoperfusion. Most often, blood flow through the middle cerebral artery is measured. Continuous pulsed Doppler waves are transmitted and received to produce acoustic information. Specific parameters that can be ascertained by TCD monitoring include flow direction, peak systolic and end-diastolic flow velocity, flow acceleration time, and intensity of pulsatile flow. Microemboli can be detected by TCD, and monitoring of cerebral integrity during

specific surgical cases such as carotid endarterectomy may be beneficial.^{36,37} A specific limitation associated with TCD monitoring is that, in individuals with greater thickness of the temporal bone, the Doppler waves can be impeded, which hinders accurate analysis.

Jugular Bulb Oxygen Venous Saturation

Measurement of a mixed venous blood sample from the jugular bulb ($SjvO_2$) provides an estimation of the degree of global oxygen extraction by the brain. The internal jugular vein has a dilated region known as the *jugular bulb*. The jugular bulb is the portion of internal jugular vein that enters the jugular fossa. Located at the base of the skull, the jugular bulb receives blood drainage from both left and right cerebral hemispheres—approximately 70% from the ipsilateral hemisphere and 30% from the contralateral hemisphere. The jugular bulb can be accessed from 1 cm below and 1 cm anterior to the mastoid process. A fiberoptic catheter can be inserted through the internal jugular vein and into the jugular bulb under fluoroscopy. The $SjvO_2$ catheter has two optical fibers: the first emits light, and the second absorbs the light and transmits it to a photosensor. The absorption of the reflected light from oxygenated and deoxygenated hemoglobin is then expressed as a percentage.

$SjvO_2$ monitoring has been used in patients with increased ICP to evaluate cerebral ischemia. An $SjvO_2$ between 55% and 75% has been found to be a reasonable predictor of positive outcomes for traumatic brain injury if the ICP is also maintained within a normal range. Those patients with an $SjvO_2$ less than 55% or greater than 75% and an elevated ICP had poor outcomes.^{38,39}

Evoked Potentials

Evoked potentials are electrical potentials that are measured in response to a particular type of stimulus. As anesthetic medications have an inhibitory effect on cerebral activity, the ability to determine a neurologic response may be altered. Intraoperatively, EPs are used to guide the surgical strategy and to act as a warning of neurologic deficits to prevent irreversible damage. Auditory, visual, motor, and somatosensory stimuli are commonly used for clinical EP studies during surgical procedures. Injuries to neural structures can arise from heat (electrocautery), mechanical stress (retraction), ischemia (ligation, edema, and vessel damage), and loss of functional integrity (transection). Many nervous system structures encountered during surgical procedures lack perineurium, which protects against longitudinal retraction, and epineurium, which protects against retraction. The “elastic limit” of such nerves is approximately 20%, suggesting that stretching the nerve farther may produce irreversible damage.⁴⁰ EPs also can be affected by hypothermia, hypotension, positioning, and anemia. These systemic effects may develop slowly, and they are potentially reversible if prompt intervention occurs.

Early detection is the key to reducing serious complications. Early detection must then be paired with continuous communication between the anesthesia provider, surgeon, and neurophysiologist. There is variability in the amount of change in latency or amplitude that necessitates intervention in different patients. For instance, stimulation of a peripheral nerve evokes a neurologic response. This response is recorded as voltage over time. The general appearance of an SSEP waveform is presented in [Fig. 19.3](#). Acute changes or trends in waveform patterns as compared to the patient's baseline tracing are monitored. The morphology of the EP tracing varies depending on the peripheral nerve that is stimulated ([Fig. 19.4](#)). Three components of the waveform that are examined are the general appearance, amplitude, and latency. Amplitude represents the intensity of the evoked response, and latency is indicative of the time necessary for the evoked response to be measured in the brain. A 50% decrease in amplitude or a 10%

increase in latency is suggestive of the possibility of cerebral ischemia, and the surgical team should be made aware of this change.³³ The threshold or stimulating current that is used also aids in assessment of neurologic integrity.

FIGURE 19.3 Visual evoked response tracing of amplitude versus time after stimulus. The measurement of latency and amplitude for the negative peak at 70 msec (N_{70}) is shown. (From Cottrell JE, Patel P. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Elsevier: Edinburgh; 2017: 114.)

FIGURE 19.4 Example of somatosensory-evoked potential peaks. (From Wiederholt WC, et al. Stimulating and recording methods used in obtaining short-latency somatosensory evoked potentials [SEPs] in patients with central and peripheral neurologic disorders. *Ann N Y Acad Sci.* 1982;18(6):388:349.)

What are the best anesthetic agents to use for surgical procedures when using EPs? A balance must be established between providing an adequate depth of anesthesia while optimizing conditions that allow monitoring of neurologic structures. Each specific type of EP has a unique interaction with the anesthetic delivered. Lipophilic agents that interfere with neuronal membrane conduction also interfere with subcortical conduction. Therefore, these agents cause an increase in both interpeak latencies and control conduction time. Anesthetic agents that interfere with EEG also interfere with EP: changes occur because the component frequencies of the EP are the same as of the EEG. Lastly, inhalation and intravenous anesthetic agents depress EP waveforms in a dose-dependent manner. Generally, inhalation agents have a greater depressant effect of EP waveforms as compared to intravenous agents. The combination of inhalation and intravenous anesthetic agents has a synergistic depressant effect on SSEP waveforms (Fig. 19.5).

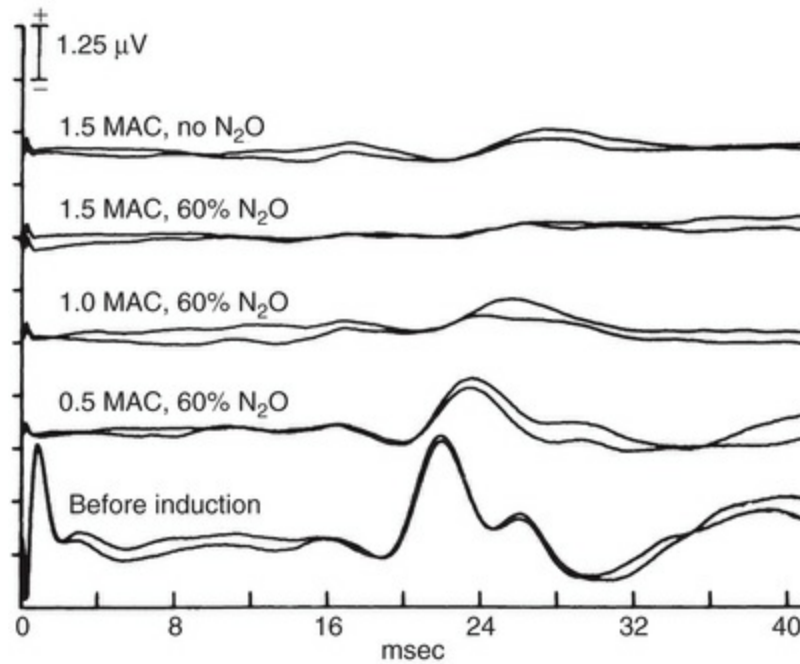

FIGURE 19.5 Representative somatosensory-evoked potential-Isoflurane. MAC, Minimum alveolar concentration; NO_2 , nitrous oxide. (From Peterson DO, et al. Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory evoked potentials in humans. *Anesthesiology*. 1986;65:35-40.)

Somatosensory-Evoked Potentials

Somatosensory-evoked potentials are used to monitor the integrity of the neural structures along both the peripheral and central somatosensory pathways of the brain and spinal cord. SSEPs are induced by stimulating peripheral nerves electrically. These stimulations can be induced through mechanical devices, but electrical stimulation gives a more robust response. A maximal electrical stimulation is not required to elicit a response from the nerve. SSEPs are usually induced by stimulation of a peripheral nerve, which contains both a sensory and motor component that combine to provide a mixed signal. Typically, the lower extremities can be monitored by stimulating the posterior tibial nerve, located between the Achilles tendon and medial malleolus of the ankle. The upper extremities are monitored by placing the stimulus at the median nerve, located between the tendons of the flexor carpi radialis and the palmaris longus. If these common sites cannot be accessed, two alternate sites are the common peroneal nerve in the

popliteal fossa (which may be used for the lower extremity) and the ulnar nerve (either at the wrist or ulnar notch) for the upper extremities.

Recording electrodes used for SSEPs are placed at C2, C3, and C4, referencing to F2 of the montage for cortical SSEPs. An electrode placed over the C7 cervical spine is used for subcortical SSEPs. For upper limb SSEP studies, electrodes are placed over Erb's point both ipsilateral and contralateral to the stimulus. Erb's point is located on the side of the neck, 2 to 3 cm above the clavicle and in front of the transverse process of the sixth cervical vertebra. Pressure over this point elicits Erb-Duchenne paralysis, and electrical stimulation over this area elicits various potentials measured in the arm. For lower limb studies, the electrode is placed at the iliac crest. Several different characteristics of SSEPs can be measured. Peak latencies are the easiest to measure and standardize, but like other characteristics, they can vary with age, tissue mass, electrical stimulus, and limb length. Spinal SSEP electrodes are placed over the spinal cord. SSEPs are usually processed signals, meaning they are processed as an average, with electrical filters to remove background noise, instead of providing real-time electrical waveforms. Interpretation of the compound action potential depends on the site of stimulus and distance to the recording electrodes.

Almost all anesthetic agents increase latency and or decrease amplitude, with the exception of ketamine, etomidate, and opiates. However, it has been noted in other studies that ketamine and etomidate may cause changes in latency and amplitude.⁴¹ Monitoring conditions for SSEPs are obtained with narcotic-based anesthetics, total intravenous anesthetics, or a 0.5 or less minimum alveolar concentration (MAC) per total end-tidal inhaled concentration of an inhalation agent.^{42,43} The use of nitrous oxide potentiates the depressant effects on the inhalation agents.⁴⁴ Administration of paralytic agents does not affect SSEP monitoring. However, if neuromuscular blockade is not administered, motor responses can be elicited.

Although sometimes limited in their evaluation of neurologic diseases, the value of SSEPs in the operative setting is high.³⁸ SSEP monitoring is employed for a variety of surgical procedures. For

instance, alterations in the SSEP waveform can indicate high-risk or neurologic injury during aortic cross-clamping. During cerebral aneurysm surgery, changes in SSEPs can indicate the possible occlusion of parental vessels, directing the positioning of important aneurismal vascular clips. In addition, monitoring SSEP waveforms allows surgeons to selectively shunt the operative carotid artery during endarterectomy.

Motor-Evoked Potentials and Electromyography

Motor-evoked potentials are used to monitor the functional integrity of motor tracts, particularly in the corticospinal tract. Stimuli used to produce MEPs can be either electrical or magnetic. Either the motor cortex or spinal cord can be used for sites of stimulation. Magnetic stimulation of the motor cortex can be accomplished using a rapidly changing magnetic field (as compared to the constant field used for magnetic resonance imaging). Based on the Faraday law, an electrical current is created in a nearby conductor, generating the stimulus. Although useful, magnetic stimulation is cumbersome in the operating room because of the interference of magnetic fields with other operating room equipment, as well as the size and position of equipment during the procedure. Magnetic stimulation also generates intense heat that needs to dissipate to safe levels, and can therefore prolong procedures. Magnetic fields also produce a high-intensity (though brief) noise, so ear protection is recommended. Contact with magnetic stimulation is contraindicated in patients with pacemakers, spinal or bladder stimulators, epilepsy, a metallic foreign body, or previous craniotomy. Direct stimulation of the motor cortex may also be produced by cutaneous electrodes on the scalp or electrodes placed directly on the brain after surgical exposure. Electrical stimulation is more commonly used during spinal surgery.

Evoked potentials are recorded as neurogenic potentials in the distal spinal cord or peripheral nerve. They also can be recorded as myogenic potentials of innervated muscle. Whereas SSEPs can be used to assess the dorsal column (fasciculus cuneatus and gracilis) and the lateral sensory tract of the spinal cord, the data provided by SSEPs can also lead clinicians to make assumptions on changes in

anterior motor tracts because the stimulation is a mixed nerve (motor and sensory) signal. However, because they are not directly measured, motor deficits can occur despite the presence of normal SSEP waveforms.

Advances in technology and the refinement of methodologies are significantly changing intraoperative neurophysiologic monitoring of the spinal cord. The clinical application of spinal D wave and muscle MEP recordings is becoming standard in many procedures. D wave changes have proven to be the strongest predictors of maintained corticospinal tract integrity, and therefore of motor function/recovery. Combining the use of muscle MEPs with D wave recordings provides the most comprehensive approach for assessing the functional integrity of the spinal cord motor tracts during select surgeries. MEPs are considered the gold standard for monitoring the motor pathways, whereas SSEPs continue to be valuable for assessing the integrity of the dorsal (sensory) column. Therefore, multimodal monitoring combining SSEP and MEP monitoring is the standard for spinal surgery.⁴³

Stimulation and monitoring of motor components of nerves are important in the operating room, but they require an active stimulus to produce an action potential. Electromyography (EMG) can be both passive and active. EMG has the capability to stimulate a motor nerve and monitor the known innervated muscle groups, as well as passively “listen” to all muscle groups. The ability to passively monitor nerves allows the surgeon to be more aware of what nerve is being stimulated with surgical manipulation.

EMG analysis of the facial nerve for related surgeries has been used and researched extensively. Other cranial nerves can and have been used for monitoring purposes as well. Monitoring needle electrodes are typically placed in the orbicularis oculi and the orbicularis oris muscles. To assess the cervicofacial and temporofacial divisions of the facial nerve as it divides from the posterior aspect of the parotid gland, both of these muscles require monitoring. The frequency and density of discharges elucidate the type of damage to the actual nerve. Simple benign contact with the nerve causes few random discharges. A response train is associated with more significant nerve irritation. Neurotonic discharges are associated with nerve irritation, as well as impending nerve

damage. Elimination of environmental factors should be considered prior to diagnosing nerve damage. Trains of stimulation can also be caused by thermal changes (electrocautery or cold irrigation), drilling, traction, and/or nerve ischemia. Additionally, EMG inspection of the right and left recurrent laryngeal nerves during thyroidectomy and other head and neck surgical procedures can be performed with use of a nerve integrity–monitoring endotracheal tube.⁴⁵ The choice of anesthesia is essentially unrestricted, with the exception of avoiding paralytic agents. Additionally, the efficacy of partial paralysis has not been studied extensively. Monitoring methods for cranial and spinal nerves are shown in [Tables 19.5](#) and [19.6](#).

TABLE 19.5
Monitoring of Cranial Nerves

Cranial Nerve	Monitoring Site or Method*	
I	Olfactory	No monitoring technique
II	Optic	Visual-evoked potentials
III	Oculomotor	Inferior rectus muscle
IV	Trochlear	Superior oblique muscle
V	Trigeminal	Masseter muscle and/or temporalis muscle (sensory responses can also be monitored)
VI	Abducens	Lateral rectus muscle
VII	Facial	Orbicularis oculi and/or orbicularis oris muscles
VIII	Auditory	Auditory brainstem responses
IX	Glossopharyngeal	Stylopharyngeus muscle (posterior soft palate)
X	Vagus	
	Superior laryngeal branch (motor)	Cricothyroid muscle
	Recurrent laryngeal branch (motor)	Posterior cricoarytenoid Lateral cricoarytenoid Thyroarytenoid Transverse arytenoid Oblique arytenoid Thyroepiglottic Aryepiglottic
XI	Spinal accessory	Sternocleidomastoid and/or trapezius muscles
XII	Hypoglossal	Genioglossus muscle (tongue)

*Unless otherwise specified, monitoring is performed via electromyographic activity of the muscle(s) listed.

Brainstem Auditory–Evoked Potentials

Brainstem auditory–evoked potentials are used to monitor the entire auditory pathway from the distal auditory nerve to the midbrain, inadvertently allowing monitoring of basic brainstem function. The stimulus used is typically a standard broadband repeating click. Repetition is generally approximately 10 Hz, and the intensity is approximately 65 to 70 dB above the click-perception threshold. The stimulus is delivered via an earphone placed in the auditory canal. For best results, care must be taken (1) to place the transducer after the head is positioned, so as not to cause abrasive injury to the ear canal and (2) to ensure that the internal auditory canal is free of any built-up cerumen or fluid. Fluid, saline, cerebrospinal fluid, and soap can dampen or change the sound and delay responses. Recording electrodes are determined by the type of BAEPs stimulated in the patient.

Brainstem auditory–evoked potentials have five main peaks, which are represented by roman numerals (Fig. 19.6). Peak I relates to the peripheral portion of the cochlear nerve inside the internal auditory canal. Peak II relates to the cochlear nucleus and the area where the eighth cranial nerve enters the brainstem. Peak III

correlates to the area of the brainstem at the level of the cochlear nucleus, and potentially the ipsilateral superior olivary nucleus. Peaks IV and V relate to the brainstem along the ascending auditory pathway between the cochlear nucleus and the inferior colliculi. Measured peaks must be compared with relative norms for age, sex, intensity, polarity, and repetition rate.

FIGURE 19.6 Auditory-evoked potentials—common potentials (labeled with Roman numerals) that can be measured to assess different areas of the auditory and brainstem pathways. Peak I relates to the peripheral portion of the cochlear nerve inside the internal auditory canal. Peak II relates to the cochlear nucleus and the area where the 8th cranial nerve enters the brainstem. Peak III correlates to the area of the brainstem at the level of the cochlear nucleus, and potentially the ipsilateral superior olivary nucleus. Peaks IV and V relate to the brainstem along the ascending auditory pathway between the cochlear nucleus and the inferior colliculi. Peak VI relates to the medial geniculate body. Peak VII (not shown) relates to auditory radiations. (Modified from Barlow HB, Mollon JD. *The Senses*. Cambridge, England: Cambridge University Press; 1982.)

The clinical usefulness of BAEPs include that they are very resistant to interference (other than structural pathology within the brainstem). As such, BAEPs are not significantly affected by narcotics, benzodiazepines, ketamine, nitrous oxide, propofol, or muscle relaxants. However, the use of a lidocaine infusion has been known to affect BAEPs.^{46,47} Additionally, inhalation agents can

affect BAEPs, and their effect is proportional to the dose of inhalation agent administered.⁴⁶

A common effect on BAEPs during anesthesia and surgery is hypothermia. Even mild hypothermia (patient temperature less than 35°C) has been associated with increased latency and prolonged interpeak intervals during BAEP analysis.⁴⁸ BAEPs can also be exaggerated, as demonstrated by an increase in latency with low partial pressure of carbon dioxide (PaCO₂) seen during hyperventilation.

The auditory nerve can be directly monitored by the surgeon during the surgical procedure. The monitoring electrode is placed on the nerve itself after surgical exposure, and its response is measured as an auditory nerve compound action potential (AN-CAP). When the eighth nerve is involved, the AN-CAP is referred to as the eighth nerve potential. The AN-CAP, like the BAEP, can be used to determine auditory nerve insult or injury. For auditory brainstem responses, the noninverting (positive) electrode is placed at C2 or high on the forehead. The inverting (negative) electrode is typically placed on the mastoid or earlobe. However, if neither of these sites is practical (owing to surgical exposure), then the tragus of the ear may be used as an alternate site.

Electrocochleography (ECochG) is a specific test used to provide information about the cochlea and the distal section of the auditory nerve. It is typically used to evaluate and/or verify blood supply to the cochlea. The measure itself is called the ECochG-CAP (compound action potential). The inverting electrode is placed near the cochlea, tympanic membrane, or cochlear promontory. The noninverting electrode is placed on the opposite ear.

Otoacoustic emissions (OAEs) are sometimes used, but this test is not an EP. Because a stimulus is not used, there is only a recording device. No stimulus is required because the normal cochlea does not just receive sound, but also emits OAEs, which are produced specifically by the cochlea and most probably by the cochlear outer hair cells as they expand and contract. These sound transmissions can be recorded; they are typically used to assess auditory hair cell function and not the internal structure of the ear.

Visual-Evoked Potentials

Visual-evoked potentials are used to monitor the function of the visual pathway, which comprises the retina to the occipital cortex and everything in between, including the optic nerve and the optic chiasm. A series of visual stimuli are produced, and the cerebral responses are amplified, averaged by a computer, and displayed. The two major classes of VEP stimulation are patterned and unpatterned (luminance). Typically, awake tests consist of a pattern stimulus. The two most common pattern stimuli are pattern reversal and pattern onset/offset stimuli. Pattern reversal stimulus consists of black-and-white checks (checkerboard) that change phase (but maintain the same luminescence) at a predetermined number of reversals per second. Pattern onset/offset stimulus consists of a black-and-white checkerboard that exchanges with a diffuse background with the same luminescence.

Because such stimulation cannot be used in conjunction with anesthesia or even sedation, a stroboscopic flash (luminescence) stimulus must be used in such cases. The flash VEP is created from a flash that has a predetermined strength against a dim background of certain luminance. Recording electrodes are fixed to the scalp and, as always, placed relative to bony landmarks. The active electrode is placed on the scalp over the visual cortex. The ground electrode can be placed at the forehead, mastoid, earlobe, or both earlobes.

Monocular stimulation is typically used to avoid masking of unilateral conduction abnormality. Care should be taken to ensure that no light enters the eye not being stimulated. Closure with a patch and tape is usually sufficient to block light. Preoperatively, a comprehensive ocular physical assessment should be made to use as a comparison to the postoperative result. For example, extreme pupillary size or anisocoria (inequality of pupil diameter) can be compared to the preoperative pupillary size. Pupils do not need to be dilated for flash VEPs, and the cornea should be carefully moistened to prevent drying. Mydriatics and miotics should not be used with awake tests. It is also important to compare VEPs with appropriate age- and sex-related normal values.

The action potential of VEPs varies depending on the type of stimulus used. Flash VEPs consist of a series of negative and positive waves, with the earliest detectable response occurring

approximately 30 ms poststimulus. For flash VEP, the N2 and P2 peaks are the most robust components, peaking at approximately 90 and 120 ms, respectively (Fig. 19.7). Unfortunately, flash VEPs are more variable between subjects than between pattern responses. Some question the usefulness of intraoperative VEPs, because in anesthetized patients, stable recording was either not obtainable or not consistent among study participants.^{49,50} Indications for monitoring EPs are noted in Table 19.7 (see also Table 8.4).

FIGURE 19.7 Flash visual-evoked potential. The three positive deflections that characterize the potential and are subsequently measured are denoted as P1, P2, and P3. The three negative deflections that characterize the potential and are subsequently measured are denoted as N1, N2, and N3. (Adapted from Odom J, et al. Visual evoked potentials standard. *Doc Ophthalmol.* 2004;108:115–123.)

Bispectral Index

Extensive research with bispectral index (BIS) monitoring has allowed for the analysis and processing of EEG electrical signals; the result is then displayed as a numeric value between 0 and 100, which is representative of the patient's level of consciousness. This technology relies on a combination of bispectral analysis, power spectral analysis, and time domain analysis in combination with a proprietary mathematical algorithm that produces an index of the anesthetic depth of the patient. BIS measurement is effective in determining the level of anesthesia produced with inhalation agents, but remains less predictable with pediatric patients and during regional and intravenous anesthesia.⁵¹

Several devices on the market today use a combination of processed EEG signals to determine the depth of anesthesia, including BIS monitoring (Aspect Medical Systems), S/5 Entropy Module (GE Healthcare), Cerebral State Monitor (Danmeter), SNAP II monitor (Stryker), AEP Monitor/2 (Danmeter), and SEDLine Patient State Analyzer (Hospira).

The BIS monitor processes a single frontal EEG signal to calculate a dimensionless number that provides a measure of the patient's level of consciousness. BIS values range from 100 (awake) to 0 (absence of brain activity). BIS values between 40 and 60 suggest adequate general anesthesia for surgery. Values below 40 indicate a deep hypnotic state. Targeting a range of BIS values between 40 and 60 is advocated to prevent anesthesia awareness while still allowing a reduction in the administration of anesthetic agents (Fig. 19.8).⁵² The ability of the BIS monitor to successfully prevent awareness remains controversial. BIS-guided anesthesia reduces the incidence of awareness with recall in high-risk patients.⁵³ A study comparing BIS-guided anesthesia to measurement of the end-tidal anesthetic concentration (ETAC) found that ETAC, which is routinely monitored, was superior in preventing recall.⁵⁴ It has been suggested that deep anesthesia, as defined by a sustained BIS value of less than 40 for more than 5 minutes, is associated with increased postoperative mortality (as shown in the Bispectral index monitoring to prevent awareness during anesthesia [B-Aware]

trial).⁵⁵ The concern was that adverse outcomes are increased with additional risk factors such as hypotension, high concentrations of anesthetic gases, and patient comorbidities. Other studies do not support the B-Aware trial results and state that the use of BIS is no more effective than evaluating ETAC.⁵⁶ The BIS has also been used to assess the depth of anesthesia prior to and during emergence, to potentially decrease the time between termination of the surgical procedure and extubation. However, as compared with anesthetic management guided by ETAC, BIS guidance does not increase the incidence of earlier tracheal extubation in patients undergoing fast-track cardiac surgery.⁵⁷ The BIS may be most advantageous when used as a trend monitor that can be interpreted with other objective data (e.g., vital signs, end-tidal concentration of an inhalation agent, intravenous agents used) to help guide anesthetic depth.

FIGURE 19.8 Methods for assessing CNS integrity.

Summary

The use of neurologic monitors does not guarantee prevention of neurologic injury. However, given recent advances in technology, neurologic monitoring helps to ensure patient safety. Several factors contribute to intraoperative EEG and EP changes, making the monitoring device more challenging to interpret. Some of these factors include hypothermia, hyperthermia, volatile and intravenous anesthetic agents, surgical intervention, previous neurologic injury, and excessive auditory and visual stimulation. Providing anesthesia for neurologic surgical procedures requires knowledge of both basic and advanced anesthesia techniques. The anesthesia provider must combine the data and trends from clinical monitoring devices with clinical signs and symptoms to best assess patient neurological function and wellbeing. Postoperative neurologic changes may also occur, so continued monitoring is essential to reduce the incidence of preventable permanent changes. Cooperation and communication between the surgeon, the neurobiologist, and the anesthetist remains vital keys for safe neurologic monitoring and improved surgical outcomes.

UNIT IV

Preoperative Preparation

OUTLINE

20 Preoperative Evaluation and Preparation of the Patient

20

Preoperative Evaluation and Preparation of the Patient

Rex A. Marley, Sarah A. Sheets

A crucial element of the perioperative care of the surgical patient includes a timely and thorough preoperative assessment. A fine-tuned approach to patient evaluation then enables appropriate interventions when required to properly prepare the patient for the upcoming anesthesia and surgery. For any patient scheduled to undergo anesthesia, preoperative evaluation is compulsory to help identify factors that increase the risk associated with anesthesia, and the status of the patient relative to the proposed surgery. Essential goals of preoperative assessment and preparation of the patient include the following:

- Optimize patient care, satisfaction, comfort, and convenience.
- Minimize perioperative morbidity and mortality by accurately assessing factors that influence the risk of anesthesia or might alter the planned anesthetic technique.
- Minimize surgical delays or preventable cancellations on the day of surgery.
- Determine appropriate postoperative disposition of the patient (i.e., given the patient's status, whether the procedure is best performed on an ambulatory, inpatient, or intensive care basis).
- Evaluate the patient's overall health status, determining which if any preoperative investigations and specialty consultations are required.
- Optimize preexisting medical conditions by encouraging requisite lifestyle changes, i.e., weight reduction, smoking termination, minimizing alcohol ingestion, access to ongoing health care monitoring.
- Formulate a plan for the most appropriate perianesthetic care and

postoperative supportive patient care.

- Communicate patient management issues effectively among care providers.
- Communicate and provide specific instruction to patients in regards to preoperative preparation, i.e., fasting and *nil per os* (NPO) guidelines, blood glucose management, home medication administration.
- Educate patient regarding surgery, anesthesia, and expected intra- and postoperative care, including postoperative pain treatments, to reduce patient anxiety and increase patient satisfaction.
- Ensure time-efficient and cost-effective patient evaluation.

During the preoperative visit patient assessment begins with a thorough review of the patient's medical records and patient interview, followed by the physical examination. A comprehensive medical history and physical examination are the cornerstones of a systematic approach to continued patient preparation. Information gathered from this evaluative process guides further individualized assessment (e.g., obtaining diagnostic tests, specialist consultation). The extent of this preoperative workup depends on the existing medical condition of the patient, the proposed surgical procedure, and the type of anesthesia. Significant findings from this initial evaluation enable the anesthesia provider to make adjustments in the patient's care (i.e., initiate specific treatment modalities to optimize the patient's condition for the proposed surgery and anesthesia). A thoughtfully executed preoperative history and physical has been found to be more predictive of surgical complications than objective preoperative testing.¹

Important strategies for achieving high-quality, cost-effective patient evaluation include the following:

- Educating the practitioner (e.g., regarding the cost of diagnostic tests) and thereby modifying practice patterns.
- Developing and implementing evidence-based best practice guidelines.
- Using clinical pathways (interdepartmental teamwork required).
- Disseminating information regarding protocols, thereby avoiding duplication of services.

- Performing economic analyses of services, including cost-effectiveness, and cost-benefit studies.
- Rendering efficient resource management.
- Providing for outcomes measurement.

Preanesthesia Assessment Clinic

The preanesthesia assessment clinic has emerged as the most effective means of providing convenient “one-stop shopping” designed to (1) permit patient registration, (2) obtain a medical history and perform a physical examination, (3) promote patient teaching, (4) meet or schedule appointments with medical consultants, (5) complete any required preoperative diagnostic testing, and (6) improve regulatory compliance and operating room efficiency. Successful preanesthesia assessment clinics have realized a reduction in patient anxiety, direct cost, last-minute surgical cancellations, overall length of hospitalization after surgery, and diagnostic testing, in addition to improvement in patient education and a shift from inpatient to outpatient surgery status. The preanesthesia assessment clinic allows patients scheduled for elective surgery to be evaluated and their condition optimized sufficiently in advance of the surgery.²

Timing of Patient Assessment

To allow ample time for necessary risk assessment, preoperative testing, and specialty consultations, ideal preoperative assessment for surgery and anesthesia should take place well in advance of the proposed surgery. Patients with complex medical conditions should be evaluated at least 1 week before the scheduled procedure. Because of the present economic realities patients undergoing more complex procedures, and those who have complicated medical conditions (Box 20.1)³, are frequently not admitted to the hospital before the day of surgery. Preoperative evaluation on the day of surgery can result in last-minute discoveries (e.g., of inappropriate fasting, suspected difficult airway, preexisting medical condition) that may result in surgical delay or cancellation. The timing of the preanesthesia assessment does not appear to influence outcome of anesthesia.⁴ In one study, no difference in the cancellation rate for ambulatory patients was observed between groups seen within 24 hours and groups seen within 1 to 30 days of the scheduled surgery.⁵ Regardless of when

performed, this focused evaluation must be performed by a **Box 20.1** ~~Practitioner~~ other qualified to administer anesthesia.

Conditions That Would Benefit From Early Preoperative Evaluation

General

- Medical conditions inhibiting ability to engage in normal daily activity
- Medical conditions necessitating continual assistance or monitoring at home within the past 6 months
- Admission within the past 2 months for acute episodes or exacerbation of chronic condition
- Use of medications (e.g., anticoagulants or monoamine oxidase inhibitors) for which modification of schedule or dosage might be required

Cardiocirculatory

- History of angina, coronary artery disease, myocardial infarction, symptomatic arrhythmias
- History of cardiac rhythm device in case device interrogation or reprogramming by appropriate personnel will be necessary
- Poorly controlled hypertension (diastolic greater than 110 mm Hg, systolic greater than 160 mm Hg)
- History of congestive heart failure

Respiratory

- Asthma or chronic obstructive pulmonary disease that requires chronic medication; acute exacerbation and progression of these diseases within the past 6 months

- History of major airway surgery, unusual airway anatomy, or upper or lower airway tumor or obstruction
- History of chronic respiratory distress requiring home ventilatory assistance or monitoring

Endocrinologic

- Diabetes treated with insulin or oral hypoglycemic agents (unable to control with diet alone)
- Adrenal disorders
- Active thyroid disease

Hepatic

- Active hepatobiliary disease or compromise

Musculoskeletal

- Kyphosis or scoliosis causing functional compromise
- Temporomandibular joint disorder with restricted mobility
- Cervical or thoracic spine injury

Oncologic

- Patients receiving chemotherapy
- Other oncologic process with significant physiologic residua or compromise

Gastrointestinal

- Morbid obesity (greater than 140% ideal body weight)
- Hiatal hernia

- Symptomatic gastroesophageal reflux

Chart Review

To provide the basis for and direction of the patient interview and physical assessment, the patient's past and current medical records should be reviewed preoperatively. Ideally the anesthesia provider will have the opportunity to review the patient's medical records before the interview with the patient or caregiver.

Past Medical Records

For a patient who has undergone surgery at the same institution in the past, previous anesthesia records should be retrieved and reviewed, especially if complications are suspected. If past medical records are not available, the patient must provide details of significant anesthetic experiences. If this information suggests that the patient has an unusual condition (e.g., atypical plasma cholinesterase, susceptibility to malignant hyperthermia), surgery may be delayed so that medical records can be obtained for review to provide further information that might affect patient care, or measures should be taken (e.g., avoidance of succinylcholine; provision of trigger-free anesthetic technique) to avoid consequences associated with the condition.

Patient Chart or Electronic Medical Record

A review of the current medical record includes verifying that the surgical and anesthesia consents are accurate and complete. The names of the patient and surgeon, the date, and the proposed procedure should be matched with those on the operating room schedule. Demographic or baseline data, such as the age, height, and weight of the patient, can often be obtained from the admitting record. Vital-sign trends and input-output totals are transcribed from graphic flow sheets, which may also contain pertinent data (e.g., daily blood glucose values for the diabetic patient).

Progress notes and consultation reports provide a valuable overview of the health history and physical status of the patient. Medical treatments, such as drug dosages and schedules, may be derived from these materials, but diagnostic test results should be

obtained directly from their original sources. This retrieval of primary data prevents the possible misinterpretation of data that were transcribed incorrectly. Knowledge gleaned from a review of progress notes and consultative reports enables the anesthesia provider to formulate supplementary questioning, seek further specialist consultations, or obtain additional diagnostic testing as needed.

Baseline data concerning the patient, such as cultural diversity, coping mechanisms, or patient limitations (e.g., hearing impairment), can often be derived from nursing notes, and can effectively guide the anesthesia provider in conducting a thorough preoperative interview. Increasingly the anesthetist must be able to appropriately interact with culturally diverse populations to properly evaluate and educate patients.

A preanesthesia questionnaire is included on the patient's chart and should be part of the admission paperwork to be completed by the patient or the patient's caregiver and consists of a concise checklist regarding the patient's health history and medical care. When properly completed and readily available on the chart, the preanesthesia questionnaire enables the anesthesia provider's visit with the patient to be accomplished more efficiently. Interview questions and physical assessment are appropriately directed toward abnormal findings and areas of concern.

Patient Interview

The preoperative interview may be conducted in person or by telephone. The in-person patient interview is preferred, but for patients who are unable to visit the hospital setting (e.g., who live far from the hospital or have transportation constraints), an opportunity to participate in a telephone interview should be made available. Regardless of the location or approach used, the interview promotes a trusting relationship between the patient and anesthesia provider. When the interview is performed in a caring and unhurried manner, the patient's degree of trust and confidence in anesthesia care is enhanced. Furthermore, compliance with perioperative instructions is increased when the patient is treated with respect; an example of such respect is using the surname (Mr. Smith, Mrs. Jones) unless instructed differently by the patient.

The title of the anesthesia provider and his or her specific role in the patient's perioperative care should also be defined. The patient is entitled to know what role the interviewer plays in the perioperative process. Many times a nurse practitioner or physician assistant may conduct the assessment. The professional appearance and attitude of the anesthesia provider can also create a positive impression during the preoperative visit.

The environment of the preoperative interview should be staged to maximize the quality and effectiveness of the interaction. Adequate lighting enhances effective communication with the patient. Distractions such as an operating television set can be eliminated. The interviewer should ensure that the time and location of the interview, whether it occurs in person or by telephone, are convenient and private for the patient. A return visit or call may be necessary if the patient is eating or receiving medical therapy.

Because the preoperative interview is a private interaction between the patient and the clinician, a tactful request that visitors remain outside the interview area, unless the patient wishes family members to be present, will be necessary. Otherwise the patient may not volunteer confidential health information, such as a history of substance abuse or sexual history. In certain situations, however,

assistance from a family member or caregiver is required. The health history may be provided, for example, by the parent of a pediatric patient or by an interpreter for a patient with cognitive or language barriers.

The patient interview is designed to achieve specific objectives (Box 20.2).⁶ The interview process, along with patient education, yields beneficial consequences of reduced patient anxiety and increased patient satisfaction. A valuable step in preparing the patient or responsible caregivers (e.g., family members, legal guardian) for the scheduled surgery includes an educational process during which the staff counsels the patient concerning fundamental perioperative issues (Box 20.3).⁶ Reinforcing information to the patient verbally and in writing is essential to gaining patient compliance. Coordinating the patient's visit to the preanesthesia assessment clinic to include educational time is ideal for the patient.

Objectives of the Preoperative Interview

- Ensure that the goals of preoperative assessment are met.
- Provide preoperative education to the patient and family.
- Obtain written documentation of informed and witnessed consent.
- Acquaint the patient and family with the surgical process (to reduce stress and increase familiarity).
- Evaluate the patient's social situation with respect to surgery (e.g., support network).
- Motivate the patient to comply with preventive care strategies (e.g., smoking cessation, improvement of cardiovascular fitness).

Modified from Cassidy J, Marley RA. Preoperative assessment of the ambulatory patient. *J Perianesth Nurs*. 1996;11(5):334–343.

Box 20.3

Patient Education Objectives

- Promote interactive communication between patient and care provider.
- Encourage patient participation in making decisions about perioperative care.
- Maximize and enhance patient self-care skills and participation in continuing care during the postoperative phase.
- Increase the patient's ability to cope with his or her health status.
- Increase patient compliance with perioperative care.
- Provide individualized preoperative instructions regarding the following:
 1. Where and when laboratory tests, consultations, and diagnostic procedures will be completed
 2. Appropriate time at which the patient should cease ingestion of food and drink
 3. Personal considerations (e.g., comfortable clothes to wear; no jewelry or makeup; what personal items to bring; leave valuables at home; bring favorite toy, comforter, or book)
 4. Postoperative considerations and instructions (e.g., anticipated recovery course, discharge instructions, how to deal with complications)
 5. Person to contact if the patient's physical condition changes (e.g., upper respiratory tract

infection, cancellation)

- Detail the process of arrival and registration on arrival to the surgical facility (i.e., time and location of arrival).
- Review advance directive information as required by law in some states.
- Explain the surgical facility policies to the patient and family.

Modified from Cassidy J, Marley RA. Preoperative assessment of the ambulatory patient. *J Perianesth Nurs*. 1996;11(5):334–343.

Medical History

The extent of a patient's health history depends partly on the amount of information available in the chart before surgery. If the surgeon has already documented a thorough medical history and physical examination, the interview can focus on confirming major findings and obtaining information that directly relates to the anesthetic management of the patient. The anesthesia provider must obtain and document a detailed health history, however, if the history is unavailable in the chart during the preoperative visit.

The health history should be obtained in an organized and systematic way, as with the preanesthesia questionnaire, to minimize possible omission of important data. Open-ended and direct questions targeting each category of the checklist can be posed. With this approach, more detailed and graded responses are elicited from the patient. To avoid overwhelming or confusing a patient, questions are asked separately and formulated in comprehensible or layperson's terms.

Surgical History

The surgical history of a patient may be learned from the chart or preoperative interview. Most patients only vaguely recall surgical experiences, even from childhood operations. Information regarding complications related to previous operations such as a peripheral nerve injury or uncontrolled blood loss should be

elicited to determine the need for further investigation.

Anesthetic History

Past anesthetic experiences are often not as easily defined as the surgical history. It is vitally important to determine the reaction of a patient to previously administered anesthetics. Adverse reactions to anesthetic agents and techniques (e.g., prolonged vomiting, difficult airway, malignant hyperthermia, postoperative delirium, anaphylaxis, and cardiopulmonary collapse) may have simply been an annoyance to the patient or could have been life threatening. Preoperative knowledge of these complications allows the anesthetic approach to be modified and the recurrence of the complication thereby prevented. Causative factors are also thoroughly investigated in patients who note that a previous operation was aborted. Difficulties with airway management can alter the approach to endotracheal intubation, if indicated. Vague reports of fever and convulsions merit further investigation to rule out an episode of malignant hyperthermia.

Familial Anesthetic History

Numerous inherited diseases involving metabolic derangements may affect a patient's reaction to stress and certain drugs, including anesthetic agents. The patient is specifically asked whether any family member ever experienced an adverse reaction to anesthesia during surgery. Familial tendencies for diseases such as atypical plasma cholinesterase, malignant hyperthermia, porphyria, or glycogen storage diseases (e.g., glucose-6-phosphate dehydrogenase deficiency) are then investigated. A diagnosis should be established before the surgery proceeds, because adjustments in the anesthetic management of the patient may be required.

Drug History

A preoperative drug history provides an excellent guide for the direction and depth of the patient interview and assessment. Drug dosages, schedules, and durations of treatment are reviewed and

the patient questioned about the purpose and effectiveness of these medications. For example, an interview with a patient receiving β -adrenergic blockers can focus in greater detail on the cardiovascular system. Patients on medications for hypertension or angina pectoris require further investigation and possibly specialty consultation if they have not been recently evaluated.

Adverse Drug Effects and Interactions

During the preoperative evaluation current drug therapy must be carefully reviewed for side effects and potential interactions with anesthetic agents. One drug-management strategy is to discontinue nonessential medications preoperatively in the hope of reducing the potential for adverse interactions. The therapeutic benefits of these drugs are weighed against the risks of abrupt discontinuation. Abrupt discontinuation of long-standing medication may lead to the development of undesirable withdrawal symptoms. With occasional exceptions the majority of medications are continued preoperatively. Should a decision be made to withhold a particular drug before surgery, sufficient time should be allowed for metabolic clearance (ideally three to five half-lives).⁸

Drug Allergies

A patient's drug history should include information regarding allergic reactions to certain foods and medications. The most common cause of drug hypersensitivity reactions during anesthesia are antibiotics.¹⁸ Prior allergic responses are investigated so they can be differentiated from adverse drug reactions. Use of certain antibiotics and opioids may be avoided because of gastrointestinal side effects. However, these do not represent a true allergic response. A distinction between allergic reactions and adverse effects is crucial because an allergy to a drug is an absolute contraindication to its use. Medications within the same classification of a drug allergy should be avoided, and heightened awareness of a potential allergic reaction is required during the perioperative period.

Latex Sensitivity

Patient sensitivity to latex products may be the basis of an allergic reaction. The incidence of intraoperative reaction to latex is on the decline secondary to heightened awareness and preventative measures¹⁹; however up to 20% of intraoperative anaphylactic reactions have been attributed to latex sensitivity.²⁰ The preoperative questioning of patients should include inquiry regarding specific latex sensitivity or allergy. Patients at increased risk for latex sensitivity should be cared for in a no-latex setting and scheduled as the first case of the day to reduce the likelihood of aeroallergen latex exposure. The diagnosis of latex allergy is based on the findings of the history and physical examination and if necessary in vivo (skin-prick test is the most sensitive) and in vitro testing. Preoperative testing is indicated only when there is a family history of reactions or when patients report experiencing symptoms such as a rash, swelling, or wheezing when exposed to latex.²¹ Patients at high risk for latex sensitivity include those with a history of the following:²⁰

- Chronic exposure to latex-based products (e.g., industrial workers using protective gear; occupational exposure to latex)
- Spina bifida, urologic reconstructive surgery
- Repeated surgical procedures (more than nine)
- Intolerance to latex-based products (e.g., balloons, rubber gloves, condoms, dental dams, rubber urethral catheters)
- Allergy to food and tropical fruits (e.g., avocado, banana, buckwheat, celery, chestnut, kiwi, mango, papaya, passion fruit, peach)
- Intraoperative anaphylaxis of uncertain cause
- Health care professionals, especially with a history of atopy or severe dermatitis, hand eczema

Social History

The addictive nature of tobacco and alcohol, in addition to illegal drugs, exerts a detrimental influence on several aspects of life in the United States.

- Approximately 24.6 million Americans aged 12 years of age or older (9%) were classified as illicit drug users in 2010.²²

- Nearly one-quarter of all deaths (75,000 annually)²³ in the United States are caused by addictive substances.²⁴
- The economic burden of addiction (e.g., health care expenditures, missed work, crime) is estimated at more than \$400 billion annually.²⁴

Certain drugs, despite their social or recreational application, may be associated with adverse and life-threatening consequences with long- or short-term use or overdose. The social history provides an excellent opportunity to explore the extent of self-medication. Open-ended questions, posed in a professional and nonjudgmental manner, are most likely to elicit detailed information from the patient. At this time the patient can also be educated about the adverse consequences of substance abuse, especially as such substances affect anesthetic care.

Tobacco Use

Many patients arrive for anesthesia and surgery with a history of tobacco smoking. In the United States some disturbing statistics are associated with this form of substance abuse:

- One in five deaths in the United States is related to smoking. Cigarette smoking is the leading cause of preventable premature death in the United States (approximately 480,000 premature deaths annually). Smokers are 12 to 13 times more likely to die than nonsmokers.²⁵
- Cigarette smoking has declined in youth (9.3% in US high schools), however the use of electronic cigarettes and Hookahs has increased.²⁶
- Since 2010, 19.2% of US 12th grade students used cigarettes within 30 days; however, the use of marijuana during the same time (21.4%) surpassed cigarette use.²⁷
- Smoking causes nearly 90% of all lung cancer and 80% of all deaths from chronic obstructive pulmonary disease (COPD).²⁵
- Smoking increases the risk of coronary heart disease and stroke two to four times.²⁵
- Exposure to secondhand smoke causes 7300 deaths a year from lung cancer and 34,000 deaths from coronary heart disease in adult

nonsmokers in the United States.²⁵

The inhaled components of tobacco smoke lead to multiple pathophysiologic changes within the body. Nicotine and carbon monoxide are just two of the more than 6000 noxious components that have been identified in tobacco smoke.²⁸ Nicotine, a toxic alkaloid, produces ganglionic stimulant effects and is the tobacco component that affects the cardiovascular system.²⁹ The overall adverse impact tobacco smoking has on health is vast (Table 20.1).³⁰ Carbon monoxide readily occupies the oxygen-binding sites of hemoglobin (approximately 250 to 300 times greater affinity for hemoglobin than oxygen).³¹ Oxygen transport to the tissues and resultant oxygen use is thereby drastically reduced. In the heavy smoker carboxyhemoglobin may be as high as 15%, which effectively reduces the patient's oxyhemoglobin percentage accordingly. The adverse effects of nicotine on the cardiovascular system and carbon monoxide on oxygen-carrying capacity are short lived (half-life of nicotine is 40 to 60 minutes³²; half-life of carbon monoxide if room air is breathed is 130 to 190 minutes).³³

TABLE 20.1
Effects of Tobacco Smoking

System	Pathophysiologic Effects	Perioperative Effects
Respiratory	Recurrent cough Mucus hypersecretion Mucociliary dysfunction Loss of integrity of airway epithelium Increased upper and lower airway reactivity Recurrent chest infections Loss of elasticity of airways Increased closing volume COPD	Laryngospasm and bronchospasm Sputum retention Hypoxemia Baro/volutrauma Need for reintubation Postoperative atelectasis Postoperative chest infection
Cardiovascular	Tachycardia Hypertension Raised carbon monoxide levels Reduced oxygen carrying capacity Left shift of oxyhemoglobin dissociation curve Reduced oxygen delivery Increased blood viscosity Atheroma and clot formation Risk of myocardial, cerebral and peripheral vascular ischemia/infarction Venous thromboembolism risk	Tachycardia Hypertension Perioperative risk of myocardial ischemia Venous thromboembolism risk
Hematology	Hypercoagulability Increased blood viscosity High white blood cell count Impaired humoral activity and cell-mediated	Risk of perioperative sepsis Risk of perioperative arterial/venous clot formation

	immunity Increased risk of infection Vulnerable to autoimmune diseases Reduced ability to attack malignant cells	
Wound healing	Prolonged wound healing because of long term immunosuppression and poor tissue perfusion	Wound breakdown Perioperative wound infection
Bones	Reduced bone density and osteoporosis Increased fracture risk	
Cancer associations	Lung Gastrointestinal (esophageal, stomach, liver, pancreas, bowel) Head and neck Genitourinary (bladder, ovarian, cervical) Leukemia	

COPD, Chronic obstructive pulmonary disease.

From Shorrock P, Bakerly N. Effects of smoking on health and anaesthesia. *Anaesth Int Care Med.* 2015;17:141–143.

Patients should be instructed to stop smoking at least 12 to 48 hours before surgery. Short-term (e.g., 12 hours) preoperative abstinence from tobacco smoke reduces the deleterious effects of nicotine and carbon monoxide on cardiopulmonary function.³⁴ Smoking cessation for even one night before surgery reduces heart rate, blood pressure, and circulating catecholamine levels³⁵ and allows carboxyhemoglobin values to return to normal levels.³⁶

Patients who smoke have a higher incidence (a nearly sixfold increase³⁷) of postoperative pulmonary complications (pneumonia and atelectasis).³⁸ A smoking history of more than 20 pack years equates to an increased risk of perioperative complications.³⁹ Smoking cessation of less than 4 weeks does not reduce the risk of postoperative respiratory complication.^{4,40} Longer periods of smoking cessation (8 weeks or longer) result in a marked improvement in pulmonary mechanics (e.g., enhanced ciliary function, decreased mucous secretion and small airway obstruction, and enhanced immune function).⁴¹ Patients who stopped smoking less than 2 months before surgery had nearly four times the pulmonary complications (e.g., purulent sputum, secretion retention, bronchospasm, pleural effusion, pneumothorax, segmental pulmonary collapse, pneumonia) of those who abstained from smoking for longer than 2 months.⁴² However, even short-term smoking cessation is effective in reducing postoperative complications when compared with patients who continued to smoke up until the time of surgery.⁴¹ A reduction in postoperative

wound-related complications occurs in patients who stop smoking preoperatively.⁴³ Patients who smoke should be advised to quit, even immediately prior to surgery, without fear of worsening pulmonary outcomes or increasing psychological stress as a result of acute abstinence.⁴⁴ Effective interventions, including behavioral support and nicotine replacement therapy, should be made available to smokers considering abstinence at this time.⁴⁵

The influence of environmental tobacco smoke (also known as *secondhand* or *passive smoke*) on children has been found to produce disturbing respiratory consequences, including increased reactive airway disease, abnormal results of pulmonary function tests, and increased respiratory tract infections.^{46,47} The perioperative complications in children exposed to smoke include laryngospasm, coughing on induction or emergence, breath holding, postoperative oxyhemoglobin desaturation, and hypersecretion.⁴⁸

Alcohol Intake

Alcohol-attributable deaths reached 1.5 million in 2010 globally.⁴⁹ Perioperative complications, such as arrhythmias, infection, and alcohol withdrawal syndrome, are increased twofold to fivefold in chronic excessive alcohol users.⁵⁰ Postoperative complications can be reduced with 4 or more weeks of abstinence prior to surgery.⁵¹ Information regarding the type and amount of alcohol regularly consumed and the frequency of consumption is important in the evaluation for anesthesia and surgery. Often an accurate assessment of a patient's alcohol intake may be difficult to obtain. The Alcohol Use Disorders Identification Test (AUDIT), a self-reporting questionnaire designed to identify problem drinkers, can be incorporated into the preoperative interview of suspected problem drinkers.⁵² A less confrontational and a reliable approach to evaluating a patient's potential for an alcohol problem uses the mnemonic *CAGE*, which refers to the following four questions⁵³:

1. Do you feel you should cut down on your alcohol consumption?
2. Have people annoyed you by criticizing your drinking habits?
3. Have you felt guilty about your drinking?

4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*eye-opener*)?

A patient reporting more than two positive responses is at high risk for alcoholism and an increased likelihood of experiencing withdrawal symptoms.⁵⁴ Both AUDIT and CAGE have been shown to be effective in identifying the abusive alcohol consumer.⁵⁵

In the heavy drinker, it is important to determine whether the patient has experienced seizures, abrupt withdrawal syndrome, or delirium tremens as a consequence of alcohol abuse. Clinical signs suggestive of alcohol withdrawal include increased hand tremors, autonomic hyperactivity (e.g., sweating, tachycardia, systolic hypertension), insomnia, anxiety, restlessness, nausea or vomiting, transient hallucinations (visual, tactile, or auditory), psychomotor agitation, and grand mal seizures.⁵⁴

Chronic alcohol abuse results in the development of tolerance, physical dependence, and multisystem organ dysfunction. Tolerance to alcohol is evidenced by a resistance or cross-tolerance to other central nervous system (CNS) depressants. For example, the anesthetic requirement of hypnotics, opioids, and inhalation agents is increased in the chronic alcoholic; however, exaggerated responses to anesthetic agents are likely during periods of acute intoxication or advanced alcoholism. This effect is attributed to the additive depressant effects of alcohol and anesthetic agents. Enzymatic function and plasma albumin concentrations may also be reduced in patients with alcoholic hepatic insufficiency. As a result, greater circulating concentrations of unbound intravenous agents may result in an exaggerated and prolonged drug effect.⁵⁶ This enhanced drug response has not been shown to occur with propofol in patients with moderate liver cirrhosis.⁵⁷

An insidious progression of multisystem organ dysfunction is also characteristic of long-term alcohol abuse. Numerous illnesses are attributable to the toxic adverse effects of advanced alcoholism on overall health and nutrition. Predictably, postoperative morbidity and mortality rates are increased in alcoholic patients as a result of poor wound healing, infection, bleeding, pneumonia, and further hepatic deterioration.⁵⁸

Illicit Drug Use

Use of illicit drugs (e.g., cocaine, cannabis, “crack,” lysergic acid diethylamide-25 [LSD], amphetamines, heroin, hallucinogens, inhalants, prescription-type psychotherapeutics used nonmedically) is a significant health care issue in the United States. The most popular recreational drugs continue to be cocaine and marijuana. Monthly drug abuse among Americans included 19.8 million marijuana and hashish users, 6.4 million prescription-type psychotherapeutic nonmedical drug users, 1.5 million cocaine users, and 1.3 million hallucinogen users in 2013.⁵⁹ The 2016 data from Centers for Disease Control and Prevention (CDC) have shown continued escalation of prescription opioid use with opioid overdose deaths topping all previous estimations.⁶⁰ The use of these substances increases the risk for adverse consequences and drug interactions during anesthesia. An accurate illicit drug history is often difficult to obtain because of the patient's fear of legal reprisal or refusal to believe a drug problem exists. During the physical examination, the anesthesia provider should look for signs that indicate illicit drug use by the patient. A diagnosis of recent or continuing drug abuse should be suspected in patients exhibiting the following on physical examination⁶¹:

- Evidence of drug injection (e.g., track marks or scarring), thrombotic veins, phlebitis, tattoos (may be used to mask the sites), ablation of venous return leading to unilateral edema of the nondominant hand, subcutaneous skin abscesses
- Ophthalmologic changes, such as pupillary constriction from opioid use, pupillary dilation with amphetamine use, nystagmus from phencyclidine (PCP) use
- Lymphadenopathy secondary to nonspecific activation of the immune system as a result of repeated injections of impurities
- Malnourishment as a result of amphetamine abuse (opioid users tend to be well nourished)
- Poor dental care and bruxism (involuntary grinding and clenching of teeth) from amphetamine use
- Nasal perforation from cocaine abuse

Primary concerns for the anesthesia provider are the likelihood of

the patient exhibiting acute abuse or possible withdrawal syndrome.⁶² Signs and symptoms of acute abuse of the more common substances are listed in [Box 20.4](#).^{61,62} Elective surgery should be delayed or canceled in patients suspected of being under the influence of an illicit drug until further patient evaluation can be performed. Suspicion of acute substance abuse should be followed up with a urine screen for drug identification. Abstinence syndrome typically exhibits increased sympathetic and parasympathetic responses resulting in hypertension, tachycardia, abdominal cramping and diarrhea, tremors, anxiety, irritability, [Box 20.4](#) [Continuation](#), mydriasis, algid sweat, and yawning.⁶³

Signs and Symptoms of Acute Substance Abuse

Cannabis (Marijuana or Hashish)

- Tachycardia, labile blood pressure, headache
- Euphoria, dysphoria, depression, occasional anxiety and panic reactions, psychosis (rare)
- Poor memory and decreased motivation with chronic use

Cocaine and Amphetamines

- Tachycardia, labile blood pressure, hypertension, myocardial ischemia, arrhythmias, pulmonary edema
- Excitement, delirium, hallucinations to psychosis
- Euphoria: feeling of excitation, well-being, and enhanced physical strength and mental capacity
- Hyperreflexia, tremors, convulsions, mydriasis, sweating, hyperpyrexia, exhaustion, coma with overdose

Hallucinogens: LSD, PCP

- Sympathomimetic and weak analgesic effects

- Altered perception and judgment; high doses may progress to toxic psychosis
- PCP produces dissociative anesthesia with increasing doses

Opioids

- Respiratory depression, hypotension, bradycardia, constipation
- Euphoria (most marked with heroin)
- Pinpoint pupils with overdose; decreased level of consciousness to coma

LSD, Lysergic acid diethylamide-25; *PCP*, phencyclidine.

From Cheng DCH. The drug addicted patient. *Can J Anaesth.* 1997;44(5 Pt2):R101–R111; Cavaliere F, et al. Anesthesiologic preoperative evaluation of drug addicted patient. *Minerva Anesthesiol.* 2005;71(6):367–371.

Synthetic Androgens

Anabolic steroids are self-administered in an attempt to increase muscle mass, strength, and growth, and improve athletic performance, but such actions can result in hepatic and endocrine system dysfunction. Risks associated with long-term androgen steroid supplementation include impaired liver function, cholestatic jaundice, hepatic adenocarcinoma, peliosis hepatis, myocardial infarction (MI), atherosclerosis, hypercoagulopathy, stroke, hypertension, dyslipidemia, and psychiatric and behavioral disturbances in susceptible patients.^{64–67} The hepatotoxic effects have important implications for the anesthetic management of a chronic steroid abuser, particularly with agents metabolized by the liver, and such patients should undergo preoperative liver function testing.

Herbal Dietary Supplements

Patients should be questioned regarding their use of nonprescription herbal medications to determine the herb's name, the duration of herbal therapy, and the dose taken. If patients are in

doubt as to the herbal medications they are taking, they should be encouraged to bring the herbal products with them to their preoperative workup. Certain herbal products are known to influence blood clotting, affect blood glucose levels, produce CNS stimulation or depression, or interact with psychotropic drugs (Table 20.2).^{68,69} When practical, discontinuation of dietary supplements should be encouraged two to three weeks prior to anesthesia.⁷⁰

TABLE 20.2

Clinically Important Effects and Perioperative Concerns of Selected Herbal Medicines and Recommendations for Discontinuation of Use Before Surgery

Herb: Common Name(s)	Relevant Pharmacologic Effects	Perioperative Concerns	Preoperative Discontinuation
Echinacea: purple coneflower root	Activation of cell-mediated immunity	Allergic reactions; decreased effectiveness of immunosuppressive actions of corticosteroids and cyclosporine; potential for immunosuppression with long-term use; inhibition of hepatic microsomal enzymes may precipitate toxicity of drugs metabolized by the liver (e.g., phenytoin, rifampin, phenobarbital)	No data
Ephedra: ma huang	Increased heart rate and blood pressure through direct and indirect sympathomimetic effects	Risk of myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane; long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability (control hypotension with direct vasoconstrictor, e.g., phenylephrine); life-threatening interaction with monoamine oxidase inhibitors	At least 24 hours before surgery
Garlic: <i>Allium sativum</i>	Inhibition of platelet aggregation (may be irreversible); increased fibrinolysis; equivocal antihypertensive activity	Potential to increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	At least 7 days before surgery
Ginkgo: duck foot tree, maidenhair tree, silver apricot	Inhibition of platelet-activating factor	Potential to increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	At least 36 hours before surgery
Ginseng: American ginseng, Asian ginseng,	Lowers blood glucose; inhibition of platelet aggregation (may be irreversible);	Hypoglycemia; potential to increase risk of bleeding; potential to decrease anticoagulation effect of warfarin	At least 7 days before surgery

Chinese ginseng, Korean ginseng	increased PT-PTT in animals; many other diverse effects		
Kava: awa, intoxicating pepper, kawa	Sedation, anxiolysis	Potential to increase sedative effect of anesthetics; potential for addiction, tolerance, and withdrawal after abstinence unstudied	At least 24 hours before surgery
St John's wort: amber, goat weed, hardhay, <i>Hypericum</i> , klamathweed	Inhibition of neurotransmitter reuptake, monoamine oxidase inhibition is unlikely	Induction of cytochrome P-450 enzymes, affecting cyclosporine, warfarin, steroids, protease inhibitors, and possibly benzodiazepines, calcium channel blockers, and many other drugs; decreased serum digoxin levels	At least 5 days before surgery
Valerian: all heal, garden heliotrope, vandal root	Sedation	Potential to increase sedative effect of anesthetics; benzodiazepine-like acute withdrawal; potential to increase anesthetic requirements with long-term use	No data

PT-PTT, Prothrombin time–partial thromboplastin time.

Patient Evaluation: Overview of Systems

Upper Airway

Assessment of the airway should be performed preoperatively in every patient regardless of the plan of anesthetic management. It is important to evaluate the patient before anesthesia to identify those patients at risk for difficult airway management, for example, difficult bag mask ventilation, or endotracheal intubation. The initial physical examination of the patient includes careful inspection of the teeth, inside of the mouth, mandibular space, and neck in a sequential fashion to determine predictors of airway management difficulties (Table 20.3).⁷¹ Certain body structural features, metabolic disease states, and congenital or acquired structural anomalies are associated with difficult airway management (Box 20.5).^{72,73} The combination of subtle or minor physical anomalies may result in a difficult tracheal intubation even when each factor individually is not expected to pose a problem.

TABLE 20.3

Components of the Preoperative Airway Physical Examination

Airway Examination Component	Nonreassuring Findings
Length of upper incisors	Relatively long
Relation of maxillary and mandibular incisors during normal jaw closure	Prominent "overbite" (maxillary incisors anterior to mandibular incisors)
Relationship of maxillary and mandibular incisors during voluntary protrusion of the jaw	Patient cannot bring mandibular incisors anterior to (in front of) maxillary incisors
Interincisor distance	Less than 3 cm
Visibility of uvula	Not visible when tongue is protruded with patient in sitting position (e.g., Mallampati class greater than II)
Shape of palate	Highly arched or very narrow
Compliance of mandibular space	Stiff, indurated, occupied by mass, or nonresilient
Thyromental distance	Less than three ordinary fingerbreadths
Length of neck	Short
Thickness of neck	Thick
Range of motion of head and neck	Patient cannot touch tip of chin to chest or cannot extend neck

From Apfelbaum JL, et al. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task

Box 20.5

Conditions Associated With Difficult Airway Management

Head

- Mass defects (e.g., encephalocele, soft-tissue sarcoma)
- Macrocephaly (e.g., severe hydrocephaly, Dandy Walker syndrome, mucopolysaccharidoses [Hurler syndrome])
- Interference with airway access (e.g., thoracopagus conjoined twins, stereotactic frame)

Facial Anomalies

- Maxillary and mandibular deformities
- Maxillary hypoplasia (e.g., Apert syndrome, Crouzon disease)
- Mandibular hypoplasia, microgenia, micrognathia (e.g., Pierre Robin syndrome, Treacher Collins syndrome, Goldenhar syndrome, cri du chat syndrome, Nager syndrome)
- Mandibular hyperplasia (e.g., cherubism)
- Temporomandibular joint anomalies
- Reduced mobility (e.g., arthrogryposis multiplex congenita, diabetes, Dutch-Kentucky syndrome, Hecht-Beals syndrome), ankylosis (inflammatory, congenital, traumatic, infectious)

Thoracoabdominal

- Morbid obesity, sleep apnea syndrome, Prader-Willi syndrome
- Kyphoscoliosis

- Prominent chest or large breasts
- Full-term or near-term pregnancy

Mouth and Tongue Anomalies

- Microstomia
- Congenital anomalies (e.g., Freeman-Sheldon [whistling face] syndrome)
- Acquired anomalies (e.g., burn)
- Stomatitis (e.g., noma)
- Tongue disease
- Macroglossia
- Congenital (e.g., Beckwith-Wiedemann syndrome, Down syndrome, congenital hypothyroidism, Pompe disease)
- Swelling (e.g., burns, trauma, Ludwig angina)
- Tumors (e.g., hemangiomas, lymphangioma)
- Protruding upper incisors (e.g., Cockayne syndrome)
- Foreign body

Nasal Pathology

- Choanal atresia
- Tumors (e.g., encephaloceles, gliomas, foreign body)

Palate Pathology

- Arch and cleft defects

- Soft-palate swelling and hematomas

Pharynx

- Adenoid and tonsillar disease
- Hypertrophy
- Tumors and abscesses
- Lingual tonsils
- Pharyngeal wall pathology
- Retropharyngeal and parapharyngeal abscesses
- Inflammatory disease (e.g., epidermolysis bullosa, erythema multiforme bullosum)
- Scarring (e.g., Behçet syndrome)

Laryngeal Pathology

- Supraglottic
- Laryngomalacia
- Supraglottis (epiglottitis)
- Glottic
- Congenital lesions (vocal cord paralysis, laryngeal web, cyst, laryngocele)
- Papillomatosis
- Granuloma formation
- Foreign body
- Subglottic

- Congenital stenosis
- Infectious (croup)
- Inflammatory (edema, traumatic stenosis)

Tracheal and Bronchial Tree Pathology

- Tracheomalacia (e.g., Larsen syndrome)
- Croup
- Bacterial tracheitis
- Mediastinal masses
- Vascular malformation
- Foreign body aspiration
- Other (e.g., tracheal stenosis, webbing, fistula, diverticulum)

Neck

- Mass lesions
- Lymphatic malformation, hemangioma, teratoma, goiter, abscess
- Skin contracture (postburn, inflammatory [scleroderma, epidermolysis bullosa, erythema multiforme bullosum])
- Webbed (e.g., Turner syndrome)

Spine

- Limited cervical spine mobility
- Congenital (e.g., Klippel-Feil syndrome)
- Acquired (e.g., surgical [fusion], trauma [vertebral fracture],

inflammatory [ankylosing spondylitis])

- Cervical spine instability
- Congenital (e.g., Down syndrome, Larsen syndrome, Möbius syndrome, Morquio syndrome)
- Acquired (e.g., trauma [subluxation, fracture], inflammatory [rheumatoid arthritis])

Modified from Holzman RS. Airway management. In Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia: Elsevier; 2017; Litman RS et al. The pediatric airway. In: Cote CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*, 5th ed. Philadelphia: Elsevier; 2013.

Tests for Prediction of Difficult Intubation

Several screening tests for predicting difficult endotracheal intubation are recommended as part of the preoperative patient evaluation. No single test should be relied on exclusively when the airway is evaluated; a combination of evaluative criteria should be used to increase the predictive value for difficult intubation.

Mallampati Classification.

A popular technique for airway assessment is the modified Mallampati airway classification, which entails examination of tongue size relative to the oral cavity.⁷⁴ During the assessment for the Mallampati classification, the patient is seated upright with the head in neutral alignment, while the examiner sits opposite the patient at eye level. The patient is asked to open the mouth as wide as possible and maximally extrude the tongue. The patient is encouraged not to phonate during this maneuver because phonation may inappropriately elevate the soft palate. The airway is then classified based on the structures visible on direct examination of the oropharynx (Fig. 20.1).⁷⁴ Endotracheal intubation is generally easy in a patient with a Mallampati class I airway and can be expected to be difficult in a patient with a Mallampati class III or IV airway. Mallampati airway classification has been criticized as not being a reliable or sensitive predictor of difficult intubating conditions.⁷⁵ Because of the unusually high

incidence of false-positive and false-negative findings associated with the system, it should not be used as the only means of screening for the difficult airway.

FIGURE 20.1 Modified Mallampati classification of pharyngeal structures. *Class I*, Soft palate, tonsillar fauces, tonsillar pillars, and uvula visualized. *Class II*, Soft palate, tonsillar fauces, and uvula visualized. *Class III*, Soft palate and base of uvula visualized. *Class IV*, Soft palate not visualized. (From Samsoon GL, Young JR. Difficult tracheal intubation: a retrospective study. *Anaesthesia*. 1987;42:487–490.)

Thyromental Distance.

Thyromental distance can be quantified to enable prediction of difficulties with laryngoscopy. Thyromental distance represents the straight distance, with the neck fully extended and the mouth closed, between the prominence of the thyroid cartilage and the bony point of the lower mandibular border. In adults, a thyromental distance of less than 7 cm, which is approximately three adult fingerbreadths, is associated with difficult endotracheal intubation because the pharyngeal and laryngeal axes may not properly align, and difficult laryngoscopy can be anticipated.⁷⁶

Interincisor Distance.

The degree of mouth opening, largely a function of the temporomandibular joint, is a vital component of airway assessment. Limited temporomandibular joint movement is a well-recognized contributor to difficult endotracheal intubation. An adult should be able to open the mouth at least 4 cm, allowing two large fingers to be placed between the upper and lower incisors. An interincisor gap of less than two fingerbreadths is associated with

difficulty in endotracheal intubation.⁷⁷ Some patients who are able to open their mouths sufficiently while awake experience limitations in temporomandibular joint mobility after anesthesia is induced. This limited movement renders the visualization of laryngeal structures difficult. In this situation, forward protrusion of the mandible can be attempted for opening the mouth adequately to allow direct laryngoscopy.⁷⁸

Head and Neck Movement (Atlantooccipital Function).

Moderate flexion of the neck on the chest and full extension of the atlantooccipital joint aligns the oral, pharyngeal, and laryngeal axes into the McGill or “sniff” position. In this position, less tongue obscures the laryngeal view during laryngoscopy. Limitations to atlantooccipital joint extension, which are frequently attributed to cervical arthritis or a small C-1 gap, enhance the convexity of the neck and push the larynx anteriorly. This situation can impair laryngoscopy and render endotracheal intubation difficult.

Mandibular Mobility.

Have the patient demonstrate the ability to move the jaw forward and bite their upper lip. Being able to protrude the mandible in front of the central incisors indicates relative ease for maneuvering the laryngoscope.

Dentition

The incidence of perianesthetic dental injury in patients undergoing general anesthesia involving endotracheal intubation ranges from 0.02% to 0.07% and is associated with patients who have preexisting poor dentition and characteristics linked with difficult laryngoscopy and intubation (e.g., limited neck motion, previous head and neck surgery, craniofacial abnormalities, history of previous difficult tracheal intubation). Because dental injuries are the most common reason for anesthesia-related medicolegal claims (accounting for one-third of all claims in the United States),⁷⁹ a preanesthesia inspection of the teeth should be performed and documented for each patient. Otherwise fractured or missing teeth may be falsely attributed to damage occurring during airway

instrumentation. The patient with protuberant or loose maxillary incisors should also be informed of the increased risk of tooth injury or loss with laryngoscopy. An informed consent to proceed with the anesthetic plan, despite this dental risk, must then be documented. If the patient is properly informed of the likelihood of dental damage, the anesthesia provider may not be held liable should dental injury occur.⁸⁰

The location and condition of crowns, braces, and other significant dental work are also noted. Prosthetic devices such as partial plates and dentures are removed before surgery, unless they significantly improve the mask fit. An extremely loose tooth may be extracted before laryngoscopy to prevent its aspiration during anesthesia.

Musculoskeletal System

Obesity

Evaluation of the musculoskeletal system usually begins with a general assessment of the size and stature of the patient. Baseline height and weight information can be obtained from the admission data or by direct questioning of the patient during the health history interview. Body weight is then compared with normal values for a given height in relation to the patient's age and gender. Ideal body weight, for example, can be determined for men and women (Box 20.6). The actual weight of the patient is compared with the calculated ideal body weight. Body weight that is 20% in excess of the ideal body weight at a particular height constitutes obesity. A body weight that is twice the ideal body weight is

Box 20.6 Severe or morbidly obese.

Calculation of Ideal Body Weight and Body Mass Index

Ideal Body Weight (IBW)

IBW (male) = 105 lb + 6 lb for each inch > 5 ft

IBW (female) = 100 lb + 5 lb for each inch > 5 ft

To Calculate Body Mass Index (BMI):

$$\text{BMI} = \text{Weight in kg} / (\text{height in meters})^2$$

Example 1:

$$70 \text{ kg} / 1.7 \text{ m}^2 = 70 \text{ kg} / 2.89 \text{ m} = 24 \text{ kg/m}^2$$

Example 2:

$$125 \text{ kg} / 1.7 \text{ m}^2 = 125 \text{ kg} / 2.89 \text{ m} = 43 \text{ kg/m}^2$$

A more scientific approach to describing weight in relation to height uses the measure of body mass index (BMI). [Box 20.6](#) presents the formula for calculating BMI and incorporates it into examples for an average and an overweight individual of the same height. The adult patient weight classification based on BMI is as follows: overweight, 25 to 29.9 kg/m²; moderate obesity, 30 to 34.9 kg/m²; severe obesity, 35 to 39.9 kg/m²; and morbidly obese, greater than or equal to 40 kg/m².⁸¹ Two-thirds of the adult population in the United States are overweight or obese.⁸² Obese patients are at risk of illness from a multitude of pathologic conditions that require detailed workup.⁸¹ Anesthesia management of the obese patient is discussed in detail in [Chapter 48](#).

The morbidly obese patient is at greater risk for cardiopulmonary aberrations, sleep-disordered breathing, and abnormal airway issues. Preoperative assessment scheduled in advance of the surgery should reflect careful attention to these concerns.⁸¹ Appropriate diagnostic testing prior to bariatric surgery has been proposed ([Box 20.7](#)).^{83,84} Much of this testing centers around the likelihood of patients presenting for bariatric surgery with preexisting metabolic complications or nutritional deficiencies. The extent of preexisting comorbid medical conditions needs to be thoroughly evaluated preoperatively, typically by internal medicine physicians. Serious or life-threatening comorbid conditions associated with obesity are noted in [Box 20.8](#).⁸³ Patients should receive cardiac assessment in accordance with the American Heart Association guidelines.⁸⁵ Asymptomatic patients should be

screened for coronary disease if they have an abnormal baseline electrocardiogram, a history of coronary artery disease/valvular disease, or are more than 50 years of age with at least two of the following: metabolic syndrome, diabetes, hypertension, smoking, dyslipidemia, or family history of coronary disease.⁸⁶ Patients without comorbid conditions may not require further preoperative workup because diagnostic testing should be individualized based on identified needs.⁸⁷

Recommended Diagnostic Testing of Candidates for Bariatric Surgery

- 12-lead electrocardiogram— if at least one risk factor for coronary heart disease, poor functional capacity, or both
- Chest radiograph (posteroanterior and lateral)— if BMI 40 kg/m² or greater
- Complete blood cell count
- Glycosylated hemoglobin
- Serum chemistries with parameters for liver and kidney function
- Fasting blood glucose
- Lipid profile (total cholesterol, triglycerides, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol)
- Thyroid function (thyrotropin)
- Coagulation studies
- Ferritin
- Vitamins (B₁₂, 25-Hydroxyvitamin D, other fat-soluble vitamins if considering a malabsorptive procedure)
- Minerals and trace elements, for example, zinc, selenium, calcium, magnesium

Adapted from Eldar S, et al. A focus on surgical preoperative evaluation of the bariatric patient—the Cleveland Clinic protocol and review of the literature. *The Surgeon*. 2011;9(5):273–277; Poirier P, et al. Cardiovascular evaluation and management of severely obese patients undergoing surgery: a science advisory from the American Heart Association. *Circulation*. 2009;120(1):86–95; Thompson J, et al. Anesthesia case management for bariatric surgery, *AANA J*. 2011;79(2):147–160.

Box 20.8

Comorbid Conditions Associated With Obesity

- Known sleep apnea in which patient is noncompliant with continuous positive airway pressure (CPAP)
- HbA_{1c} (glycosylated hemoglobin) greater than 8% (average blood sugar greater than 200 mg/dL)
- Diabetic nephropathy, retinopathy, or neuropathy
- Cirrhosis
- Pulmonary hypertension
- Pseudotumor cerebri (with severe headaches or impending vision loss)
- Significant coagulopathy (including history of pulmonary embolus, bleeding diathesis, hypercoagulable syndrome, excessive bleeding, more than one deep venous thrombosis, taking Coumadin or clopidogrel medication)
- Chronic steroid therapy
- Oxygen dependent (does not necessarily have to be constant)
- Wheelchair-bound most of the time
- Systemic disease and poor functional capacity (including multiple sclerosis, inflammatory bowel disease, scleroderma, lupus, cancer)

- Severe venous stasis ulcers
- Recent complaint of chest pain (undiagnosed)

Adapted from Eldar S, et al. A focus on surgical preoperative evaluation of the bariatric patient—the Cleveland Clinic protocol and review of the literature. *The Surgeon*. 2011;9(5):273–277.

Obstructive sleep apnea is a breathing disorder, prevalent in the obese population, distinguished by periodic, partial, or complete obstruction of the upper airway during sleep.⁸⁸ More than 70% of patients presenting for bariatric surgery have obstructive sleep apnea.⁸⁷ Particular attention is given to a history of snoring, apneic episodes, frequent arousals during sleep (vocalization, shifting position, extremity movements), morning headaches, and daytime somnolence. The physical examination would include airway evaluation, nasopharyngeal characteristics, neck circumference, tonsil size, and tongue volume.⁸⁸ A concise, easy to use screening questionnaire for undiagnosed obstructive sleep apnea known as *STOP-Bang* (Box 20.9)⁸⁹ has been shown to be highly sensitive for **Box 20.9** diagnosing obstructive sleep apnea severity.⁸⁹

STOP-Bang Questionnaire for Obstructive Sleep Apnea Screening

STOP		
1. Snoring: Do you <i>snore</i> loudly (loud enough to be heard through closed doors)?	Yes	No
2. Tired: Do you often feel <i>tired</i> , fatigued, or sleepy during daytime?	Yes	No
3. Observed: Has anyone <i>observed</i> you stop breathing during your sleep?	Yes	No
4. Blood Pressure: Do you have or are you being treated for high blood <i>pressure</i> ?	Yes	No
Bang		
BMI: BMI more than 35 kg/m ² ?	Yes	No
Age: Age over 50 years old?	Yes	No
Neck circumference: Neck circumference > 40 cm?	Yes	No
Gender: Male?	Yes	No

High risk of OSA: Yes to ≥ 3 questions.

Low risk of OSA: Yes to < 3 questions.

From Chung F, et al. High STOP-Bang score indicates a high probability of obstructive sleep apnoea. *Br J of Anaesth*. 2012;108:768–775.

Polysomnography is the current gold standard test for establishing a clinical diagnosis of obstructive sleep apnea. If the

findings of the history and physical examination are suggestive of obstructive sleep apnea, a decision in consultation with the surgeon should be made regarding obtaining a preoperative sleep study. If the diagnosis of obstructive sleep apnea is confirmed, the patient will be evaluated to determine optimal levels of continuous positive airway pressure (CPAP) therapy. Patients already receiving CPAP therapy will be asked to bring their cleaned home CPAP units to the hospital for postoperative application as needed. If the hospital is to provide the CPAP device, the patient needs to be queried as to the type of interface device the patient uses, pressure settings, and whether supplemental oxygen is required.

Particular attention is given to airway evaluation to determine the likelihood of difficult endotracheal intubation. Patients who are obese, have short, thick necks, or have obstructive sleep apnea have a higher incidence of difficult or failed endotracheal intubation (8%)⁹⁰ than the general population (1:2200).⁸¹ If a problem is anticipated and an awake or fiberoptic tracheal intubation is planned proper patient preparation, which includes a drying agent and proper upper airway anesthesia, should be instituted.

The patient should be questioned about the use of antiobesity drugs such as amphetamines, nonamphetamine Schedule IV appetite suppressants, and antidepressants (e.g., fluoxetine, sertraline).⁹¹

Ankylosing Spondylitis and Rheumatoid Arthritis

Disorders of the musculoskeletal system include degenerative disk disease (osteoarthritis), ankylosing spondylitis, and rheumatoid arthritis. The chronic pain and inflammation of spinal or extraspinal joints associated with these diseases limit the degree of patient mobility. Tolerance for positions required during surgery and regional anesthesia techniques should therefore be ascertained preoperatively. Traditional ankylosing spondylitis multimodal approach of treatments (nonsteroidal antiinflammatory drugs, sulfasalazine, glucocorticoids, and local corticosteroid injections), and biologic therapies (tumor necrosis factor [TNF]- α antagonists) may be included in pharmacologic regimens for such patients.⁹²

If the dosage and duration of corticosteroid therapy are considerable in patients with rheumatoid arthritis, perioperative supplementation also may be necessary to avoid hemodynamic instability. Patients considered at risk for adrenal insufficiency include those who received the hydrocortisone equivalent of more than 20 to 30 mg daily for longer than 2 weeks during the previous year and those who are receiving replacement corticosteroid treatment for adrenal insufficiency.⁹³ Patients with proven or suspected adrenal insufficiency or suppression should be evaluated for perioperative steroid coverage (Table 20.4).⁹⁴ The least amount of steroid supplement perioperatively should be used to minimize the risk of surgical site infection and postoperative wound complications.⁹⁵

TABLE 20.4
Recommendations for Perioperative Glucocorticoid Coverage

Degree of Surgical Stress	Recommended Dose
Minor (inguinal hernia repair)	Preoperative corticosteroid dose + hydrocortisone 25 mg or equivalent
Moderate (lower extremity revascularization, total joint replacement)	Preoperative corticosteroid dose + hydrocortisone 50 mg to 75 mg or equivalent
Major (cardiac surgery, aortic aneurysm repair)	Preoperative corticosteroid dose + hydrocortisone* 100 mg to 150 mg or equivalent every 8 hr for 48 to 72 hr

*Hydrocortisone has mineralocorticoid activity at doses above approximately 100 mg per day. The mineralocorticoid activity of hydrocortisone may produce undesirable side effects including fluid retention, edema, and hypokalemia. It is preferable to use a glucocorticoid without mineralocorticoid activity, such as methylprednisolone, when the total dose of hydrocortisone exceeds 100 mg per day. Methylprednisolone 4 mg is equivalent to hydrocortisone 20 mg.

From Nagelhout J, Elisha S, Waters E. Should I continue or discontinue that medication? *AANA J.* 2009;77(1):59–73.

Although less common than osteoarthritis, ankylosing spondylitis and rheumatoid arthritis have greater implications for anesthetic management. Systemic manifestations are extensive during the advanced stages of both disorders. Patients frequently have pain, inflammation, and limited mobility in affected joints, such as those in the back and hands. Extreme ankylosis and joint deformity often make peripheral venous access and intraoperative positioning a challenge. On physical examination, limited range of

motion of the temporomandibular joint and cervical spine, and reduced mouth opening, can make tracheal intubation more difficult. In rheumatoid arthritis, this limitation is compounded by restrictions in vocal cord movement or tracheal stenosis caused by cricoarytenoid arthritis. These changes may be evidenced by preoperative hoarseness, stridor, painful speech, or dysphagia. Restrictive lung disease, polychondritis, pleural and pericardial effusions, and cardiac conduction abnormalities may be present during advanced stages of ankylosing spondylitis or rheumatoid arthritis.^{92,96}

Neurologic System

Preoperative evaluation of the neurologic system includes the determination of CNS or peripheral nervous system dysfunction. An initial neurologic examination consisting of the following should be performed⁹⁷:

- *Musculoskeletal (motor) system*: Observe the patient's gait, ability to perform toe-and-heel walk, ability to maintain the arms held forward; evaluate the patient's grip strength
- *Sensory system*: Physical distinction of vibration, pain, and light touch on the patient's hands, feet, and limbs
- *Muscle reflexes*: Deep, superficial, and pathologic
- *Cranial nerve abnormalities*: Obtained by patient medical history and observation
- *Mental status and speech pattern*: Appearance, mood, thought processes, cognitive function

Knowledge of clinical manifestations of neurologic disease is essential for the preoperative evaluation of patients with CNS or peripheral nervous system disorders. Signs and symptoms of increasing intracranial pressure and cerebral ischemia are important to note and document a detailed account of preexisting neurological impairment (**Box 20.10**). These abnormalities are most often attributed to vasospasm after a subarachnoid hemorrhage, but myocardial ischemia should be ruled out before surgery.⁹⁸ Fever and leukocytosis can also follow a subarachnoid hemorrhage as a result of meningeal irritation by subarachnoid blood. The

progression of neurologic dysfunction to coma, obtundation, and decerebrate rigidity worsens the overall prognosis of the patient with an intracranial mass or hemorrhage. This prognosis mirrors that of a patient who has sustained an acute head injury. The patient with an initial Glasgow Coma Scale (Table 20.5)⁹⁹ score of less than eight is considered comatose. Patients with a score of eight or less usually require tracheal intubation and mechanical ventilation.¹⁰⁰

Signs and Symptoms of Increased Intracranial Pressure and Ischemia

- Papilledema
- Unilateral or bilateral mydriasis
- Headaches, postural, worse in morning, made worse by coughing
- Nausea and vomiting
- Slurred speech
- Disorientation, and altered levels of consciousness
- Flaccid hemiplegia or hemiparesis
- Abducens or oculomotor palsy
- Neck rigidity
- Respiratory disturbances
- Arterial hypertension, with corresponding decreases in heart rate (represents a physiologic attempt to enhance cerebral perfusion when intracranial pressure is high)
- The appearance of Q waves, deep and inverted T waves, prolonged QT intervals, and ST segment elevations on the electrocardiogram (ECG) may reflect hypothalamic ischemia and sympathetic overactivity.

TABLE 20.5**Glasgow Coma Scale**

Response	Score
Eyes Open	
Spontaneously	4
To speech	3
To pain	2
Never	1
Best Motor Response	
Obeys commands	6
Localizes pain	5
Withdraws (flexion)	4
Abnormal flexion (decortication)	3

Inappropriate words	3
Incomprehensible sounds	2
None	1
Range of Scores	3–15

Modified from Teasdale G, Jennett B. Assessment of coma and impaired consciousness: a practical scale. *Lancet*. 1974; 2(7872):81–84.

Diagnostic reports should be reviewed so that the extent of neurologic and coexisting disease can be determined. These reports include the results of electromyography, conduction velocity studies, electroencephalography, computed tomography (CT), magnetic resonance imaging (MRI), and cerebral arteriography studies. Consultation with a neurologist and obtaining preoperative electromyography, for example, are recommended for patients with complaints of extremity weakness, pain, or paresthesia. This screening is especially important in patients at greater risk for peripheral neuropathy (e.g., patients with long-standing diabetes, patients with uremia, and chronic alcoholics with nutritional deficits).

Documentation of symptoms and reports of abnormal preoperative neurologic findings is important in these patients. Preoperative CT or MRI that reveals a 0.5 cm midline shift of the brain is significant and can confirm suspicions of intracranial hypertension. Additional radiologic signs of raised intracranial pressure include mass, hydrocephalus, cerebral edema, obliteration of cerebral fluid cisterns around the brainstem, and effacement of

ventricles and cortical sulci.¹⁰⁰ The size and location of an intracerebral aneurysm are represented on cerebral arteriography. This information can facilitate the prediction of the surgical approach and guide the evaluation of neurologic involvement. The degree of collateral circulation in the patient with cerebrovascular occlusive disease can be determined from arteriographic films. In a patient with vertebral artery involvement, for example, extremes in head flexion, extension, and rotation are avoided. Because of the associated risks of perioperative myocardial ischemia and infarction in patients undergoing a carotid endarterectomy procedure, a thorough cardiac evaluation by a cardiologist, including 12-lead electrocardiogram (ECG) and stress testing, is advised.¹⁰¹

Information gained from the preoperative evaluation of neurologic function can enlighten the management of a patient with a CNS or peripheral nervous system disorder. For example, sedatives are avoided in patients with intracranial hypertension, especially when an altered level of consciousness accompanies the hypertension. Affected patients may be extremely sensitive to the CNS-depressant effects of such drugs as opioids.

Doses, schedules, and adverse effects of therapeutic regimens should also be considered before surgery. Serum concentrations of anticonvulsants such as phenytoin and phenobarbital do not need to be documented unless drug withdrawal or significant changes are expected.¹⁰² A complete blood cell count is obtained for patients receiving prolonged phenytoin therapy because of the risk of agranulocytosis associated with this drug. As with anticonvulsant therapy, corticosteroid therapy is continued perioperatively in patients with a CNS tumor. Although the exact mechanism of the beneficial effects of corticosteroids is unknown, it is theorized to involve the reduction of cerebrospinal fluid production or cerebral edema as a result of capillary membrane stabilization. Blood glucose levels are also determined for the patient treated with either dexamethasone or methylprednisolone, because hyperglycemia frequently accompanies the use of these drugs. Heightened risks of pulmonary infection and gastrointestinal irritation are unlikely in the patient undergoing perioperative therapy.¹⁰³

Cardiovascular System

Preanesthesia patient evaluation for cardiovascular risk includes the determination of the following: (1) preexisting cardiac disease (e.g., hypertension, ischemic heart disease, valvular dysfunction, cardiac arrhythmias, and cardiac conduction abnormalities, with or without evidence of ventricular failure); (2) disease severity, stability, and prior treatment; (3) comorbidity (e.g., diabetes mellitus, peripheral vascular disease, chronic pulmonary disease, obesity); and (4) surgical procedure. The type of surgery for which the patient is scheduled impacts on the likelihood of developing perioperative adverse cardiac events (cardiac death, MI) within 30 days following surgery (Box 20.11)⁴ The prevalence and adverse consequences of cardiovascular disease make it a prime consideration in the overview of systems.

Surgical Risk Estimates

High Risk (Cardiac Risk Greater Than 5%)

- Aortic surgery
- Major vascular surgery
- Peripheral vascular surgery

Intermediate Risk (Cardiac Risk 1–5%)

- Intraperitoneal
- Transplant (e.g., renal, liver, pulmonary)
- Carotid
- Peripheral arterial angioplasty
- Endovascular aneurysm repair
- Head and neck surgery
- Major neurologic/orthopedic (e.g., spine, hip)

- Intrathoracic
- Major urologic

Low Risk (Cardiac Risk Less Than 1%)

- Breast
- Dental
- Endoscopic
- Superficial
- Endocrine
- Cataract
- Gynecologic
- Reconstructive
- Minor orthopedic (e.g., knee surgery)
- Minor urologic

From De Hert S, et al. Preoperative evaluation of the adult patient undergoing noncardiac surgery: guidelines from the European Society of Anaesthesiology. *Eur J Anaesthesiol.* 2011;28(10):684–722.

Major cardiac conditions that correlate with increased perioperative morbidity and mortality have been described by the European Society of Anaesthesiology (Box 20.12).⁴ In addition, risk indices are available to establish where the patient is on the continuum of risk. There are three tools recommended by the American College of Cardiology Foundation/American Heart Association (ACC/AHA) that serve as predictors for perioperative morbidity and mortality based on cardiac risk factors (Table 20.6)⁸⁵ Lee et al.¹⁰⁴ developed a Revised Cardiac Risk Index (Box 20.13), which offers an improved predictive risk index for major postoperative cardiac complications. The RCRI is the simplest and

most prevalently used, but like the other indices has its limitations on its ability to predict morbidity and mortality in certain subsets of patients.¹⁰⁵ Whenever a patient has signs of significant cardiovascular disease, referral to a cardiologist is indicated for **Box 20-12** assessment and possible intervention.⁴

Active Cardiac Conditions for Which the Patient Should Undergo Evaluation and Treatment Before Noncardiac Surgery

Unstable Coronary Syndromes

- Unstable or severe angina
- Recent myocardial infarction (MI) within 30 days

Decompensated Heart Failure

Significant Arrhythmias

- High-grade atrioventricular block
- Symptomatic ventricular arrhythmias
- Supraventricular arrhythmias with uncontrolled ventricular rate (greater than 100 beats/min at rest)
- Symptomatic bradycardia
- Newly recognized ventricular tachycardia

Severe Valvular Disease

- Severe aortic stenosis (mean pressure gradient greater than 40 mm Hg, area less than 1 cm² or symptomatic)
- Symptomatic mitral stenosis

Clinical Risk Factors

- History of ischemic myocardial disease
- Currently stable but history of heart disease
- History of cerebrovascular disease
- Diabetes (insulin dependent)
- Renal failure (serum creatinine [SCr] greater than 2 mg/dL)

From De Hert S, et al. Preoperative evaluation of the adult patient undergoing noncardiac surgery: guidelines from the European Society of Anaesthesiology. *Eur J Anaesthesiol.* 2011;28(10):684–722.

Box 20.13

Revised Cardiac Risk Index

Risk Categories

- High-risk surgery (aortic, major vascular, peripheral vascular)
- Ischemic heart disease (previous myocardial infarction; previous positive result on stress test, use of nitroglycerin; typical angina; ECG Q waves; previous PCI or CABG)
- History of compensated previous congestive heart failure (history of heart failure; previous pulmonary edema; third heart sound; bilateral rales; evidence of heart failure on chest radiograph)
- History of cerebrovascular disease (previous TIA; previous stroke)
- Diabetes mellitus (with or without preoperative insulin)
- Renal insufficiency (creatinine greater than 2.0 mg/dL)

Estimated Rates for Postoperative Major Cardiac Complications Per Number of Risks

- 0 Risk Factors: 0.4%
- 1 Risk Factor: 0.9%
- 2 Risk Factors: 7%
- 3 or more Risk Factors: 11%

CABG, Coronary artery bypass grafting; *ECG*, electrocardiogram; *PCI*, percutaneous coronary intervention; *TIA*, transient ischemic

attack.

From Lee TH, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100(10):1043–1049; Freeman WK, Gibbons RJ. Perioperative cardiovascular assessment of patients undergoing noncardiac surgery. *Mayo Clin Proc*. 2009;84(1):79–90.

The patient's functional capacity, measured in metabolic equivalents (METs), can be simply and accurately assessed preoperatively by asking a set of questions (Table 20.7)^{85,106} and is recommended as part of cardiac risk assessment.¹⁰⁷ Patients with good functional capacity (more than 4 METs) may proceed for surgery provided patients with cardiac risk factors are properly managed with statin and β -blocker therapy as described later in this section.¹⁴ Good functional capacity (more than 4 METs) may be determined by an affirmative answer to two simple questions: (1) Are you able to walk four blocks without stopping regardless of limiting symptoms? (2) Are you able to climb two flights of stairs without stopping regardless of limiting symptoms?¹⁰⁸ The inability to climb two flights of stairs or walk a short distance is indicative of poor functional capacity and is associated with an increased incidence of postoperative cardiac complications in noncardiac surgery.^{109,110} Patients with moderate to poor functional capacity (less than 4 METs) should be further assessed to identify cardiac risk factors.¹¹¹

TABLE 20.7

Exercise Tolerance in Metabolic Equivalents (METs) for Various Activities

Estimated Energy Expenditure	Physical Activity
1 MET*	<i>Poor functional capacity</i> Self-care. Eating, dressing, or using the toilet. Walking indoors and around the house. Walking one to two blocks on level ground at 2 to 3 mph ² .
4 METs	<i>Good functional capacity</i> Light housework (e.g., dusting, washing dishes). Climbing a flight of stairs without stopping, or walking up a hill longer than 1 to 2 blocks. Walking on level ground at 4 mph Running a short distance. Heavy housework (e.g., scrubbing floors, moving heavy furniture). Moderate recreational activities (e.g., golf, dancing, doubles tennis, throwing a baseball or football).
Greater than 10 METs	<i>Excellent functional capacity</i> Strenuous sports (e.g., basketball, cross-country skiing [> 8 km/hr] ³ , rope skipping,

running, soccer, swimming [> 3.5 km/hr], weight training).

*MET is defined as the amount of oxygen consumed while sitting at rest and is equal to 3.5 mL oxygen/kg per min.

mph, Miles per hour; *km/hr*, kilometer per hour.

Modified from Jetté M, et al. Metabolic equivalents (METS) in exercise testing, exercise prescription, and evaluation of functional capacity. *Clin Cardiol.* 1990;13(8):555–565; Fleisher LA, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery. *J Am Coll Cardiol.* 2014;64:e77–e137.

A standard means of categorizing the degree of cardiovascular disability is the New York Heart Association classification tool (Table 20.8).¹¹² When the patient interview is conducted, specific inquiry should be made regarding the presence of dyspnea, chest pain, fatigability, syncope, palpitation, and the factors that predispose to angina.

TABLE 20.8

New York Heart Association Functional Classification of Cardiovascular Disability

Classification	Cardiovascular Status
Class I	<i>Patients with cardiac disease</i>
	No functional limitations to physical activity, such as walking or climbing stairs. Ordinary physical activity is not associated with undue fatigue, palpitations, dyspnea, or anginal pain.
Class II	<i>Patients with cardiac disease who are comfortable at rest</i>
	Slight functional limitations to physical activity, such as walking or climbing stairs rapidly, or during emotional stress. Patients are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
Class III	<i>Patients with cardiac disease resulting in marked limitations to physical activity</i>
	Patients are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.
Class IV	<i>Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort</i>
	Symptoms of cardiac insufficiency or anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

Modified from Horak J, et al. Assessment of cardiac risk and the cardiology consultation. In Kaplan JA, Reich DL, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*, 6th ed. Philadelphia: Elsevier; 2011.

Hypertension

Hypertension, defined as a systolic blood pressure greater than 140/90 mm Hg for patients aged 30 to 59 years and 150/90 for

patients aged 60 years and older,¹¹³ is the most common circulatory derangement to affect humans, and is a major risk factor for coronary artery disease¹¹⁰ and increased perioperative mortality.¹¹⁴ Approximately 52.6% of the population has a formal diagnosis of hypertension, with 60% being adults older than 60 years.¹¹⁵ Increasingly, patients undergoing surgery have stage 2 hypertension and accompanying target-organ damage, or uncontrolled stage 3 hypertension (systolic blood pressure greater than 180 mm Hg, diastolic pressure greater than 110 mm Hg, or both). This problem can be attributed to the lack of or inadequacy of medical treatment, or to patient noncompliance. In such a situation, elective surgery may be postponed for further patient assessment and normalization of the preoperative blood pressure.^{116,117} Consultation with an internist can be pursued for the medical evaluation and treatment of the patient with uncontrolled or newly diagnosed hypertension. These recommendations are aimed at reducing the occurrence of perioperative hemodynamic instability and consequently the incidence of myocardial ischemia. Both complications are more likely to occur when hypertension is not effectively treated before surgery.¹¹⁸ With the goal of reducing perioperative risk, delaying surgery is justified in hypertensive patients with target-organ damage (or suspected damage) such as ischemic heart disease, heart failure, renal damage, and cerebrovascular diseases if either of the following scenarios is probable¹¹⁹:

- Conditions can be improved by such postponement to the extent that the perioperative risk would be considerably decreased.
- Care may be influenced by further preoperative examination.

Delaying elective surgery in patients with mild to moderate hypertension only for the purpose of blood pressure control may not reduce perioperative risk.¹¹⁹ A systolic blood pressure below 180 mm Hg and diastolic blood pressure below 110 mm Hg is not an independent risk factor for perioperative cardiovascular complications.⁸⁵

The practitioner taking the medical history should focus on identifying comorbid diseases, such as diabetes mellitus, and social risk factors (i.e., tobacco use, alcohol or caffeine consumption, illicit drug use [especially cocaine or amphetamines]). What medications

the patient takes to manage hypertension should be established. In general, the substances used affect the central and peripheral components of the sympathetic nervous system by altering the synthesis, release, biotransformation, or end-organ action of norepinephrine. Because the circulatory-depressant effects of general anesthesia may be additive, the combination of antihypertensive drugs and anesthetics is of concern. Complaints of syncope and dizziness also are investigated. These symptoms may be the clinical manifestations of cerebrovascular insufficiency, although a diagnosis of drug-induced orthostatic hypotension should be considered preoperatively. This diagnosis can be confirmed by measuring a significant decrease in the blood pressure as the patient rises from the supine position. The lack of hemodynamic compensatory responses that normally accompany positional changes may then predict their absence during anesthesia and surgery.

The physical examination of the patient includes the following¹²⁰:

- *Overall appearance*: Truncal obesity with purpura and striae suggestive of Cushing disease
- *Vital signs*: Measurement of blood pressure in both arms
- *Fundusoscopic examination*: Hypertensive retinopathy
- *Neck*: Carotid bruits, distended veins, or enlarged thyroid gland
- *Heart*: Abnormal rhythm or size, murmurs, or heart sounds
- *Lungs*: Rales or bronchospasm
- *Abdomen*: Bruits, masses, enlarged kidneys, or abnormal aortic pulsation
- *Extremities*: Delayed or absent femoral pulses secondary to aortic coarctation; evidence of atherosclerosis, peripheral edema
- *Neurologic evaluation*: See the discussion of the neurologic system earlier in this chapter.

Ischemic Heart Disease

Myocardial ischemia occurs secondary to insufficient oxygen and nutrient supply (increased demand, reduced blood supply, or both) to meet the metabolic requirements of the myocardial cells. Nearly one-third of the estimated 30 million patients undergoing surgery

annually in the United States is at high risk for coronary artery disease or factors for cardiovascular disease.¹²¹ Risk factors for ischemic heart disease include advanced age, smoking, diabetes mellitus, hypertension, pulmonary disease, previous MI, left ventricular wall motion dysfunction, and peripheral vascular disease.¹²² The preoperative evaluation of a patient with known or suspected ischemic heart disease is aimed at determining the severity, progression, and functional limitations imposed by cardiovascular disease. Myocardial ischemia, cardiac arrhythmias, and left ventricular dysfunction are usually precipitating factors for patient symptomatology. Complaints of undue fatigue, angina pectoris, palpitations, syncope, or dyspnea should be thoroughly investigated. A 12-lead ECG can be reviewed for evidence of myocardial ischemia or infarction, cardiac arrhythmias or conduction abnormalities, and ventricular hypertrophy. Routine testing with a 12-lead ECG is not recommended for low risk surgeries. Testing with a 12-lead ECG is recommended only for patients with known coronary heart disease or other significant structural heart disease.⁸⁵ However, signs and symptoms of myocardial ischemia may not be apparent at rest. Therefore, the response of the patient to various activities such as walking a certain distance or climbing several stairs must be determined (see [Tables 20.7^{85,106}](#) and [20.8](#)).¹¹²

Anginal symptoms can also be classified according to the stability of precipitating factors, the frequency of the events, and the duration of pain. Stable angina (characterized as substernal discomfort brought on by exertion, relieved by rest or nitroglycerin or both in less than 15 minutes, and having a typical radiation to the shoulder, jaw, or the inner aspect of the arm)¹¹² poses no greater threat of MI perioperatively than the absence of anginal symptoms.¹²³ Unstable angina is defined as newly developed angina occurring within the past 2 months; angina that has progressively worsened, that occurs with increased frequency, intensity, or duration, that is less responsive to medicine, or that occurs when the patient is at rest; or angina that lasts longer than 30 minutes, exhibiting transient ST- or T-wave changes without development of Q waves or diagnostic elevation of enzymes.¹¹² *Unstable angina is associated with the highest risk for perioperative MI.*¹²⁴

In the patient with unstable angina, elective surgery is canceled until the cardiovascular status of the patient has been thoroughly evaluated and optimized. Advanced diagnostic techniques such as coronary angiography and exercise ECG may be used for determination of the extent and functional impairment of ischemic heart disease.

The overall risk of MI after general anesthesia is approximately 0.3% in the population at large.¹²⁵ In patients known to have had an MI between 3 and 6 months of surgery, the risk of perioperative reinfarction increases to approximately 6%. If the MI occurred 1 to 2 months prior to surgery, the risk of reinfarction is approximately 19%. The reinfarction rate is 33% if surgery is performed within less than 30 days of the MI.⁸⁵ If reinfarction occurs, the mortality rate is approximately 50%. The highest at-risk period appears to be within 30 days after an acute MI; therefore the ACC/AHA⁸⁵ guidelines recommend waiting at least 60 days after an MI before a patient undergoes elective surgery. Patients who have survived coronary revascularization and are asymptomatic are at lower risk of reinfarction when undergoing noncardiac surgery.⁸⁵ The new clinical classification of MI is noted in [Table 20.9](#).¹²⁶

TABLE 20.9
New Clinical Classifications of Myocardial Infarction

Classification	Description
1	Spontaneous myocardial infarction (MI) related to ischemia due to a primary coronary event, such as plaque erosion and/or rupture, fissuring, or dissection
2	MI secondary to ischemia due to an imbalance of O ₂ supply and demand, as from coronary spasm or embolism, anemia, arrhythmias, hypertension, or hypotension
3	Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggesting ischemia with new ST segment elevation, new left bundle branch block, or pathologic or angiographic evidence of fresh coronary thrombus—in the absence of reliable biomarker findings
4a	MI associated with PCI
4b	MI associated with documented in-stent thrombosis
5	MI associated with CABG surgery

CABG, Coronary artery bypass graft; *PCI*, percutaneous coronary intervention.

From Thygensen K, et al. Writing group on behalf of the Joint ESC/ACCF/AHA/WHF Task Force for the redefinition of myocardial infarction. Third universal definition of myocardial infarction. *Global Heart*. 2012;7:275–295.

Coronary Stents.

Approximately 528,000 coronary stents are placed annually in US patients to open clogged coronary arteries.¹²⁷ Coronary stents (either bare metal or drug-eluting) were designed to prevent arterial restenosis after percutaneous coronary intervention (PCI) with balloon angioplasty. Bare metal stents, although beneficial over balloon angioplasty in reducing the incidence of restenosis, experience a restenosis rate of 20%.¹²⁸ Drug-eluting stents were developed to further reduce the incidence of stent thrombosis, and restenosis rates approaching 5% after 2 years are reported.¹²⁹ Postprocedure pharmacotherapy involves long-term oral dual antiplatelet therapy (DAPT) consisting of aspirin (continued almost always indefinitely) and a P2Y₁₂ inhibitor (clopidogrel, prasugrel, or ticagrelor), which is continued for a minimum of 6 months to prevent in-stent coronary artery restenosis.¹³⁰ Approximately 5% of these patients will require noncardiac surgery within 1 year after placement of coronary stents.¹³¹ There is an increased risk of coronary stent thrombosis, perioperative MI, hemorrhagic complications, and death in patients having noncardiac surgery performed early after stent placement.^{132,133} Fig. 20.2¹³⁰ describes preoperative assessment and management considerations for patients presenting for surgery in which coronary artery stents have been placed. Management of patients with coronary stents is discussed in detail in [Chapter 38](#).

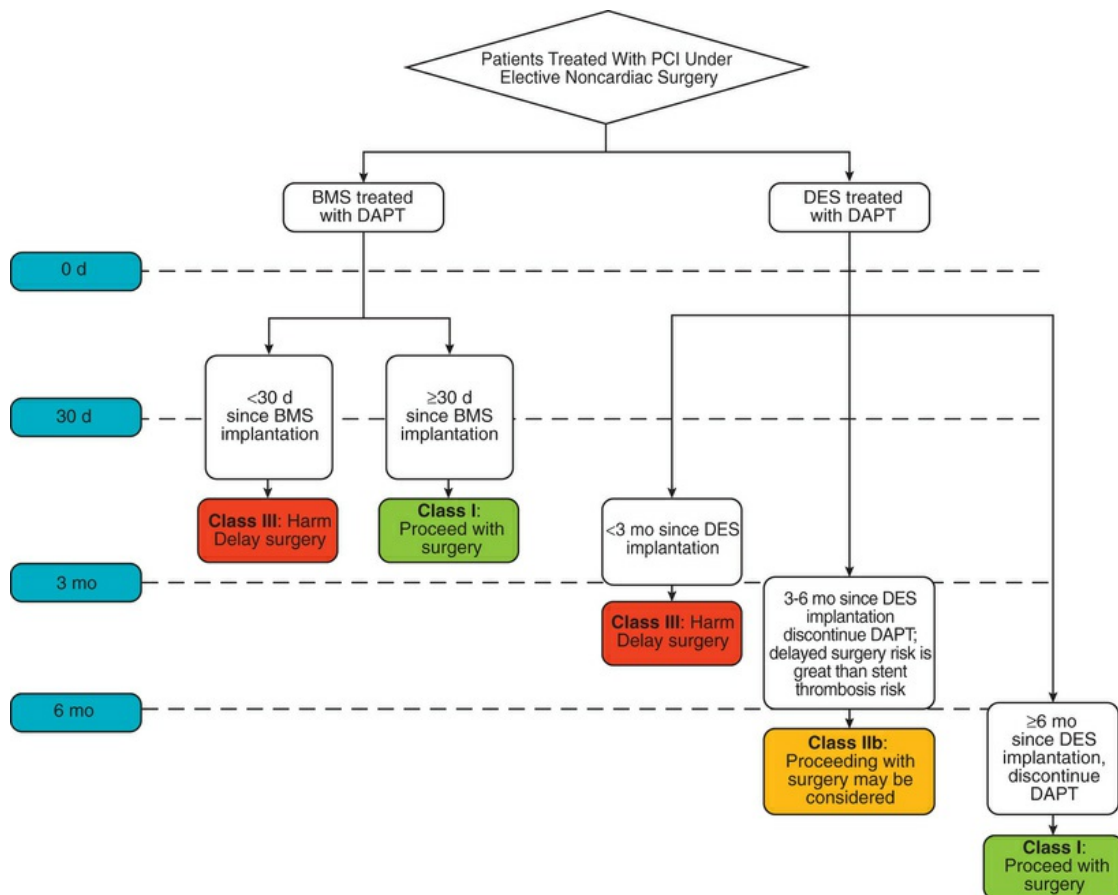

FIGURE 20.2 Treatment algorithm for the timing of elective noncardiac surgery in patients with coronary stents. *BMS*, Bare metal stent; *DAPT*, dual antiplatelet therapy; *DES*, drug-eluting stent; *PCI*, percutaneous coronary intervention. (From Levine GN, et al. 2016 ACC/AHA Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients With Coronary Artery Disease: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *J Am Coll Cardiol*. 2016;68:1082–115.)

Left Ventricular Dysfunction

Active left ventricular failure is the prominent cardiovascular risk factor for patients undergoing noncardiac surgery.¹³⁴ Heart failure can be broken down into two subsets of patients: those with preserved ejection fraction (EF \geq 50%), and those with reduced ejection fraction (EF $<$ 49%).¹³⁵ Although patients with heart failure with preserved EF (HFpEF) have better perioperative outcomes than do patients with reduced EF (HFrEF), a diagnosis of heart failure places patients at significantly higher risk of perioperative

mortality than other disease processes.⁸⁵ Patients with ischemic cardiomyopathy are at even greater risk for perioperative MI and ventricular dysfunction.¹³⁶ Heart failure is defined by the presence of any of the following: history of congestive heart failure, pulmonary edema, or paroxysmal nocturnal dyspnea; physical examination showing bilateral rales or S₃ gallop; or chest x-ray showing pulmonary vascular redistribution.⁸⁵ Prominent signs include moist rales in the lungs often associated with tachypnea. These extraneous sounds may be confined to the bases, with mild degrees of left ventricular failure, or they may be generalized throughout the lungs with acute pulmonary edema. As a result of sympathetic nervous system stimulation, resting tachycardia may also be present. A third heart sound (S₃) or ventricular gallop, jugular vein distention, and peripheral edema are significant. In the presence of congestive heart failure as confirmed by a chest radiograph, elective surgery should be postponed until optimal ventricular performance can be achieved.

Patients exhibiting dyspnea of unknown origin, current or prior heart failure with worsening dyspnea, or other relevant change in clinical status should undergo preoperative evaluation of left ventricular function if an assessment has not been performed within the previous 12 months.⁸⁵ Tests of resting left ventricular function include cardiac magnetic resonance,¹³⁷ radionuclide angiography, two-dimensional echocardiography, and contrast ventriculography. Systolic left ventricular dysfunction is defined as a left ventricular ejection fraction of less than 50% with and without accompanying diastolic dysfunction.¹³⁸ A left ventricular ejection fraction of less than 35% as determined by echocardiography is associated with greater incidence of postoperative heart failure and death.¹³⁹

Valvular Heart Disease

Basic lesions of valvular heart disease may involve stenosis, incompetence, or both. In adults aortic and mitral valve lesions are more common than those involving the tricuspid or pulmonic valve. Despite decreasing incidence, rheumatic heart disease is still the most common cause of adult valvular disease. Degenerative

disorders (sclerosis, fibrosis) and congenital diseases are less common causes. With stenosis the chamber proximal to the obstruction must increase the work of maintaining a stroke volume; this eventually results in hypertrophy. Normal valves can episodically accommodate up to seven times the normal cardiac output—for example, in intense physical exercise in the normally active patient. Valvular stenosis is usually chronic and severe before cardiac output decreases. In valvular incompetence, the chambers both proximal and distal to the lesions are involved, because regurgitant flow during one phase of the cardiac cycle is added to forward flow during subsequent systole. Because lesions are almost never entirely unitary, in stenosis some regurgitation is common and vice versa. It is important to identify the type of valvular lesion before surgery. Evaluation of the clinical symptoms and cardiac catheterization data regarding valve area and gradients, combined with assessment of data from any surgical history (e.g., correction of congenital heart lesions), is an important component of the preoperative evaluation of patients with valvular heart disease.

Severe aortic stenosis poses the greatest patient risk for noncardiac surgery,⁸⁵ especially when the cross-sectional area of the aortic valve is less than 1 cm². Severe aortic stenosis is associated with a fourteenfold greater incidence of perioperative sudden death.¹⁴⁰ When moderate to severe valvular stenosis or regurgitation is suspected, an echocardiogram should be obtained if one has not been performed within the previous year, or if significant change in clinical status is present.⁸⁵ For patients in whom aortic stenosis is symptomatic, elective noncardiac surgery should be postponed until after cardiac surgical consultation.⁸⁵ [Chapter 25](#) describes the perioperative care of patients with valvular heart disease.

Arrhythmias

Patients with cardiac arrhythmias must have an adequate preoperative evaluation to ascertain the nature of the arrhythmia, associated underlying heart disease, and type of antiarrhythmic therapy. Whether symptoms of palpitations or dizziness have been relieved may be a sign of successful therapy or continuing

problems. Other cardiac symptoms such as dyspnea, angina, or syncope may suggest worsening of associated cardiac disease. Treatment of the underlying disease preoperatively may aid in control of arrhythmia in the perioperative period. All patients with a history of symptomatic arrhythmias should undergo electrocardiography with rhythm strip before surgery. Other preoperative laboratory evaluations should include measurement of potassium and magnesium levels, determination of antiarrhythmic drug levels (if possible), and chest radiography (in the presence of structural cardiac disease).

Ventricular arrhythmias are classified into three categories: benign ventricular arrhythmias (unifocal premature ventricular contractions); potentially malignant ventricular arrhythmias (patient has known organic heart disease and is on antiarrhythmic therapy); and malignant ventricular arrhythmias (patient has organic heart disease, hemodynamic compromise, and possibly a family history of sudden death).¹⁴¹ Few data are available to help correlate the risk of arrhythmias and perioperative risk.¹¹² In the absence of cardiac disease, benign ventricular arrhythmias do not carry a significantly increased surgical risk.¹⁴² In patients with severe coronary artery disease, recent MI, or peripheral vascular disease, arrhythmias may increase perioperative risk.^{143,144}

Cardiovascular Implantable Electronic Devices (Pacemaker, Implantable Defibrillators)

When a patient presents for surgery with an implanted cardiac device, preprocedural planning must be employed to minimize risk both to the patient and the device. This planning includes knowledge of the device, its indication for use, and functional assessment ([Box 20.14](#)).¹⁴⁵⁻¹⁴⁸ Because of the evolving complexity of these devices, direct interrogation by a qualified member of the cardiovascular implantable electronic device (CIED) management team remains the only trustworthy method for evaluating battery status, lead performance, and adequacy of current settings.¹⁴⁹ Pacemakers can mask the toxicity of antiarrhythmic drugs, electrolyte disorders, and myocardial ischemia and irritability. In general, the ECG should be examined for pacemaker malfunction as

evidenced by unexpected pauses. If the patient's heart rate is slower than the pacing rate, pacing spikes should appear on the ECG. To determine whether these pacing impulses are associated with myocardial contractions, the clinician should palpate a peripheral pulse. Evaluation of a pacemaker becomes more difficult when the patient's heart rate is faster than the pacing rate. A Valsalva maneuver slows the patient's rate so that pacing impulses appear on the ECG. Generally, because sensing is lost before pacing, the pacemaker is probably functioning normally if: (1) it has been in place for fewer than 2 years, (2) chest radiography demonstrates that leads are intact, and (3) impulses do not appear on the ECG.¹⁵⁰ Chest radiography should provide information on electrode placement, the presence of electrode fracture, and even battery

Box 20.14¹⁵¹

Perioperative Guidelines for the Patient With a Cardiovascular Implantable Electronic Device

Preoperative Key Points

- Establish the indication for the permanent pacemaker, for example, symptomatic third-degree heart block, type II second-degree heart block, sinus node dysfunction, recurrent neurally mediated syncope, some forms of cardiomyopathy.
- Establish the indication for the implantable defibrillator, for example, history of cardiac arrest not secondary to a temporary condition.
- Identify device and manufacturer (available from manufacturer's identification card).
- Notify the cardiovascular implantable electronic device (CIED) management team of the planned procedure, including anatomic location of surgery, whether monopolar electrosurgery will be used, and whether other sources of electromechanical interference (EMI) will be present. Have the pacemaker or defibrillator interrogated by a qualified member of the CIED

management team (physicians or staff) who monitor the device function shortly before the anesthetic. Pacemakers should be routinely interrogated annually and implantable cardioverter devices (ICDs) every 3 to 4 months. Pacemakers should be assessed within 12 months of elective surgery. ICD function should be assessed within 6 months of surgery.

- Obtain a copy of this interrogation, including current settings. Ensure that the device will pace the heart with appropriate safety margins.
- A prescription for the perioperative management of the patient with the CIED should be communicated to the procedure team from the CIED team.
- Consider replacing any device near the end of its elective replacement period in a patient scheduled to undergo either a major surgery or surgery within 25 cm of the generator.
- Is the patient device dependent for antibradycardia? Determine the patient's underlying rhythm/rate to evaluate the need for backup pacing support.
- Evaluate effect of magnet on pacemaker function. Identify the magnet rate and rhythm if a magnet mode is present and magnet use is planned. Will device automatically reset to preoperative settings when a magnet is removed?
- Program minute ventilation rate responsiveness to "Off," if present.
- Program all rate enhancements to "Off."
- Consider increasing the pacing rate to optimize oxygen delivery to tissues for major cases.
- Inactivation of ICD tachyarrhythmia detection is recommended for all procedures using monopolar electrosurgery or radiofrequency ablation above the umbilicus. ICD arrhythmia detection can be suspended by placement of a magnet over the

pulse generator.

Intraoperative Key Points

- Is electromagnetic interference (EMI) likely during the procedure? Interference is unlikely if the device is less than 10 years old and bipolar cautery is greater than 15 cm (below the umbilicus) from device lead or generator.
- Have a magnet immediately available for patients with CIEDs who are undergoing a procedure that may involve EMI.
- Monitor cardiac rhythm/peripheral pulse with pulse oximeter or arterial waveform.
- Disable the “artifact filter” on the electrocardiogram (ECG) monitor.
- Avoid use of monopolar electrosurgery.
- Use bipolar electrocautery system or ultrasonic (harmonic) scalpel if possible; if not possible, then pure cut (monopolar electrosurgery) with short bursts of 5 seconds or less is better than “blend” or “coag.”
- Position the electrosurgical unit (ESU) current return pad in such a way that it will prevent electricity from crossing the generator-heart circuit, even if the pad must be placed on the distal forearm and the wire covered with sterile drape.
- If the ESU causes ventricular oversensing, pacemaker quiescence, or tachycardia, limit the period(s) of asystole or reprogram the device.

Postoperative Key Points

- Have the device interrogated by a qualified member of the team (physician or staff) who monitors the device function postoperatively. Some rate enhancements can be reinitiated, and

optimum heart rate and pacing parameters should be determined. The ICD patient must be monitored until the antitachycardia therapy is restored.

If each pacing impulse is not associated with a pulse, or if the symptoms that led to pacemaker implantation have returned, cardiology consultation should be considered.¹⁵⁰ Anesthesia providers sometimes must decide whether a transvenous, temporary pacing wire should be inserted preoperatively. Persistent bradycardia not responsive to intravenous administration of atropine or exercise is one indication. Bifascicular block in a patient with a history of syncope suggests underlying, unrecognized complete heart block. Such patients can benefit from the availability of transvenous pacing.

It also must be determined whether exercising the muscles adjacent to the generator causes dizziness. The presence of this symptom, indicating that myopotentials may be inhibiting the pacemaker, implies that muscle fasciculations caused by succinylcholine and shivering should be avoided. A complete discussion of anesthetic management of patients with cardiac devices can be found in [Chapter 27](#).

Diagnostic Testing to Assess Cardiovascular Disease

Multiple tests are available to define the presence of cardiac disease. Preoperative cardiac testing should not be performed unless the results are likely to influence patient management. The ACC/AHA guidelines include an algorithm for determining the appropriateness of preoperative testing.⁸⁵

Several noninvasive tests are available for preoperative assessment of the high-risk patient (i.e., three or more risk factors and poor functional capacity). A 12-lead ECG alone is not a predictor of perioperative major adverse cardiac events. Therefore it is often useful to use this test as an adjunct to other noninvasive testing regimens.¹⁵² The exercise stress ECG is preferred.¹³⁷ Stress testing with exercise or pharmacologic stress agents is designed to increase myocardial work and permit measurement of myocardial

response to the increased workload. The exercise stress test not only is a standardized means of obtaining a functional history of angina but also provides excellent documentation of how ischemia manifests its effects on the cardiovascular system. By examining the stress test report one can learn the extremes of blood pressure and heart rate the patient can tolerate while awake (although exactly how these correlate with the anesthetized state is a matter of debate), the location of ischemic leads, and whether arrhythmias are associated with ischemia. Significant coronary disease is likely if ST segment depression is greater than 0.2 mV, if ST depression occurs early in the test, if little increase in blood pressure or heart rate occurs at the time of ST depression, or if hypotension occurs. Hypotension is considered an ominous finding and usually prompts cardiac catheterization.

Patients with good exercise tolerance rarely benefit from more than the exercise stress test.¹⁵³ Perioperative risk is considered low if exercise stress testing does not produce signs of myocardial ischemia at a reasonable workload (greater than 85% of predicted maximum heart rate).¹⁵⁴ Although it is useful in diagnosing coronary artery disease, its value as a preoperative test has been questioned,¹⁰⁴ even in patients undergoing major vascular surgery.¹⁵⁵ Stress testing is not indicated in patients with intermediate risk factors (i.e., fewer than three risk factors), even if major vascular surgery is planned, provided the patient has complete heart rate control with β -blocker therapy.¹⁰⁸ Patients who are able to tolerate a good exercise stress workload, even those with stable angina, are unlikely to have myocardial dysfunction.¹⁵⁶

Pharmacologic stress testing can be performed in patients unable to exercise or in those who take digoxin. Two pharmacologic techniques, which incorporate either echocardiography or radionuclide scintigraphy, are used: (1) dipyridamole or adenosine, both of which cause a coronary steal phenomenon by redistributing coronary blood flow without direct negative inotropic effects, and (2) dobutamine for inotropic stress testing.¹⁵⁷

Additional noninvasive studies are available for preoperative testing such as stress myocardial perfusion imaging (MPI), stress echocardiography, resting transthoracic echocardiography, pharmacologic stress echocardiography, cardiac computed

tomography, cardiac magnetic resonance (CMR), and adenosine stress CMR.^{137,158} The discovery of any defect is highly predictive of an increased likelihood of a postoperative cardiac event.⁸⁵ There is insufficient evidence to support the clinical utility and development of appropriate guidelines for these tests at this time.¹³⁷

Cardiac catheterization provides definitive information about the distribution and severity of coronary artery disease and may be indicated for patients with New York Heart Association class III or IV criteria who are undergoing high-risk surgical procedures.¹⁵⁴ Significant stenosis means narrowing of a major coronary artery by more than 70%, or narrowing of the left main coronary artery by more than 50%. However, it is important to look beyond the coronary anatomy and concentrate on other findings that can guide perioperative decision making.

Three readily identifiable findings that indicate poor ventricular function are a cardiac index of less than 2.2 L/m², a left ventricular end-diastolic pressure of greater than 18 mm Hg, and an ejection fraction of less than 40%.¹⁵⁹ Taking note of ischemia-induced dysfunction of the papillary muscles can help in avoiding later confusion about the configuration of the pulmonary wedge pressure waveform and the significance of intraoperative changes in wedge pressure. Wall motion abnormalities should be noted. Areas of akinesis (no movement during systole) usually represent nonviable regions of myocardium and are relatively fixed deficits. In contrast, areas of hypokinesis (reduced contraction during systole) may represent ischemic but nonetheless viable regions of myocardium. This should alert anesthesia providers to a potentially dynamic situation in which alterations in the balance of myocardial oxygen supply and demand can either improve or worsen regional ischemia and associated contractility.

Cardioprotective Pharmacotherapy

Appropriate pharmacologic therapy should be instituted preoperatively in patients exhibiting clinical risk factors (e.g., angina pectoris, prior MI, heart failure, stroke/transient ischemic attack, renal dysfunction, and diabetes mellitus requiring insulin therapy) and moderate to poor functional capacity. Patients having up to two clinical risk factors should be managed with statin and β -

blocker therapy preoperatively.¹⁴ If stable left ventricular dysfunction is present, angiotensin-converting enzyme (ACE) inhibitor therapy is recommended.

Statins.

In addition to their lipid-lowering benefit, statins are valuable for enhancing endothelial function, improving atherosclerotic plaque stability, decreasing oxidative stress, and reducing vascular inflammation. Common statins used perioperatively include atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin.¹⁶⁰ Recommendations are as follows¹⁶¹:

- Institute therapy between 30 days and at least 1 week before high-risk surgery.
- Continue statin therapy perioperatively.

β-Blockers.

Low-dose titration of β-blockers restores the oxygen supply/demand mismatch, reduces perioperative ischemia, redistributes coronary blood flow to the subendocardium, stabilizes plaques, increases ventricular fibrillation threshold, and may reduce the risk of MI and death in high-risk patients undergoing cardiac surgery.¹⁴ The routine use of β-blockers in low-risk patients or patients having noncardiac surgery has been associated with increased rates of mortality and morbidity from hypotension, bradycardia, and stroke^{85,161,162} Recommendations are as follows:

- Continue β-blockers in patients previously treated with β-blockers for ischemic heart disease, symptomatic arrhythmia, or hypertension.
- Indicated for patients with high cardiac risk, known ischemic heart disease, or stress-induced myocardial ischemia who present for high-risk cardiovascular surgery.
- Initiation of β-blocker therapy should occur long enough in advance of the procedure (> 45 days) in order to assess patient tolerance to therapy.

ACE Inhibitors.

ACE inhibitors are beneficial in reducing heart failure, MI, and

death when administered in the perioperative period in patients with left ventricular dysfunction.¹⁶³ Common ACE inhibitors used perioperatively include captopril, enalapril, lisinopril, benazepril, and ramipril. Recommendations are as follows¹⁴:

- Recommended in cardiac stable patients with left ventricular dysfunction for intermediate- to high-risk surgery and considered for those scheduled for low-risk surgery.

Antiplatelet Agents.

DAPT is prescribed for patients who have undergone PCI with coronary artery stent placement. The regimen includes aspirin and a P2Y₁₂ inhibitor (clopidogrel, prasugrel, ticagrelor, cangrelor). Recommendations regarding the perioperative continuation or discontinuation of these agents take into account the risks of stent restenosis, the risks of intraoperative bleeding, and the type of stent the patient has implanted. If the implantation of the stent occurred prior to the year 2003, it is safe to assume that it is a bare metal stent. Further useful information includes the type of drug-eluting stent, given that different agents are used to prevent stent restenosis and may have differing DAPT requirements. [Fig. 20.2](#) outlines the new algorithm introduced by the ACC/AHA for decision making regarding this regimen. The guidelines recommend the following¹³⁰:

1. Elective noncardiac surgery should be delayed 30 days after bare metal stent (BMS) implantation and optimally 6 months after drug-eluting stent (DES) implantation.
2. In patients treated with dual antiplatelet therapy (DAPT) after coronary stent implantation who must undergo surgical procedures that mandate the discontinuation of P2Y₁₂ inhibitor therapy, it is recommended that aspirin be continued if possible and the P2Y₁₂ platelet receptor inhibitor be restarted as soon as possible after surgery.
3. When noncardiac surgery is required in patients currently taking a P2Y₁₂ inhibitor, a consensus decision among treating clinicians as to the relative risks of surgery and discontinuation or continuation of antiplatelet therapy can be useful.

4. Elective noncardiac surgery after DES implantation in patients for whom P2Y12 inhibitor therapy will need to be discontinued may be considered after 3 months if the risk of further delay of surgery is greater than the expected risks of stent thrombosis.

5. Elective noncardiac surgery should not be performed within 30 days after BMS implantation or within 3 months after DES implantation in patients in whom DAPT will need to be discontinued perioperatively.

Novel Oral Anticoagulants.

New oral anticoagulant agents (Table 20.10)¹⁶⁴ are prescribed for management of patients with a history of atrial fibrillation, deep venous thrombosis, pulmonary embolism, and at times prosthetic heart valves. These agents can either be Factor Xa inhibitors (rivaroxaban, apixaban) or thrombin inhibitors (dabigatran). As with antiplatelet agents, the risks of surgical bleeding versus recurrent thrombosis need to be considered. New reversal agents like darucizumab (Praxbind) are becoming available for emergency situations that require rapid reversal of anticoagulant effects. Recommendations for the perioperative management of these agents are as follows:

TABLE 20.10
Anticoagulant Medications

Agent	Indication	Mechanism of Action	Recommended Interval Between Last Dose and Procedure
Antiplatelet Agents			
Aspirin	Dual anti-platelet therapy (DAPT)	Cyclooxygenase Inhibitor	7–10 days
Cilostazol (Pletal)	Claudication associated with peripheral vascular disease	Phosphodiesterase Inhibitor	2 days
Thienopyridine Agents	Clopidogrel (Plavix)	DAPT	P2Y12 ADP receptor antagonist
	Prasugrel (Effient)	DAPT	P2Y12 ADP receptor antagonist
	Ticagrelor (Brilinta)	DAPT	P2Y12 ADP receptor antagonist

Novel Oral Anticoagulants				
Dabigatran (Pradaxa)		Atrial fibrillation, DVT, PE	Direct thrombin inhibitor	1–2 days (CrCl ≥ 50 mL/min), 3–4 days (CrCl < 50 mL/min)
Rivaroxaban (Xarelto)		Atrial fibrillation, DVT, PE	Direct factor Xa inhibitor	1 day for normal renal function, 2 days (CrCl 60–90 mL/min), 3 days (CrCl 30–59 mL/min), 4 days (CrCl 15–29 mL/min)*
Apixaban (Eliquis)		Atrial fibrillation, DVT, PE	Direct factor Xa inhibitor	1–2 days (CrCl > 60 mL/min); 3 days CrCl 50–59 mL/min, 5 days (CrCl ≤ 30–49 mL/min)

*Hart RG, et al. Anticoagulants in atrial fibrillation patients with chronic kidney disease. *Nature Reviews Nephrology*. 2012;8:569

ADP, Adenosine diphosphate; CrCl, creatinine clearance; DVT, deep venous thrombosis; PE, pulmonary embolism.

From Baron TH, et al. Current concepts: Management of antithrombotic therapy in patients undergoing invasive procedures. *N Engl J Med*. 2013;368:2113–2124.

- Cessation for patients with atrial fibrillation depends on their CHADS₂ score (CHADS₂: congestive heart failure; hypertension; age > 75; diabetes; previous stroke. All criteria get 1 point except the stroke, which gets 2 points. CHADS score of more than 4 = high risk, 3 to 4 intermediate risk; less than 3 low risk).¹⁶⁴
- For agents without a reversal, it is recommended that the drug be stopped 3 elimination half-lives prior to the procedure.⁷
- Agents should be resumed 24 to 48 hours after a surgical procedure provided that surgical bleeding is controlled.^{165,166}
- Bridging therapies should be considered for high-risk patients.

Respiratory System

A detailed evaluation of the respiratory system is crucial because of the relative frequency of and complications associated with respiratory disease. From an epidemiologic perspective some form of lung disease is present in nearly 25% of the adult population. The most common problems are COPDs, such as chronic bronchitis, emphysema, and asthma, which are major predictors for postoperative pulmonary disorders.¹⁶⁷ In their acute or chronic forms, the lung diseases are second only to coronary artery disease as a cause of death. Patients with COPD are twice as likely to have postoperative pulmonary complications.¹⁶⁸ Risk factors associated with increased postoperative respiratory morbidity and mortality

rates include preoperative sepsis, emergency operations, age (begins at age 50 and increases with each additional decade), history of smoking, comorbid diseases (e.g., cardiovascular disease, congestive heart failure, diabetes, chronic kidney disease, neurologic impairment, American Society of Anesthesiologists [ASA] physical status class III or greater), preoperative weight loss, functional dependence for activities of daily living, chronic bronchitis, asthma, interstitial lung disease, upper respiratory infection, obstructive sleep apnea, obesity (as little as 20% overweight), type of surgery (abdominal, thoracic), prolonged duration of anesthesia (3 to 4 hours or longer), elevated creatinine, and pulmonary hypertension.¹⁶⁸⁻¹⁷¹ The surgical site (major abdominal, aortic and thoracic surgeries) has been found to be the most important risk factor for the development of postoperative pulmonary complications.^{171,172}

Emphysema and Chronic Bronchitis

The preparation of a patient with two forms of COPD—emphysema and chronic bronchitis—depends largely on the severity of the respiratory disease as reflected by the preoperative history, physical examination, and diagnostic testing. Elective surgery is postponed when severe dyspnea, wheezing, pulmonary congestion, or hypercarbia (partial pressure of arterial carbon dioxide [PaCO_2] greater than 50 mm Hg) is evident. The risk of postoperative respiratory failure in such circumstances is drastically increased. Consultation with a pulmonologist may be necessary for further evaluation and optimization of the respiratory status of the patient before anesthesia and surgery. Interventions to improve the pulmonary status of the patient with chronic bronchitis are the primary focus before surgery. Prophylactic measures that may reduce pulmonary risk are cited in [Box 20.15](#).^{170,173-175} Specific antibiotic therapy is initiated in patients with thick, purulent sputum, and pulmonary infiltrates on the chest radiograph. Administration of prophylactic antibiotics to “sterilize” the sputum is not recommended because secondary resistant infections may develop and complicate the perioperative management of the patient. To enhance the mobilization and clearance of pulmonary

secretions, chest physiotherapy and adequate hydration can be instituted. There is a lack of quality studies demonstrating the benefit of chest physiotherapy for noncardiothoracic surgery. Incentive spirometry may be beneficial in reducing postoperative pulmonary complications after upper abdominal surgery.⁴

Box 20.15

Therapeutic Maneuvers to Decrease Risk of Pulmonary Complications

Preoperative

- Instruction in and application of respiratory maneuvers
- Smoking cessation
- Antibiotic treatment of pulmonary infection
- Antibiotic treatment of chronic bronchitis
- Expectorants
- Psychologic preparation
- Bronchodilator therapy for asthmatics
- Maintenance of good nutrition
- Chest physiotherapy
- Weight reduction

Postoperative

- Adequate pain control with minimization of postoperative opioid analgesia with epidural analgesia, when appropriate, and PCA administration of opioids (rather than intravenous boluses as needed)
- Selective nasogastric intubation

- Maximal inspiration maneuvers, incentive spirometry, chest physiotherapy
- Mobilization of secretions
- Early mobilization of elderly patients
- Cough encouragement
- Heparin prophylaxis in selected cases

Data from Mohr DN, Lavender RC. Preoperative pulmonary evaluation. Identifying patients at increased risk for complications. *Postgrad Med.* 1996;100(5):241–244,247–248,251–252; Marienau MES, Buck CF. Preoperative evaluation of the pulmonary patient undergoing nonpulmonary surgery. *J Perianesth Nurs.* 1998;13(6):340–348; Wang JS. Pulmonary function tests in preoperative pulmonary evaluation. *Resp Med.* 2004;98(7):598–605; Pfeifer KJ, Smetana GW. Pulmonary Risk Assessment and Optimization. *Hospital Medicine Clinics.* 2016;5:176–188.

The most reliable way to reduce the incidence of perioperative pulmonary complications is to have patients stop smoking cigarettes. Eight weeks after smoking cessation the pulmonary complication rate correlates with that of nonsmokers.⁴² This intervention may not be feasible when initial meetings with the patient occur within days or hours of the scheduled procedure.

Several diagnostic tests are used for clinically differentiating bronchitis and emphysema in patients in the advanced stages of COPD. Arterial blood gases, for example, may document the presence of preoperative hypoxemia or hypercarbia. An abnormally low partial pressure of arterial oxygen (PaO₂) value (less than 60 mm Hg) with or without PaCO₂ retention, often reflects a state of chronic bronchitis. A PaCO₂ of greater than 45 mm Hg and an arterial oxygen saturation (SpO₂) of less than 90% is associated with an increased incidence of postoperative pulmonary complications; however it is not predictive of whether the patient is fit for surgery.¹⁷⁶ Over time the patient develops cor pulmonale because of the adverse effects of chronic hypoxemia on pulmonary vasculature. Neither preoperative hypoxemia nor hypercarbia have been found to be independent predictors for the development of postoperative pulmonary complications and are not absolute

contraindications for noncardiac surgery.¹⁷¹ Preoperative arterial blood gas analysis is considered routine for thoracic surgery, except in a fit patient.¹⁷⁷ The chest radiograph may suggest a diagnosis of COPD if slight abnormalities on the chest radiograph, including emphysemic bullae and pulmonary hyperlucency (which reflect vascular deficiencies in the lung periphery) are apparent. Diaphragmatic flattening and a vertical orientation of the cardiac silhouette also are characteristic. Chronic bronchitis, on the other hand, is rarely recognized through chest radiography unless secondary infections are present. Preoperative chest radiographs seldom change patient management and have not been shown to impact on the incidence of postoperative pulmonary complications,⁴ and may only be indicated in patients with known cardiopulmonary disease who are scheduled to undergo higher-risk surgical procedures, i.e., upper abdominal, esophageal, thoracic, or aortic surgery.^{171,177}

In addition to their role in categorizing patients with COPD, pulmonary function tests are occasionally used as diagnostic adjuncts for confirming the severity of airflow obstruction and its reversibility with bronchodilator therapy. In both chronic bronchitis and pulmonary emphysema, a decrease of the forced exhaled volume in 1 second (FEV_1) occurs in comparison with the forced vital capacity (FVC). FEV_1/FVC ratios of less than 80% indicate the presence of an obstructive process. Individual values of pulmonary function test results may be misleading. The FEV_1 , for example, may already be low if the vital capacity is also decreased or the patient is uncooperative with the spirometric tests.

Numerous studies have found routine preoperative pulmonary function studies to be poor indicators of postoperative pulmonary complications and are not recommended.^{4,178} All patients scheduled to undergo lung resection should have spirometric assessment preoperatively to estimate postoperative FEV_1 and suitability for resection.^{168,179} It is not necessary to routinely obtain spirometric data prior to high-risk noncardiothoracic surgery. The value of pulmonary function testing prior to noncardiothoracic surgery is unproven and should be reserved for symptomatic patients with chronic debilitating conditions, i.e., myasthenia gravis.^{171,180}

Asthma

Unlike other COPDs, asthma is characterized by reversible airflow obstruction. Inflammation of the airways is the hallmark of asthma. Distal bronchoconstriction results from airway hyperreactivity to stimuli that have little or no effect on normal airways. Precipitating factors include allergens, exercise, upper respiratory tract infections (URTIs), emotional stressors, and unidentified triggers.¹⁷⁹ Pertinent data obtained from the medical history are detailed in [Box](#)

Box 20-16

Pertinent Data Obtained From the Medical History

Asthma Control and Current Therapy

- The frequency of asthmatic attacks, wheezing at exercise, or wheezing more than three times in last 12 months
- The time interval since the last attack
- Recent asthma exacerbation? How long since the patient was last hospitalized or treated in the emergency department for an asthmatic attack?
- Increased use of inhaled short-acting β -agonists? Use per week?
- Current or past use of inhaled corticosteroids?
- Most recent course of oral corticosteroids?
- What works best for treating an acute asthmatic event?

Asthma History and Complicating Conditions or Factors

- Recent upper respiratory tract infection (< 2 weeks) or sinus infection?
- Recent pneumonia? Was this documented on chest radiograph?

- What triggers an asthmatic attack?
- The severity of attacks: Was endotracheal intubation or intensive care unit admission required?
- History of pulmonary complications with prior surgical procedures?
- History of long-term corticosteroid use or corticosteroid-dependent asthma?
- Nocturnal dry cough
- Hay fever
- Exposure to passive smoke
- Obesity
- Obstructive sleep apnea

Modified from Karlet M, Nagelhout J. Asthma: an anesthetic update. *AANA J.* 2001;69(4):317–24; Tirumalasetty J, Grammer LC. Asthma, surgery, and general anesthesia: a review. *J Asthma.* 2006;43(4):251–254; Regli A, von Ungern-Sternberg BS. Anesthesia and ventilation strategies in children with asthma: part I – preoperative assessment. *Current Opinion in Anaesthesiology.* 2014;1:288–294.

Information gleaned from these questions will help establish the nature and stability of the disease process. Patients with a history of coexistent cardiovascular disease, copious sputum production, previous perioperative complications from asthma, recurrent nocturnal awakenings from asthma, frequent or continuous systemic corticosteroid requirement, or a recent hospitalization or emergency visit for asthma are considered to be at greater risk for perioperative aggravation of their asthma. Asthma should be under optimal medical management before a patient undergoes elective surgery and anesthesia. If the patient has a persistent cough, dyspnea, wheezing, or tachypnea on the day surgery is scheduled, it is best to reschedule surgery to allow for additional treatment of the asthma.¹⁸³

The need for diagnostic testing is based on the clinician's

assessment of the severity of the disease and magnitude of the operative procedure. An ECG is indicated if right ventricular hypertrophy is presumed, typically implying long-standing insufficient therapy. A chest radiograph is considered only if the patient is suspected of having an acute infiltrative process (e.g., pneumonia, pneumothorax in an acute exacerbation), or if a recent change in the patient's physical status is suggestive of a worsening pulmonary condition.¹⁸⁴ Arterial blood gases are usually indicated only when signs of debilitating chronic respiratory insufficiency (e.g., hypoxia, hypercarbia) are suspected or in patients with acute asthma who require emergency surgery. If age appropriate, spirometric evaluation consisting of a peak expiratory flow rate should be performed the morning of surgery if active disease is suspected. The results should be compared with the patient's best value in recent weeks. Findings will be as follows:

- *Normal*: 80% to 100% of baseline
- *Moderate exacerbation*: 50% to 80% of baseline
- *Severe episode indicating the need for delay of surgery and more intensive therapy*: Less than 50% of baseline

Peak expiratory flow is of limited use in assessing asthma preoperatively, because other symptoms or clinical signs of poor asthma control are usually present.¹⁸⁴

Early preoperative patient assessment promotes optimizing pharmacotherapy in the days prior to the scheduled surgery (Table 20.11).¹⁸³ Patient medications should be continued up to and on the day of surgery. Prophylactic β -adrenergic metered-dose inhalers should be used on the morning of surgery and accompany the patient to the operating room. Oral medications (e.g., theophylline) may be taken with a sip (1 to 2 oz) of water up to 1 to 2 hours before surgery. Therapeutic serum theophylline levels, 10 to 20 mcg/mL, should be confirmed if theophylline is used. Supplemental stress doses of corticosteroids may be appropriate if the patient has recently taken corticosteroids. Antianxiety premedication should be considered; psychologic triggers such as anxiety are common.

TABLE 20.11**Stepwise Treatment for Children With Asthma; > 5 Years of**

Age

Using two or more canisters of β_2 -agonist per month or > 10–12 puffs per day, $\geq 3 \times$ symptomatic per week, or waking one night a week indicates poorly controlled asthma and requires a step up in asthma treatment
Step 1: Mild intermittent asthma Inhaled short acting β_2 -agonist as required
Step 2: Regular preventer therapy Add inhaled steroids (in addition to inhaled short acting β_2 -agonist) Start with budesonide or beclametasone 100 mcg bid., fluticasone 50 mcg bid. or equivalent < 5 years of age: consider leukotriene antagonist if inhaled steroids cannot be used
Step 3: Initial add-on therapy Add inhaled long acting β_2 -agonist (in addition to inhaled steroids) Consider <ul style="list-style-type: none">• increasing inhaled steroids• adding leukotriene antagonists• theophylline < 5 years: addition of leukotriene antagonist if already on inhaled steroid (see Step 4)
Step 4: Persistent poor control Increase inhaled steroids up to 800 mcg of budesonide equivalent per day < 5 years: refer to a pediatric respiratory specialist
Step 5: Continuous or frequent use of oral steroids Lowest oral dose for adequate control Maintain high-dose inhaled steroids Refer to a pediatric respiratory specialist < 5 years: refer to a pediatric respiratory specialist

From Regli A, von Ungern-Sternberg BS. Anesthesia and ventilation strategies in children with asthma: part I – preoperative assessment. *Current Opinion in Anaesthesiology*. 2014;1:288–294.

Ensure adequate hydration (e.g., minimize the fasting interval) to reduce airway desiccation and improve mobilization of secretions. If signs and symptoms of infection are present, surgery may be postponed until antibiotic therapy, based on sputum Gram stain and cultures, is initiated.

Upper Respiratory Tract Infection

Children with URTIs, particularly those younger than 1 year, have an increased risk (twofold to sevenfold increase) of respiratory-related adverse events intraoperatively and postoperatively (e.g., bronchospasm, laryngospasm, hypoxemia, atelectasis, croup, and stridor). Signs and symptoms of URTI include sore throat; inflamed and reddened nasopharyngeal and oropharyngeal mucosa; sneezing; rhinorrhea (clear secretions) or mucopurulent nasal secretions; nasal congestion, including watery eyes; malaise; bulging, tender eardrums with associated inflammation;

nonproductive cough; fever of 37.5°C to 38.5°C (greater than 38°C associated with lower respiratory tract involvement); laryngitis or tonsillitis; viral ulcers in the oropharynx; and white blood cell count greater than 12,000 cells/mm³ with a left shift. Positive chest findings such as pulmonary congestion and rales are usually associated with lower respiratory tract involvement.

Each case should be reviewed individually. The decision to operate frequently depends on the urgency of the surgery, the duration and complexity of the surgery, and the need for instrumentation of the airway (Fig. 20.3).¹⁸⁵ Children with uncomplicated URTIs may undergo elective procedures without significantly increasing anesthesia complications. It is important to obtain a specific history to distinguish a chronic state from an acute, superimposed symptomatic infectious process, which has predictive value for morbidity. Parents will be the best resource for establishing baseline conditions. If the parents state that the child typically has a cold or chronic runny nose (clear rhinorrhea) and is in his or her optimal state (afebrile, without respiratory distress), short elective procedures may be considered. If the child has a productive cough from lower respiratory tract involvement or an infectious purulent-appearing runny nose, elective surgery should be postponed for at least 2 weeks.¹⁸⁶ However, it may be necessary to schedule children who have chronic URTIs for procedures such as myringotomy with ventilation tube placement or tonsillectomies, because URTIs are commonly associated with these conditions. Exercise caution with children younger than 5 years (consider postponing the procedure for children less than 1 year of age) because risks are increased. If the child is older than 1 year with a resolving URTI, it is reasonable to proceed with minor procedures not requiring endotracheal intubation (intubation with URTI increases risk elevenfold).

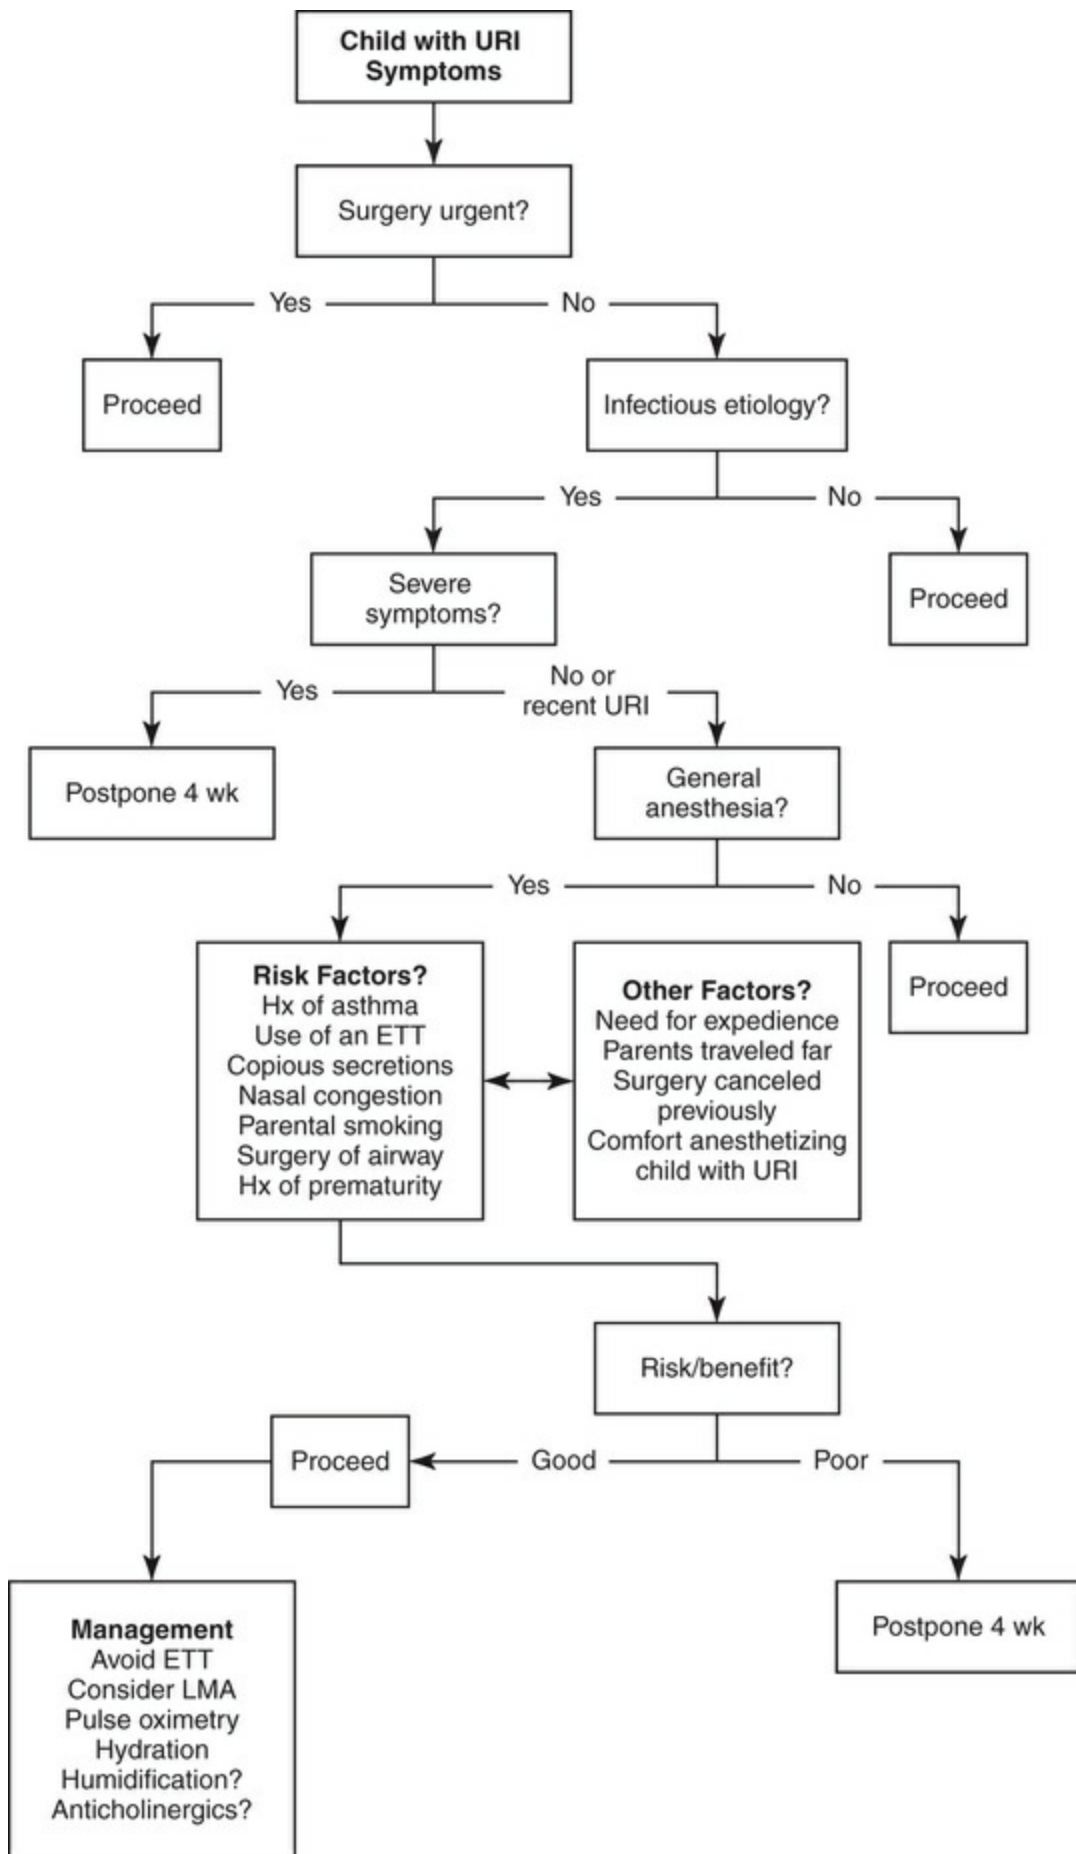

FIGURE 20.3 Suggested algorithm for the assessment and anesthetic management of the child with an upper respiratory infection. *ETT*, Endotracheal tube; *Hx*, history; *LMA*, laryngeal mask airway; *URI*, upper respiratory infection. (From Tait AR, Malviya S. Anesthesia for the child with an upper respiratory tract infection: still a dilemma? *Anesth Analg*. 2005;100:59–65.)

Infectious nasopharyngitis (without lower respiratory tract involvement) requires postponing the surgery for 2 weeks after peak symptoms.¹⁸⁷ If the child exhibits signs and symptoms of lower respiratory tract involvement, it is prudent to postpone an elective surgical procedure for 4 to 6 weeks, the time necessary to minimize airway hyperactivity.

Laboratory testing may consist of a complete blood count, including differential. The value of obtaining a preoperative white blood cell count has been questioned because it is of little value and rarely is a factor in determining whether to proceed with the surgery.¹⁸⁸ Nasal or throat cultures may be obtained if signs of an infectious process are observed. A chest radiograph is not warranted, especially if chest sounds are clear. Pulmonary function tests and arterial blood gas analysis rarely offer any useful information.

Gastrointestinal System

Evaluation of the gastrointestinal system includes preoperative determination of the presence of nausea and vomiting, diarrhea, occult or overt gastrointestinal bleeding, abdominal or referred pain, abdominal distention, palpable masses, dysphagia, or gastric hyperacidity with or without reflux. The fluid and electrolyte status of the patient is reviewed, especially when gastrointestinal symptoms are associated with weight loss or malabsorption. Active bleeding requires preoperative hemoglobin concentration measurement. The hematocrit value may be falsely elevated as a result of hemoconcentration in patients with acute or chronic bleeding. Radiographic and CT scans of the abdomen are reviewed for evidence of obstruction or masses. The presence of peptic ulcer disease or esophageal hiatal hernia is also ascertained. For affected patients, prophylactic measures to reduce the risk of aspiration and its adverse pulmonary sequelae (e.g., aspiration pneumonitis) are

instituted before surgery.

Hepatobiliary System

Preoperative evaluation of the hepatobiliary system includes screening for the presence of acute or chronic liver parenchymal disease such as hepatitis or cirrhosis, or cholestatic liver disease. Because of the tremendous reserve of the liver, progression of hepatic disease is often insidious. Signs and symptoms may be inapparent or vague until physiologic functions of the hepatobiliary system (Box 20.17) are markedly affected. Liver function tests are also limited in their ability to reflect the acuity and extent of hepatobiliary disease.¹⁸⁹ Considerable damage to the liver may be **Box 20.17** before laboratory test results are altered.

Physiologic Functions of the Hepatobiliary System

Bilirubin Formation and Excretion

- Conjugation of free bilirubin and secretion into bile

Carbohydrate Metabolism

- Glycogenesis
- Gluconeogenesis
- Glycogenolysis

Fat Metabolism

- Lipogenesis
- Lipolysis

Protein Metabolism

- Formation of proteins, such as albumin, prothrombin, transferrin, and glycoprotein

- Synthesis of plasma cholinesterase
- Deamination of proteins, such as hormones, into ammonia and urea

Hormone Metabolism Drug Detoxification

- Conversion of lipophilic drugs into inactive hydrophilic substances
- Hydrolysis of ester linkages by plasma cholinesterase

Vitamin Storage

- Storage of fat-soluble vitamins A, D, E, and K
- Storage of antipernicious anemia factor, vitamin B₁₂

Synthesis of Coagulation Factors and Inhibitors

- Synthesis of most clotting factors, including prothrombin, fibrinogen, factors V, VII, IX, and X
- Synthesis of antithrombin
- Mast-cell production of heparin

Phagocytosis

- Filtration and destruction of bacteria and debris in blood circulating through hepatic sinusoids by Kupffer cells

During the early stages of hepatitis or cirrhosis, the clinical presentation ranges from one in which the patient is asymptomatic with normal liver function tests to one in which the patient has malaise, weight loss, abdominal discomfort, and mild jaundice with mild elevations in bilirubin levels. In cases of unexplained jaundice or elevated transaminase levels, suspicions of hepatobiliary dysfunction should be thoroughly investigated by a preoperative

consultation with a gastroenterologist. Elective surgery is postponed until a definitive diagnosis and treatment are established and indicators of active inflammation (e.g., transaminase levels, cellular infiltration on liver biopsy, etc.) have subsided.¹⁹⁰ Further decompensation of hepatic function may follow anesthesia and surgery, notably after intraabdominal procedures.

Progression of hepatobiliary disease to overt hepatic failure may be evidenced by gross abnormalities of liver function test results including coagulopathy; extreme jaundice with or without cyanosis; generalized tremors and increased deep tendon reflexes; ascites, spider nevi, and hepatosplenomegaly; hepatorenal failure; and signs of hepatic encephalopathy.¹⁹² Elective surgery is avoided at this time because surgery on a patient with hepatic failure is associated with an extremely high incidence of morbidity and mortality. Anesthesia may be required, however, for a patient who requires a palliative or emergent procedure. Placement of a portocaval shunt and the surgical control of hemorrhage from esophageal varices are common procedures, given the growing number of patients with advanced liver disease. Anesthetic management is supportive in such situations and is focused on minimizing the risk of further hepatobiliary deterioration. Administration of phytonadione (AquaMEPHYTON) and transfusion of fresh frozen plasma and cryoprecipitate may be required for the correction of preoperative coagulopathy. Sedative premedicants are avoided in the disoriented or somnolent patient in whom hepatic encephalopathy has been diagnosed. Because of the rapid development of hypoglycemia, the patient's blood glucose level is checked preoperatively. The acid-base balance, electrolyte status, and extent of hepatorenal reserve may be determined by arterial blood gas analysis, serum multiphasic profiles, and liver function tests.¹⁹²

The interpretation of liver function tests should be approached cautiously. Differential diagnosis of parenchymal versus cholestatic liver disease is limited by the insensitivity and nonspecificity of current laboratory analysis, especially serum transaminase and alkaline phosphatase levels.¹⁹³ Aspartate transaminase (AST), or serum glutamic oxaloacetate transaminase (SGOT); alanine transaminase (ALT), or serum glutamic pyruvic transaminase

(SGPT); and lactate dehydrogenase (LDH) are commonly measured hepatocellular enzymes also distributed throughout cells of the lungs, heart, kidneys, and skeletal muscles. Increases in their serum concentrations are therefore not always indicative of hepatobiliary disease. Greater specificity can be derived from isoenzyme-5 fractions of the enzymes such as LDH.¹⁹⁴

In cases of biliary obstruction or irritation, alkaline phosphatase enzymes may be released from the cells of bile ducts. Increases in serum concentrations of these enzymes also help differentiate hepatic dysfunction caused by parenchymal disease from that caused by cholestasis. The interpretation of these results is again limited by the presence of extrahepatic stores of alkaline phosphatase. In this situation cholestatic liver disease can be confirmed by high serum levels of conjugated (direct) bilirubin.¹⁹⁵ Causative factors are then determined from discussions with a gastroenterologist and the results of ultrasound, CT, and endoscopic retrograde cholangiopancreatographic scans.

When acute parenchymal injury is evident, prolongation of prothrombin time offers the most rapid and reliable hallmark of liver dysfunction and is shown to have prognostic significance. It reflects the inability of the acutely damaged liver to synthesize clotting factors. Although the production of albumin is also affected, its plasma half-life exceeds that of prothrombin. Hypoalbuminemia may then be inapparent for days after an acute hepatocellular insult.¹⁹⁶

Once a functional impairment of the liver has been established, the cause is investigated as part of the preoperative evaluation. Cirrhosis and hepatitis, for example, are frequently associated with long-standing alcohol abuse. The increasing consumption of alcohol in the United States parallels the rising incidence of liver disease. Exposure to hepatotoxic agents in the workplace, such as carbon tetrachloride or vinyl chloride, should be ruled out. Hepatotoxic drugs may then be discontinued or avoided before surgery. These drugs commonly include acetaminophen and other nonsteroidal antiinflammatory drugs, aspirin, methyldopa, isoniazid, and rifampin.^{197,198} Finally a diagnosis of infectious hepatitis should be pursued in patients with hepatobiliary disease of unknown cause and in patients considered to be at high risk, which includes those

with a history of hemodialysis, multiple blood transfusions, or intravenous drug abuse. Because of the virulent nature of the hepatitis viruses, care of an infected patient also poses an occupational hazard for anesthesia providers.¹⁹⁹ Maximum precautions must be consistently exercised, and vaccination with the hepatitis B virus as recommended by the CDC should be performed.²⁰⁰

The Child-Pugh score was developed to predict surgical mortality in patients with cirrhosis. It assigns points for five variables: total bilirubin level, serum albumin level, international normalized ratio (INR), ascites, and hepatic encephalopathy. Patients are categorized into Child-Pugh class A, B, or C. The predicted perioperative mortality for intraabdominal surgery in these patient groups is Class A (10%), Class B (30%), and Class C (80%). Patients in Child-Pugh classes A and B are suitable candidates for surgery with preoperative optimization. Patients in Child-Pugh class C are usually treated medically. Surgery, if necessary, is delayed until liver function improves.¹⁹⁵ A further discussion of anesthesia and liver disease can be found in [Chapter 33](#).

Renal System

Evaluation of the kidneys and urinary tract includes preoperative determination of the patient's volume status and presence of polyuria; urinary incontinence or retention; microscopic or frank hematuria; recurrent infections in the form of glomerulonephritis, pyelonephritis, or cystitis; dysuria; and oliguria or anuria. Fluid balance is calculated from the patient's intake and output during the hospital stay. For example, preoperative dehydration may be evident with symptoms such as dry mucous membranes, postural hypotension, increased capillary refill time, and tachycardia in a patient receiving long-term diuretic therapy. Polyuria, when not attributed to diuretics, may reflect glycosuria, or rarely, inadequate secretion of antidiuretic hormone (diabetes insipidus). Urinary retention and other signs of neurogenic bladder may be caused by a spinal cord injury or long-standing diabetes mellitus. Frequent catheterizations are often necessary in such situations increasing the patient's risk for developing chronic urinary tract infections. Preoperative urinalysis and culture are therefore required so that infection can be ruled out. Treatment and resolution should be accomplished before elective surgery is performed, especially for procedures involving the placement of a prosthetic graft for a mitral valve or total hip replacement. Problems with intraoperative bladder catheterization can be anticipated in patients with dysuria or voiding difficulties. In older men these problems are frequently attributed to chronic prostatism. Untreated prostatic hypertrophy, in addition to renal calculi and congenital malformations of the ureters, results in obstructed urinary outflow. Over time these conditions may lead to a state of chronic renal insufficiency or failure.

Any suspicion of renal dysfunction should be investigated before surgery. Unfortunately, clinical evidence of renal insufficiency may not be apparent until at least 70% of nephrons are nonfunctional. Accurate diagnosis of renal insufficiency is further limited by the insensitivity of laboratory tests (Table 20.12).²⁰¹ Acute kidney injury where there is rapid deterioration in kidney function is defined by: elevated creatinine of greater than 26.4 $\mu\text{mol/L}$ within 48 hours; elevated serum creatinine of greater than 1.5 times baseline, which

is known or presumed to have occurred within the previous 7 days; urine output less than 0.5 mL/kg for 6 hours.²⁰² Blood urea nitrogen (BUN) concentrations, for example, do not accurately reflect glomerular filtration rate (GFR). Although urea is freely filtered at the glomerulus, it is reabsorbed to a large and variable extent through the tubules. BUN levels are also affected by the amount of protein ingested in the gastrointestinal tract and the amount of urea metabolized by the liver, as well as by the catabolic state of the patient. Because tubular reabsorption of creatinine does not occur, creatinine levels correlate more with the GFR than do BUN concentrations. The serum levels of creatinine, a by-product of skeletal muscle metabolism, can reflect the muscle mass and catabolic state of each patient. This characteristic limits its precision in determining the magnitude of nephron loss. Normal serum creatinine levels may be higher in a muscular man than in a woman. Conversely, serum creatinine levels can remain within the normal range in the elderly patient despite a progressive decline in glomerular function,²⁰³ because of the decrease in muscle mass associated with aging.

TABLE 20.12
Common Renal Function Tests

Test	Reference Range
Urea nitrogen	5–25 mg/dL
Creatinine	0.5–1.5 mg/dL
Sodium	133–147 mmol/L
Potassium	3.2–5.2 mmol/L
Chloride	94–110 mmol/L
CO ₂	22–32 mmol/L
Uric acid	2.5–7.5 mg/dL
Calcium	8.5–10.5 mg/dL
Phosphorus	2.2–4.2 mg/dL
Urinalysis, Routine	
Color	Straw-amber
Appearance	Clear-hazy
Protein	0 mg/dL
Blood	Negative
Glucose	0 mg/dL
Ketone	0 mg/dL
pH	4.5–8
Specific gravity	1.002–1.030
Bilirubin	Negative
Urinalysis, Micro	
Red blood cells	0–3/high-power field

White blood cells	0–5/high-power field
Casts	0–2/low-power field

Modified from Brenner BM, et al, eds. *Brenner and Rector's The Kidney*. 10th ed. Philadelphia: Elsevier; 2016.

The most commonly used endogenous marker of renal reserve or GFR is creatinine clearance, which reflects the ability of glomeruli to excrete creatinine into the urine at a given blood concentration.²⁰⁴ The drawbacks of this assessment lie in the cost and time required for the collection of urine samples. As a general principle, urine is collected over a 24-hour period and the creatinine clearance rate is measured by the following equation:

$$\text{GFR (mL/min)} = \frac{UV}{P}$$

Where U is the urinary concentration of creatinine (mg/dL), V is the volume of urine (mL/min), and P is the plasma concentration of creatinine (mg/dL).

Accurate measures of GFR also can be calculated from a 2-hour specimen.²⁰⁵ Creatinine clearance or GFR values between 50 and 80 mL/min are indicative of mild renal dysfunction. Renal failure is otherwise evident when creatinine clearance levels decrease to less than 10 mL/min.

Practically all surgical patients with chronic renal failure are undergoing dialysis, usually hemodialysis performed at the hospital or renal facility. Others undergo continuous ambulatory peritoneal dialysis. The goal of dialysis therapy is to maintain a reasonable degree of homeostasis, although BUN and creatinine concentrations remain abnormal. The preoperative evaluation and preparation of the patient with chronic renal failure should therefore focus on fluid and electrolyte balance, and on the extent of concomitant diseases.²⁰⁶ Estimates of volume status are derived from the amount of weight gained between periods of dialysis. Fluid overload may also be evidenced by jugular vein distention, peripheral and periorbital edema, and bibasilar rales.

Preoperative measurement of serum potassium concentration is recommended within 6 to 8 hours of surgery regardless of whether dialysis is performed, because unexpected hyperkalemia with its adverse cardiac effects is known to occur rapidly. In cases in which

the serum potassium level exceeds 5.5 mEq/L and congestive heart failure is apparent, elective surgery should be delayed until after dialysis. When postponement is not feasible, as with emergency surgery to relieve a pericardial effusion or procedures to revise a hemodialysis shunt, measures to reduce the serum potassium concentration are then instituted.

Although hemoglobin ranges from 5 to 8 mg/dL are not unusual in patients with chronic renal failure, a hemoglobin level should also be obtained as part of the preoperative evaluation. Chronic anemia is predominantly caused by decreases in renal erythropoietin production and enhanced fragility of red blood cells in the presence of uremia. It is further exacerbated by blood loss experienced with hemodialysis and chronic gastrointestinal bleeding. When extreme fatigue and pallor, limited exercise tolerance, and persistent tachycardia are evident before major surgery, the transfusion of packed red blood cells may be necessary. Because repeat transfusion and immunosuppression therapy are often required during the course of chronic renal failure, the patient is at greater risk for being infected with the hepatitis virus, human immunodeficiency virus (HIV), or both. Coagulopathies are also suspected. The most likely cause is a decrease in platelet adhesiveness secondary to the chronic state of metabolic acidemia. Hemodialysis can be effectively used for the correction of prolonged bleeding times before surgery in this situation.

Throughout the perioperative period most therapeutic regimens for patients with chronic renal failure can be continued, including the administration of antihypertensives, digitalis preparations, corticosteroids, and insulin.²⁰⁷ Requirements for preoperative sedation may be less than anticipated, and medications with prolonged durations such as diazepam, are avoided.²⁰⁸ Peripheral arteriovenous shunts should be assessed for patency and infection. Measurement of noninvasive blood pressures and application of intravenous lines are avoided in the limb of the graft. Administration of gastrointestinal preparations (e.g., antacids and gastrokinetic agents) and drainage of peritoneal dialysate aimed at reducing the risks of regurgitation and pulmonary aspiration are instituted when preparing the patient with chronic renal failure for anesthesia and surgery.

Endocrine System

Endocrine diseases of concern in the preoperative evaluation include diabetes mellitus, thyroid gland disorders, and adrenocortical dysfunctions. End-organ effects of each of these diseases increase perioperative risk substantially. For example, morbidity and mortality rates are 5 to 10 times greater in diabetic patients with renal and autonomic nervous system involvement.²⁰⁹

Diabetes

Diabetes mellitus is the most common endocrine disorder, affecting more than 20.8 million people—8.3% of the population—in the United States. Twenty-seven percent of people ages 65 years or older report having diabetes.²¹⁰ It represents a dysfunction in glucose metabolism caused by impaired synthesis, secretion, or use of insulin.

Most patients with diabetes (90% to 95%) are not dependent on exogenous insulin for the regulation of blood glucose levels. As shown in [Table 20.13](#), the patient with noninsulin-dependent (also known as adult onset or type 2) diabetes often benefits from diet modification, weight control, and exercise alone. An oral or injectable hypoglycemic agent ([Table 20.14](#)) may also be added to the patient's therapeutic regimen.²¹¹ The remaining 5% to 10% of patients with diabetes are dependent on insulin preparations listed on [Table 20.15](#) and are therefore classified as having insulin-dependent, or type 1 diabetes mellitus.^{212,213} These patients are susceptible to periods of hyperglycemia and ketoacidosis. As a result of microvascular changes they are also prone to the development of severe end-organ complications, including diabetic retinopathy and cataract formation, somatic and autonomic insufficiency (orthostatic hypotension, bradycardia, gastroparesis), and nephropathy. Because of acquired abnormalities in the macrovasculature, patients with type 2 diabetes are more likely to have hypertension, coronary artery disease (which frequently is asymptomatic), and peripheral vascular disease. Death in the majority of patients with diabetes is secondary to complications of atherosclerosis (MI, stroke).²¹⁴

TABLE 20.13**Distinguishing Features of Diabetes Mellitus**

	Type 1	Type 2
Previous name	Insulin-dependent diabetes	Noninsulin-dependent diabetes
Age of onset	Childhood	Middle age or elderly
Timing of onset	Abrupt	Gradual
Predisposing factors	Genetic	Obesity, pregnancy, drugs
Prevalence	0.2–0.3%	2–4%
Insulin requirement	Always	Infrequent
Ketoacidosis	Common	Rare
Systemic complications	Frequent	Frequent

TABLE 20.14**Oral and Non-Insulin Injectable Hypoglycemic Therapy**

Drug Class	Drug Name	Onset	Duration of Action
Oral Agents			
Second-generation sulfonylureas	Glyburide	30 min	24 hr
	Glipizide	IR 30 min	IR 24 hr
		ER 2–4 hr	ER 24 hr
	Glimepiride	2–3 hr	24 hr
DPP-4 Inhibitors	Sitagliptan	1 hr	8 hr
	Saxagliptan	1 hr	8 hr
	Linagliptan	1 hr	8 hr
GLP-1 Analogs	Exenatide	1–2 hr	24 hr
	Liraglutide	1–2 hr	24 hr
Biguanides	Metformin	1–3 hr	17 hr
Thiazolidinediones	Rosiglitazone	1–3 hr	4 hr
	Pioglitazone	2 hr	N/A
Nonsulfonylurea secretagogues (glinides)	Repaglinide	30–90 min	4 hr
	Nateglinide	30–60 min	4 hr
α -Glucosidase inhibitor	Acarbose	2 hr	4 hr
	Miglitol	1 hr	4 hr
Injectables			
Drug Class	Drug Name	Peak Plasma Time	Dosing Interval
Glucagon-like peptide 1 receptor agonists	Exenatide (Bydureon ER, once weekly dosing)	2.1 hr	Once weekly
	Byetta (shorter duration exenatide)	2.1 hr	Every 12 hours
	Liraglutide (Victoza)	8–12 hr	Once daily
Amylin Analog	Pramlintide (Symlin)	Duration of Action 3 hr	Prior to every major meal

DPP-4, Dipeptidyl peptidase-4; *ER*, extended release; *GLP-1*, glucagon-like peptide 1; *IR*, immediate release; *N/A*, not available.

TABLE 20.15
Insulin Preparations and Guidelines

Insulin Type	Onset	Peak (hr)	Duration (hr)	Comments
Very Rapid				
Lispro; Aspart	IV immediate; subcut 5–15 min	Subcut 0.5–1.5	Subcut 3–4	Usually administered immediately prior to a meal; use subcut or via an insulin pump, but not recommended for continuous infusion
Short-Acting				
Regular	IV immediate; subcut 30–60 min	Subcut 2–3	Subcut 3–6	Usually administered 30–60 min before meals; most common in continuous IV infusions
Intermediate-Acting				
NPH	Subcut 2–4 hr	Subcut 6–10	Subcut 10–16	Often combined with regular insulin
Lente	Subcut 3–4 hr	Subcut 6–12	Subcut 12–18	
Long-Acting				
Ultralente	Subcut 6–10 hr	Subcut 10–16	Subcut 18–20	Perioperative use uncommon
Glargine	Subcut 4 hr	Minimal peak activity	Subcut 24	May be administered as usual to provide basal insulin levels during surgery
Combinations				
75/25 (75% protamine lispro, 25% insulin lispro)	Subcut 30–60 min	Dual	10–14	
70/30 (70% NPH, 30% regular)	Subcut 30–60 min	Dual	10–16	Usually given before breakfast
50/50 (50% NPH, 50% regular)	Subcut 30–60 min	Dual	10–16	Usually given before dinner

IV, Intravenous; NPH, neutral protamine Hagedorn; *subcut*, subcutaneous.

Proper perioperative glucose management reduces postoperative morbidity and mortality; therefore the aim of an evaluation of a patient with diabetes, notably one with type 1 diabetes mellitus, is ascertaining the degree of preoperative blood glucose control and the presence of major organ system dysfunction. Renal and cardiovascular complications of diabetes substantially heighten perioperative risk. Particular attention should be paid to:

- Diabetes—type of disease, method of home monitoring and usual metabolic control

- Drugs—antidiabetic medication, medication for associated diseases
- Cardiovascular disease—including an assessment of exercise tolerance
- Renal disease—electrolyte assessment, hemodialysis regime if applicable
- Neuropathy—peripheral and autonomic, in particular gastric paresis
- Airway—diabetics with stiff joint syndrome (due to glycosylation) often have limited mobility of the upper cervical spine and are more likely to have a poor view on direct laryngoscopy; therefore they may present difficulties with tracheal intubation.²¹⁵ Patients with a long-standing history of diabetes require a close look at the airway to assess for potential difficulties.⁴

Early preoperative evaluation and workup of diabetic patients are important. This is especially true in patients who are noncompliant, patients whose blood glucose level is poorly controlled, and patients with newly diagnosed diabetes, because modifications in their care may be necessary before surgery. Early assessment of a patient allows for consultation with a medical internist to optimize the patient's preoperative condition before anesthesia and surgery. An internist can begin monitoring of hemoglobin A1C (HbA_{1C}) values and determine what interventions, if any are indicated. Efforts to reduce the HbA_{1C} to as close to normal as possible are desirable. Levels less than 5.7% are normal, 5.7% to 6.4% are high risk, and 6.5% or more are diabetic. These values can give a good indication of glycemic control perioperatively and should be considered in the perioperative period regarding glucose management.²¹⁶

Patients with preoperative hyperglycemia (216 mg/dL or greater), but without an official diagnosis of diabetes and thus are untreated, have higher mortality long-term at 1-year postsurgery.²¹⁷

For this reason, elective surgery is postponed in cases of extreme hyperglycemia and ketoacidosis until such time that corrective measures may be instituted.

Consultation with a cardiologist may also help a practitioner evaluate and improve the preoperative cardiac status of a patient

with diabetes, especially if the patient is undergoing a procedure associated with a greater risk of perioperative myocardial ischemia, such as a carotid endarterectomy or an abdominal aortic aneurysm resection. Because of the high incidence of ischemic heart disease in this population, exercise stress testing and a 12-lead ECG may be performed. Orthostatic hypotension, resting tachycardia, and lack of respiratory variability in cardiac rhythm may reflect autonomic neuropathy (present in 20% to 40% of diabetic patients). Abnormalities in autonomic function may also result in bladder atrophy and delayed gastric emptying times in nearly 50% of diabetic patients.²¹⁸ Administration of a gastrokinetic agent such as metoclopramide should be considered before surgery to reduce the incidence of regurgitation and pulmonary aspiration during general anesthesia.

It is best to schedule surgery as early in the day as possible to minimize the fasting period. Just before surgery, diabetic patients who require insulin or oral hypoglycemic agents should have blood glucose checked. Depending on the type and length of surgery and the lability of diabetes, blood glucose levels are checked intraoperatively and in the postanesthesia care unit at 1 to 4 hour intervals. There continues to be discussion as to optimal levels; however, a safe goal of perioperative insulin therapy is to maintain the serum glucose level at less than 180 mg/dL, while avoiding hypoglycemia.²¹⁹ Several different regimens are available for the treatment of diabetic patients undergoing surgery and anesthesia. Consultation with the physician responsible for managing the diabetes is helpful in determining an acceptable range of serum glucose and when and what type of insulin therapy may be appropriate. Considerations for managing the diabetic patient are as follows:

Mild hyperglycemia is preferable to hypoglycemia.

- For patients with either insulin-dependent or noninsulin-dependent diabetes, the most important goal of perioperative management is the prevention of hyperglycemia and especially

hypoglycemia, in addition to their adverse consequences, during surgical stress.

Night before the procedure:

- Continue usual dose of PM (afternoon/evening) glargine/NPH (neutral protamine Hagedorn) or mixture (can recommend two-thirds usual dose if tightly controlled) as long as the patient is allowed a usual diet.

Morning of procedure:

- Patients undergoing short, simple procedures early in the morning where preoperative fasting is required can be managed by delaying the patient's normal diabetes treatments until the patient is ingesting food in the early postoperative period. It should be noted that procedures requiring a patient with diabetes to fast are customarily scheduled early in the morning to minimize disruption of routine diabetic treatments.
- Patients taking oral hypoglycemic agents should withhold the short half-life agents (e.g., repaglinide) on the day of surgery and withhold the longer-lasting agents (e.g., chlorpropamide and glimepiride) for up to 48 hours.
- Fasting patients who are receiving insulin should

have intravenous access established. A crystalloid solution containing 5% glucose should be available to infuse for maintenance of optimal blood glucose levels. The intravenous route still has the risk of making the patient hyperglycemic or hypoglycemic if the glucose or insulin infusions become unbalanced. The tighter the control of glucose levels, the more frequent the glucose monitoring. The subcutaneous route of insulin administration has been criticized as being too unpredictable in its absorption, especially perioperatively, with alterations in blood pressure and cutaneous blood flow.²²⁰

- Patients should not take a short-acting insulin bolus the morning of the procedure unless the blood glucose level is greater than 200 mg/dL, and more than 3 hours preoperatively.
- In the patient with type 1 diabetes a common approach, especially for brief procedures, is to subcutaneously administer a fraction (50% of usual dose) of the patient's usual morning dose of intermediate- or long-acting insulin and institute continuous 5% glucose infusion.

Insulin Pumps²²¹

- Determine the type of insulin in the pump, basal pump rate, and the insulin sensitivity factor (an estimate of magnitude of reduction in the blood glucose level when 1 unit of the pump insulin is administered). [Table 20.16](#) outlines the suggested

perioperative management of the patient with an insulin pump.

TABLE 20.16

Perioperative Management of the Patient with an Insulin Pump

Preoperative preparation: Topics to discuss with patient	Choice to continue the pump during surgery
	Ensure adequate supply of pump consumables for entire surgical stay
	Re-site the infusion set the day before surgery and monitor blood glucose
	Position of infusion site away from operative field and cautery and accessible to anesthetist
	Overnight basal assessment prior to surgery
	Consultation with the management team and patient to confirm self-management competency
Perioperative management	Assess glucose hourly
	If glucose is not controlled switch to an intravenous infusion
	Disconnect the pump in emergency surgery and switch to intravenous insulin
	Do not use in radiology procedures
Postoperative management	Check capillary glucose hourly until the patient is able to self manage
	Increase frequency of testing for 48 hours postoperatively

Adapted from Partridge H. et al. Clinical recommendations in the management of the patient with type 1 diabetes on insulin pump therapy in the perioperative period: a primer for the anaesthetist. *Br. J Anaesth.* 2016;116(1):18-26.

- Prior to any sedation ascertain whether the patient is able to recognize symptoms of hypoglycemia, and whether they plan to properly manage the pump.
- Examine the pump for signs of irritation or leakage.
- Considerations regarding the type of procedure include:
 - Positioning requirements (i.e., prone). For this position in particular, the pump should be padded or relocated depending on the duration of surgery and encroachment by position.
 - Discontinuation of the pump may need to be considered for lengthy noncardiac surgery, and in procedures involving x-ray, MRI, or defibrillation exposure regardless of duration or procedure.

Thyroid Gland Disorders

Although disorders of the thyroid gland are relatively uncommon, the anesthesia provider may still encounter patients with hyperthyroidism or hypothyroidism who require surgery. Most have undergone adequate medical therapy before anesthesia and surgery are performed. Nevertheless, the anesthesia provider should be aware of the clinical manifestations of thyroid gland dysfunctions (Table 20.17).^{95,222,223}

TABLE 20.17
Clinical Features of Thyroid Gland Disorders

	Hyperthyroidism	Hypothyroidism
General	Heat intolerance; weight loss; tremor; excessive sweating; warm, moist skin	Cold intolerance, thinning or coarsened hair, alopecia, arthralgia, "strawberries and cream" complexion, dry skin, gruff voice
Metabolic	Pyrexia, hyperglycemia, hypercalcemia	Hypothermia, hypoglycemia, hyponatremia
Cardiovascular	Sinus tachycardia, premature ventricular contractions, wide pulse pressure, elevated systolic blood pressure, decreased diastolic blood pressure, peripheral edema, increased left ventricular contractility, cardiac output and ejection fraction, atrial fibrillation, ischemic heart disease, congestive heart failure	Bradycardia, heart block, QT prolongation, reduced contractility, diastolic hypertension, cardiomegaly, ischemic heart disease, congestive heart failure, increased peripheral resistance, pericardial effusions
Respiratory	Dyspnea, increased minute volume, respiratory muscle weakness, reduced vital capacity, reduced compliance	Hypoventilation, attenuated response to hypoxia/hypercapnia, reduced diffusion capacity, myxedematous infiltration of respiratory muscles, sleep apnea
Gastrointestinal & liver	Diarrhea, nausea, vomiting, abdominal pain, elevated liver function tests	Decreased gastrointestinal motility, constipation
Neurologic	Anxiety, irritability, hyperactive reflexes, tremor, insomnia; depression, psychosis, withdrawal, and apathy in elderly	Fatigue, lethargy, slow mental function, hypoactive reflexes, depression, psychosis, myxedema coma
Musculoskeletal	Goiter, weight loss, proximal myopathy, bone resorption	Goiter, lethargy, large tongue, amyloidosis, peripheral neuropathy, muscle stiffness
Ophthalmic	Exophthalmos, lid lag, upper lid retraction, reduced blinking, corneal ulceration	Periorbital edema
Renal		Impaired free water clearance
Hematologic	Thrombocytopenia, neutropenia, mild anemia	Anemia, reduced plasma volume, coagulopathy
Neuromuscular	Peripheral myopathy, generalized muscle weakness, familial periodic paralysis, myasthenia gravis	
Goiter	Airway compromise, stridor, positional dyspnea, dysphagia, altered voice	Airway compromise, stridor, positional dyspnea, dysphagia,

Hyperthyroidism.

Hyperthyroidism is caused by an excess secretion of thyroid hormones 3,5,3'-triiodothyronine (T_3) and tetraiodothyronine (thyroxine or T_4). It is evident in such conditions as Graves disease, toxic goiter (multinodular, single), thyroid carcinoma, and pituitary tumors that oversecrete thyroid-stimulating hormone (TSH). Signs and symptoms reflect a hypermetabolic state with sympathetic overactivity (e.g., tachycardia, atrial fibrillation, fever, tremor) resulting from the primary effects of thyroid hormones on the adenylate cyclase system.⁹⁶

The preoperative preparation of the hyperthyroid patient is aimed at attaining a euthyroid state. This may be accomplished through administration of antithyroid drugs such as methimazole or propylthiouracil for 6 to 8 weeks, followed by iodine for 7 to 14 days.²¹² Not only does propylthiouracil decrease the overall synthesis of thyroxine, it also lessens its conversion into the more potent T_3 . Reversible agranulocytosis is infrequently seen with long-term therapy.²²⁴ A complete blood cell and platelet count should be determined preoperatively. β -Antagonist drugs such as propranolol and atenolol daily are also useful adjuncts in the management of hyperthyroidism. Oral atenolol, 25 mg to 50 mg or more as required daily, should be used to maintain a heart rate of less than 80.²²³ These drugs ameliorate signs of sympathetic nervous system overstimulation such as tachycardia, diaphoresis, and tremors.

All drugs used to manage hyperthyroidism, including propylthiouracil and propranolol, should be continued perioperatively including the morning of surgery, and elective surgery is postponed until the patient is rendered euthyroid. If emergency surgery cannot be delayed for a patient with symptomatic hyperthyroidism, a continuous infusion of esmolol (100 to 300 mcg/kg per min) may be initiated to control unwanted tachycardia (goal heart rate less than 90 beats/minute).²²⁵ Higher doses of preoperative anxiolytics and sedatives such as benzodiazepines may also be required. Anticholinergics are avoided because of their interference with normal heat-regulating

mechanisms and their potentiation of tachyarrhythmias.

Hypothyroidism.

Hypothyroidism represents several conditions, such as chronic thyroiditis or Hashimoto disease, in which tissues are exposed to decreased circulating concentrations of T_3 and T_4 . The cause of hypothyroidism may be primary, resulting from the destruction or hypofunction of the thyroid gland, or secondary, resulting from insufficient TSH production. The diagnosis of hypothyroidism is confirmed by decreased serum concentrations of T_3 and T_4 , with or without secondary increases in TSH levels.²²⁶

The treatment of hypothyroidism consists of administration of T_4 , levothyroxine sodium (Synthroid) replacement therapy, with the restoration of intravascular volume and electrolyte status. Elective surgery need not be delayed for patients with mild to moderate hypothyroidism. No difference in perioperative outcome has been noted between untreated hypothyroid patients and patients who are euthyroid.²²⁷

Adrenocortical Disorders.

Disorders of the adrenal cortex, ranging from hyperadrenocorticism to hypoadrenocorticism, are the result of primary disease of the adrenal cortex or pituitary gland, ectopic production of adrenocortical hormones by malignant tissue, or most commonly treatment with exogenous corticosteroids. Steroids are commonly used to treat bronchial asthma, autoimmune diseases, and connective tissue disorders such as rheumatoid arthritis. Their high-dose administration for prolonged periods or their excess levels in circulating glucocorticoid hormones characteristically results in a syndrome referred to as *Cushing syndrome*. This syndrome is clinically manifested as hypertension and hypovolemia, truncal obesity with an accumulation of interscapular fat (“buffalo hump”), abdominal and gluteal striae, plethoric facial appearance (*moon facies*), easy bruising, osteoporosis, personality changes, menstrual irregularities, and hirsutism.

Hyperaldosteronism—an excess of mineralocorticoid hormones—may be manifested as hypertension in association with marked hypokalemia (plasma potassium [K] less than 3 mmol/L). Its major

alterations involve sodium and water retention, potassium depletion, and metabolic alkalosis.

Adrenocortical insufficiency may be of a primary origin (Addison disease) or caused by the secondary inhibition of adrenocortical function by prolonged exogenous steroid therapy. Clinical signs are less obvious than those of Cushing disease and include skin hyperpigmentation, weight loss, muscle wasting, hypotension, intravascular volume depletion, hypoglycemia, hyponatremia, and hyperkalemia.²²⁸

The preoperative preparation of a patient with adrenocortical dysfunction includes the correction of fluid and electrolyte disturbances and the treatment of coexisting disorders such as hypertension and diabetes mellitus. Glucocorticoid or mineralocorticoid replacement therapy is also continued perioperatively. Patients are at risk for depression of the hypothalamic-pituitary-adrenal (HPA) axis if they have: (1) received 20 mg or more of prednisone, or equivalent, for 5 or more days, or (2) have been treated for 1 month or more. HPA axis suppression may persist for 6 to 12 months after discontinuation of treatment.²²⁹ A reliable test to assess adrenocortical function, the short adrenocorticotrophic hormone (ACTH) stimulation test, may be performed to evaluate the need for a supplemental steroid.²³⁰ If the patient presenting for surgery is at risk for HPA axis depression, or if findings (i.e., hyponatremia, hyperkalemia, hypotension, eosinophilia) are consistent with adrenal insufficiency, then need for exogenous corticosteroid supplementation should be assessed (see [Table 20.4](#)).⁹⁴ For patients currently receiving high-dose steroid therapy, such as those with chronic hypoadrenocorticism or Addison disease, further supplementation of the daily maintenance doses may be required based on the surgical stress. This recommendation, although controversial regarding the need for additional supplementation,^{231,232} is based on concerns that additional cortisol may not be released from the adrenal cortex as a result of its primary hypofunction or secondary suppression in response to surgical stress. Unexplained hypotension in spite of intravenous fluid repletion or cardiovascular collapse may then ensue during major surgical procedures.

Diagnostic Testing

Appropriate laboratory evaluations and diagnostic procedures should be obtained and the results considered to determine the patient's surgical and anesthetic risk, in addition to the need for appropriate health care modifications. The controversy lies in which tests are necessary and appropriate for specific settings. The rationale for performing “routine” tests has been under intense scrutiny, primarily because of recent and ongoing changes in health care economics. A protocol that delineates the indications for testing should be established by each surgical facility and approved by the medical staff. When protocols are followed for ordering preoperative laboratory tests, the total number of tests performed has been reduced 50% to 60%, and the appropriateness of the tests has improved.²³³ A necessary step in the implementation process for preoperative testing guidelines is the education of the medical staff. Centralizing the test-ordering process such as in the preoperative assessment clinic makes standardization and compliance more attainable.

Routine Diagnostic Testing

It has been traditional practice, even within the past decade, to order a battery of routine evaluative tests before a patient undergoes surgery and anesthesia. Routine ordering of preoperative diagnostic tests remains a common practice in many institutions. Until the early 1990s, the rationale for obtaining preoperative diagnostic tests was rarely questioned. Tests were frequently ordered for a variety of reasons but were often unrelated to findings based specifically on the patient's history and physical examination. Reasons cited for ordering the standard battery of preoperative tests included the following²³⁴⁻²³⁶:

- To follow customary practice at an institution
- To adhere to institutional or legislative mandates that dictate the tests be performed
- To further evaluate and determine the progress of a known disease or condition, because preexisting medical conditions have

a greater risk for intraoperative and postoperative complications

- To detect asymptomatic yet modifiable conditions that could alter anesthetic and surgical care
- To detect asymptomatic but unmodifiable conditions that could alter anesthetic and surgical risk
- To screen for conditions unrelated to the planned surgery
- To acquire baseline results that might be useful in the perioperative period
- To protect against medicolegal involvement

When considering the value of preoperative tests, the following must be considered:

1. The diagnostic procedure should be cost effective—that is, the costs saved from knowing the results exceed the expense of performing the test.
2. The diagnostic procedure should have a positive benefit-risk ratio—that is, the benefit derived from conducting the test outweighs the harm that might ensue from a false-positive result.
3. Test results are available for interpretation and recuperative intervention before surgery.
4. Test results will yield information that could not be obtained from the history and physical examination.
5. Abnormal test results in an asymptomatic patient would influence the patient care, the surgery, or the anesthesia management.

Without any clinical sign the likelihood of observing a significant anomaly is very small for diagnostic procedures such as ECG,²³⁵ chest radiography,^{235,237,238} or laboratory tests.^{235,239} Asymptomatic disease is rarely of clinical concern in perioperative surgical care. In addition, unexpected abnormal findings from preoperative testing tend not to affect the upcoming surgery.²⁴⁰ When a battery of routine preoperative tests are conducted, abnormal test results potentially alter patient care only 0.22% to 0.56% of the time.^{235,239} A

consistent conclusion of most studies is that routine preoperative laboratory screening is not cost-effective or predictive of postoperative complications^{234,241} and is unnecessary when an extensive history and physical examination do not suggest any patient abnormalities.^{1,242-249} However, there still is the tendency on the part of the preoperative physician to continue ordering the battery of routine tests in spite of professional society recommendations to the contrary.^{250,251}

Limitations to Routine Preoperative Diagnostic Testing

Studies estimate that at least 10% of the more than \$30 billion spent on laboratory testing annually in the United States goes to preparing patients for surgery.²⁵² Although added health care costs are the most apparent limitation to performing the routine battery of preoperative tests, additional factors can negatively affect the patient and care providers. The indiscriminate ordering of tests for diagnostic evaluation increases the likelihood that at least one test will be abnormal in a healthy patient.²³⁶ False-positive, or even false-negative, test results can lead to additional medical evaluation and the potential for increased morbidity. Abnormal laboratory tests for continuous data are defined in probabilistic terms and assume a normal patient population distribution.^{235,236} The end-points of the bell-shaped distribution curve are arbitrarily set at 2.5%; therefore 5% of test results in normal patients are reported as abnormal. False-positive test results may lead to additional follow-up tests, which can place the patient at risk of increased morbidity.²⁵³ Abnormal test results that were not further pursued, and lack of documentation of the rationale for not investigating abnormal test results, have increased the medicolegal risk for physicians.²⁵⁴

Timing of Diagnostic Testing

In general, diagnostic testing results are deemed current within 6 months of the scheduled surgery if the test results are normal and if the patient's current health status indicates no change has occurred since the test was performed.²⁵⁵ However, specific tests require

more current data analysis. A serum potassium level should be obtained within 7 days of surgery for patients receiving diuretics or digitalis, and blood glucose level determinations should be obtained on the day of surgery for patients with diabetes controlled by medication. An ECG, when indicated, is considered adequate within 30 days prior to elective surgery for patients with stable disease.⁸⁵ Chest radiographs taken within 6 months are generally acceptable if the patient's pulmonary condition is stable.²⁵⁶

Indications for Diagnostic Testing

A continuing point of controversy relates to disagreement about which tests are appropriate for specific patients, surgeries, and conditions. Difference of opinion exists among and within medical specialties regarding which tests are appropriate. Suggested guidelines for ordering various diagnostic tests based on results of the patient's history and physical examination have been offered for ordering diagnostic procedures ([Box 20.18](#)) and laboratory tests ([Box 20.19](#)).

Indications for Diagnostic Procedures

Chest Radiograph

- Previous abnormal results on chest radiography
- History of malignancy in which pulmonary metastasis might alter the surgical therapy
- History of tuberculosis (TB) or a positive skin test result for TB and no history of treatment
- History suggestive of pulmonary infection (e.g., new or chronic productive cough or blood-tinged or purulent-appearing sputum)
- Suspected intrathoracic pathologic condition (e.g., tumors, vascular ring)
- History of congenital heart disease

- History of prematurity associated with residual bronchopulmonary dysplasia
- Severe obstructive sleep apnea (patient may have cardiomegaly)
- Down syndrome (patient may have asymptomatic subluxation of the atlantoaxial junction)
- Symptomatic or debilitating asthma, chronic obstructive pulmonary disease, or cardiovascular disease

Electrocardiogram

- Patients at risk for cardiovascular disease (e.g., because of cocaine abuse, hypertension, chest pain, renal insufficiency, peripheral vascular disease, thyroid disease, diabetes mellitus [age 40 years or older], inability to exercise, significant pulmonary disease, smoking [more than 40 pack years], history of ischemic heart disease, history of compensated or prior heart failure, history of cerebrovascular disease)
- History of previously unevaluated pathologic-sounding murmur or palpitation
- Family history reveals possibility of inherited prolonged QT syndrome
- Patients with history of morbid obesity, moderate to severe sleep apnea, or chronic anatomic airway obstruction (e.g., Pierre Robin syndrome) may be at risk for right-sided heart strain

Box 20.19

Indications for Laboratory Testing

Complete Blood Count

- Hematologic disorder
- Vascular procedure
- Chemotherapy
- Unknown sickle cell syndrome status

Hemoglobin and Hematocrit

- Age less than 6 months (less than 1 year if born prematurely)
- Hematologic malignancy
- Recent radiation or chemotherapy
- Renal disease
- Anticoagulant therapy
- Procedure with moderate to high blood loss potential
- Coexisting systemic disorders (e.g., cystic fibrosis, prematurity, severe malnutrition, renal failure, liver disease, congenital heart disease)

White Blood Cell Count

- Leukemia and lymphomas
- Recent radiation or chemotherapy
- Suspected infection that would lead to cancellation of surgery
- Aplastic anemia
- Hypersplenism

- Autoimmune collagen vascular disease

Blood Glucose Level

- Diabetes mellitus
- Current corticosteroid use
- History of hypoglycemia
- Adrenal disease
- Cystic fibrosis

Serum Chemistry

- Renal disease
- Adrenal or thyroid disease
- Chemotherapy
- Pituitary or hypothalamic disease
- Body fluid loss or shifts (e.g., dehydration, bowel prep)
- Central nervous system disease

Potassium

- Digoxin therapy
- Diuretic therapy
- ACE inhibitors or angiotensin receptor blockers

Creatinine and Blood Urea Nitrogen

- Cardiovascular disease (e.g., hypertension)

- Renal disease
- Adrenal disease
- Diabetes mellitus
- Diuretic therapy
- Digoxin therapy
- Body fluid loss or shifts (e.g., dehydration, bowel prep)
- Procedure requiring radiocontrast

Liver Function Tests

- Hepatic disease
- Exposure to hepatitis
- Therapy with hepatotoxic agents

Coagulation Studies

INR, Prothrombin Time, and Partial Thromboplastin Time

- Leukemia
- Hepatic disease
- Bleeding disorder
- Anticoagulant therapy
- Severe malnutrition or malabsorption
- Postoperative anticoagulation to establish a baseline

Platelet Count and Bleeding Time

- Bleeding disorder
- Abnormal hemorrhage, purpura, history of easy bruising

Urinalysis

- Not indicated as a routine screening test

Pregnancy Test

- Possibility of pregnancy

Medication Levels

- Monitor for medications (e.g., theophylline, phenytoin, digoxin, carbamazepine) if patient exhibits signs of ineffective therapy, potential drug side effects, or poor drug compliance or has recently changed medication therapy without documentation of the drug level

ACE, Angiotensin-converting enzyme; *INR*, international normalized ratio (prothrombin time).

Pregnancy Testing

Routine preoperative pregnancy testing in women of childbearing age remains controversial. If a patient is concerned about possible pregnancy, uncertain of her pregnancy status, or if the physical examination or medical history suggests the possibility of pregnancy (e.g., because of information regarding sexually active status, time of last menstrual period, presence or absence of birth control methods), a preoperative pregnancy test should be offered with the patient's consent on the evening prior to or morning of the surgery.^{1,257} A serum human chorionic gonadotropin (hCG) measurement performed either the day prior to surgery or on the morning of surgery (realizing the potential for delay while awaiting the hCG result) should be considered for patients less than 1 month past the expected date for their initial missed period.

Currently available urine pregnancy tests may yield falsely

negative or falsely positive results until week 5 of the pregnancy.²⁵⁸ Depending on the test used, the test may not detect certain variants of hCG or may only have a window of detection for very early pregnancy. In addition, factors such as the hydration status of the patient being tested may skew results.²⁵⁹

Issues to address when deciding whether to test include the following:

- Policies of the hospital or health care facility based on medical staff bylaws. The medical facility should have established guidelines, supported on ethical, legal, financial, and scientific relevance that delineate when testing for pregnancy is appropriate.²⁶⁰
- All women should be advised of the potential fetal risk (e.g., premature labor, spontaneous abortion) secondary to the underlying surgical condition and surgical uterine stimulation that is unrelated to anesthesia.²⁵⁷ The incidence of congenital abnormalities is no greater in pregnant women who undergo surgery than it is in those with a surgery-free pregnancy.^{261,262} There is not enough evidence to support or deny the risk of anesthesia on the parturient in early pregnancy.²⁶³

Despite this finding, patients are sometimes advised to postpone elective surgery until postpartum or at the least well after the first trimester, when fetal organogenesis is complete.

- Patients should be privately questioned about the possibility of pregnancy. Female staff should interview adolescent patients in the absence of family members.
- Patients should be offered pregnancy testing despite history, except in patients with a history of hysterectomy or bilateral salpingo-oophorectomy.²⁶⁴

Chest Radiography

A preoperative chest radiograph is of minimal predictive importance and is not cost effective as a screening test for postoperative respiratory problems. Therefore it is not to be recommended without specific indications from the medical history and physical examination, that is, new or unstable

cardiopulmonary disease.^{1,4,265,266} The risk of performing a routine preoperative chest radiograph in asymptomatic patients less than 75 years of age is greater than the benefit.²⁵⁴

Electrocardiography

A routine preoperative ECG is not necessary unless a specific indication is present.^{1,245,251} Many medical facilities continue to use an age-specific criterion for acquiring a preoperative ECG, regardless of indications—or lack of indications—based on the patient's medical history and physical examination. The recommended minimum age for routinely conducting a baseline ECG, if deemed necessary by the facility, has gradually increased to 65 years or older and is considered current if tested within 1 year of the procedure provided no changes in the patient's condition have occurred.^{85,267} Inquiry has even been raised regarding the appropriateness of an age-only basis for preoperative ECG testing, especially as the Centers for Medicare and Medicaid Services (CMS) no longer reimburse for routine, age-based testing.²⁴⁵

The value of obtaining a routine preoperative 12-lead ECG in asymptomatic, low-risk patients who are having cataract surgery²⁶⁸ has been questioned.^{269,270} This rethinking of indications for when to order a preoperative ECG has been challenged for the following reasons:

- It has not been shown to be cost effective.^{240,271,272}
- It is a poor predictor of perioperative complications.^{270,272,273}
- It is of limited value in detection of ischemia in asymptomatic individuals.^{274,275}
- Abnormal preoperative ECGs rarely lead to alteration in patient care.^{240,271,276}
- No evidence supports the value of a “baseline” ECG.^{269,270,277}

Fasting Considerations

Part of the anesthesia provider's role in patient preparation involves establishing an appropriate fasting interval for the patient. This requires knowledge of risk factors for pulmonary aspiration of gastric contents weighed against the consequences of prolonged fasting. The risk of perioperative pulmonary aspiration of gastric contents that results in morbidity or mortality is relatively low, so the recommendations for withholding oral feeding before elective surgery have recently become much more liberal. When studies were conducted challenging the traditional fasting times (7 hours or greater) for clear liquids, the results appeared to show that a reduced fasting interval does not increase the risk of pulmonary aspiration in normal, healthy individuals.²⁷⁸

The traditional policy of fasting after midnight fails to address three variables that influence gastric emptying for surgery: (1) the time of the scheduled surgery, (2) the time at which the patient retired for the night, and (3) the variability in gastric emptying for solids and fluids among individuals. Prolonged fasting, especially in children, can be highly distressing in addition to causing physiologic alterations. Periods of long preoperative fasting have been shown to contribute to the following:

- Dehydration²⁷⁹
- Hypoglycemia (in smaller children)²⁸⁰
- Hypovolemia
- Increased irritability²⁸⁰
- Enhanced preoperative anxiety²⁸¹
- Reduced compliance with preoperative fasting orders²⁷⁹
- Thirst²⁸² and related discomforts (e.g., hunger, headache, unhappiness)

Pulmonary Aspiration Risk

Recent ingestion of food and liquid before surgery does contribute to an increased risk of pulmonary aspiration. Solid foods must be digested to a bolus diameter of less than 2 mm before the food can

pass through the pylorus.²⁸³ This process normally takes several hours for solids, whereas liquids pass through the pylorus in 1 to 2 hours. Historically, patients have been required to fast for extended periods in an attempt to ensure an empty stomach. However, sustained fasting does not guarantee that the stomach will be empty at the time of surgery.²⁸⁴

Part of the preoperative evaluation process identifies patients who are at risk for aspirating gastric contents into the lungs and developing aspiration pneumonia. Factors associated with an increased risk of pulmonary aspiration of gastric contents are listed

Box 20.20. ^{285–296}

Conditions That Increase the Risk of Regurgitation and Pulmonary Aspiration During Anesthesia

- Age extremes (less than 1 yr or older than 70 yr)
- Anxiety
- Ascites
- Collagen vascular disease (e.g., scleroderma)
- Depression
- Esophageal surgery
- Exogenous medications (e.g., opioids, premedication)
- Failed intubation or difficult airway history
- Gastroesophageal junction dysfunction (e.g., hiatal hernia)
- Mechanical obstruction (e.g., pyloric stenosis, duodenal ulcer)
- Metabolic disorders (e.g., hypothyroidism, chronic diabetes, hepatic failure, hyperglycemia, obesity, renal failure, uremia)
- Neurologic sequelae (e.g., those of developmental delays, head

injury, hypotonia, seizures)

- Pain
- Pregnancy
- Prematurity with respiratory problems
- Smoking
- Type and composition of gastric contents (e.g., solid foods and milk products)

Fasting Interval

When the fasting interval is minimized, patients (especially children) are reported to be less irritable, less thirsty, and less hungry; to have fewer headaches; to be more comfortable; and generally to tolerate the preoperative phase better than patients who have fasted for longer periods of time. Modest amounts of clear liquids taken orally 2 hours²⁹⁷⁻³⁰¹ to 3 hours^{302,303} preoperatively, when compared with a conventional fasting interval of “7 to 8 hours” or “after midnight,” are acceptable and have been shown to lower residual gastric volume (stimulation of the gastric emptying reflex) and raise gastric pH in a majority of patients. Acceptable clear fluids (e.g., water, apple juice, black coffee, black tea, clear juice drinks, clear Jell-O, clear broth, ice, popsicles, Pedialyte) may be given to healthy, unpremedicated patients. A 2016 study found no, or only a minimal, increase in gastric volume in patients allowed reduced fat milk to coffee at 2 hours postingestion, thus making the proposal to allow milk to hot drinks up until 2 hours prior to anesthesia.³⁰⁴ Chewing gum or sucking on candy does not warrant delay or cancellation of the operation,³⁰⁵ and should be avoided once fasting from clear liquids has commenced.³⁰⁶ In light of these findings, recommended fasting guidelines for otherwise healthy individuals have been liberalized **Box 20.21**.^{296,305,307}

Fasting Guidelines for Healthy Patients

(All Ages) Undergoing Elective Surgery

- No chewing gum (nicotine gum allowed with patient counseling) or candy after midnight (foreign body aspiration concern)
- Clear liquids up to 2 hours before surgery*
- Breast milk until 4 hours before surgery
- No infant formula, nonhuman milk,[†] or light meal[‡] for at least 6 hours before surgery
- Prescribed medications (e.g., premedication) administered with a sip of water or prescribed liquid mixture (up to 150 mL for adult; up to 75 mL for children) up to 1 hour before anesthesia

*Consider the possibility that the case may proceed earlier than scheduled.

[†]Because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.

[‡]A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

From American Society of Anesthesiologists Committee. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters, *Anesthesiology*. 2011;114(3):495–511.

American Society of Anesthesiologists Physical Status Classification System

With the conclusion of the preanesthesia assessment, assignment of an ASA physical status classification is made for each patient. The classification ideally represents a reflection of the patient's preoperative status and is not an estimate of anesthetic risk. For greater accuracy to be attained from its interpretation, the ASA status should also remain independent of the proposed surgical procedure.³⁰⁸⁻³¹¹

Advent and Purpose

In 1940 the ASA developed a system “to classify the physical condition of a patient requiring anesthesia and surgery.” This six-category classification was then revised by the ASA in 1961 to the current system of five categories (Table 20.18).³¹² The purpose of the ASA classification, then and now, is to provide a consistent means of communication to anesthesia staff, within and among institutions, about the physical status of a patient.³¹ Furthermore, it allows for a standardized interpretation of anesthesia outcome based on one criterion.

TABLE 20.18
ASA Physical Status Classification System

ASA PS Classification	Definition	Examples, Including, but Not Limited to:
ASA I	A normal healthy patient	Healthy, nonsmoking, no or minimal alcohol use
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional limitations. Examples include (but not limited to): current smoker, social alcohol drinker, pregnancy, obesity (30 < BMI < 40), well-controlled DM/HTN, mild lung disease
ASA III	A patient with severe systemic disease	Substantive functional limitations; one or more moderate to severe diseases. Examples include (but not limited to): poorly controlled DM or HTN, COPD, morbid obesity (BMI ≥ 40), active hepatitis, alcohol dependence or abuse, implanted pacemaker, moderate reduction of ejection fraction, ESRD undergoing regularly scheduled dialysis,

		premature infant PCA < 60 weeks, history (>3 months) of MI, CVA, TIA, or CAD/stents
ASA IV	A patient with severe systemic disease that is a constant threat to life	Examples include (but not limited to): recent (< 3 months) MI, CVA, TIA, or CAD/stents, ongoing cardiac ischemia or severe valve dysfunction, severe reduction of ejection fraction, sepsis, DIC, ARD or ESRD not undergoing regularly scheduled dialysis
ASA V	A moribund patient who is not expected to survive without the operation	Examples include (but not limited to): ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the face of significant cardiac pathology or multiple organ/system dysfunction
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes	
<ul style="list-style-type: none"> • The addition of "E" denotes emergency surgery: An emergency is defined as existing when delay in treatment of the patient would lead to a significant increase in the threat to life or body part. 		

ARD, Acute renal disease; *ASA*, American Society of Anesthesiologists; *BMI*, body mass index; *CAD*, coronary artery disease; *COPD*, chronic obstructive pulmonary disease; *CVA*, cerebral vascular accident; *DIC*, disseminated intravascular coagulation; *DM*, diabetes mellitus; *ESRD*, end-stage renal disease; *HTN*, hypertension; *MI*, myocardial infarction; *PCA*, post-conceptual age; *TIA*, transient ischemic attack.

From

<http://www.asahq.org/~media/sites/asahq/files/public/resources/standards-guidelines/asa-physical-status-classification-system.pdf>

Despite rough correlations between patient physical status and postoperative outcome, *the ASA classification system does not represent an estimate of anesthesia risk.*³⁰⁸⁻³¹¹ Although a patient in poor physical health is known to be at greater risk for negative outcome, this does not account for other factors that influence perioperative morbidity and mortality. These factors include the duration and involvement of the surgical procedure, the degree of perioperative monitoring, and unfortunate circumstances such as human error or equipment failure.

Definition

The current ASA classification system ranges from class I through

VI, with E denoting an emergent procedure. By definition a patient classified as ASA status I is a healthy individual except for the condition that has necessitated surgery. A healthy young woman about to undergo an emergency dilation and curettage for vaginal bleeding, for example, is classified as ASA status IE. At the other end of the spectrum, a 74-year-old man with hypertension, uncontrolled diabetes, and unstable angina who is scheduled for a coronary artery bypass graft procedure is classified as ASA status IV.³¹²

Limitations of the Current System

Despite the numerous benefits of the ASA classification system, it has its shortcomings. Namely the current system is not explicit enough in its categorization to account for every patient, and this can result in patient misclassification. If the physical status classification system is used for statistical or reimbursement purposes within a department, overclassification is often the consequence. Overclassification of a patient also occurs when the proposed surgical procedure is incorporated into the assignment of ASA physical status. This improper classification, or overclassification, of patient status thereby limits the degree of accuracy attained from its original interpretation. As a result, correlations between preoperative status and postoperative outcome are skewed. Despite the shortcomings of the system, ASA physical status continues to be assigned to each patient as a summary of the preoperative evaluation.

Preventing Operative Errors

The Joint Commission has endorsed a universal protocol for eliminating wrong site, wrong procedure, and wrong patient surgeries. It has been endorsed by more than 40 of the leading medical, nursing, and health care leadership organizations. The guidelines are to be used in all hospitals, ambulatory care surgery centers, and office-based surgery sites, as shown in [Box 20.22](#).

Guidelines for Implementing the Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery

Conduct a Preprocedure Verification Process

Address missing information or discrepancies before starting the procedure.

- Verify the correct procedure, for the correct patient, at the correct site.
- When possible, involve the patient in the verification process.
- Identify the items that must be available for the procedure.
- Use a standardized list to verify the availability of items for the procedure. (It is not necessary to document that the list was used for each patient.) At a minimum, these items include:
 1. Relevant documentation. Examples: History and physical, signed consent form, preanesthesia assessment
 2. Labeled diagnostic and radiology test results that are properly displayed. Examples: Radiology

images and scans, pathology reports, biopsy reports

3. Any required blood products, implants, devices, special equipment

- Match the items that are to be available in the procedure area to the patient.

Mark the Procedure Site

At a minimum, mark the site when there is more than one possible location for the procedure and when performing the procedure in a different location could harm the patient.

- The site does not need to be marked for bilateral structures.
Examples: tonsils, ovaries
- For spinal procedures: Mark the general spinal region on the skin. Special intraoperative imaging techniques may be used to locate and mark the exact vertebral level.
- Mark the site before the procedure is performed.
- If possible, involve the patient in the site marking process.
- The site is marked by a licensed independent practitioner who is ultimately accountable for the procedure and will be present when the procedure is performed.*
- Ultimately, the licensed independent practitioner is accountable for the procedure—even when delegating site marking.
- The mark is unambiguous and is used consistently throughout the organization.
- The mark is made at or near the procedure site.
- The mark is sufficiently permanent to be visible after skin

preparation and draping.

- Adhesive markers are not the sole means of marking the site.
- For patients who refuse site marking or when it is technically or anatomically impossible or impractical to mark the site (see examples below): Use your organization's written, alternative process to ensure that the correct site is operated on. Examples of situations that involve alternative processes:

1. Mucosal surfaces or perineum

2. Minimal access procedures treating a lateralized internal organ, whether percutaneous or through a natural orifice

3. Teeth

4. Premature infants, for whom the mark may cause a permanent tattoo

Perform a Time-Out

The procedure is not started until all questions or concerns are resolved.

- Conduct a time-out immediately before starting the invasive procedure or making the incision.
- A designated member of the team starts the time-out.
- The time-out is standardized.
- The time-out involves the immediate members of the procedure team: the individual performing the procedure, anesthesia providers, circulating nurse, operating room technician, and other active participants who will be participating in the

procedure from the beginning.

- All relevant members of the procedure team actively communicate during the time-out.
- During the time-out, the team members agree, at a minimum, on the following:

1. Correct patient identity

2. Correct site

3. Procedure to be done

- When the same patient has two or more procedures: If the person performing the procedure changes, another time-out needs to be performed before starting each procedure.
- Document the completion of the time-out. The organization determines the amount and type of documentation.

*In limited circumstances, site marking may be delegated to some medical residents, physician assistants (PA), or advanced practice registered nurses (APRN).

Summary

An important feature of patient care is a timely and thorough preoperative assessment to identify factors that increase the risk of anesthesia and surgery. The preoperative evaluation and preparation of the patient involve integration of information obtained from the patient interview, chart review, physical examination, and interpretation of the results of necessary diagnostic tests. The anesthesia provider can then assimilate the assessment data and devise and implement the most appropriate anesthetic plan for the patient.

Fluid Administration, Perioperative Goal-Directed Fluid Therapy, and Electrolyte Disorders

Crystal Trinooson, Nilu G. Patel

Fluid Volume, Types of Fluids, and Overview of Fluid Management

Perioperative fluid management is an integral component of anesthetic practice, which involves maintaining intravascular volume, augmenting cardiac output (CO), maintaining tissue perfusion, promoting oxygen delivery, correcting and maintaining electrolyte balance, enhancing microcirculatory flow, and facilitating the delivery of nutrients and clearance of metabolic waste.^{1,2} Targeted fluid administration is a crucial tool to compensate for acute volume alterations intraoperatively, and to mitigate increased oxygen demands associated with metabolic derangements and surgical trauma.

Fluid management is arguably one of the most consequential aspects of anesthetic care. The impacts of perioperative fluid handling are seen acutely in the intraoperative and immediate postoperative periods, but recently there has been a tremendous focus on the relationship between perioperative fluid administration and long-term outcomes in surgical patients. A growing body of evidence suggests that fluid balance and the complications associated with inappropriate fluid administration not only have an impact on acute postsurgical recovery, but may also influence long-term morbidity and mortality.³⁻⁹

Normal Physiologic Distribution and Regulation of Fluids

An understanding of body fluid distribution and regulation is essential for anesthetic practice. Total body water (TBW) in an average adult represents roughly 60% of lean body mass.¹⁰ Fluid is physiologically distributed as intracellular volume (ICV), which represents roughly two-thirds of TBW, and extracellular volume (ECV), which represents one-third of TBW.¹¹ The normal electrolyte composition of ICV differs greatly from that of ECV.¹² The primary cation of the ECV is sodium and the primary anion is chloride. Potassium is the primary cation of the ICV and phosphate the primary anion.^{10,12} The resting membrane gradient for these electrolytes is maintained by the sodium-potassium adenosine triphosphate enzyme (Na + K + ATPase) in the cell membrane that uses cellular energy to actively transport sodium ions into the ECV.^{12,13} The cell membrane is permeable to water and as a result, the ICV and ECV maintain a state of osmotic equilibrium despite their varied solute composition.^{12,13} The daily fluid volume required to maintain TBW homeostasis in a healthy adult who is normothermic with standard metabolic function is approximately 25 to 35 mL/kg per day (~2–3 liters per day).^{10,14,15}

Extracellular volume is further subdivided by the vascular endothelium into two additional compartments. The intravascular compartment contains plasma volume, and represents about one-fourth of ECV. The interstitial compartment is composed of extravascular fluid in the tissue spaces, and represents roughly three-fourths of ECV (Fig. 21.1).^{12,13,16} ECV is also composed of a small amount of transcellular fluids, including cerebrospinal fluid, synovial fluid, gastrointestinal secretions, and intraocular fluid.^{10,12,17} Transcellular fluids are anatomically isolated from the fluid dynamics that impact the remaining ECV, and therefore they are considered nonfunctional.^{17,18} Each of these volumes can be corroborated in laboratory testing with the use of radioactive water, isotope-tagged red blood cells, and selectively permeable protein-bound radioactive tracers.^{10,19}

FIGURE 21.1 Fluid compartments. Fluids comprise approximately 60% of the body weight. Two-thirds of the fluid is intracellular and one-third is extracellular, which includes interstitial fluid and plasma. (Adapted from Applegate E. *The Anatomy and Physiology Learning System*. 4th ed. St. Louis: Elsevier; 2011:408.)

Fluid exchange between the extracellular compartments is largely dependent on the Starling forces, four transcapillary pressures whose gradients dictate direction of fluid movement across the capillary epithelium.¹⁹ Capillary hydrostatic pressure (P_c) is the intravascular blood pressure, driven by the force of the CO and impacted by vascular tone. Interstitial fluid pressure (P_{if}) is the hydrostatic pressure of the interstitial space. Relative to atmospheric pressure, P_{if} of most tissues is slightly negative; this is

thought to be due to the contraction of lymphatic vessels in the interstitium.¹⁹⁻²¹ Rigid or encapsulated tissues of the kidneys, brain, bone marrow, and skeletal muscle have a slightly positive Pif.^{19,21} Plasma oncotic pressure (π_p) is the osmotic force of colloidal proteins within the vascular space. Interstitial oncotic pressure (π_{if}) is the osmotic force of colloidal proteins within the interstitial space (Fig. 21.2).¹⁹ Because of its smaller molecular weight and higher concentration relative to other plasma proteins, albumin is the primary determinant of both capillary and interstitial oncotic pressures.^{19,20} Increases in P_c and π_{if} favor filtration of fluid into the interstitial space; increases in P_{if} and π_p favor absorption of fluid into the intravascular space.^{10,12,17} The relationship between these forces is described by the Starling equation as noted^{10,19,21}:

FIGURE 21.2 Capillary filtration forces. Water, electrolytes, and small molecules exchange freely between the vascular compartment and the interstitial space at the

site of capillaries and small venules. The rate and amount of exchange are driven by the physical forces of hydrostatic and oncotic pressures and the permeability and surface area of the capillary membranes. The two opposing hydrostatic pressures are capillary hydrostatic pressure and interstitial hydrostatic pressure. The two opposing oncotic pressures are capillary oncotic pressure and interstitial oncotic pressure. The forces that favor filtration from the capillary are capillary hydrostatic pressure and interstitial oncotic pressure, and the forces that oppose filtration are capillary oncotic pressure and interstitial hydrostatic pressure. The sum of their effects is known as *net filtration pressure* (NFP). In the example of normal exchange illustrated here, a small amount of fluid moves to the lymph vessels, which accounts for the net filtration difference between the arterial and venous ends of the capillary. (Adapted from McCance KL, et al. *Pathophysiology*. 7th ed. St. Louis: Elsevier; 2014:106.)

$$\text{Net Filtration (Jv)} = K_f ([P_c - P_{if}] - \sigma[\pi_p - \pi_{if}])$$

where J_v is the net fluid movement between compartments; K_f is a filtration coefficient that accounts for capillary surface area and endothelial permeability to water (capillary hydraulic conductivity); $[P_c - P_{if}] - \sigma[\pi_p - \pi_{if}]$ is the net driving force.

Increased K_f favors filtration.^{20,22} σ is a reflection coefficient that ranges from 0 to 1 and accounts for the varying degree of endothelial permeability to substances such as albumin and large polar molecules. A σ of 0 indicates that the endothelium is freely permeable to the substance; a σ of 1 indicates that endothelium is completely impermeable to the substance (during capillary filtration, 100% of the substance is reflected back into the vascular lumen).²⁰⁻²³

Positive net filtration favors fluid exudation into the tissues; negative net filtration favors fluid absorption into the vasculature.^{10,19} Net filtration tends to be slightly positive at the arterial end of capillaries and slightly negative at the venous end.^{19,20} The overall balance of filtration pressures within the capillaries of the entire body is slightly positive such that a small percentage of intravascular volume is constantly filtered into the

interstitial space at a rate of approximately 2 mL/min under normal physiologic conditions.^{19,20} This volume is returned to the intravascular space via the lymphatic system. Under euvolemic conditions, net fluid filtration is roughly equal to lymphatic flow.^{19–22}

Starling's description of transcapillary forces has helped form the basis for our understanding of microcirculatory fluid dynamics over the past century, but recent evidence examines the importance of the capillary epithelium specifically, the endothelial glycocalyx in maintaining fluid homeostasis.^{16,24} The glycocalyx is a gel layer on the luminal surface of the vascular endothelium that plays an important protective role in transcapillary fluid exchange, microcirculatory flow, blood component rheology, plasma oncotic pressure, signal transduction, immune modulation, and vascular tone.^{16,25,26}

Ranging from 0.1 to 1.2 micrometers (mcm) in diameter, the glycocalyx is composed of a backbone matrix of glycoproteins, polysaccharides, and hyaluronic acid that bind to ionic side chains and plasma proteins to create a physiologically active barrier within the vascular space.^{11,16,25} This dynamic barrier ionically repels negatively charged polar compounds in addition to blood components, to create a zone of exclusion between the surface of the glycocalyx and the center of the vessel, aiding in the prevention of blood component adhesion to the vascular wall and augmenting laminar blood flow.²⁵ By binding to circulating plasma albumin, the glycocalyx also helps to preserve capillary oncotic pressure and decrease capillary permeability to water, thus modulating the impact of plasma hydrostatic pressure on net filtration.^{24,25} This regulating function has been described as the *double barrier* effect^{11,13} and it has led to the development of a revised Starling equation as follows²⁵:

$$\text{Net Filtration (Jv)} = K_f ([P_c - P_{if}] - \sigma[\pi_p - \pi_{sg}])$$

where π_{sg} is the oncotic pressure in the subglycocalyx space between the endothelium and the glycocalyx. Furthermore, the glycocalyx plays an important role in modulating inflammatory

processes. This space is thought to contain inflammatory mediators whose binding sites are enclosed by the matrix, thus helping prevent leukocyte adhesion except in circumstances of acute inflammation or endothelial damage.²⁵ Other functions of the glycocalyx include scavenging of free radicals, binding and activation of anticoagulation factors, and signal transduction that helps regulate local vasoactive responses to mechanical stress.^{15,25}

In addition to the microcirculatory dynamics that govern transcapillary fluid volume distribution, there are a series of neurohormonal influences and feedback mechanisms that help to finely regulate electrolyte and fluid balance.¹² Normal daily alterations in TBW are minute and intricately regulated by the renin-angiotensin-aldosterone-system (RAAS), antidiuretic hormone (ADH), and atrial natriuretic peptide (ANP) pathways.^{10,12,15,27} Sodium is one of the primary determinants of serum osmolality and water transport; thus the regulation of ECV is largely dependent on sodium homeostasis.¹² This concept becomes tremendously important when discussing perioperative sodium loading and appropriately selecting intravenous fluids.

The RAAS is an important regulator of physiologic sodium hemostasis.¹² In response to hypotension (as detected by intracardiac and renal afferent arteriole baroreceptors) and systemic sympathetic stimulation, the juxtaglomerular cells of the kidney release the enzyme renin. The interaction of circulating renin with the precursor angiotensinogen causes cleaving of angiotensinogen to the active substance angiotensin I. Angiotensin I exerts local vasoconstrictor activity, but its primary role is as a precursor for the more potent angiotensin II. This change occurs in the lungs as a result of angiotensin converting enzyme (ACE) acting as a catalyst for the conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor and directly stimulates the renal tubules to reabsorb sodium and water. It also causes the adrenal cortex to release aldosterone, which further stimulates sodium and water retention by the kidneys.^{12,19}

The ADH pathway functions primarily to regulate water balance. In response to even minute increases in serum osmolality (as detected by osmoreceptors in the hypothalamus), the posterior pituitary gland releases ADH, which causes aquaporin channels

within the kidney to transiently reabsorb large quantities of water. This helps preserve circulating volume and contributes to a tremendous increase in urine concentration and osmolality.^{12,19} ADH also plays an important role in preserving blood pressure by acting as a potent arterial vasoconstrictor. Decreases in circulating blood volume (as detected by baroreceptors in the atria, carotid body, and aorta) stimulate this hormones release, although this mechanism is much less sensitive than osmolality-mediated secretion.¹⁹ The detection of increased serum osmolality also causes the hypothalamus to stimulate thirst.¹²

Stretch receptors within the cardiac atrial walls stimulate the release of ANP from cardiac myocytes as a result of increased-preload or hypervolemic states. This stimulates the kidney to release sodium and water, thus reducing circulating blood volume and offloading the heart. ANP also produces specific vasoactive responses in the afferent and efferent renal arterioles to increase the glomerular filtration rate, and it inhibits the release of renin and ADH.²⁸ Conversely, during periods when preload is decreased, atrial receptors inhibit the release of ANP.¹⁵

These mechanisms combine with many other complex renal, hormonal, vascular, and metabolic processes to carefully maintain fluid and electrolyte balance.¹⁵ In the healthy adult, inputs such as water and electrolyte intake (nutrition and free water intake) are maintained within such narrow limits (sweat, respiratory losses, gastrointestinal losses, and urine output) that daily water fluctuation only represents approximately 0.2% of TBW.^{10,15}

Composition and Relative Advantages of Various Intravenous Fluids

The selection of intravenous fluids for perioperative management is one of the more controversial decisions in modern anesthetic practice. Despite a general consensus in the overall goals of fluid resuscitation to restore intravascular volume, microvascular flow, and tissue perfusion, there continues to be a longstanding debate over the safety and efficacy of crystalloid solutions as compared to colloid solutions for volume resuscitation during the perioperative period.²⁹

Crystalloids

Crystalloids are aqueous electrolyte solutions that have been a mainstay of volume resuscitation in surgical patients for over a century.^{17,30,31} Crystalloid infusions are preferable for resuscitation of dehydration conditions (conditions of TBW loss leading to plasma hypertonicity) such as prolonged fasting states, active gastrointestinal losses, polyuria, and hypermetabolic conditions.³² The administration of isotonic crystalloid solutions under these circumstances contributes to the hydration of the entire ECV, restoring water and electrolyte homeostasis to both intravascular and interstitial spaces for normal cellular processes. The use of crystalloids to replace active intravascular losses in the perioperative setting is beneficial for providing immediate restoration of circulating vascular volume, preservation of microcirculatory flow, decrease in hormone-mediated vasoconstriction, and correction of plasma hyperviscosity associated with acute hemorrhage. Crystalloids are also preferred for their lack of allergenic potential, their ease of metabolism and renal clearance (compared to colloids) when infused in appropriate volumes, and their preservation of electrolyte balance despite active intraoperative plasma losses.^{1,13,14} However, because isotonic crystalloids are distributed evenly throughout the extracellular space, their ability to expand plasma volume is transient. Because of their low molecular weight, crystalloid solutions contribute to

hemodilution of plasma proteins and loss of capillary hydrostatic pressure. This favors filtration of approximately 75% to 80% of administered volumes into the interstitial space.^{1,17,33} The composition of common isotonic crystalloid solutions varies (Table 21.1). Their relative advantages and disadvantages are further discussed below.

TABLE 21.1
Composition of Crystalloid Solutions

Concentration	Plasma	Plasmalyte-A/Normosol-R/Isolyte-S	Lactated Ringer	0.9% Sodium Chloride
Sodium (mEq/L)	142	140–141	130	154
Potassium (mEq/L)	4	5	4	
Chloride (mEq/L)	103	98	110	154
Phosphate (mEq/L)	1.4	1*		
Magnesium (mEq/L)	2	3		
Calcium (mEq/L)	5		3	
Lactate (mEq/L)			28	
Acetate (mEq/L)		27		
Gluconate (mEq/L)		23		
pH	7.4	7.4	6.2	5.6
Osmolality(mOsm/L)	291	294–295	275	310

*Isolyte-S only

Sodium chloride is the original crystalloid solution 0.9% saline solution, known as *normal saline* (NS),” and is currently the most commonly administered intravenous fluid worldwide.^{13,14,31,34,35} NS was determined to be a physiological solution over a century ago based on in vitro erythrocyte studies comparing the effects of a 0.9% saline infusion with those of a 0.6% solution; the term NS persists today.³¹ However, of all of the isotonic crystalloid preparations available for fluid resuscitation, 0.9% saline is the least physiologic.¹⁵

Normal saline contains roughly equal concentrations of sodium and chloride, although the normal physiologic concentration of sodium in plasma is higher than that of chloride.³⁴ The presence of an extraordinarily high chloride load contributes to acid-base imbalances and the well-recognized tendency for 0.9% saline to contribute to dose-dependent hyperchloremic metabolic acidosis.^{14,31,36} Even if compensatory mechanisms preserve a normal plasma pH, the use of 0.9% saline for volume resuscitation in acute

losses is associated with marked alterations in base excess secondary to chloride load. This effect may exacerbate volume overload if negative base excess is used as an infusion trigger.³⁴

Hyperchloremia may also have a significant impact on renal function. This is thought to be due in part to the impact of excess renal reabsorption of chloride on renal arteriolar vascular resistance, leading to a decrease in glomerular filtration rates.^{31,37} Hyperchloremia may also impair renal handling of bicarbonate. The increased sodium load introduced by large volumes of 0.9% saline has been shown to cause increased salt and water retention, hemodilution, and interstitial edema well into the postoperative period. Studies have demonstrated that the administration of 2 L of 0.9% saline to healthy volunteers contributes to a positive sodium and water balance that takes 2 days to excrete.^{11,38} This duration may be significantly prolonged in surgical patients.^{11,15} NS has a dose-dependent association with renal impairment and postoperative bowel dysmotility; these effects may be more pronounced in patients with preexisting renal disease.³⁴

A study comparing the perioperative impact of 0.9% saline against that of Plasmalyte found that patients in the saline group had a greater incidence of kidney failure requiring dialysis, acidosis requiring the administration of buffering agents, blood transfusions (likely secondary to the impact of acidosis on coagulation), and postoperative wound infections than did those in the Plasmalyte group.^{36,39} The British Consensus Guidelines on Intravenous Fluid Therapy for Adult Surgical Patients (GIFTASUP) issued a series of recommendations for perioperative fluid management, including a strong recommendation that the use of 0.9% saline be replaced by “balanced salt solutions” for fluid resuscitation except in cases of hyponatremia.⁴⁰ The primary role of NS in modern anesthetic practice is in the administration of small volumes to neurosurgical patients. As a result of its mild hyperosmolality, 0.9% saline is the preferred fluid for patients at risk for cerebral edema.³⁶ NS may also be indicated in fluid management of patients with anuria and end-stage renal disease who cannot excrete the potassium content of more balanced crystalloid solutions.¹⁴ Hypertonic saline solutions of 3% or greater are used in low-dose infusions in trauma and head-injured patients. These solutions promote volume expansion that

mobilizes intracellular and interstitial fluids into the intravascular space. This may confer some protection for patients with intracranial hypertension, but there are significant risks associated with its infusion including vascular irritation, a sudden and pronounced fluid shift into the intravascular space, and the potential for dehydration of neural cells leading to osmotic demyelination syndrome.^{14,41}

Lactated Ringer solution (LR) is a multiple electrolyte solution that contains sodium lactate as a bicarbonate substrate, or buffering agent.^{33,41,42} This helps to maintain the electrochemical balance and neutral pH of the solution while decreasing the anionic requirement for chloride.^{14,41} LR is a relatively low-cost solution compared to other balanced salt solutions, and its use as a resuscitative fluid has also been shown to be more effective in preserving intravascular volume than the use of 0.9% saline. LR is not recommended for large-volume administration in diabetic patients because the byproducts of hepatic metabolism of lactate are gluconeogenic.^{35,41} The infusion of LR may also contribute to a mild metabolic alkalosis because of the alkalinizing effect of lactate metabolism. LR is mildly hypotonic and may cause transient serum hypo-osmolality and associated cerebral edema. As a result, LR is contraindicated in patients with traumatic brain injury or other neurovascular insults.^{14,30} LR also contains calcium and is contraindicated for infusion with citrated transfusion products because of the risk of coagulation.³⁶

Plasmalyte-A, Normosol-R, and Isolyte S are the most isotonic of the balanced salt solutions.^{30,36} These solutions have the most favorable acid-base profile compared to plasma; they preserve physiologic pH, renal perfusion, and overall renal function better than 0.9% saline.^{35,36} They also utilize sodium gluconate and sodium acetate as alkalinizing buffers rather than lactate. Furthermore, because they do not contain calcium, these solutions are compatible with blood products.^{11,36,43} A 2012 Cochrane review examined the perioperative administration of buffered versus nonbuffered solutions and found that whereas there was no significant difference in mortality between the cohorts, patients who received buffered solutions had less acid-base alterations and received fewer transfusions than those who received nonbuffered solutions.⁴⁴

Colloids

Colloids are suspensions of high-molecular weight molecules in electrolyte solutions that produce intravascular volume expansion by directly increasing π_p and interacting with the endothelial glycocalyx to decrease transcapillary filtration.^{11,30} Because of their effectiveness as plasma volume expanders, colloid solutions are often used perioperatively for their fluid sparing effects compared to crystalloids.^{31,36} Aside from packed red blood cells, albumin is the only naturally-occurring colloid solution available for infusion; a variety of synthetic colloids are also available worldwide.⁴⁵ Colloid solutions are classified by molecular weight, concentration, and half-life.¹⁵

Dextrans are among the oldest artificial colloids, and they possess high-molecular weight polymers (40–70 kDa) derived from bacterial metabolism of sucrose. They were first manufactured in the 1940s.^{31,41,46} They are markedly hyperosmolar and have a half-life of roughly 6 to 12 hours.^{36,46} These compounds are known to cause acute renal failure by multiple mechanisms, including indirect hyperosmotic renal injury and direct renal tubular damage as a result of accumulation.^{15,36,41} They have coagulopathic effects as demonstrated by dextran's impairment of von Willebrand factor, activation of plasminogen, and interference with platelet aggregation.⁴¹ Dextrans can adhere to the surface of platelets and red blood cells and interfere with cross-matching of blood products.⁴⁶ Dextrans were briefly popular in microvascular surgery settings for their antithrombotic effects, but they have largely been abandoned for this use and as plasma volume expanders resulting from their unfavorable risk ratio.^{15,36} They are highly allergenic and are no longer available in many countries because of their propensity to induce anaphylaxis.³¹

Gelatins are synthetic colloids derived from bovine components.¹⁵ They have a molecular weight of 30 to 35 kDa; this is lower than most other colloids and contributes to a shorter half-life (roughly 4 hours) and limited duration of plasma expansion.^{36,38,41} Gelatins, like dextrans, have a high propensity for causing anaphylaxis, and therefore they are not available in the United States.^{36,38,41} They are also nephrotoxic and can stimulate histamine release.^{11,27} There have been concerns regarding their potential to transmit bovine

spongiform encephalitis (BSE). The actual risk of this transmission is unknown.¹³

Hydroxyethyl starches (HES) are synthetic macromolecules derived from starchy plants including potatoes, maize, and sorghum. Consequently they have allergenic potential in patients with reactivity to these and other components.¹¹ HES are synthesized by substituting hydroxyl groups at the second, third, and sixth carbon atoms of the macromolecule, and are classified according to their molecular weight and substitution ratios. The C2/C6 ratio compares the degree of substitution at the second carbon to that at the sixth. A high C2/C6 ratio indicates that HES will be difficult to metabolize and will thus provide prolonged plasma volume expansion.⁴¹ The use of HES in clinical practice has been controversial. Many of the landmark initial studies on the safety and efficacy of HES were later retracted as a result of the discovery that the supporting evidence was fabricated.^{29,35,36} Despite this, HES have been widely used, particularly in Europe.⁴⁷ The clinical impact of HES has been studied extensively because of the prevalence of their use in perioperative and critical care settings.¹¹ First-generation HES (hetastarches and hexastarches) are the highest molecular weight solutions (> 450 kDa) and often have the greatest substitution ratios (0.6–0.7).^{36,41} These solutions are associated with dose-dependent coagulopathy because of hemodilution and binding of clotting factors, interference with platelet adhesion, and alterations in plasma viscosity.^{1,11} HES can also accumulate to form interstitial colloid deposits in subcutaneous and other organ tissues leading to severe pruritus and nephrotoxicity.^{10,11,31} This effect was originally thought to be associated with the prolonged metabolic profile of first-generation HES, but studies have demonstrated that this effect occurs across all generations of HES.^{11,35} Second-generation solutions, pentastarches, are medium-weight solutions (200–260 kDa) with a substitution ratio of 0.5. Third-generation HES are low molecular-weight tetrastarches (70–130 kDa) with a substitution ratio of 0.4.^{36,41} HES continues to be the subject of many conflicting studies. Randomized controlled trials have demonstrated the risk of kidney injury, dialysis requirements, coagulopathy, and even increased mortality associated with HES.¹¹ The European Society of Intensive Care

Medicine (ESICM) assembled a task force to evaluate the impacts of various colloid solutions on patient outcomes in critically ill patients. In 2012, they issued recommendations that gelatins and HES should be avoided in patients with severe sepsis, kidney impairment, neurologic injury, and in organ donors.⁴⁷ Many other studies have determined that the use of HES in critically ill patients may increase the risk of renal failure and even mortality.^{11,41,43} The Crystalloid Versus Hydroxyethyl Starch Trials (CHEST) study assigned 7000 intensive care patients to receive either 0.9% saline or low-molecular weight HES. The study found no difference in mortality, but the patients in the HES group was found to have a significantly greater incidence of renal failure requiring renal replacement therapy (RRT).^{15,48} Furthermore, these adverse impacts have been shown to persist up to 90 days after HES administration.⁴⁹ Based on these and other findings, the United States Food and Drug Administration (FDA) issued a black box warning for HES solutions in 2013 to notify the public of the risks of renal injury and increased mortality.^{30,50}

There is, however, a body of conflicting evidence. A 2016 systematic review evaluated the relative risk of HES compared to crystalloids in patients having elective noncardiac surgery. The investigators determined that there was insufficient evidence to identify a significant difference in outcomes (mortality, acute kidney injury, length of stay, and infection).⁵¹ Another study on the impact of low-molecular weight HES compared to 0.9% saline found that HES improved tissue perfusion, as measured by increased sublingual microcirculation in septic patients.⁵² A meta-analysis of randomized clinical trials of colloids versus crystalloids examined over 16,000 patients, critically ill patients, as well as surgical patients and those with traumatic injuries. Their analysis found that the risks of renal injury and increased mortality were significant only in the critically ill subgroup.³⁸ This may be the result of a loss of endothelial glycocalyx integrity causing alterations in transcapillary fluid dynamics in the critically ill.⁴³

Albumin is a fractionated blood product produced from pooled human plasma. It has a molecular weight of 65 to 69 kDa and is heat-treated to inactivate pathogens and eliminate the risk of disease transmission.^{15,16,41} Commercially prepared albumin

solutions were developed in the mid-1940s as plasma volume expanders for use in military trauma settings.³¹ The use of albumin in these settings was preferred for rapid restoration of circulating volume in active loss situations where transfusion was not readily available. Albumin is often utilized in modern-day anesthetic practice as a volume expander in circumstances of active loss not requiring transfusion.⁴³ Small volumes of albumin provide a greater degree of intravascular resuscitation as compared to equal or greater volumes of crystalloid. Albumin is often utilized in goal-directed approaches to reduce complications associated with tissue edema.^{13,23} However, it is significantly more costly than other colloid solutions.³⁶ Albumin preparations may also cause anaphylaxis.^{11,53}

Albumin is a carrier for a number of protein-bound ionic substances, including drugs and their metabolites, electrolytes, enzymes, and hormones. In the presence of hypoalbuminemia, the administration of albumin may be advised.²⁰ Because of its negative electrostatic charge, albumin molecules bind ions, which increase plasma osmolality and intravascular volume; this phenomenon is known as the *Donnan effect*.¹⁹ One of the more commonly cited outcome assessments associated with albumin is the Saline Versus Albumin Fluid Evaluation (SAFE) study, a trial of nearly 7000 critically ill patients, who were randomized to receive 0.9% saline or 4% albumin solutions. The study demonstrated that no difference in clinical outcomes existed, except in cases of neurotrauma, where patients in the albumin cohort had a higher incidence of mortality.⁵⁴

A critical theme in the administration of colloid solutions is the careful consideration of endothelial integrity. As a result of the targeted expansion of the intravascular space, colloids may be the preferred solution for replacement of circulating blood volume in patients with intact endothelial glycocalyx undergoing acute volume losses.^{16,42} However, the use of albumin and other colloids in patients with endothelial injuries may lead to pulmonary edema and other end-organ complications.²³ Furthermore, the administration of colloid solutions to patients who are euvolemic has been known to contribute to ANP-mediated hypervolemic endothelial disruption.^{16,25,54,55} If patients have clinical conditions that

are likely to precipitate endothelial injury such as hyperglycemia or sepsis, colloid solutions should be avoided.^{16,43} A Cochrane review of the risks and benefits of crystalloids and colloids in critically ill patients concluded that there is no benefit to the administration of colloids as compared to crystalloids, and that their cost does not justify their use in critically ill patients.^{29,36,43} Evidence suggests an acceptable safety profile for albumin alone; the use of HES remains controversial. However, the cost of albumin may not justify its use except in certain circumstances.³⁵ The use of albumin in small allotments is still warranted in the context of goal-directed administration to volume-responsive patients.³⁰

The majority of data on patient outcomes with administration of colloid solutions is based on 0.9% saline. Further research is needed on the clinical impacts of colloid suspensions in balanced salt solutions. A prospective study of 760 intensive care patients examined the relationship between chloride-rich solutions (0.9% saline, 4% gelatin, and 4% albumin) and chloride-restricted solutions (balanced salt crystalloids and 20% “chloride-poor” albumin). Although chloride restriction conferred no benefit in terms of mortality or hospital length of stay, patients in this cohort had a significantly lower incidence of renal injury and RRT requirements.³⁷ Further studies on elective surgical patients and the availability and impact of balanced salt colloids will help to define the role of colloid administration in anesthetic practice.

Impact of Surgery and Anesthesia on Vascular Flow and Organ Perfusion

Surgery and anesthesia exert complex physiologic responses that impact vascular flow and organ perfusion. Stimulation of somatic and autonomic afferent nerves in the area of surgical incision triggers the activation of the hypothalamic-pituitary axis (HPA).⁵⁶ As a result of this central nervous activation, the hypothalamus releases corticotropin-releasing hormone, prompting the anterior pituitary gland to secrete adrenocorticotrophic hormone, which then elicits the creation and release of cortisol from the adrenal cortex.^{19,57,58} Cortisol stimulates protein catabolism, hepatic gluconeogenesis and glycogenolysis, and increased hepatic production and release of plasma proteins.¹⁹ These processes maintain energy substrate levels and contribute to increased π_p to help preserve intravascular volume. Such evolutionary mechanisms provide cellular energy and circulating volume for the body in times of increased metabolic demand, but may be maladaptive in the setting of hyperglycemia or vascular overload. Unchecked, hyperglycemia is a major risk factor for damage or destruction of the endothelial glycocalyx; it also impairs wound healing and contributes to osmotic diuresis.⁵⁷

The physiological stimulation associated with surgery also causes the release of catecholamines. Surgical trauma causes direct stimulation of sympathetic nerves, which trigger a substantial release of catecholamines from the adrenal medulla, causing sympathetic nervous system effects such as increased heart rate, increased systemic vascular resistance (SVR), microcirculatory vasoconstriction, which results in increased basal metabolic rate, and increased oxygen demand.¹⁹ Sympathetic stimulation, in combination with hyperosmolar conditions, triggers the release of ADH and causes vasoconstriction, reabsorption of water, and potassium excretion.⁵⁷ Depending on the magnitude of the surgical trauma and the resulting hemodynamic changes, this release may continue for hours postoperatively.⁵⁷

Surgical trauma and tissue injury stimulate local endothelial

release of cytokines and other inflammatory mediators that contribute to hyperthermia, increased oxygen demands, and regional alterations in microcirculatory flow.^{57,58} Low-level cytokine release may confer benefit by promoting local hemostasis and migration of neutrophils to the site of injury; unrestricted release can contribute to vasodilation, endothelial damage, increased filtration, tissue edema, intravascular loss, hypotension, and decreased organ perfusion.^{57,59} Severe tissue damage associated with prolonged surgery or traumatic injury, particularly in open abdominal cases, may promote inflammatory loss of gastrointestinal endothelial integrity leading to translocation of bacteria and systemic inflammatory responses.⁶⁰ One of the most beneficial effects of cortisol is the profound anti-inflammatory effect it exerts by inhibiting the production, release, and vascular aggregation of inflammatory mediators.^{57,58}

During periods that result in hypovolemia or hemorrhage, decreased P_c favors absorption and supplies an autotransfusion of fluid volume from the interstitial space into the intravascular space. Conversely, hypervolemia or vascular overload may cause a marked increase in P_c and a dilutional decrease in π_p that favor filtration, overfilling the interstitial space, and overwhelming the lymphatic system. The development of interstitial edema is a primary cause of tissue congestion, capillary collapse, loss of waste removal and nutrient exchange capabilities, decreased microcirculatory flow, and tissue ischemia.²⁰

Laparoscopic surgery is often preferred because its minimally invasive approach contributes to a reduction in tissue damage, blood loss, and inflammatory release (particularly of cytokines). However, laparoscopy carries risks of its own.^{57,58} Increased intra-abdominal pressure, secondary to pneumoperitoneum, causes direct mechanical suppression of splanchnic blood flow leading to transient splanchnic ischemia and microcirculatory changes.⁶¹ Sympathetically-mediated vasoconstriction of the splanchnic circulation also sacrifices gut mucosal tissue perfusion and predisposes the gastrointestinal epithelium to ischemia-reperfusion injury when vascular flow is restored.^{43,60}

During insufflation of the abdomen, particularly if done rapidly or to high pressures (>12–15 mm Hg), peritoneal and mesenteric

afferent receptors may stimulate a vagal response.⁶¹ Abdominal insufflation contributes to a significant increase in central venous pressure (CVP) as a result of the shunting of blood from the splanchnic circulation into the thorax. This elevation in right ventricular preload also stimulates the release of ANP.⁶² Increased intra-abdominal pressures may contribute to a decrease in cardiac preload by decreasing venous return. Furthermore, insufflation in hypovolemic patients may cause cardiac collapse if insufflation pressures are high enough to compress the inferior vena cava.⁶¹

Afterload is markedly increased because of elevated intrathoracic pressure and compensatory increases in SVR; this contributes to a reduction in stroke volume (SV). Although vascular flow may be markedly decreased, mean arterial pressure (MAP) is often elevated because of increased SVR. A study on the impact of pneumoperitoneum on patients who were classified as American Society of Anesthesiologists (ASA) I and II found that insufflation to pressures of 10 to 15 mm Hg significantly decreased both right and left ventricular ejection fractions.⁶² Patients with normal myocardial function are able to compensate for these hemodynamic alterations with tachycardia and increased left ventricular stroke work to preserve CO at the expense of increased oxygen demand. However, patients with volume overload or have decreased ventricular function may develop cardiac failure as a result of their inability to compensate.^{61,62}

High intra-abdominal pressure decreases renal perfusion and activates RAAS. This increases vasoconstriction and fluid reabsorption associated with ADH.⁶¹ Pneumoperitoneum associated decreases in renal perfusion are often transient and well-tolerated at low insufflation pressures, but the use of oliguria as a target for fluid administration is of particular concern in this setting as a result of the risk for volume overload causing increased myocardial oxygen consumption.⁶¹

The use and systemic absorption of carbon dioxide for insufflation can lead to hypercarbia. Increasing minute ventilation frequently helps to correct the associated hypercarbia, but decreased lung compliance may inhibit the ability of respiratory mechanisms to compensate.⁶² The resultant acidosis contributes to myocardial depression and related end-organ complications.⁶¹

Anesthetic interventions may help mitigate many of these responses. High-dose opioids are known to be very effective at reducing HPA-mediated stress responses; however, enhanced recovery strategies discourage the administration of large doses of opioids.⁶³ Neuraxial anesthesia helps to mitigate spinal cord transmission of autonomic afferent impulses, which would otherwise stimulate HPA. This effect is most pronounced in procedures of the lower extremities and pelvis.^{57,58} Low-dose clonidine is being studied for its potential as a premedication to provide opioid-sparing analgesic effects and to attenuate the hemodynamic stress of laparoscopy.^{63,64}

Anesthetic agents also exert significant impacts on perfusion. Propofol infusion may provide some regional vasodilatory effects, but these are mitigated by a dose-dependent decrease in myocardial contractility.⁵⁷ Volatile anesthetic agents are also known to reduce myocardial contractility, but this effect is attenuated in most modern agents (isoflurane, desflurane, and sevoflurane) by enhanced reflex sympathetic activity. These agents do contribute to a dose-dependent reduction in myocardial contractility and SVR that can manifest as significant hypotension.⁶⁵

The concept of goal-directed fluid management is intricately connected to physiologic changes during surgery. Judicious and timely administration of fluids and vasoactive support to meet defined perfusion targets has been shown to support oxygen balance and mitigate the body's neuroendocrine response to surgical stress.²⁷ Furthermore, maintenance of euvolemia throughout the perioperative period helps to preserve the glycocalyx and its associated microvascular functions.¹⁷

Historical Approach to Fluid Management

Fluid management techniques have relied on formulaic fixed-volume approaches to standardize fluid administration for all surgical patients, regardless of volume status at onset of surgery, myocardial and renal function, and vascular tone. These traditional methods often involved uniform calculations to assess the fluid requirement of a given patient. Perhaps the most common of these was the 4-2-1 calculation; this was used in combination with estimates of fasting deficit, formulaic assessments of surgical insensible losses, and calculated ratios for replacement of blood loss (Box 21.1).⁶⁶ The driving concept behind many of these approaches was the theory that fasting patients incurred a preoperative “fluid debt” and required volume preloading to help maintain physiologic stability and homeostasis.¹³ Scientific evidence challenges this assessment because it does not account for cardiovascular and renal function in individual patients, nor does it consider the true impact of fasting in elective surgical patients.¹⁷ A 2008 study evaluated the impact of preoperative fasting on blood and plasma volumes in gynecologic surgery patients without cardiac disease who had not received mechanical bowel preparations. Measurements of tagged erythrocytes and tracer-dilution analysis of total plasma volume demonstrated that patients had normal circulating intravascular volumes after 10 hours of preoperative fasting.⁶⁷ The routine use of preemptive fluid administration to correct perceived fasting deficits often contributed to overload-associated perioperative complications.¹⁶ Furthermore, current knowledge indicates that prophylactic volume administration in euvolemic patients is an antiquated practice with substantial risk of disrupting the endothelial glycocalyx and contributing to pathologic fluid

Box 21.1 ^{10,16,17}

Historical Fluid Management Calculations

4-2-1 Calculation for Determining Maintenance

Fluid Requirement

- 0–10 kg: 4 mL/kg per hr
- 11–20 kg: 4 mL/kg per hr for the first 10 kg; 2 mL/kg per hr for every kg >10
- >20 kg: 4 mL/kg per hr for the first 10 kg; 2 mL/kg per hr for the next 10 kg; 1 mL/kg per hr for every kg >20

Estimated Fluid Deficit

- Estimated Fluid Deficit = Maintenance Fluid Requirement × Fasting Hours

Guidelines for Replacement of Surgical Losses

- Superficial Trauma (orofacial): 1–2 mL/kg per hr
- Minimal Trauma (herniorrhaphy): 2–4 mL/kg per hr
- Moderate Trauma (major nonabdominal or laparoscopic abdominal surgery): 4–6 mL/kg per hr
- Severe Trauma (major open abdominal surgery): 6–8 mL/kg per hr

Recommendation for Replacement of Blood Loss

- Crystalloid – 3 : 1 (3 mL for every 1 mL estimated blood loss)
- Colloid or Blood – 1 : 1 (1 mL for every 1 mL estimated blood loss)

Such data does not discount the possibility of hypovolemia in the preoperative period. Given the substantial risks of arbitrary fluid administration, current evidence encourages the utilization of hemodynamic measures to evaluate fluid responsiveness in patients with active preoperative volume losses.¹⁷ It is important to

note that the use of bowel preparations may cause excessive fluid losses. As a result of the impact of these mechanisms on perioperative outcome, enhanced recovery strategies focus on reducing fasting times and decreasing or eliminating the use of hypertonic bowel preparations. Practice guidelines by the Canadian Society of Colon and Rectal Surgeons from 2010 recommend against the use of bowel preparations.⁶⁸

Formulaic estimates of surgical volume losses were problematic in their complete lack of acknowledgement of individual cardiovascular function, their overestimation of insensible losses, and their reliance on the unfounded concept of the “third space.”¹⁷ The calculation of insensible surgical losses in open abdominal procedures assumed steady-state evaporation from exposed abdominal tissue. Animal studies that were conducted as early as the 1970s measured evaporative abdominal losses in closed chambers and demonstrated that evaporative losses from fully exteriorized bowel surfaces plateaued at 1 mL/kg per hr.⁶⁹ The tendency for traditional calculations to overestimate fluid requirements in open abdominal cases was the impetus for a multitude of studies on the impact of restrictive and goal-directed fluid therapies in improving outcomes of colorectal patients.⁶⁹⁻⁷⁵

The concept of the “third space” was introduced in the 1960s as a nonfunctional component of the ECV. Prior to understanding the role of neuroendocrine mechanisms in the stress response, the original study hypothesized that redistribution of extracellular fluids (ECFs) contributed to the tendency of postoperative patients to retain sodium and water.⁷⁶ By excluding fluid administration and utilizing isotope tracers to tag plasma components, the investigators hoped to identify the mechanisms of fluid redistribution. They measured suction contents, specimens, sponges, and laparotomy packs for isotopes and hemoglobin. They ultimately concluded that there was a measurable deficit in functional ECV (volume subject to transcapillary fluid dynamics) not attributable to blood loss, hence the third space.⁷⁶ The third space concept became a justification for the use of liberal perioperative fluid administration to compensate for redistribution of ECV into this nonfunctional space.¹⁷ Multiple studies have since attempted to quantify the third space with the use of various tracers. Despite some results that supported a

functional ECV deficit, none of these studies were able to identify the anatomical location of this transcellular fluid reservoir.¹⁸

Nonetheless, the practice of replacing third space deficits became a doctrine of historical anesthetic practice.⁷⁷ Fluid management techniques that continue to account for the third space have been shown to result in poor clinical outcomes and gross fluid accumulation of up to 10 kg of perioperative weight gain.^{10,16,17}

The tendency of historical approaches to support liberal fluid administration continues in the recommendations for managing acute blood loss. The 3 : 1 ratio of crystalloid solutions to estimated blood loss (EBL) was introduced to preserve intravascular volume while accounting for the interstitial filtration of crystalloids. However, evidence demonstrates that the actual observed ratio is less than 2 : 1.^{10,24}

A significant limitation of historical methods that are associated with fluid administration is the reliance on static and nonspecific indices of fluid balance such as MAP, CVP, and urine output. Despite the value of these measures in the context of standard monitoring and basic vital support, they are not predictive of volume responsiveness.² MAP is an unreliable index of volume status; hypotensive patients may have a “relative hypovolemia” associated with altered vascular tone or impaired cardiac function despite adequate or excessive intravascular volume. Conversely, patients who are dependent on adequate preload may have intact compensatory mechanisms that preserve normotension.³⁰ Historic approaches often rely on fluid volume to treat hypotension, regardless of the cause (e.g., volume preloading to treat or prevent hypotension related to neuraxial sympathectomy, bolus fluids on induction of anesthesia to compensate for myocardial depression and vasodilation).⁵⁶ CVP is largely dependent on venous return; baseline values may also be altered in patients with right heart impairment, severe pulmonary disease, valvular disease, and portal hypertension.¹ Studies involving critically ill patients, including those with sepsis, demonstrated that only half of patients with low CVP values are fluid-responsive.⁷⁸ Therefore the use of CVP as a fluid administration target leads to an extraordinarily high incidence of fluid overload in patients who may not be able to compensate for the increased vascular volume.³⁰

Reliance on urine output as a measurement of volume status is not an accurate target for fluid administration because it can be impacted by a myriad of factors, including enhanced neuroendocrine responses.⁷⁹ Furthermore, volume administration in anesthetized oliguric patients with high levels of circulating ADH may preferentially expand the interstitial space.^{23,80} ADH secretion can continue in the postoperative period and patients who receive excessive intraoperative fluid volume may have difficulty excreting their salt and water overload postoperatively.⁵⁷

Traditional fluid management strategies have relied on infusing large volumes of fluid in the hope that renal injury could be avoided. However, there are multiple mechanisms that cause renal failure, including RAAS-mediated decreases in renal blood flow, microcirculatory congestion, renal cortical ischemia, and global perfusion deficits. A systematic review comparing restrictive perioperative fluid management with conventional techniques aimed at reversing oliguria, and the result indicated that there was no difference in the incidence of oliguria or postoperative renal failure.⁷⁹ Another observational study on data mined from the Sepsis Occurrence in Acutely Ill Patients (SOAP) trial examined approximately 3,000 critical care patients and found that a positive fluid balance resulted in an increased incidence of acute renal failure.⁸¹ These and other studies challenge the classic concepts that (1) excess perioperative fluid is easily filtered by the kidneys, and (2) large fluid volumes are nephroprotective.³¹

The limitations of fixed volume approaches have led to an interest in the value of restrictive perioperative fluid therapy. Examination of these management techniques in comparison to traditional methods (often retroactively titled *liberal*) yielded various results. A partial explanation for this variability is the high degree of inconsistency in terms of defining *liberal* versus *restrictive* approaches. One study found that a liberal approach, as defined by one author, was only 10 mL different than a restrictive approach, as defined by another.⁸²

The limitations of traditional methods have been recognized since the early 1980s, when clinicians acknowledged both the inappropriateness of current methods and the lack of measurable clinical end-points for fluid therapy. In an insightful review article

about the relative risks of perioperative crystalloids, Twigley and Hillman wrote:

Fluid is poured into the interstitial space on clinical information gained from changes in the intravascular space, such as blood pressures, urine output, etc. The end point of such therapy is not clinically detectable unless it is in its grossest form, peripheral or pulmonary oedema [sic].²⁷

Historical perspectives associated with fluid management have taught us that the administration of intravenous fluid is associated with advantages but also unintended physiologic consequences that can impair homeostasis. Much like other pharmaceutical interventions, intravenous fluids have clear indications, benefits, and (dose-dependent) side effects.^{16,83} Despite the controversy related to the amount, strategy, and type of fluids to be administered perioperatively, there is growing recognition among anesthesiologists and critical care providers related to the consequences associated with intravenous fluid administration (Box 21.2).³⁰

Consequences of Inappropriate Fluid Administration

Under-Resuscitation	Over-Resuscitation
<ul style="list-style-type: none"> • Hypovolemia; decreased circulating volume • Decreased microvascular perfusion leading to decreased oxygen delivery • Reduced tissue perfusion • End organ complications • PONV • Renal dysfunction • Myocardial ischemia • Hemoconcentration leading to increased blood viscosity, thrombotic events 	<ul style="list-style-type: none"> • Vascular overload; acute CHF • Microvascular congestion leading to decreased oxygen delivery • Endothelial glycocalyx disruption • Decreased tissue oxygenation • Altered coagulation and potential hemorrhage • Hemodilution leading to anemia, thrombocytopenia, altered viscosity, coagulopathy, decreased oxygen carrying capacity • Decreased gut motility (ileus, delayed gastric emptying, anastomotic leak) • Increased infection rates; poor wound healing • Decreased organ perfusion • Increased EVLWI and prolonged postoperative mechanical ventilation • Increased incidence of ventilator-associated pneumonia • Hepatic congestion and dysfunction • Abdominal compartment syndrome

CHF, Congestive heart failure; EVLWI, extra vascular lung water index; PONV, postoperative nausea and vomiting.

Perioperative Goal-Directed Fluid Therapy

The impact of perioperative goal-directed therapy (PGDT) on clinical outcomes of surgical patients has made this approach a crucial component of anesthetic practice particularly within the milieu of outcome-driven care. In the late 1980s, based on the observation that survivors of high risk surgical procedures had greater oxygen delivery (DO_2), arterial oxygen content (CaO_2), and cardiac index (CI) than did non-survivors, Shoemaker et al. set out to evaluate the impact of targeting supranormal hemodynamic and oxygen transport values in patients undergoing high risk surgical procedures. By placing pulmonary artery catheters (PACs) in subjects preoperatively and utilizing the hemodynamic data to help augment CI and oxygen delivery index (DO_2I) throughout the perioperative period, they were able to significantly impact survival. Patients in the PA catheter protocol group had reduced mortality, reduced intensive care stays, and reduced perioperative complications, compared to those in the control.⁸⁴ Shoemaker went on to publish a large body of work on the impact of hemodynamic monitoring and measures of oxygen transport on survival among surgical patients in addition to critically ill patients in septic shock.⁸⁵⁻⁸⁷ Although supranormal hemodynamic targets are no longer advocated, Shoemaker's work continues to be valued for its fundamental contribution to the advancement of goal-directed therapy.⁸⁸

As a result of concerns regarding supranormal hemodynamic end-points, Gattinoni and the mixed venous oxygen (SvO_2) Collaborative Group studied over 10,000 patients across 56 intensive care units in 1995 to determine if targeting supranormal hemodynamic values improved survival in critically ill patients. They concluded that normal values of CI and DO_2 yielded the same results as did supranormal values. Thus there was little to no benefit in attempting to “force feed” oxygen to the tissues during periods of increased consumption.⁸⁹

The breakthrough development in goal-directed therapy was the

publication of a large study that evaluated protocol-based resuscitation of critical care patients and used in-hospital mortality as the primary end-point. Hemodynamic optimization utilizing vasoactive and inotropic support, fluid therapy, and transfusion in these patients yielded an absolute reduction in 28-day and 60-day mortality compared to standard care.⁹⁰ This study helped form the basis for the Surviving Sepsis Campaign and is widely considered to be the landmark study in the development of a definitive protocol for fluid resuscitation.

The following year (2002), a study highlighting intraoperative goal-directed therapy in patients undergoing major surgery with anticipated EBL greater than 500 mL was accomplished. Using esophageal Doppler to maximize SV, it demonstrated a decrease in perioperative complications and hospital length of stay.⁹¹ The utility of goal-directed therapy in the intraoperative setting was appreciated and catalyzed the discussion of collaboration between intraoperative and postoperative care providers in the provision of unified perioperative management of surgical patients.

As a result of the impact of these and other studies, PGDT became a subject of broad interest and the focus of multiple research efforts.^{73,92} However, there were concerns about the necessity of PAC placement to obtain hemodynamic values. A study on goal-directed fluid therapy in 3803 high-risk surgical patients found no advantage over standard treatment because of the added risks of pulmonary embolism and catheter-associated infection.⁹³ During the same time period, Cannesson published one of many studies on the relationship between respiratory variation in plethysmography and arterial pressure.⁹⁴ This relationship and the concept of pulse contour analysis are the basis for many of the minimally invasive and noninvasive technologies available today.^{95,96}

A meta-analysis of 16 randomized clinical trials involving approximately 3400 patients found that by maintaining systemic oxygen transport, PGDT overwhelmingly yielded a significant reduction in gastrointestinal complications, morbidity, and postoperative stay compared to the control.⁹⁷ The National Institute for Health and Care Excellence (NICE) recommended that PGDT use esophageal Doppler monitoring as a standard of care in

patients undergoing high-risk surgical procedures.^{2,98} PGDT has now been widely adopted as a standard of care in Europe and it is increasingly being accepted as a guideline for clinical practice in the United States.⁹⁹

The ultimate aim of PGDT is to utilize individualized hemodynamic end-points to support oxygen transport balance by minimizing oxygen demand and optimizing CO, tissue oxygenation, capillary and macrovascular flow, oxygen and nutrient delivery, and end-organ perfusion.^{7,98} This augments the ability of high-risk surgical patients to tolerate the metabolic and hemodynamic disturbances associated with surgery and improves clinical outcomes (Box 21.3). The ability to recognize relevant clinical end-points and manipulate real-time physiologic targets to optimize regional and global perfusion during surgery allows anesthesiologists to focus on definitive interventions (fluids, vasoactive support, inotropy, transfusion).

Measured Outcomes of PGDT as Compared to Standard Fluid Management Approaches in High-Risk Surgical Patients

- ↓Infection rate
- ↓Duration of mechanical ventilation
- ↓Bowel motility
- ↓PONV
- ↓Coagulopathy
- ↓Hemorrhage
- ↓Cardiovascular complications
- ↓Respiratory complications
- ↓Anemia
- ↓Hypotension

- ↓Length of hospital stay
- ↓30-day organ complication rate
- ↓ICU length of stay in high risk patients
- ↓Urinary tract infections
- ↓Incidence of postoperative renal impairment
- ↓Perioperative mortality rates among patients at very high risk for perioperative death

ICU, Intensive care unit; *PGDT*, perioperative goal-directed therapy; *PONV*, postoperative nausea and vomiting.

Hemodynamic Monitoring and Patient Goal-Directed Therapy

Perioperative goal-directed therapy relies on modern hemodynamic modalities to provide measurable clinical end-points as guides for both initiation and cessation of fluid administration. Measures of fluid responsiveness, oxygen transport, and microvascular flow help focus fluid delivery to ensure optimal volume and to mitigate the significant consequences associated with fluid mismanagement (Fig. 21.3).

FIGURE 21.3 Optimal fluid administration. *FC*, Flow cell; *SV*, stroke volume. (From Miller TE, et al. State-of-the-art fluid management in the operating room. *Best Pract Res Clin Anaesthesiol.* 2014;28(3):262.)

The Frank–Starling Mechanism

The basis of the Frank-Starling mechanism is the relationship between left ventricular end diastolic volume (LVEDV) and myocardial contractility (as measured by SV). An increase in left ventricular preload will, to an extent, increase myocardial contractility by stretching cardiac sarcomeres and optimizing the overlap of actin and myosin filaments to generate greater myocardial force.¹⁹ This allows the myocardium to compensate for increases in ventricular preload. The Frank–Starling mechanism is highly effective until the point at which the sarcomere cannot generate additional force; further increases in preload after this point will generate no further increases in SV.¹⁰⁰

This relationship is depicted as a classic left ventricular pressure-volume curve, with volume (LVEDV) appearing on the x-axis and pressure (SV) appearing on the y-axis (Fig. 21.4).¹¹ The ascending portion of this curve represents preload dependence. Patients whose cardiac profile correspond to this curve will respond to fluid volume by increasing SV. The plateau portion of the curve represents preload independence and patients along this portion of the curve are unable to generate any additional myocardial force in

response to fluid volume. Knowledge of individual patient physiology is important in assessing a patient's position along the curve. Patients with normal left ventricular function are on the physiologic curve. The long ascent of this curve suggests that the heart will continue to increase contractility in response to greater volumes of fluid. Patients with heart failure or ventricular dysfunction are on the pathophysiologic curve. The long plateau of this curve indicates that the heart can tolerate only small volumes of fluid before it is unable to increase contractility. Patients with poor ventricular compliance may proceed from a state of preload dependence to one of volume overload with the addition of very small volumes of fluid.

FIGURE 21.4 Quadrant diagram relating cardiac output to left ventricular end-diastolic pressure. The *thick blue curve* is a typical normal Frank–Starling curve. To the right are shown curves representing progressive left ventricular failure. *Top left* is the safe quadrant, which contains a substantial part of the normal curve, but much less of the curves representing ventricular failure. *Top right* is the

quadrant representing normal cardiac output but raised left atrial pressure, attained at the upper end of relatively normal Frank–Starling curves (e.g., hypervolemia). There is a danger of hemodynamic pulmonary edema. *Bottom left* is the quadrant representing normal or low left atrial pressure but low cardiac output, attained at the lower end of all curves (e.g., hypovolemia). The patient is in shock. *Bottom right* is the quadrant representing both low cardiac output and raised left atrial pressure. There is simultaneous danger of pulmonary edema and shock, and the worst Frank–Starling curves hardly leave this quadrant.

(From Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia: Elsevier; 2017:413.)

This underscores the importance of small fixed-volume fluid boluses as part of PGDT protocols.³⁰ The differentiation between preload dependence and preload independence is perhaps one of the most vital components of PGDT in tailoring interventions to individual cardiovascular status and preventing complications associated with fluid overload. Failure to recognize preload independence in hypotensive patients is often the mechanism for inappropriate fluid administration.

Dilution Techniques

Dilutional techniques involve the introduction of a fixed volume of injectate into the vascular system and the consequent measure of CO and other hemodynamic variables based on the area under a time-temperature or concentration-time curve.¹⁰¹ The thermodilutional PAC is the classic dilutional monitoring device. A fixed volume of chilled injectate is introduced into the right atrium (RA), and blood temperature is measured with a thermistor in the pulmonary artery. CO is calculated according to the area under the time-temperature curve.¹⁰¹ Low CO coincides with a larger area under the curve because of the time required for the chilled fluid to transit through the heart. The PAC is the most invasive of the hemodynamic monitors used in PGDT, but it is useful in the comprehensive assessment of cardiac function.¹

The PiCCO Plus hemodynamic monitor (Pulsion Medical Systems AG, Munich, Germany) applies the same thermodilutional principles using separate central venous and central arterial lines.

The chilled injectate is introduced into the venous line and blood temperature is measured in the artery. This technology also applies pulse waveform analysis to provide measures of fluid responsiveness.¹⁰²

The LiDCO Plus/PulseCO hemodynamic monitoring system (LiDCO Ltd, Cambridge, UK) utilizes a chemical dilution technique. A fixed volume of lithium chloride is administered intravascularly and lithium ion concentration is measured with a sensor in the artery. The software component of the system also evaluates preload responsiveness and it can be used to calculate measures of oxygenation with the input of blood gas values.¹⁰³

Pulse Contour Analysis

Pulse contour analysis provides dynamic measures of preload responsiveness by quantifying the degree of change of arterial, capnography, or pulse oximetry waveforms associated with cyclic respiratory variations and the resulting pleural pressure. Measures of fluid responsiveness include plethysmography variability index, stroke volume variation, systolic pressure variation, and pulse pressure variation. These dynamic indices are particularly valuable in assessing real-time response to fluids and vasoactive interventions, and are often utilized as part of minimally invasive or noninvasive technologies. The utility of noninvasive monitoring platforms lies not only in their favorable risk profile, but also offers the additional advantage of continued monitoring during the immediate postoperative period. The ability to evaluate hemodynamic measures throughout the perioperative period helps ensure continuity of PGDT and promotes enhanced recovery strategies. The use of noninvasive technology to measure dynamic parameters is based on the physiology of cyclic intracardiac pressure changes during ventilation.⁶

The increase in pleural pressure of mechanically ventilated patients during inspiration augments left ventricle (LV) filling as a result of compression of pulmonary veins and pleural restriction of right ventricle (RV) filling (leading to enhanced LV compliance); this contributes to an increase in SV. During expiration SV falls when the reduced RV preload has had time to transit through the heart.¹⁰² The degree of variation in SV is more prominent in during

hypovolemia due to (a) increased intrathoracic pressure from positive pressure ventilation decreases RV filling, (b) greater inspiratory impact on RV afterload if alveolar pressure exceeds pulmonary arterial and venous pressures impeding RV ejection, and (c) greater ventricular contractility in response to the LV preload “bolus” if the patient is on the ascending portion of the Frank–Starling curve.¹⁰⁴

Dynamic measures derived from pulse contour analysis are considered to be predictive of fluid responsiveness if the calculated value is greater than 13% to 15%.¹⁰⁵ However, there is a well-documented gray zone in which values of 9% to 13% fail to accurately predict fluid responsiveness in up to 25% of patients; correlation with additional hemodynamic measures is recommended.^{2,30} Despite the utility of these parameters for predicting fluid responsiveness and providing real-time measures of cardiovascular response to interventions, there are some known limitations with their use (Table 21.2).^{6,30} The EV1000 hemodynamic monitoring system (Edwards Lifesciences, Irvine, CA, USA) allows for integration of both noninvasive and invasive (pulmonary artery, central venous, arterial) inputs to provide dynamic measures of fluid responsiveness across all inputs in addition to global hemodynamic values and measures of tissue oxygenation in the presence of invasive access.¹⁰⁶ A summary of hemodynamic measures can be found in Table 21.3.

TABLE 21.2
Limitations of Dynamic Measures

Limitation	Cause
Spontaneous Ventilation	Spontaneous ventilation produces a dissimilar waveform variation as a result of negative intrathoracic pressure. Furthermore, the degree of variance produced by spontaneous ventilation is small, and respiratory rate and tidal volume may be irregular.
Small Tidal Volumes	The dynamic variables measured by pulse contour analyses have been tested using tidal volumes of 8 mL/kg. Smaller tidal volumes may be insufficient to produce significant intrathoracic pressure changes to predict fluid responsiveness. In the setting of low-tidal volume ventilation, small values may not be predictive, but values > 13%–15% will still indicate fluid responsiveness.
Open Chest	Measurements based on intrathoracic pressure variations lose their reliability in open thorax conditions; echocardiography is recommended.
Sustained Arrhythmias	Variations in stroke volume are likely to be caused by beat-to-beat variability in SV secondary to decreased cardiac filling times or loss of atrial kick, rather than fluid responsiveness.
PEEP	High levels of PEEP may elevate intrathoracic pressure such that hemodynamic variables will be falsely elevated.

Right Heart Dysfunction	Elevation of dynamic variables in patients with severe right heart disease may reflect ventilation-associated alterations in RV afterload rather than volume responsiveness.
-------------------------	--

PEEP, Positive end expiratory pressure; RV, right ventricle; SV, stroke volume.

TABLE 21.3
Common Hemodynamic Measures

Abbreviation	Parameter	Normal Values	Measures
CO/CI	Cardiac output/cardiac index	CO: 4–8 L/min CI: 2.5–4 L/min per m ²	Measures volume of blood pumped by the left ventricle in one minute; CI is normalized for body surface area (BSA)
DO ₂ I	Oxygen delivery index	DO ₂ I: 450–650 mL/min per m ²	Calculated value, which combines hemoglobin concentration, hemoglobin carrying capacity, CI, and arterial oxygen saturation to provide an indicator of tissue perfusion
EVLWI	Extravascular lung water index	3–7 mL/kg	Measure of fluid filtration into the interstitial space of the lung; index of pulmonary edema
FTc	Corrected flow time	330–360 ms	Measures the forward flow of blood through the aorta during systole (flow time) and corrects it to a heart rate of 60 beats per minute; surrogate index of left ventricular ejection time
GEDI	Global end-diastolic index	680–800 mL/m ²	Preload (end-diastolic) measurement of all cardiac chambers; measure of volume status normalized for BSA
O ₂ ER/O ₂ ERe	Oxygen extraction ratio/oxygen extraction ratio estimate	Values are organ-dependent; normal range from 22–30%	O ₂ ER is a direct measure of the difference between arterial and venous oxygen saturation at a given tissue; O ₂ ERe is calculated based on the difference between arterial and mixed or central venous oxygen saturation.
ΔPV	Change in peak velocity	>12% predicts preload responsiveness	Change in peak aortic pulse wave velocity
PPV/ΔPP	Pulse pressure variation/Δ pulse pressure	>13% predicts preload responsiveness	Variation in arterial pulse pressure
PVI	Plethysmography variability index	>14% predicts preload responsiveness	Calculated variability in amplitude of pulse oximetry plethysmography
ScvO ₂	Central venous oxygen saturation	Normal value 70% (~2–8% lower than SvO ₂ values caused by cerebral oxygen consumption)	Venous oxygen saturation of blood in the superior vena cava as measured by a central venous catheter
SPV	Systolic pressure variation	>14% predicts preload responsiveness	Variation in systolic pressure based on pulse contour analysis
SV/SVI	Stroke volume/stroke volume index	SV: 60–100 mL/beat SVI: 33–47 mL/m ² per beat	SV measures volume of blood pumped by the left ventricle in one heartbeat; SVI is normalized for BSA
SVR/SVRI	Systemic vascular resistance/systemic vascular resistance index	SVR: 800–1200 dynes-sec/cm ⁻⁵ per m ² SVRI: 1970–2390	Measure of resistance of peripheral circulation; index of afterload; SVRI is normalized for BSA

		dynes-sec/cm ⁻⁵ per m ²	
SvO ₂	Mixed venous oxygen saturation	Normal value 60–80% (~2–8% higher than ScvO ₂ values due to mixed venous blood from both the IVC and SVC)	Venous oxygen saturation of blood in the pulmonary artery as measured by a PAC
SVV	Stroke volume variation	>13% predicts preload responsiveness	Variation in stroke volume calculated by esophageal Doppler monitoring measurements or based on pulse-contour analysis

Esophageal Doppler and Echocardiography

Esophageal Doppler monitoring uses Doppler ultrasound technology to provide real-time measures of LV function and aortic compliance in addition to dynamic measures of preload responsiveness such as corrected flow time (FTc), SV, and change in peak aortic pulse wave velocity (ΔP).¹⁰⁷ It offers a less invasive means for direct measurement of hemodynamic parameters and esophageal Doppler monitoring has become a standard of care in the United Kingdom.⁹⁸ Transesophageal echocardiography is a gold standard for direct evaluation of cardiac function and volume status, although its use is limited to those who have been board certified by the National Board of Echocardiography.¹⁰⁸ Perioperative echocardiography can provide invaluable data by providing real-time visualization of ventricular size, systolic and diastolic functional status, valvular abnormalities, volume status, wall motion abnormalities, and cardiac handling of fluid administration.³⁰

Measures of Tissue Oxygenation

The use of oxygen transport measures as targets for PGDT has long been known to impact survival rates in high-risk and critically ill patients.⁵ Measures of tissue oxygenation evaluate global tissue oxygen balance with measurement of arterial, mixed venous, central venous blood gases and calculation of oxygen consumption (VO_2) and delivery (DO_2). Integrated invasive technologies combine invasive lines (PAC, central venous catheter, arterial line) with software inputs of blood gas data to calculate tissue oxygenation

measures. The primary goal for PGDT is to maintain oxygen transport balance by optimizing DO_2 (fluid optimization, preservation of CO and microcirculatory flow, transfusion) and to minimize VO_2 (opioids, β -blockers, maintenance of normothermia).^{109–111} Active blood loss during surgery causes an imbalance in oxygen transport through loss of both circulating volume and oxygen carrying capacity. The judicious administration of packed red blood cells to optimize DO_2 is an important and often controversial consideration in perioperative fluid management. This topic is discussed in detail in [Chapter 22](#).

Perioperative Goal Directed Therapy Protocols

The success of PGDT in improving clinical outcomes is largely the result of its algorithmic approach evaluating fluid responsiveness, identifying appropriate support measures when fluid is not indicated, and optimizing oxygen transport balance.³⁰ PGDT protocols often begin with a baseline assessment of target hemodynamic measures, followed by the administration of a small volume fluid bolus (200–250 mL) to assess the patient's position along the Frank–Starling curve. By integrating fluid administration triggers, small volume boluses, and defined targets for cessation of fluid therapy, PGDT protocols provide important clinical end-points for assessing response to fluid intervention and preventing vascular overload. These guidelines also provide prompts for consideration of vasoactive or inotropic support. Most protocols promote constant reassessment of factors such as preload responsiveness and oxygen delivery (every 5–10 minutes). This aids in the timely administration of fluid and other interventions that have been shown to have a tremendous impact on preserving both endothelial and global perfusion.^{2,30}

Perioperative Goal Directed Therapy and Enhanced Recovery

Optimal perioperative fluid replacement and management is a fundamental component of fast track programs such as Enhanced Recovery after Surgery (ERAS). ERAS is a proactive, multimodal,

patient management pathway aimed at improving surgical outcomes. Protocols for ERAS incorporate best practices that are designed to provide optimal fluid therapy, reduce the profound stress response attributed to surgery, promote non-opioid postoperative pain modalities, and maintain baseline organ function post procedure. Ultimately, the goals for the ERAS pathway for major surgical procedures is to decrease postoperative complications, to accelerate recovery after surgery, and to promote early mobilization and discharge from hospitalization.¹¹² A growing body of evidence supports the ERAS pathway based upon documented improvements with postoperative outcomes and the overall decrease in health care costs associated with surgery.¹¹³

A colorectal surgeon from Denmark, Henrik Kehlet, was the first to coin the concept of enhanced recovery in the 1990s when he asked the simple question, “why is the patient still in the hospital after surgery?” He determined the causes were multifactorial, yet he concluded that the common issues faced by postoperative patients were ultimately caused by delays in both gut function and physical mobility after surgery.¹¹⁴ Based upon these observations, protocols were developed that were aimed at addressing the issues that contribute to prolonged postoperative convalescence, and promote interventions that facilitate an improved state of health.

Enhanced Recovery After Surgery

Enhanced Recovery after Surgery was initially developed for colon resection surgery; however enhanced recovery principles are now being used for various surgical procedures including abdominal vascular surgeries, esophagectomy, pancreatectomy, gastric resection, cystectomy, colorectal surgeries, gynecologic surgeries, orthopedic, and bariatric procedures.¹¹³⁻¹¹⁵ ERAS programs, specifically for abdominal surgical procedures, have been implemented in many countries around the world, totaling 17 countries to date.¹¹³ The ERAS Society was formed in 2010 and has currently developed 22 treatment items under the ERAS Protocol (Fig. 21.5).

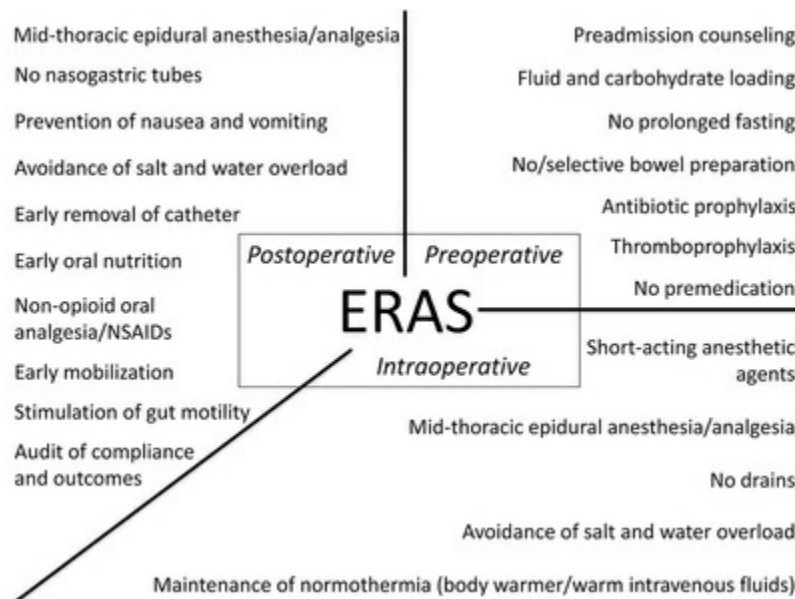

FIGURE 21.5 Components of ERAS (From Varadhan KK, et al. Enhanced recovery after surgery: the future of improving surgical care. *Crit Care Clin.* 2010;26(3):527–547.)

Lassen et al.¹¹⁶ developed a consensus review of clinical studies demonstrating optimal perioperative care utilizing ERAS protocols for patients undergoing colorectal surgery. The authors determined that 15 of the 20 treatment items reviewed suggested that the evidence demonstrated a strong indication that the ERAS protocols are beneficial and improve postsurgical outcomes. Implementation of the various ERAS protocols requires a multidisciplinary team committed to consistently integrating the treatment items for each surgical patient during the preoperative continuum, which include the preoperative, intraoperative, and postoperative time periods.

Preoperative Fluid Management in ERAS Protocol

Optimal perioperative fluid management is an essential component of the ERAS pathway and important for improving postsurgical outcomes. The current ASA practice standard for preoperative surgical patients is nil per os (NPO) for at least four hours. This practice renders the patient in a relatively dehydrated state prior to surgery.^{117,118} The goal of ERAS during the preoperative period is for the patient to arrive in the operating room in a euvolemic state.^{119,120} A Cochrane review in demonstrated substantial evidence

that allowing clear fluids up to 2 hours prior to surgery during the preoperative fasting period does not increase complications.^{121,122} The current practice standard for prolonged fasting, generally 8 hours prior to surgery, has not demonstrated a reduction in gastric contents nor an increase in gastric fluid pH.¹²²

Miller et al.¹¹⁹ recommend avoiding the routine use of mechanical bowel preparation (MBP) prior to colorectal surgery as an additional means of preventing dehydration on the day of surgery. The administration of MBP for colorectal surgical patients can vary based on the surgeon's preference. The existing evidence indicates that MBP results in fluid shifts and increases postoperative morbidity.¹²²⁻¹²⁴ Reducing NPO time by implementing two ERAS interventions of supplying a carbohydrate drink up to 2 hours prior to surgery, and eliminating MBP, are proven methods that have contributed to improved optimization of the patient during the preoperative phase.^{123,124} Supplying a carbohydrate drink 2 hours prior to surgery has the added benefit of maintaining adequate preoperative glucose and insulin levels, thereby reducing preoperative thirst, hunger, and anxiety levels experienced by the patient.¹²² Decreasing NPO time results in a reduced state of relative dehydration prior to surgery. Thus the patient is less likely to develop hypotension caused by hypovolemia during the intraoperative phase. Patients are also less likely to be fluid responsive after the induction of anesthesia when compared to patients undergoing traditional preoperative fasting protocols.^{124,125}

Intraoperative Fluid Management in ERAS Protocol

Traditional intraoperative fluid management consists of replacing fluid deficits that may have occurred while the patient was NPO. The calculated fluid deficit is replaced rapidly, generally over a period of 3 hours. Usually half of the deficit is replaced within the first hour, and the other half of the total deficit is replaced within the next 2 hours. The calculated fluid deficit is replaced in addition to the calculated maintenance fluid intended to be given during the intraoperative phase. The maintenance fluid volume is based upon a fixed-volume principle, commonly referred to as the 4 : 2 : 1

principle, which calculates fluid replacement requirements adjusted for the patient's body weight in kilograms. Standard fluid replacement strategies account for insensible or third space losses that can typically range from 1 to 15 mL/kg per hr. This estimate is subjective and the volume infused varies among anesthesia providers. However, the concept of third space loss is considered controversial because the initial trials studying ECV were flawed.¹²⁶ Standard fluid replacement during surgery also incorporates the EBL during the procedure, thus an additional 3 mL of crystalloid solution is administered for each mL of blood loss that is estimated by the practitioner.

Cumulatively, the surgical patient can receive intravenous fluid replacement based upon four concepts of fluid deficit: these include NPO fluid deficit, maintenance fluid requirements, third space fluid shifts or losses, and EBL. The standard fluid replacement paradigm is subjective, and it can vary based on the anesthetist's estimates and preferences. Liberal fluid administration can result in net weight gain experienced by the patient. A modest weight gain of approximately 3 kg as a result of intravenous fluid administration after elective colonic resection is associated with delayed recovery of gastrointestinal function, increased rate of complications, and prolonged hospital length of stay.^{120,127} Overall, there is definitive scientific evidence suggesting that excessive fluid administration during the intraoperative phase contributes to detrimental side effects such as edema of the gut wall and prolonged ileus.^{120,128} Lobo et al.¹²⁰ determined that a “change in fluid management alone on the day of surgery has been shown to reduce postoperative complications by 50%.”

Perioperative Goal-Directed Therapy and ERAS

Incorporating an ERAS protocol such as PGDT reduces variations in practice in which one provider treats intraoperative hypotension with a fluid challenge, ranging from a bolus of crystalloid or colloid solution of 250 to 500 mL, whereas another provider may opt to support hypotension pharmacologically with vasopressor therapy. Surgical outcomes can be improved by using PGDT during intraoperative anesthetic management.

Postoperative Phase and ERAS

Fluid management within the ERAS protocol is continued when the patient transitions to the postoperative phase. Early discontinuation of intravenous fluid therapy and initiation of oral intake is encouraged. The authors conclude that the several liters of crystalloid fluid administered on postoperative day one to treat reduced urine output can cause postoperative ileus and delay hospital discharge.^{119,128}

New Paradigm in Perioperative Fluid Management

Fluid therapy utilizing an ERAS pathway is largely based upon the goal of maintaining euvolemia.^{30,119,120} Fluid and electrolyte preparations are the most commonly prescribed medications in hospitals. Fluid replacement during surgery is necessary and is often the first-line of treatment for hemodynamic support and a conduit for medication administration. The traditional approach to perioperative volume therapy has been standardized and simplistic based upon a fixed-volume approach. However, the subjective factors such as evaporative losses, third space loss and ambiguous EBL amounts result in variations in fluid management and often times excessive perioperative fluid administration.^{76,115}

Another component of ERAS is to mitigate the physiologic changes the body experiences in response to surgery and to avoid fluid shifts. The body releases catabolic hormones and inflammatory mediators to facilitate salt and water retention in an effort to preserve intravascular volume and maintain blood pressure.¹²⁷ The physiologic response to surgery results in indirect and direct cellular injury. Direct surgical trauma from incision, heating elements such as cautery, retraction of internal organs and so on, can lead to primary cellular injury. Primary cellular injury can impair oxygen and nutrient delivery to vital organs resulting from global and local perfusion changes. Secondary cellular injury is a process that is caused by the stress response associated with surgery that results in the release of local inflammatory mediators or the systemic effects of cytokines, inflammatory mediators, or hormones. The combination of both primary and secondary injury

at the cellular level has been attributed to delayed wound healing, gut dysfunction, and may lead to postsurgical complications.¹²⁷⁻¹²⁹ The two fundamental elements that affect postsurgical outcomes are attributed to fluid therapy and effective pain management.

Electrolyte Balance

Disorders of Sodium Balance

Sodium and water balance within the various fluid compartments are in a dynamic state of change and they are a vitally important component in determining the intravascular fluid volume. Sodium is the most abundant electrolyte in the ECV and, along with chloride, sodium chloride is responsible for the majority of the osmotic activity of the ECV. A key physiologic action of sodium relates to its effect on increasing or decreasing ECV and ICV osmolality or tonicity. Water moves between the ECV and the ICV across cell membranes from an area of increased solute concentration to an area of decreased solute concentration in order to achieve equilibrium. These changes in water concentration are largely determined by sodium. The concentration of sodium is significantly higher in the ECV as compared to the ICV (ECV = 140 mEq/L, ICV = 25 mEq/L). The action of the Na-K-ATPase pump, which is located within cellular membranes, utilizes cellular energy to maintain cation ionic neutrality between the ECV and ICV.

An example of the physiologic effect associated with sodium disorders concerns the influence of sodium on the water content within neurons in the brain. The blood-brain barrier (BBB), unlike peripheral capillary beds, has only limited permeability to ionic solutes. The result of this limited permeability in the BBB prevents equilibration of osmotically active ionic solutes between ECV and ICV. This lack of permeability to sodium (and consequent failure to equilibrate osmotically active solutes between the intravascular and interstitial spaces) changes the osmotic gradients between fluid compartments, leading to the precedence of sodium over plasma proteins as the most important osmotically active substance influencing the water content of the brain tissues.¹³⁰

Sodium imbalances reflect an impaired concentration between water and sodium. Evaluation of sodium imbalance should take into consideration both the volume of the solvent (water) and the amount of solute sodium (NA) present in the solution. Likewise, treatment of sodium imbalances can involve restriction or

expansion of water volume and enhanced elimination or supplementation of sodium. One example involves the development of dilutional hyponatremia that can occur during various surgeries including endometrial ablation and transurethral resection of the prostate. The absorption of large quantities of hypotonic fluid, which is used as irrigation, enters the ECV and causes NA to become diluted. The hyponatremia that ensues can have deleterious effects on the brain and the heart. Thus there is no actual loss of sodium, but a dilution effect has occurred. This syndrome is commonly treated by decreasing ECV with fluid restriction or by administering diuretics to decrease intravascular volume. As the ECV contracts, NA moves from the interstitial space back into the intravascular space. The result of normalizing ECV NA concentrations allows for typical physiologic functioning.

The causative factors and manifestations associated with hyponatremia are listed in [Box 21.4](#). The rapidity and extent by which significant hyponatremia occurs will determine the severity of clinical manifestations ([Table 21.4](#)). Of particular interest to anesthesiologists is hyponatremia resulting from the syndrome of inappropriate secretion of ADH (SIADH), which is further discussed in [Chapter 37](#). Water intoxication and SIADH can also [Box 21.4](#) hyponatremia from an excess of water, not loss of sodium.

Hyponatremia: Classification, Causative Factors and Manifestations*

Isotonic Hyponatremia (Pseudohyponatremia)

Serum osmolality 270–300 mOsm/kg

Causes: Hyperlipidemia, hyperproteinemia, multiple myeloma, infusion of isotonic nonelectrolytic substances (e.g., glucose, mannitol glycine)

Hypertonic Hyponatremia

Serum osmolality greater than 300 mOsm/kg

Causes: Hyperglycemia, mannitol excess glycerol therapy

Hypotonic Hyponatremia

Serum osmolality less than 270 mOsm/kg

Hypovolemic hypotonic hyponatremia

Causes: Diuretics, salt-losing nephropathy, ketonuria, Addison disease, vomiting, diarrhea, third spacing of fluids, excessive sweating

Isovolemic hypotonic hyponatremia

Causes: SIADH, renal failure, hypothyroidism, drugs, water intoxication, porphyria, pain, stress, positive pressure ventilation

Hypervolemic hypotonic hyponatremia

Causes: Nephrotic syndrome, cirrhosis, congestive heart failure, renal failure

Clinical Manifestations

- Nausea and vomiting
- Cramps
- Weakness
- Agitation
- Confusion
- Headache
- Anorexia
- Cerebral edema
- Seizures
- Coma

SIADH, Syndrome of inappropriate secretion of antidiuretic hormone.

*Serum sodium <135 mEq/L

TABLE 21.4
Sodium Levels and Physiologic Manifestations

Plasma NA Concentration mEq/L Levels	Signs/Symptoms
135–130	No signs/symptoms, mild neurologic signs/symptoms possible
129–125	Nausea, malaise
124–115	Headache, lethargy, altered level of consciousness
<115 and/or rapid onset	Seizures, coma, respiratory arrest, cerebral herniation

Hyponatremia

Hyponatremia results in a condition in which the intracellular environment is hyperosmolar relative to the ECV leading to an influx of water into the ICV. One of the most significant consequences of hyponatremia is cerebral edema. As the brain is contained within the fixed confines of the cranium, cerebral edema is poorly tolerated. Compensatory mechanisms can delay the development of symptomatic cerebral edema. Brain cells can maintain osmotic equilibrium by extruding intracellular solutes, thereby reducing intracellular osmolality. However, if the extrusion of solute by brain cells is inadequate to compensate for the hypoosmolar influence of the ECF, an intracellular influx of water may lead to symptomatic cerebral edema neuronal cell death.¹³¹

Clinical studies have demonstrated that when compared with men or postmenopausal women, menstruating women are at increased risk of brain damage resulting from hyponatremia. It is believed that estrogen and progesterone inhibit the efficiency of the Na-K-ATPase pump, which is essential to the extrusion of intracellular solutes to maintain osmotic equilibrium in hyponatremia; female sex hormones may facilitate movement of water into the brain through the mediation of ADH.¹³²

Hyponatremia is the most common electrolyte abnormality in hospitalized patients. The development of hypervolemic hyponatremia in patients with congestive heart failure (CHF) or cirrhosis is associated with an increased risk of death.^{133,134} Even

mild stable euvolemic hyponatremia caused by SIADH has been associated with cognitive defects and gait disturbances. Overly rapid correction of serum sodium, particularly in patients with chronic hyponatremia, can cause neurologic complications such as seizures, spastic quadriparesis, and coma because of osmotic demyelination.¹³⁵ Vasopressin receptor antagonists, the vaptan drug class, which includes tolvaptan (Samsca) and conivaptan (Vaprisol) are available to treat hypervolemic or euvolemic hyponatremia that is caused by CHF, cirrhosis, and polycystic kidney disease. These medications antagonize arginine vasopressin by inhibition of renal V1a, V1RA, V2, and V3RA receptors. The result is increased free water excretion by the kidneys.¹³⁵

Initial treatment of hyponatremia typically includes fluid restriction and diuresis. Intravenous conivaptan has been used for short-term treatment of euvolemic hyponatremia. Oral treatment with tolvaptan can increase serum sodium concentrations in patients with hypervolemic or euvolemic hyponatremia caused by cirrhosis, heart failure, or SIADH, but has not been shown to reduce mortality. Overly rapid correction of serum sodium can cause osmotic demyelination, but this side effect has not been reported after administration of tolvaptan.¹³⁶ Fig. 21.6 depicts differences in ECV sodium concentration and the effect on various cells.

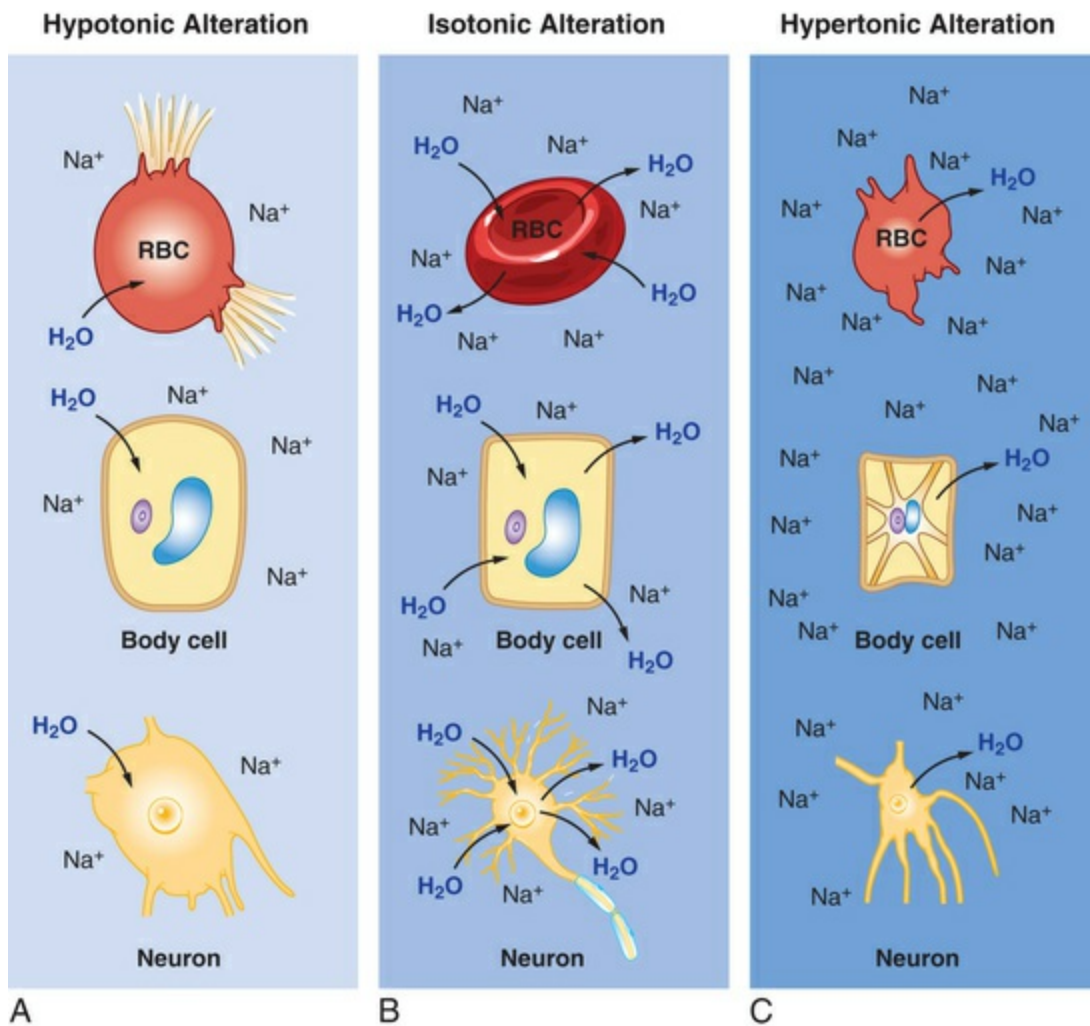

FIGURE 21.6 Effects of alterations in extracellular sodium concentration in RBC, body cell, and neuron. **A**, *Hypotonic alteration*: Decrease in ECF sodium (Na) concentration (hyponatremia) results in ICF osmotic attraction of water with swelling and potential busting of cells. **B**, *Isotonic alteration*: Normal concentration of sodium in the ECF and no change in shifts of fluid in or out of cells. **C**, *Hypertonic alteration*: An increase in ECF sodium concentration (hypernatremia) results in osmotic attraction of water out of cells with cell shrinkage. *ECF*, Extracellular fluid; *ICF*, intracellular fluid; *RBC*, red blood cell. (From McCance KL, et al. *Pathophysiology*. 7th ed. St. Louis: Elsevier; 2014:110.)

Aggressive treatment of acute hyponatremia can be associated with severe neurologic effects. Fig. 21.7 contains guidelines that highlight the treatment of hyponatremia. In instances when chronic hyponatremia occurs, rapid correction of serum sodium can lead to the neurologic disorder known as *myelinolysis*. Myelinolysis, originally known as *central pontine myelinolysis*, can lead to

disorders of the upper neurons, spastic quadriparesis, pseudobulbar palsy, mental disorders, and in some cases, death. Patients at particular risk for myelinolysis are those who have been hyponatremic for more than 48 hours, and individuals who have had orthotopic liver transplantation or a history of alcohol abuse. Optimal treatment of hyponatremia must balance the risks of cerebral edema against the risks of myelinolysis.¹³⁷

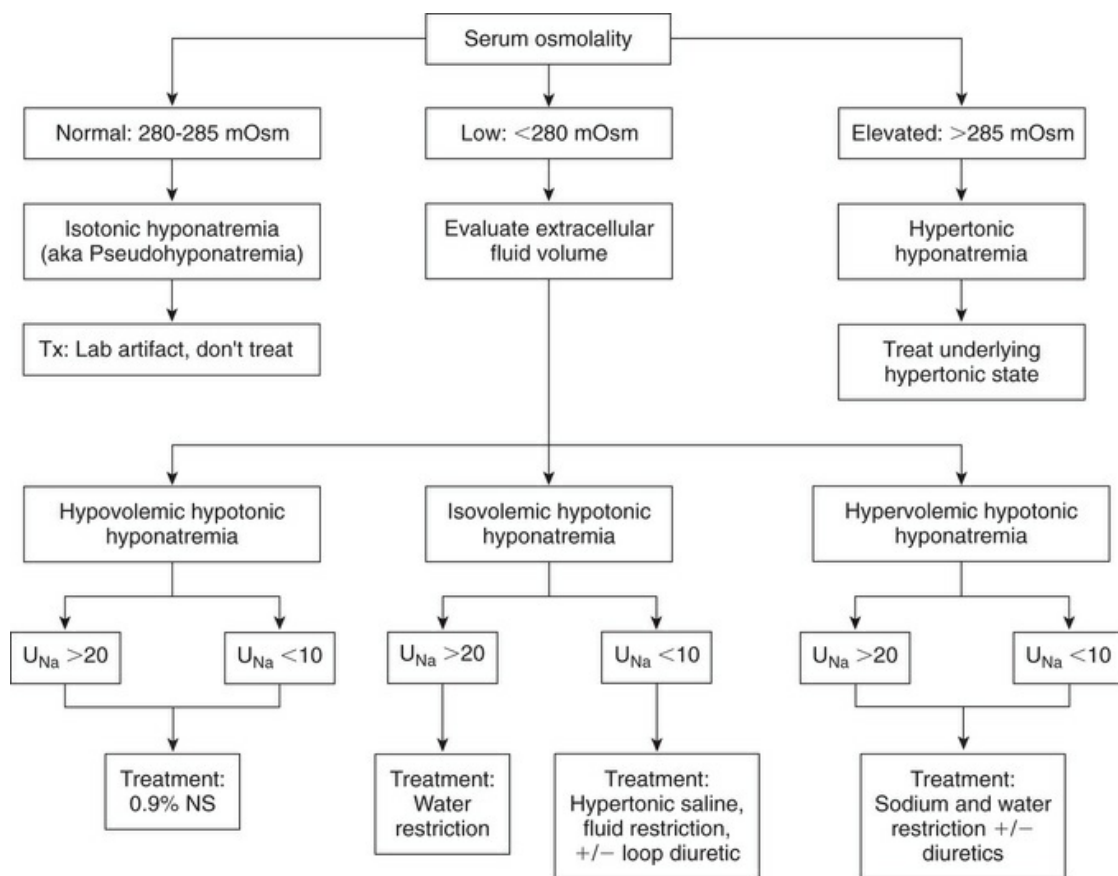

FIGURE 21.7 Treatment of hyponatremia. NS, Normal saline; Tx, treatment; U_{Na} , urinary sodium. (Modified from Ferri FF. *Practical Guide to the Care of the Medical Patient*. 8th ed. Philadelphia: Elsevier; 2011.)

The risk of myelinolysis can be reduced by correcting serum NA levels in a deliberate manner. It has been suggested that serum NA concentrations should be increased by no more than 1 to 2 mEq/L per hr. In symptomatic patients, this is accomplished by infusing 3% saline at a rate of 1 to 2 mL/kg per hr. Once the patient is clinically stable, NA administration should be slowed to raise

serum NA not more than 10 to 15 mmol/L in 24 hours.¹³⁷

Hypernatremia

Hypernatremia can result from several causes (Fig. 21.8, Box 21.5, and Table 21.5), but is usually the result of impaired water intake.¹³⁸ Inadequate administration of free water to hospitalized patients can lead to an iatrogenic hypernatremia. In cases of slow-onset hypernatremia, the brain can adapt by conserving intracellular solutes, which allows maintenance of normal ICV. Rapidly occurring hypernatremia can be accompanied by rapid shrinking of the brain and concomitant traction on intracranial veins and venous sinuses, leading to intracranial hemorrhage.¹³⁹ As with hyponatremia, rapid treatment used to correct chronic hypernatremia can lead to negative physiologic effects as large volumes of free water may lead to cerebral edema.

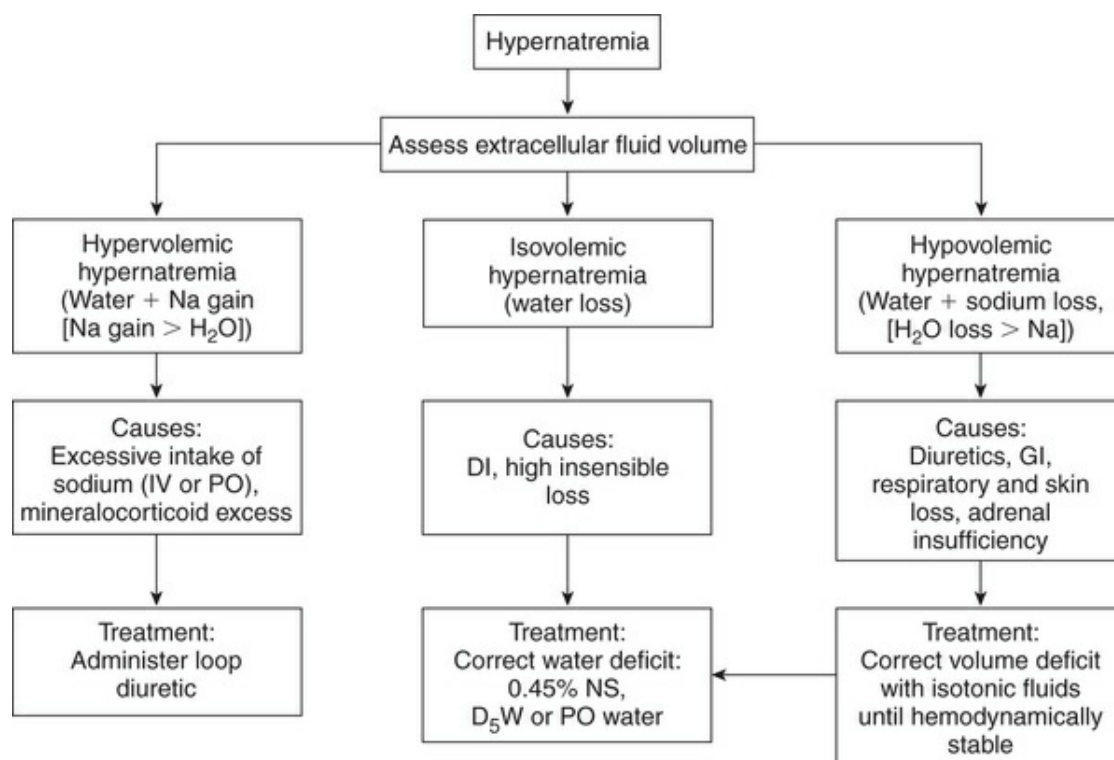

FIGURE 21.8 Hypernatremia (serum sodium [Na] greater than 145 mEq/L). *DI*, Diabetes insipidus; *GI*, gastrointestinal; *NS*, normal saline; *PO*, oral. (Modified from Ferri FF. *Practical Guide to the Care of the Medical Patient*. 8th ed. Philadelphia: Elsevier; 2011.)

Box 21.5

Hypernatremia: Classification, Causative Factors and Manifestations*

Hypernatremia With Dehydration and Low Total Body Sodium

Causes: vomiting, diarrhea, continuous gastrointestinal suctioning, osmotic diuresis (e.g., mannitol)

Hypernatremia With Low Total Body Water and Normal Total Body Sodium

Causes: diabetes, neurogenic, renal disease, sickle cell disease, medications

(e.g., aminoglycosides)

Hypernatremia With Increased Total Body Sodium

Causes: hypertonic saline infusion, Cushing syndrome, Conn syndrome, hemodialysis

Physiologic Manifestations

Neurologic

- Thirst
- Weakness
- Seizure
- Coma

- Intracranial bleeding
- Disorientation
- Hallucinations
- Irritability
- Muscle twitching
- Cerebral edema

Cardiovascular

- Increased NA-hypervolemia-tachycardia, increased preload, increased myocardial oxygen consumption
- Decreased NA-hypovolemia-tachycardia, decreased preload

Respiratory

- Increased NA-pulmonary edema

Renal

- Polyuria or oliguria
- Renal insufficiency

*Serum sodium >145 mEq/L

TABLE 21.5**Clinical Signs of Hypernatremia With Increasing Serum Osmolality**

Osmolality (mOsm/kg)	Neurologic Signs and Symptoms
350–375	Confusion, restlessness, agitation, headache
376–400	Ataxia, tremors, weakness
401–430	Hyperreflexia, muscle twitching/spasm
> 430	Coma, seizures, death

Correction of hypernatremia is accomplished by replacement of the water deficit, which can be calculated using the formulas provided in [Box 21.6](#). If the hypernatremia is acute (i.e., less than 24 hours' duration), water deficits can be replaced relatively rapidly with hypotonic solutions. If chronic hypernatremia accompanied by volume depletion is present, the volume disorder is corrected first with isotonic crystalloids. Once the circulating volume has been restored, hypotonic solutions are used to correct the water deficit. Plasma sodium should be decreased by 1 to 2 mEq/hr until the patient is clinically stable, and correction of serum sodium to normal levels should gradually progress over the subsequent 24

Disorders of Potassium Balance

Potassium (K) is the principle intracellular electrolyte within the ICV, which accounts for 98% of the body's supply. The difference between intracellular K (150–160 mEq/L) and extracellular K (3.5–5.0 mEq/L) concentrations and the dynamic balance between K within these compartments are in large part responsible for the resting membrane potential of the cell.¹⁴¹ Homeostasis is maintained by absorption of K from the gastrointestinal tract and by renal excretion or reabsorption into the peritubular capillary network. Renal regulation of K is dependent on: (1) the concentration gradient between the distal tubules and collecting duct relative to the peritubular capillary network, (2) the distal convoluted tubular flow rate and NA concentration, (3) the concentration of aldosterone, and (4) changes in pH (acidosis/alkalosis). Aldosterone has a potent effect on K levels. Hyperkalemia causes adrenal cortical synthesis and release of aldosterone, which promotes potassium excretion from the distal renal tubules. Disturbances in serum K results from an imbalance between intracellular and extracellular distribution of K or an abnormality in the total body stores of K. The symptoms associated with hyperkalemia and hypokalemia result in altered resting membrane potential.

Hypokalemia

Hypokalemia, which is defined as serum K of less than 3.5 mEq/L can result from an absolute deficiency caused by gastrointestinal loss, renal loss, intracellular shift, increased non-renal losses, endocrinopathies, and poor intake (Box 21.7). It is the most common electrolyte abnormality encountered during clinical practice. Redistribution of K from the ECV to the ICV can also lead to hypokalemia. β -Adrenergic stimulation, insulin, and alkalosis all promote the movement of K into the ICV.¹⁴²

Five Most Common Causes of Hypokalemia

1. Renal losses	Diuretic use, drugs, steroid use, metabolic acidosis, hyperaldosteronism, renal tubular acidosis, diabetic ketoacidosis, alcohol consumption
2. Increased nonrenal losses	Sweating, diarrhea, vomiting, laxative use
3. Decreased intake	Ethanol, malnutrition
4. Intracellular shift	Hyperventilation, metabolic alkalosis, drugs
5. Endocrinopathy	Cushing disease, Bartter syndrome, insulin therapy

From Marx, JA. *Rosen's Emergency Medicine*. 8th edition. Philadelphia: Elsevier; 2014:1639.

Hypokalemia is 11 times more likely to occur with patients routinely treated with thiazide diuretics, and twice as high for men as compared to women.¹⁴³ Mild decreases in serum K are often well tolerated, but symptoms that may occur include palpitations, skeletal muscle weakness, and muscle pain. With a serum K value of less than 2.5 mEq/L, signs and symptoms include paresthesia, depressed deep tendon reflexes, fasciculations, muscle weakness, and altered level of consciousness. In patients with cardiac disease, including ischemia and CHF, mild to moderate hypokalemia increases the potential for dysrhythmias. Common cardiac dysrhythmias associated with hypokalemia are first- and second-degree heart block, atrial or ventricular fibrillation, and asystole. The electrocardiographic (ECG) abnormalities associated with hypokalemia include ST segment depression, flattened T wave, and the presence of a U wave as depicted in Fig. 21.9.

FIGURE 21.9 Electrographic changes in hypokalemia.
 (From Marx JA, et al. *Rosen's Emergency Medicine*. 8th ed. Philadelphia:
 Elsevier; 2014:1640.)

Treatment of hypokalemia depends on the severity of the symptoms accompanying the K deficit. In the face of hemodynamically compromising cardiac dysrhythmias, aggressive IV administration of K is warranted. IV replacement of K should be accomplished with the patient under continuous ECG monitoring. Rates of IV administration as rapid as 40 mEq/hr can be given if K levels are less than 2.0 mEq/L, although a maximum rate of 10 to 20 mEq/hr is recommended to avoid an iatrogenic hyperkalemia.¹⁴⁴

Once serious symptoms associated with hypokalemia, such as respiratory muscle weakness or dysrhythmias have been reversed, IV replacement can be discontinued and oral supplementation is appropriate. It is recommended that IV potassium be replaced along with chloride, because the hypochloride state makes it difficult for the kidney to conserve K.¹⁴² Furthermore, KCL should be mixed in a dextrose-free solution to prevent stimulation of insulin, leading to increased redistribution of K to the intracellular space.¹⁴⁵

The association between preoperative potassium with a 30-day mortality and adverse cardiovascular event (MACE) has been a long-debated. Recently, it has been determined that patients with preoperative hyperkalemia ($K > 5.5$ mEq/L) and hypokalemia ($K < 4.0$ mEq/L) undergoing noncardiac surgery are at increased risk of developing MACE with 30 days postoperatively.¹⁴⁶

Hyperkalemia

Hyperkalemia is defined as a serum K greater than 5.0 mEq/L and

occurs less commonly as compared to hypokalemia if renal causes are excluded.¹⁴⁵ In addition to impaired renal excretion of potassium, causes of hyperkalemia include a high intake of potassium and a shift of potassium from ICV to ECV. This can lead to increased lactic acid production and apoptosis. Medications such as digoxin, angiotensin converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARBs) and β -blockers can all increase ECV potassium. By decreasing angiotensin, ACE inhibitors/ARBs can cause hyponatremia and hyperkalemia. Similarly, β blockade and specifically β -1 receptor antagonism of the macula densa, inhibits renin release, thus decreasing the release of aldosterone, potentially causing hyponatremia and hyperkalemia. Specific causes of hyperkalemia are listed in [Box 21.8](#). Because the inward and outward flux of K consistently occurs during myocardial cell depolarization and repolarization, hyperkalemia that occurs rapidly can have dramatic effects on cardiac rhythm. ECG changes that are associated with increased [Box 21.8](#) are outlined in [Table 21.6](#).

Causes of Hyperkalemia*

Pseudohyperkalemia

- Hemolysis of sample
- Thrombocytosis
- Leukocytosis
- Laboratory error

Increased Potassium Intake and Absorption

- Potassium supplements (oral and parenteral)
- Dietary (salt substitutes)
- Stored blood
- Potassium-containing medications

Impaired Renal Excretion

- Acute renal failure
- Chronic renal failure
- Tubular defect in potassium secretion
- Renal allograft
- Analgesic nephropathy
- Obstructive uropathy
- Interstitial nephritis
- Chronic pyelonephritis
- Potassium-sparing diuretics
- Miscellaneous (e.g., lead, systemic lupus erythematosus, pseudohypoaldosteronism)
- Hypoaldosteronism
- Primary (Addison disease)
- Hyporeninemic hypoaldosteronism (renal tubular acidosis type 4)
- Congenital adrenal hyperplasia
- Drug-induced (e.g., nonsteroidal antiinflammatory drugs; angiotensin-converting enzyme; heparin; cyclosporine)

Transcellular Shifts

- Acidosis
- Hypertonicity
- Insulin deficiency

- Drugs
- β -Blockers
- Digitalis toxicity
- Succinylcholine
- Exercise
- Hyperkalemic periodic paralysis

Cellular Injury

- Rhabdomyolysis
- Severe intravascular hemolysis
- Acute tumor lysis syndrome
- Burns and crush injuries

*Serum potassium > 5 mEq/L

From Marx JA, et al. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Elsevier; 2010:1621.

TABLE 21.6

ECG Changes Associated with Hyperkalemia

Potassium mEq/L	ECG Change
>5.5–6.5	Peaked T waves
>6.5–7.5	P wave flattening or disappearance, PR prolongation
>7.0–8.0	QRS prolongation
>8.5	QRS complex degrades to sine wave pattern, ventricular fibrillation and cardiac arrest

Treatment of hyperkalemia should be preceded by exclusion of pseudo-hyperkalemia, which is a laboratory artifact. Pseudo-hyperkalemia results from hemolysis of the blood sample,

leukocytosis, thrombosis, or prolonged fist clenching during blood drawing. The treatment strategy accomplishes three physiologic events: (1) stabilization of cardiac membrane, (2) driving K from ECV to ICV, and (3) removal of K from the body. For patients who are predisposed to developing chronic hyperkalemia (e.g., renal failure), an oral K binding medication patiromer (Veltassa) can be used. This oral agent is an unabsorbed anion polymer that exchanges a calcium-sorbitol compound for K within the gastrointestinal lumen, and leads to decreased serum K.¹⁴⁷ Treatment of hyperkalemia is based on the severity of the patient's presenting signs and symptoms (Table 21.7).

TABLE 21.7
Guidelines for Treatment of Hyperkalemia

Clinical Feature	Therapy	Onset	Duration	Mechanism of Action
Electrocardiographic Evidence of Pending Arrest				
Loss of P wave and widening QRS; immediate effective therapy indicated	1. IV infusion of calcium salts*: 10 mL of 10% calcium chloride over 10-minute period <i>or</i>	1–3 min	30–60 min	Membrane stabilization
	10 mL of 10% calcium gluconate over 3–5 minutes	1–3 min	30–60 min	Membrane stabilization
	2. IV infusion of sodium bicarbonate: 50–100 mEq over 10- to 20-minute period	5–10 min	1–2 hr	Shifts potassium intracellularly
Electrocardiographic Evidence of Potassium Effect				
Peaked T waves; prompt therapy needed	1. Glucose and insulin infusion: IV infusion of 50 mL of D ₅₀ W and 10 units of regular insulin; monitor glucose 2. Immediate hemodialysis	30 min	4–6 hr	Shifts potassium intracellularly
Biochemical Evidence of Hyperkalemia and No Electrocardiographic Changes				
Effective therapy needed within hours	1. Potassium-binding resins in the gastrointestinal (GI) tract	1–2 hr	4–6 hr	GI excretion
	2. Promotion of renal potassium excretion: diuretic—Furosemide 40 mg IV	15–30 min	2–3 hr	Renal excretion

*Calcium chloride yields three times the ionized calcium as calcium gluconate; calcium chloride = 27 mg/mL; calcium gluconate = 9 mg/mL.

Disorders of Calcium Balance

Calcium is a divalent cation and 99% is found in bones as hydroxyapatite (inorganic compound, which contributes to bone rigidity). The remaining 1% of calcium exists in the plasma and

body cells. Calcium is vitally important for structural integrity of bone, but perhaps most important to anesthetists is its role as a second messenger that couples cell membrane receptors to cellular responses. The action of calcium as a second messenger is critical to functions such as muscle contractions and release of hormones and neurotransmitters.¹⁴⁸ In addition to the second messenger function, calcium plays an important role in blood coagulation and muscle function including myocardial contractility.¹⁴⁹

Although most of the body's calcium is found in the bones, a small percentage is freely exchangeable with the ECV. Calcium in the ECV is found in three distinct fractions. Ionized calcium accounts for 50% of the calcium in the ECV and is the physiologically active portion of circulating calcium. The remainder of the circulating calcium is bound either to anions (10%) or plasma proteins, primarily albumin (40%).¹⁴⁹ Changes in pH alter the extracellular distribution of calcium, with acidemia decreasing the protein-bound fraction and increasing the ionized fraction.²³ The total fraction of calcium circulating within the blood is 9.0 to 10.5 mg/dL.

It is the ionized fraction of calcium that is most clinically significant because this form is available for physiologic reactions. Total serum calcium levels are largely dependent on the albumin concentration. Direct measurement of ionized calcium is the preferred method in critically ill patients.¹⁵⁰ Serum calcium levels are primarily maintained by the release or inhibition of parathyroid hormone (PTH), but also by vitamin D and calcitonin. During periods of hypercalcemia or hypocalcemia, the levels of PTH decrease or increase respectively and cause a series of biologic events in an attempt to normalize serum calcium as shown in [Fig. 21.10](#).

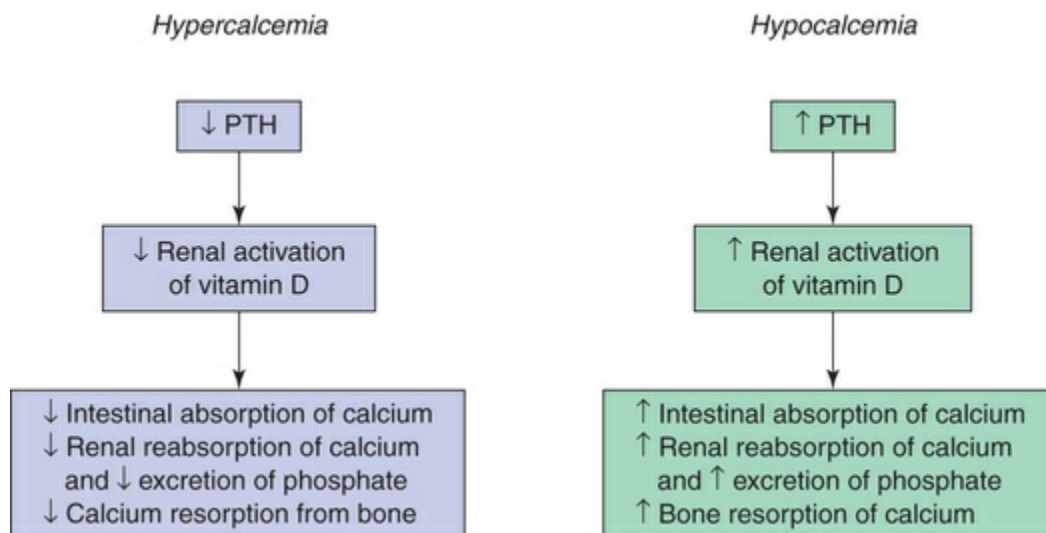

FIGURE 21.10 Hormone regulation of calcium balance.

PTH, Parathyroid hormone. (From McCance KL, et al. *Pathophysiology*. 7th ed. St. Louis: Elsevier; 2014:119.)

Hypocalcemia

The specific causes and clinical features associated with hypocalcemia are listed in (Box 21.9). In the intraoperative period, the most likely causes of hypocalcemia are hyperventilation and massive rapid transfusion. Hyperventilation leads to an increased pH, which facilitates increased protein-binding of calcium, thus decreasing serum ionized calcium. Citrate is a preservative added to packed red blood cells. This chemical chelates or binds calcium, decreasing serum calcium available for physiologic reactions. Massive rapid transfusion of packed red blood cells can cause acute hypocalcemia, and this topic is further discussed in Chapter 22.

Causes and Clinical Features of Hypocalcemia*

Causes

Parathyroid Hormone Insufficiency

Primary hypoparathyroidism

- Congenital syndromes

- Maternal hyperparathyroidism

Secondary hypoparathyroidism

- Neck surgery
- Metastatic carcinoma
- Infiltrative disorders
- Hypomagnesemia, hypermagnesemia
- Sepsis
- Pancreatitis
- Burns
- Drugs (chemotherapeutics, ethanol, cimetidine)

Vitamin D Insufficiency

Congenital rickets

Malnutrition

Malabsorption

Liver disease

Renal disease

- Acute and chronic renal failure
- Nephrotic syndrome

Hypomagnesemia

Sepsis

Anticonvulsants (phenytoin, primidone)

Parathyroid Hormone Resistance States (Pseudohypoparathyroidism)/Calcium Chelation

Hyperphosphatemia

Citrate

Free fatty acids

Alkalosis

Fluoride poisoning

Clinical Features

Neuromuscular

- Paresthesias
- Muscle weakness
- Muscle spasm
- Tetany
- Chvostek's sign (facial/eye muscle twitching)
- Trousseau's sign (carpopedal spasm)
- Hyperreflexia
- Seizures

Cardiovascular

- Bradycardia
- Angina
- Hypotension
- Congestive heart failure
- Cardiac arrest
- Digitalis insensitivity
- QT prolongation

Pulmonary

- Bronchospasm
- Laryngospasm

Psychiatric

- Anxiety
- Depression
- Irritability
- Confusion
- Psychosis
- Dementia

*Serum calcium < 8.5 mg/dL; ionized calcium < 4.0 mg/dL

From Marx JA, et al. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Elsevier; 2010:1623–1624.

Treatment of acute hypocalcemia involves the infusion of calcium

salts. Calcium chloride is the most bioavailable parenteral preparation of calcium (272 mg of elemental calcium). It results in the most rapid correction of hypocalcemia. However, it can cause significant venous irritation and tissue necrosis as compared to calcium gluconate. If a central line is present, then administration via the central route can decrease the incidence of complications. One regimen used to treat hypocalcemia includes administration of 10 mL of 10% calcium gluconate (93 mg of elemental calcium) over 10 minutes, followed by an infusion of 0.3 to 2 mg/kg per hr of elemental calcium.²³ Correction of serum calcium should be guided by ionized calcium levels.

Hypercalcemia

Hypercalcemia typically results from the movement of calcium from bone to the ECV which exceeds the ability of the kidney to excrete calcium (Box 21.10). Primary hyperparathyroidism accounts for more than half of all cases of hypercalcemia, with malignancy being the second most common cause. Treatment of hypercalcemia involves volume expansion with NS, which increases renal excretion of calcium. The addition of a loop diuretic further enhances renal excretion. Bisphosphonates, mithramycin, calcitonin, glucocorticoids, and phosphate salts have also been used to treat hypercalcemia.¹⁵¹ For patients who rapidly develop hypercalcemia, which results in life threatening dysrhythmias, hemodialysis is an acute treatment to rapidly lower serum calcium.

Causes and Clinical Features of Hypercalcemia

Definition

- *Mild hypercalcemia*: Serum Ca 10.5–11.9 mg/dL (2.5–3 mmol/L) or Ionized Ca 5.6–8 mg/dL (1.4–2 mmol/L)
- *Moderate hypercalcemia*: Serum Ca 12–13.9 mg/dL (3–3.5 mmol/L) or Ionized Ca 8–10 mg/dL (2–2.5 mmol/L)
- *Hypercalcemic crisis*: Serum Ca 14–16 mg/dL (3.5–4 mmol/L) or

Ionized Ca 10–12 mg/dL (2.5–3 mmol/L)

Causes

Primary Hyperparathyroidism

Malignant Disease

- Parathyroid hormone–related protein
- Ectopic production of 1,25-dihydroxyvitamin D
- Other bone-resorbing substances
- Osteolytic bone metastasis

Medications

- Thiazide diuretics
- Lithium
- Estrogens
- Vitamin D toxicity
- Vitamin A toxicity
- Calcium ingestion

Granulomatous Disorders

- Sarcoidosis
- Tuberculosis
- Coccidioidomycosis
- Berylliosis
- Histoplasmosis

- Leprosy

Nonparathyroid Endocrine Disorders

- Hyperthyroidism
- Adrenal insufficiency
- Pheochromocytoma
- Acromegaly
- Vasoactive intestinal polypeptide–producing tumor

Miscellaneous

- Milk-alkali syndrome
- Immobilization
- Idiopathic hypocalcemia of infancy
- Physiologic (in the newborn)

Clinical Features

Neurologic

- Fatigue, weakness
- Confusion, lethargy
- Seizures
- Coma
- Hypotonia, diminished deep tendon reflexes

Cardiovascular

- Hypertension
- ST segment elevation
- Sinus bradycardia/arrest, atrioventricular block
- ECG abnormalities (short QT interval, bundle branch block)
- Ventricular dysrhythmias
- Potentiation of digoxin toxicity

Renal

- Polyuria, polydipsia
- Dehydration
- Loss of electrolyte
- Prerenal azotemia
- Nephrolithiasis
- Nephrocalcinosis

Gastrointestinal

- Nausea, vomiting
- Anorexia
- Peptic ulcer disease
- Pancreatitis
- Constipation, ileus

Disorders of Magnesium Balance

Magnesium is the second most abundant intracellular cation, second only to potassium. Approximately 40% to 60% is stored in muscle and bone, 30% within cells, and 1% in serum. Regulation of magnesium metabolism occurs in the intestines and kidneys. The physiologic importance of magnesium includes its role as a cofactor in numerous enzymatic reactions, including those involving energy metabolism, protein synthesis, neuromuscular excitability, and the function of the Na-K-ATPase pump. Chronic hypomagnesemia increases cardiovascular death in both men and women by 8% and 16% respectively.¹⁵²

An IV infusion of magnesium may relieve severe bronchospasm and it can decrease postoperative pain.^{153,154} Normal magnesium plasma concentrations range from 1.5 to 3.0 mEq/L.

Hypomagnesemia

Hypomagnesemia is common in hospitalized patients, especially critically ill patients. Magnesium deficiency can be the result of increased renal or gastrointestinal loss or poor magnesium intake and or medications¹⁵⁵ (Box 21.11). Hypomagnesemia has an inhibitory effect on the Na-K-ATPase dependent pump resulting in decreased ICV potassium. This can alter the cardiac resting membrane potential, specifically phase 4 (resting membrane potential) of the cardiac action potential. ECG changes seen with hypomagnesaemia include flat T-waves, presence of U-waves, prolonged QT interval, widened QRS complexes, and atrial and ventricular arrhythmias. Thirty percent of patients who consume excessive amounts of alcohol are admitted to the hospital with hypomagnesemia caused by poor dietary intake and the associated diuretic effect.¹⁵⁶ Severe hypomagnesemia can be treated with IV administration of 1 to 2 g of magnesium sulfate over 5 minutes while the ECG is monitored, followed by administration of 1 to 2

Box 21.11

Causes of Hypomagnesemia*

Excessive alcohol intake

Pregnancy

Renal losses

- Acute and chronic renal failure
- Postobstructive diuresis
- Acute tubular necrosis
- Chronic glomerulonephritis
- Chronic pyelonephritis
- Interstitial nephropathy
- Renal transplantation

Gastrointestinal losses

- Chronic diarrhea
- Nasogastric suctioning
- Short-bowel syndrome
- Protein-calorie malnutrition
- Bowel fistula
- Total parenteral nutrition
- Acute pancreatitis

Endocrine disorders

- Diabetes mellitus
- Hyperaldosteronism
- Hyperthyroidism
- Hyperparathyroidism
- Acute intermittent porphyria

Medications

- Aminoglycosides
- Amphotericin
- β -Agonists
- Cisplatin
- Cyclosporine
- Diuretics
- Foscarnet
- Pentamidine
- Proton pump inhibitors
- Theophylline

Congenital disorders

- Familial hypomagnesemia
- Maternal diabetes
- Maternal hypothyroidism
- Maternal hyperparathyroidism

*Serum Mg <1.5 mEq/L

From Marx JA, et al. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Mosby; 2010:1627.

Hypermagnesemia

Hypermagnesemia is most commonly the result of iatrogenic causes (e.g., intravenous administration) (Box 21.12).

Hypermagnesemia can result from the treatment of preeclampsia, preterm labor, ischemic heart disease, and cardiac dysrhythmias.

The symptoms of hypermagnesemia include depression of the peripheral and central nervous system, hypotension, QRS segment widening, PR and QT segment prolongation, heart block, and cardiac arrest. The symptoms are dependent on the rapidity and degree of increased magnesium levels. Magnesium potentiates the action of nondepolarizing neuromuscular relaxants and their use should be carefully monitored in patients with

hypermagnesemia.¹⁵⁸ Treatment of hypermagnesemia involves discontinuing the administration of magnesium; in urgent situations, such as bradycardia, heart block, and respiratory

Box 21.12 depression, calcium chloride should be used as an antagonist.

Hypermagnesemia*

Causative Factors

- Renal failure
- Excessive magnesium administration
- Adrenal insufficiency

Clinical Manifestations

Serum Magnesium Levels (mg/dL)

4–5 = Decreased deep tendon reflexes

5–7 = Hypotension

10 = Respiratory paralysis, coma

10–15 = Heart block

10–24 = Cardiac arrest

*Serum Mg >3 mEq/L

From Marx JA, et al. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 8th ed. Philadelphia: Elsevier; 2014:1648

Disorders of Phosphate Balance

The majority of phosphate is located in bone (85%). The small amount that is present within the plasma exists as: (1) phospholipids, (2) phosphate esters, and (3) inorganic phosphate, which is the ionized form. Intracellular phosphate has numerous metabolic effects, such as being a component part of adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG). It also acts as a buffer in the regulation of acid base balance. The concentration of phosphate in plasma is directly proportional to that of calcium. Phosphate levels are tightly controlled by the same mechanism that governs calcium levels, PTH, vitamin D, and calcitonin (see [Fig. 21.10](#)).

Hypophosphatemia

Hypophosphatemia is defined as a serum phosphate concentration of less than 2.0 mg/dL. The most likely causes of hypophosphatemia are increased renal excretion and intestinal malabsorption. Respiratory alkalosis can cause low phosphate levels because of the accelerated use of ATP by cells. With hypophosphatemia, decreased 2,3-DPG is available in red blood cells. This causes a leftward shift of the oxyhemoglobin dissociation curve and increases the affinity between hemoglobin and oxygen (decreased oxygen unloading to the tissues). The result of decreased oxygen delivery to cells results in anaerobic metabolism, decreased ATP formation, and acidosis. The consequence of decreased ATP includes hypoxia, heart block, bradycardia, and asystole.

Hyperphosphatemia

Hyperphosphatemia is defined as a serum phosphate level greater than 4.7 mg/dL. The majority of phosphate exists within the ECV, and cellular destruction (e.g., metastatic disease) is a leading cause. Increased phosphate levels can produce clinically significant hypocalcemia as calcium and phosphate are further deposited within bone. Therefore signs and symptoms associated with low serum phosphate are synonymous with hypocalcemia as previously described. Aluminum hydroxide, which are contained in antacids decrease serum phosphate by binding within the gastrointestinal tract. Dialysis can also be employed to treat severely elevated phosphate levels. [Table 21.8](#) includes causes and manifestations associated with phosphate imbalances.

TABLE 21.8

Alterations in Phosphate Balance

	Causes	Manifestations
Hypophosphatemia (<2.0 mg/dL)	Intestinal malabsorption related to vitamin D deficiency	Conditions related to decreased oxygen transport and ATP creation
	Magnesium/aluminum containing antacids	Platelet dysfunction
	Chronic alcohol misuse	Bone reabsorption Altered nerve and muscle function
	Malabsorption syndromes	Confusion
	Respiratory alkalosis	Coma

	Increased renal excretion associated with hyperparathyroidism	Seizures
		Muscle weakness
		Respiratory failure
		Cardiomyopathy
Hyperphosphatemia (>4.7 mg/dL)	Acute/chronic renal failure	Symptoms related to hypocalcemia
	Treatment of metastatic tumor	Chronic-calcification of soft tissues (e.g., joints, lungs, kidneys)
	Long-term use of laxatives/enemas containing phosphates	
	Hypoparathyroidism

Summary

As updated scientific information refutes commonly accepted beliefs regarding fluid administration, anesthesiologists will need to modify their practice to help ensure optimal patient outcomes. Goal-directed fluid therapy allows for a measured approach to intravenous fluid administration based on real-time physiologic data. This will result in improved perfusion to vital organs, as well as minimize the possibility of edema formation and damage to the endothelial glycocalyx. Additionally, electrolyte disorders can dramatically complicate an anesthetic course and result in morbidity and mortality. A thorough knowledge of the physiologic effects, signs and symptoms, and treatment of electrolyte abnormalities is essential for competent anesthesia practice.

Blood and Blood Component Therapy

Bernadette T. Higgins Roche, Pamela Schwartz

Trauma, disease, and surgical procedures disrupt hemodynamic homeostasis through tissue injury, fluid shifts, infectious processes, and blood loss. Instituting blood component therapies involves product procurement, compatibility testing, safeguarding transfusion processes, in addition to defining and assessing outcome parameters. The anesthetist's unique role in transfusion of blood products focuses on strategies to assure patient safety and wellbeing, while providing a means to optimize physiologic outcomes.

Blood product transfusion focuses on maintenance of red blood cell components to increase oxygen-carrying capacity, and restore intravascular volume and hemostasis. A thorough preoperative assessment and communication with the patient care team will aid in early identification and anticipation of perioperative fluid and blood losses, diagnoses of hemodynamic alteration, and ongoing outcome assessment. The American Society of Anesthesiologists (ASA) Practice Guidelines for Perioperative Blood Management are summarized in [Box 22.1](#).¹

ASA Practice Guidelines for Perioperative Blood Management—Summary

Preoperative Patient Evaluation

- Early preoperative evaluation.
- Review of medical records specifically:
- previous blood transfusion.

- history of drug-induced coagulopathy (anticoagulants, vitamins, herbal supplements).
- congenital coagulopathy.
- history of thrombotic events.
- risk factors for organ ischemia (cardio respiratory disease may lower trigger for red blood cell [RBC] transfusion).
- Discuss risks vs. benefits of blood transfusion with patients, and confirm their preference.
- Review available labs, ordering additional tests as indicated: hemoglobin (Hgb), hematocrit (Hct), and coagulation profile.
- Conduct patient physical exam: ecchymosis, petechiae, pallor.

Preadmission Patient Preparation

- Administer erythropoietin, with or without iron, in select patient populations to reduce allogeneic blood transfusion.
- If time permits, administer iron to patients with iron deficiency anemia.
- Discontinue anticoagulants, in consultation with appropriate specialists, and transition to shorter acting drugs.
- If possible, discontinue nonaspirin, antiplatelet agents in advance of surgery.
- Continue aspirin on a case by case basis.
- Weigh risks of thrombosis versus increased bleeding.

- Assure blood and components are available if significant blood loss or transfusion anticipated.
- Prior to admission, offer patient opportunity to donate autologous blood, if preferred, and time allows for erythropoietin reconstitution.

Preprocedure Preparation

- Blood Management Protocols utilize:
 - Algorithmic strategies to reduce usage of blood products.
 - Restrictive RBC transfusion strategy to reduce transfusions.
 - Evaluate potential for ongoing bleeding, intravascular volume status, organ ischemia, and cardiovascular reserve.
 - Administer RBC unit by unit with interval reevaluations.
 - Transfusion avoidance strategy in patients refusing transfusion, or is not possible.
 - Massive transfusion protocol strategy when indicated.
 - Institution's maximal surgical blood order schedule.

- Reversal of Anticoagulants
- For urgent reversal administer prothrombin complex concentrate (PCC) in consultation with a specialist, or fresh frozen plasma (FFP).
- Administer vitamin K for select patients with nonurgent reversal and restoration of warfarin.
- Antifibrinolytics for prophylaxis of excessive blood loss
- Employ prophylactic antifibrinolytics with use of allogeneic blood transfusion in patients undergoing cardiopulmonary bypass.
- Consider prophylactic antifibrinolytics in certain orthopedic, liver surgery, and procedures at high risk for excessive bleeding.
- Acute Normovolemic Hemodilution (ANH)
- Consider ANH to reduce of allogeneic transfusions in patients at risk for excessive bleeding.

Intraoperative and Postoperative Management of Blood Loss

- Allogeneic RBC Transfusion
- Administer blood without consideration of duration and storage.

- Utilize leukocyte-reduced blood to reduce complications associated with allogeneic blood transfusion.
- Reinfuse recovered RBCs, when appropriate, as a blood sparing intervention intraoperatively
- Intraoperative and Postoperative Patient Monitoring
- Periodically visual assessment of surgical field, jointly with surgeon to assess presence of coagulopathy or surgical bleeding.
- Utilize standard methods to quantify blood loss, including drains, suction canisters, and sponges.
- Monitor for perfusion of vital organs using standard monitoring, clinical and physical exam.
- Additional monitoring as indicated, including renal, cerebral oximetry, arterial blood gases (ABGs), and mixed venous oxygen support.
- Monitor Hgb and Hct for suspected anemia.
- Monitor standard coagulation tests such as international normalized ratio (INR), Activated Partial Thromboplastin Time (aPTT), fibrinogen, viscoelastic assay such as thromboelastography, and platelet count if coagulopathy suspected.
- During and after transfusion, assess for sign of

transfusion reaction including hyperthermia, hemoglobinuria, microvascular bleeding, hypoxemia, respiratory distress, increased peak airway pressure, urticaria, hypotension, and signs of hypocalcemia.

- Suspected transfusion reaction, immediately stop transfusion, initiate supportive care, and notify the blood bank.
- Treatment of Excessive Bleeding
- Before platelet transfusion, obtain platelet count and function (if drug induced dysfunction is suspected).
- Obtain coagulation tests before transfusion of FFP.
- Assess fibrinogen levels before administration of cryoprecipitate.
- Utilize Desmopressin in patients with excessive bleeding and platelet dysfunction.
- Consider topical hemostatics such as fibrin glue or thrombin gel.
- Documented fibrinolysis, consider antifibrinolytics such as e-aminocaproic acid.

- PCCs may be indicated in patients with excessive bleeding and increased INR.
- Consider recombinant activated factor VII for excessive bleeding caused by coagulopathy, as a last resort; also consider fibrinogen concentrate.

Adapted from American Society of Anesthesiologists Task Force on Perioperative Blood Management. Practice Guidelines for Perioperative Blood Management. *Anesthesiology*. 2015;122:241–275.

Estimation of Blood Volume and Loss

Estimation of patient-specific *blood volume*, and calculation of *allowable blood loss* for the patient requires consideration when initiating blood component therapy. Estimated blood volume (EBV) takes into account patient age and weight, and is summarized in [Table 22.1](#).

TABLE 22.1
Average Blood Volumes

Age	Blood Volume (mL/kg)
Premature infant at birth	90–105 mL/kg
Term newborn infant	80–90 mL/kg
Infants (< 3 months)	70–75 mL/kg
Childhood to Adult	
Male	70 mL/kg
Female	65 mL/kg
Obese	Lean body weight plus 20%

Once blood volume has been estimated, the volume of blood loss that would decrease hematocrit (Hct) to a target value can be determined. The formula for *maximum allowable blood loss* (MABL) is as follows²⁻³:

$$\text{MABL} = \frac{\text{EBV} \times (\text{Initial Hct} - \text{Lowest Acceptable Hct})}{\text{Initial Hct}}$$

Estimation of intraoperative blood loss is fraught with error because of a lack of practical objective measures. Traditional guidelines for estimating perioperative blood loss by viewing and/or weighing surgical sponges, laparoscopy sponges, drapes, and volume suctioned into canisters can vary significantly. Visual blood loss estimates equate a fully soaked surgical sponge to equal 10 mL blood, and a fully soaked laparotomy sponge to equal 100 to 150 mL blood.⁴

A prospective study examined 140 patients undergoing total joint replacement and revealed a 30% overestimation and 70% underestimation of blood loss based on visual estimates in and

around the operative field; blood loss greater than 500 mL decreased the accuracy of the estimate.⁵ Rapid intraoperative measurement of hemoglobin (Hgb) and Hct has become widespread with the introduction of easy-to-use, point-of-care monitors.⁶ However, these devices do not measure the amount of blood loss.⁷ Ortho, et al. examined the accuracy of conventional, subjective techniques for estimation of blood loss by comparing the results of conventional techniques to those derived from an objective technique (sodium fluorescein dye). Investigators found a significant difference between subjective and objective techniques; in general, blood loss was underestimated by an average of approximately 300 mL when subjective techniques were used.⁸ In a prospective study, Adkins, et al., examined type of anesthesia provider and estimation of simulated blood loss. Their findings confirmed previous studies, and indicated equivalent inaccuracies in visual estimation of blood loss regardless of provider type or level of experience. The study also revealed decreased blood loss estimation confidence with increasing blood loss.⁴ Recommendations include didactic education and simulation scenarios to improve accuracy of blood loss estimation.

Intraoperative assessment should additionally include a patient's hemodynamic response to blood loss. Symptoms such as tachycardia and decreased mixed venous oxygen saturation are suggestive of anemia, especially in the setting of intraoperative hemorrhage. Ongoing assessment of vital organ perfusion as advocated in the 2014 ASA guidelines include: echocardiography, urine output, cerebral oximetry, arterial blood gas analysis, and mixed venous oxygen saturation. Suspicions of anemia should trigger monitoring of Hgb and Hct levels. Significance of coagulopathy can be assessed by monitoring platelets, fibrinogen, thromboelastography (TEG), international normalized ratio (INR), and activated partial thromboplastin time (aPTT).¹ Emerging assessment technologies, such as the *sonic estimation of elasticity via resonance* (SEER Sonorheometry), introduce ultrasound as a potential tool, which can rapidly discern coagulation dynamics.⁹

Transfusion Thresholds and Indications

Deciding when to administer blood components is an important clinical judgment that should be based on sound evidence, not custom. In recent years, critical attention has been directed to transfusion practices because of concerns regarding expense, availability, and risks of transfusion. In 1996 and 2006, the ASA convened task forces on blood component therapy to develop guidelines to help inform clinicians of best practices in transfusion therapy.^{10,11}

A single threshold for transfusion, a so-called “transfusion trigger,” has been the subject of much discussion and study. A 1987 report, based largely on clinical experience with Jehovah Witnesses, describes survival of patients with Hgb values as low as 1.8 g/dL, although significant mortality is associated with Hgb values of less than 5 g/dL.¹² During anemic episodes oxygen delivery to the tissues can be improved by increased cardiac output and improved microvascular blood flow resulting from the decreased viscosity of diluted blood.¹³ The ASA Task Force concluded that transfusion is “usually unnecessary” in patients with Hgb greater than or equal to 10 g/dL, and should “usually be administered” when Hgb is less than 6 g/dL.¹¹ Transfusing patients with a Hgb level of 6 to 10 g/dL is based on specific clinical factors. Factors which affect selection of a transfusion threshold in individual patients include consideration of cardiopulmonary reserve, experienced and expected blood loss, O₂ consumption (reflected in indices such as arterial oxygen saturation and mixed venous oxygen saturation), and the presence or absence of atherosclerotic disease.¹⁰⁻¹²

Carson and Kleinman reviewed outcomes in patients whose transfusions were guided by restrictive triggers. A restrictive (versus liberal) trigger to transfuse red blood cells (RBCs) implies transfusion of less blood and at a lower Hgb.¹⁴ The Cochrane Injuries Group conducted a systematic review of 17 studies examining restrictive transfusion triggers. Reviewers concluded that in patients without cardiovascular disease, renal failure, or

hematologic disorders, withholding transfusions in those with Hgb as low as 7g/dL was a justifiable practice.¹⁵

The American Association of Blood Banks (AABB) 2012 clinical practice recommendations for RBC transfusions are supported by a *Grading* system. The quality of evidence to support each recommendation is assigned a grade for strength of evidence, which ranges from high to very low. AABB recommendations are not based on a single transfusion trigger, rather an evidentiary **Box 22.2** several critical elements (**Box 22.2**).¹⁴

The American Association of Blood Banks (AABB) Red Blood Cell Transfusion Recommendations

1. Restrictive transfusion strategy for hemoglobin (7–8 mg/dL) in hospitalized, stable patients. *Grade: High*
2. Restrictive transfusion strategy for hemoglobin (8 mg/dL or less) in hospitalized patients with preexisting cardiovascular disease with symptoms. *Grade: Moderate*
3. No recommendation for liberal or restrictive transfusion threshold in stable hospitalized patients with acute coronary syndrome. *Grade: Very low*
4. Transfusion decision should be influenced by symptoms in addition to hemoglobin concentration. *Grade: Low*

From Carson JL, et al. Red blood cell transfusion: a clinical practice guideline from the AABB. *Ann Intern Med.* 2012;157(1):49–58.

Patient Blood Management

Patient blood management (PBM) has been adopted worldwide as a strategy to reduce unnecessary transfusions and maximize patient outcomes. PBM is a multidisciplinary, multimodal care strategy for timely use of safe, effective medical and surgical techniques designed to prevent anemia, and decrease bleeding in an effort to improve outcomes.¹⁶⁻²¹ Three strategies of PBM include: optimizing the patient's own red blood cell mass, minimizing blood loss, and optimizing the patient's physiologic tolerance of anemia.

Major goals for PBM are listed in [Box 22.3](#). Additionally, in 2011 The Joint Commission (TJC) published transfusion performance measures as accreditation goals ([Table 22.2](#)).^{16,19} The 2014 ASA practice guidelines advocate evaluation of patient risk for bleeding throughout the perioperative period. The guideline time frame incorporates preoperative, preadmission, preprocedure, intraoperative, and postoperative management of blood loss. The practice guidelines rank strength of cumulative evidence to support recommendations (see [Box 22.1](#)).¹ Concerns regarding cost, availability, and complications associated with blood and blood products have led to conservation strategies to reduce the risk of intraoperative blood loss. A focus on specific perioperative time frames allows the practitioner to recognize conditions that place the patient at increased risk of hemorrhage. In the surgical setting, these conditions generally include medications that affect coagulation, and inherited and acquired defects of coagulation.

Patient Blood Management Strategies Summary

Preoperative Suggestions

- Screen for and treat anemia. Manage any underlying disorders that may lead to anemia.
- Treat iron deficiency and administer erythropoiesis-stimulating agents as indicated.

- Identify and manage any bleeding risks such as medications or chronic diseases.
- Assess patient reserve and optimize patient-specific tolerable blood loss.
- Formulate management plan with evidence-based transfusion strategy.
- Preoperative autologous blood donation in select situations.
- May require preoperative visit up to 30 days prior to elective surgery to accommodate therapy.

Intraoperative Suggestions

- Perform elective surgery when hematologically optimized.
- Use meticulous blood-sparing surgical techniques.
- Continually measure and assess hemoglobin and hematocrit.
- Plan and optimize fluid management of nonblood products.
- Optimize cardiac output, oxygen delivery, and ventilation.
- Use blood salvage and autologous transfusion when possible.

Postoperative Suggestions

- Treat anemia with erythropoiesis-stimulating agents and iron deficiency as indicated.
- Vigilant monitoring and management of postoperative bleeding.
- Maintain normothermia to minimize oxygen consumption.
- Avoid and/or treat infections promptly.
- Carefully manage anticoagulant medications.

TABLE 22.2
Patient Blood Management

TJC* Performance Measures	Principles
Transfusion Consent	Formulate plan of proactive management for avoiding and controlling blood loss tailored to clinical management of individual patient, including anticipated procedures.
RBC Transfusion Indication	Employ multidisciplinary treatment approach to blood management using a combination of interventions (e.g., pharmacologic therapy, point-of-care testing).
Plasma Transfusion Indication	Promptly investigate and treat anemia.
Platelet Transfusion Indication	Exercising clinical judgment; be prepared to modify routine practices (e.g., transfusion triggers) when appropriate.
Blood Administration Documentation	Restrict blood drawing for unnecessary laboratory tests.
Preoperative Anemia Screening	Decrease or avoid the perioperative use of anticoagulants and antiplatelet agents.
Preoperative Blood Type Screening and Antibody Testing

Conservation Strategies

RBC Alternatives

In certain patient populations, erythropoietin and other RBC alternatives may reduce the need for allogeneic blood transfusion.¹ However, endogenous production of erythropoietin, which normally increases in response to hypoxia and anemia, has been shown to be blunted in critical illness.²⁰ A 2009 Cochrane review examined 10 studies in which erythropoietin was given pre and perioperatively during colorectal surgery. Outcomes revealed no significant difference in Hgb or Hct, or other factors including thrombotic events.²¹ Current evidence does not support routine use of erythropoietin perioperatively.²⁰⁻²¹

Preoperative Preparation

Preoperative administration of agents that promote coagulation or reverse anticoagulants is an important tool to reduce the risk of significant intraoperative blood loss. Judicious preprocedure administration of reversal agents such as vitamin K, prothrombin-complex concentrate (PCC), recombinant factor VII, and fresh frozen plasma (FFP) are indicated for reversal of anticoagulants. Antifibrinolytics should be considered in cases where large amounts of blood loss are anticipated such as vascular or large orthopedic procedures. This may lead to the administration of agents such as tranexamic acid.^{1,11,22}

Directed Donor

Directed blood donation is an alternative to blood transfusion from anonymous donors, which was developed in the hope of reducing patient risk with necessary blood transfusions. Donor-directed homologous blood transfusions are from a donor selected by the recipient, and believed by some to decrease the risk of transmission of disease. Studies comparing the safety of donor-directed blood with blood from anonymous donors, however, failed to demonstrate any advantage to using donor-directed blood.^{7,23}

Autologous Transfusion

A widely used alternative to allogeneic blood transfusion, autologous transfusion, can be of value in select patients.²⁴

Autologous transfusion techniques are divided into three main categories: preoperative autologous donation (PAD), intraoperative and postoperative blood salvage, and acute normovolemic hemodilution (ANH).²⁵

Preoperative Autologous Donation

PAD involves the collection and storage of the recipient's own blood for possible reinfusion at a later date. A maximum RBC storage of 35 days allows up to three units of a patient's blood to be donated prior to elective surgery.²⁶ Preoperative autologous donation is indicated in patients who are healthy enough to tolerate slight anemia and iron restoration, and undergo a surgical procedure with an expected blood loss of 5% to 10%. Additional recommendations include the last unit of patient blood should be donated at least 72 hours prior to the surgical procedure along with informed patient consent. Assuming a patient is healthy at time of donation, and the blood is processed correctly, PAD diminishes concern of transfusion acquired bacteremic, hemolytic, allergenic, antigenic, and graft versus host disease (GVHD).²⁷

Limitations of PAD include preoperative anemia and possible resultant myocardial ischemia, bacterial contamination, and clerical error leading to the administration of the wrong blood.²⁸

Furthermore, approximately half of all autologous donation blood is discarded.²⁹ Several studies have cited increased costs for PAD, and lower insurance reimbursement.^{26,30} The United Blood Services website discloses that a special processing fee is charged for PAD, because of additional recordkeeping and required handling (Box

Box 22.4

Autologous Blood Donation Summary

Advantages

- Prevents transfusion-transmitted disease

- Prevents red-cell alloimmunization
- Supplements the blood supply
- Provides compatible blood for patients with alloantibodies
- Prevents some adverse transfusion reactions
- Provides reassurance to patients concerned about blood risks

Disadvantages

- Does not affect risk of bacterial contamination
- Does not affect risk of ABO incompatibility error
- Costlier than allogeneic blood
- Results in wastage of blood not transfused
- Increased incidence of adverse reactions to autologous donation
- Subjects patient to perioperative anemia and increased likelihood of transfusion

Intraoperative Red-Blood-Cell Salvage

RBC salvage involves aspiration of blood shed from the surgical field into a specialized apparatus that concentrates and washes RBCs, and removes debris, after which the RBCs are reinfused.¹⁶ Indications for cell salvage include surgical cases in which significant blood loss is likely, as well as in cases of unexpected massive blood loss. Cell salvage or autotransfusion may be an acceptable form of transfusion to some Jehovah Witness patients, as long as the blood does not leave the patient's bedside for

processing.^{20,31}

Contraindications to cell salvage include surgery with wounds contaminated by bacteria, sepsis, bowel contents, amniotic fluid, or malignant cells.³² Cell-washing devices can provide a volume equivalent to 10 units of blood per hour for transfusion in cases of massive blood loss.²⁹ Prolonged use of cell salvage for large volume autotransfusion may be associated with dilution of clotting factors and thrombocytopenia, and regular laboratory or point of care monitoring is required. Cell salvage should be considered in all cases where significant blood loss, greater than 1000 mL, is anticipated. The use of cell salvage in combination with a leukocyte depletion filter appears safe (Table 22.3).^{32,33}

TABLE 22.3
Cell Salvage Summary

General Indications for Cell Salvage	
Specialty	Surgical Procedure
Cardiac	Valve replacement Redo bypass grafting
Orthopedics	Major spine surgery Knee replacement Hip replacement
Urology	Radical retropubic prostatectomy Cystectomy Nephrectomy
Neurosurgery	Giant basilar aneurysm
Vascular	Thoracoabdominal aortic Aneurysm repair Abdominal aortic aneurysm repair
Liver Transplant	
Other	Jehovah Witnesses Unexpected massive blood loss Red cell antibodies
Relative Contraindications to Cell Salvage	
Pharmacologic Agents <ul style="list-style-type: none"> • Clotting agents (e.g., Avitene, Surgicel, Gelfoam) • Irrigating solutions of disinfectants for topical use (e.g., oxygenated water, betadine, distilled water, alcohol, antibiotics meant for topical use) • Anticoagulant drugs • Synthetic resins such as methylmethacrylate • Catecholamines (pheochromocytoma) • Oxymetazoline (Afrin) • Papaverine Contaminants in the Operating Field <ul style="list-style-type: none"> • Urine • Bone chips • Fat • Bowel contents • Infection 	

- Amniotic fluid
- Malignant Tumors or Neoplastic Cells**
- Hematologic Disorders
 - Thalassemia, sickle cell disease
 - Miscellaneous
 - Carbon monoxide (electrocautery smoke)

From Esper SA, Waters JH. Intra-operative cells salvage: a fresh look at the indications and contraindications. *Blood Transfusion*. 2011;9(2):139–147.

Acute Normovolemic Hemodilution

Another transfusion alternative, ANH involves removal of whole blood from a patient immediately before or after initiation of anesthesia and surgery, and replacing blood volume with crystalloid or colloid solutions. The blood lost during surgery will have a low Hct, and total blood loss is reduced.¹⁶ Reinfusion of the patient's whole blood, with normal Hct and clotting factors, is initiated when intraoperative loss of blood has stopped or earlier if warranted. Advocates of ANH suggest ANH, compared with autologous donation, eliminates the expense of testing, risks of bacterial contamination, blood storage lesions, and possibility of wrong unit transfusion because the ANH remains in the operating room.^{16,29} Arguments against ANH cite lack of universal practices in transfusion methods, Hgb percent target, and blood loss estimates.⁴

Transfusion Compatibility

A prerequisite of transfusion therapy is established blood compatibility. Presence of circulating antibodies in plasma, as well as antibodies to RBC antigens, necessitate that a blood recipient receives red cells from a compatible donor (Table 22.4). Prior to transfusion, donor blood is screened for antibodies to recipient RBC antigens. Two blood groups deserve special attention.

TABLE 22.4

Relationship Among Blood Groups, Antigens, Antibodies, and Blood Compatibility

Blood Group	Antigen on Red Blood Cell	Antibodies in Serum	Blood Group Compatibility
A	A	Anti-B	A, O
B	B	Ani-A	B, O
AB	A and B		AB, A, B, O
O		Anti-A and Anti-B	O only
Rh-positive	D		Rh-positive and Rh-negative
Rh-negative		Anti-D if sensitized	Rh-negative

Group AB blood possess both A and B antigens on the RBCs, and lack anti-A and anti-B antibodies; therefore, individuals with blood AB can receive blood from any ABO group and are known as *universal recipients*. Individuals with type O blood are known as *universal donors* because their RBCs are devoid of any of the ABO antigens, but have both A and B antibodies in the plasma.^{34,35}

The most important tests of blood compatibility are those used to determine ABO and Rh (also known as *type D*) blood groupings. Transfusion of ABO or Rh incompatible blood can result in serious hemolysis. Patients who may need a transfusion and banked blood stored for transfusion are *typed* to determine ABO and Rh status. To further reduce the risk of a transfusion reaction, the patient's and banked blood are *screened* for antibodies, other than ABO and D, to all relevant RBC antigens. Donor blood is required to be either ABO-identical or ABO-compatible. For example, a patient with type A blood transfused with donor type A blood would be an *identical* match. Whereas, a patient with type AB blood transfused with type A blood would be a *compatible* match.³⁴ Two familiar tests, which

determine blood compatibility, are *type and crossmatch*, and *type and screen*.

Type and Screen

Blood compatibility tests are conducted prior to transfusion. A type and screen identifies the ABO and Rh group of a patient's blood, and expected and unexpected antibodies in the patient's serum.³⁵

Type and screen predicts compatible transfusions 99.94% of the time.

Type and Crossmatch

A type and cross match is also conducted prior to transfusion.

Donor blood and recipient serum are mixed together. If agglutination or clumping occurs during the mixing process, this indicates a donor blood and recipient plasma antigen/antibody reaction, and thus, incompatible blood.³⁵ Crossmatching increases the possibility of a compatible transfusion by only one-hundredth of one percent.²⁸

Emergency Transfusion

In an emergency situation when a patient's blood group is unknown, uncrossmatched type O, Rh blood can be given to males or females of nonchildbearing years, who have never received a previous type O Rh-positive blood transfusion. Type O Rh-negative should be reserved for females of childbearing years, or when clinicians are unsure of the patient's previous blood transfusion history in order to avoid hemolytic reaction. However, if two or more units of O-negative whole blood have been given, the patient may not be able to receive transfusions of his or her own type (A, B, or AB) because of the risk of hemolysis. It is preferred that type O Rh-negative uncrossmatched RBCs be used because packed erythrocytes have smaller plasma volumes and are almost free of antibodies. The patient may not be transfused with his or her respective blood type until the blood bank determines that the transfused anti-A and anti-B antibodies have decreased to levels that permit safe transfusion of type-specific blood.²⁸

Massive Transfusion Protocols

Massive transfusion protocols (MTP) provide practitioners with guidance for trauma or procedural events, which result in a hemorrhaging patient. Protocols typically focus on hypovolemia, coagulopathy, and strategies to obtain massive amounts of allogeneic blood and blood products to augment coagulation.¹ The definition of massive transfusion depends on the circumstances. A situation requiring 10 units of RBCs in 24 hours, or loss of one blood volume in a 70 kg patient, would be defined as massive transfusion.^{36,37} Requirements for more than four units of packed red blood cells (PRBCs) in one hour, and ongoing instability or hemorrhage should set the same MTP in motion.³⁶ Trauma is most often associated with MTP, thus forward military medical units and trauma emergency rooms have pioneered MTP development. A key element to an emergent transfusion situation is a predetermined plan or algorithm to communicate with the blood bank and trauma team.

Patient focus of MTP is fluid resuscitation for volume expansion, and red cell transfusion to maintain tissue oxygenation. Massive transfusion and prolonged shock quickly leads to coagulopathic states such as disseminated intravascular coagulation. In addition, the patient's metabolic and electrolyte abnormalities, as well as hypothermia, will aggravate resuscitation attempts. Recommendations for management of the MTP include correction of ischemia by aggressive volume expansion, maintaining blood pressure, and monitoring coagulation parameters and metabolic state, including platelet count, to maintain prothrombin time (PT), partial thromboplastin time (PTT) less than 1.5 control, or infuse FFP. Additional recommendations include giving blood products as dictated by patient condition, use of a blood warmer, and monitoring acid-base status closely.³⁷

Fractionation

Currently in the United States, most donor blood is fractionated or partitioned into its component parts (e.g., RBCs, plasma, platelets, and individual factor concentrates). Fractionation of blood components targets specific patient needs, such as diminished oxygen-carrying capacity and/or coagulopathies. RBC transfusions are used to treat hemorrhage and to improve oxygen delivery to tissues. Indications for transfusion include symptomatic anemia in high-risk patients, acute blood loss greater than 30% of blood volume, or in hemodynamically unstable patients with continuing blood loss. FFP infusion can be used for reversal of anticoagulant effects. Platelet transfusion is indicated for thrombocytopenia or platelet function defects. Cryoprecipitate is utilized for hypofibrinogenemia, which most often accompanies massive hemorrhage or consumptive coagulopathy. Other Food and Drug Administration (FDA)-approved coagulation proteins and replacement therapies available in the United States are listed in [Table 22.5](#).

TABLE 22.5

FDA-Approved Coagulation Proteins and Replacement Therapies Available in the United States

Coagulation Protein Deficiency	Inheritance Pattern	Prevalence	Minimum Hemostatic Level	Replacement Sources
Factor I (fibrinogen)			50–100 mg/dL	Cryoprecipitate, FFP, fibrinogen concentrate
Afibrinogenemia	Autosomal recessive	Rare (< 300 families)		
Dysfibrinogenemia	Autosomal dominant or recessive	Rare (> 300 variants)		
Factor II (prothrombin)	Autosomal dominant or recessive	1 in 2 million births	30% of normal	FFP, factor IX complex concentrates
Factor V (labile factor)	Autosomal recessive	1 in 1 million births	25% of normal	FFP
Factor VII	Autosomal recessive	1 in 500,000 births	25% of normal	Recombinant factor VIIa (15–20 mcg/kg), FFP, factor IX complex concentrates
Factor VIII (antihemophilic)	X-linked recessive	1 in 5000 male births	80–100% for surgery/life-	Factor VIII concentrates (recombinant preferred)

factor)			threatening bleeds, 50% for serious bleeds, 25–30% for minor bleeds	
von Willebrand disease Type 1 and 2 variants Type 3	Usually autosomal dominant Autosomal recessive	1% prevalence 1 in 1 million births	> 50% VWF antigen and ristocetin cofactor activity	DDAVP for mild to moderate disease (except type 2B; variable response to 2A); cryoprecipitate and FFP (not preferred, except in emergencies); factor VIII/VWF concentrates, viral attenuated, intermediate purity (preferred for surgery, for disease unresponsive to DDAVP, and for type 3
Factor IX (Christmas factor)	X-linked recessive	1 in 30,000 male births	25–50% of normal, depending on extent of bleeding, surgery	Factor IX concentrates (recombinant preferred); FFP not preferred except in dire emergencies
Factor X (Stuart-Prower factor)	Autosomal recessive	1 in 500,000 births	10–25% of normal	FFP or factor IX complex concentrates
Factor XI (hemophilia C)	Autosomal dominant; severe type is recessive	4% of Ashkenazi Jews; 1 in 1 million general population	20–40% of normal	FFP or factor XI concentrate
Factor XII (Hageman factor), prekallikrein, high-molecular-weight kininogen	Autosomal recessive	Not available	No treatment necessary	—
Factor XIII (fibrin stabilizing factor)	Autosomal recessive	1 in 3 million births	5% of normal	FFP, cryoprecipitate, or viral-attenuated factor XIII concentrate

DDAVP, Desmopressin; *FDA*, US Food and Drug Administration; *FFP*, fresh-frozen plasma; *VWF*, von Willebrand factor.

Best Practice Transfusion Guidelines

Packed Red Blood Cells

PRBCs are the component of choice for improving oxygen-carrying capacity. Depending on the blood bank, a typical unit of PRBC is good for 35 to 42 days, and contains 200 mL of RBCs and a Hct of 65%.²⁰ PRBC infusions are generally administered in a ratio of 1 mL for each 2 mL of blood loss (along with crystalloids or colloids for volume). The 1 to 2 ratio is the result of the higher Hct of PRBC.³⁸ A common assumption is one unit of PRBCs increases Hgb 1 g/dL and Hct 2% to 3%.^{7,39} For example, 3 ml/kg PRBCs could increase Hgb by 1 gm/dL, or 10 ml/kg, and increase Hct by 10%. Alternatively, a 3% decrease in Hct could be reversed by transfusion of one unit of PRBCs. A retrospective study of 60 patients with pelvic fractures revealed an average Hct increase of 1.9% per unit of PRBCs transfused.³⁰ Recommendations for pediatric PRBC range from 10 to 15 mL/kg, with the upper limit of 15 mL/kg for infants, with a greater blood volume per kilogram.⁴⁰ Whole blood transfusion is not typically recommended, except in the emergently anemic patient with a large volume deficit ([Table 22.6](#)).

TABLE 22.6
Characteristics of Blood Components

Blood Component	Content	Volume (mL)	Plasma (mL)	Shelf Life
Red Cell Products				
Whole blood	RBCs (Hct 40–45%), WBCs, plasma, platelets (nonviable)	500–515	~300	21–35 days at 1–6°C (depending on anticoagulant) 24 hr if unrefrigerated
Packed RBCs	RBCs (Hct 60–80%), WBCs, plasma, platelets (nonviable)	250–300	~25–50 mL	21–42 days at 1–6°C (depending on anticoagulant)
Leukocyte-reduced RBCs (filtered)	RBCs (Hct 90%), minimal plasma	200	Minimal	21–42 days at 1–6°C (depending on)

				anticoagulant)
Washed RBC	RBCs (Hct 60%), some WBCs	340	0	24 hours
Frozen RBCs	RBCs (Hct 90%, minimal WBC and platelets (nonviable)	170–190	0	10 years at –80°C
Platelets				
	Platelets, some WBCs, some RBCs, plasma			Open, 24 hours at 20–24°C with continuous agitation Closed, 5 days at 20–24°C with continuous agitation
Single donor (apheresis)	$\geq 3 \times 10^{11}$ platelets/unit	~300 (200–400)	~250	
Random donor	$\geq 5.5 \times 10^{10}$ platelets/unit	50	50	
Plasma-Derived Products				
Fresh frozen plasma (frozen within 6 to 8 hours of phlebotomy)	Plasma with all coagulation factors and inhibitors, complement, fibrinogen, albumin, globulins	<i>Whole blood donor</i> :200–250	200–250	1 year at –18°C; 24 hours at 1–6°C once thawed
		<i>Apheresis donor</i> :400–600	400–600	
Plasma frozen within 24 hours (separated from whole blood stored at 4–6°C within 24 hours of collection)	Plasma with all coagulation factors and inhibitors, but with lower levels of V and VIII; complement, fibrinogen, albumin, globulins	200–250	200–250	1 year at –18°C; 24 hours at 1–6°C once thawed
Cryoprecipitate-reduced plasma (fresh frozen plasma with cold-induced precipitate removed)	Similar to fresh frozen plasma but deficient in XIII, VIII, fibrinogen, and von Willebrand factor	200–225	200–225	1 year at –18°C; 24 hours at 1–6°C once thawed
Cryoprecipitate	Factor VIII (minimum 80 IU), XIII, fibrinogen (minimum 150 mg), von Willebrand factor, plasma, fibronectin	5–20	5–20	1 year at –18°C; 4–6 hours at room temperature once thawed

Hct, Hematocrit; *RBCs*, red blood cells; *WBCs*, white blood cells.

Fresh-Frozen Plasma

FFP contains all coagulation factors, and a unit of 200 mL replenishes inadequate factors of dilution or coagulation dysfunction.^{39,41} A unit of FFP is prepared from whole blood or apheresis, and, if frozen at –18 to –30°C within 8 hours, may be stored for up to 1 year.³⁹ Interchangeable plasma products such as

plasma frozen within 24 hours after phlebotomy (PF24), or thawed plasma (which may be kept at refrigerator temperature for up to 5 days) may be substituted for FFP. PF24 contains 65% to 80% of the FFP level of factor VIII, and thawed plasma has reduced levels of factor V and VIII.³⁹ These products are comparable in volume and other coagulation factors.³⁹ One unit of FFP typically contains 200 to 250 mL.

Indications for administration of FFP include reversal of the effects of warfarin anticoagulation, vitamin K deficiency, and correction of known coagulopathy. FFP can also be used to control microvascular bleeding in the presence of elevated PT or PTT that is greater than 1.5 times normal, and correction of microvascular bleeding in patients suspected of dilutional coagulopathy. FFP is usually administered in doses of 5 to 8 mL/kg for reversal of warfarin, and 10 to 20 mL/kg for all other purposes, and it increases coagulation levels by 20% to 30%.¹⁰⁻¹¹ Some suggested indications for the transfusion of fresh frozen plasma are listed in [Table 22.7](#).

TABLE 22.7

Suggested Indications for the Transfusion of Fresh Frozen Plasma

Indication	Recommendation
Disseminated intravascular coagulopathy	Consider transfusion with FFP, platelets and cryoprecipitate if clinical evidence of bleeding. There is no supporting evidence for prophylactic transfusion in absence of bleeding despite abnormal coagulation tests.
Reversal of warfarin effect	FFP should only be used for the reversal of warfarin anticoagulation in the presence of <i>major</i> bleeding if prothrombin complex concentrate is not available. In the absence of bleeding, over-anticoagulation should be managed by withholding warfarin therapy and initiating oral/intravenous Vitamin K.
Perioperative transfusions	Majority of FFP use in this setting is in cardiac surgery. Meta-analysis does not suggest reduction in perioperative blood loss with prophylactic FFP use.
Before invasive procedures	<i>Regional/Neuraxial blockade</i>
	For elective surgery, relevant anticoagulants and antiplatelets should be stopped according to local/national guidelines. With regard to warfarin reversal:
	Urgent procedures: consider 2.5–5 mg of oral/intravenous Vitamin K.
	Immediate reversal: consider FFP, although no high-level evidence exists to support this.
	<i>Intensive Care</i>
	Minor derangements in PT/INR are common in ICU patients and often caused by Vitamin K deficiency. As mentioned before, patients with an elevated INR can still have adequate levels of coagulation factors. Systematic reviews have not shown any clear benefit of prophylactic FFP use to reduce bleeding related to planned procedures.

FFP, Fresh frozen plasma; ICU, intensive care unit; INR, international normalized ratio; PT, prothrombin time.

From Shah A, et al. Evidence and triggers for the transfusion of blood and blood products. *Anaesthesia*. 2015;70:10–9, e3–e5.

The majority of FFP is transfused for the management of acquired bleeding disorders, and PT and the INR are the most common tests used to detect these disorders. Studies have shown that PT correlates poorly with clinical bleeding, and that transfusion of plasma provides no measurable change in the INR, with no known clinical benefit. Thus the use of FFP is discouraged if the INR is less than 2.0 in the absence of active bleeding, and the use of Vitamin K is encouraged if the patient is on warfarin.^{39,42} Hemostasis can typically be achieved when coagulation factors are at least 25% normal and fibrinogen is 75 to 100 mg/dL.²⁷ Some common laboratory cut-off points for the use of various blood components are listed in [Table 22.8](#).

TABLE 22.8
Laboratory Cut-Points for Transfusion

Laboratory Values	Blood Product Transfusion
ACT > 128	Plasma and RBCs
r-value > 1.1	Plasma and RBCs
k-time > 2.5	Cryoprecipitate/fibrinogen/plasma
α-angle < 56	Cryoprecipitate/fibrinogen/platelets
MA < 55	Platelets/Cryoprecipitate/fibrinogen
LY30 > 3%	Tranexamic acid
PT > 18.0	Plasma
aPTT > 35	Plasma
INR > 1.5	Plasma
Platelet count < 150 × 10 ⁹ /L	Platelets
Fibrinogen < 180 g/L	Cryoprecipitate/fibrinogen

Data from Holcomb JB, et al. Admission rapid thrombelastography can replace conventional coagulation tests in the emergency department: experience with 1974 consecutive trauma patients. *Ann Surg*. 2012;256:476–86.

Platelets

Platelets are essential for adequate hemostasis and transfused for thrombocytopenia or abnormal function.⁴² Platelets are available as platelet concentrates, separated from one unit of whole blood by

centrifuge from 6 to 10 donors. Alternatively, single donor apheresis platelets are available; although costlier this may be preferred in a patient with alloantibodies.²⁰ One unit of whole blood should yield approximately six platelet concentrates.^{20,23} Platelets are stored at room temperature, and thus have a relatively short shelf life of 5 days, and are prone to bacterial growth.⁴³ Transfusion of platelets is indicated when the platelet count is less than $50 \times 10^3/\mu\text{L}$. Platelet transfusions in patients with platelet counts of $50 \times 10^3/\mu\text{L}$ to $100 \times 10^3/\mu\text{L}$ are indicated if the patient displays microvascular bleeding, or is at risk for platelet dysfunction or continued bleeding. The usual dose of platelets is one platelet concentrate per 10 kg of body weight; transfusion raises the platelet count for 6 to 7 days (Box 22.5).^{10,11,43} Typical dosing for an adult is a pool of six whole blood derived (sometimes referred to as random donor) platelets, or one apheresis platelet concentrate. This is expected to raise the platelet count by 30,000 to 60,000/uL in a 70 kg patient.⁴³ Some suggested minimum platelet counts before invasive procedures are noted in Box 22.6. Common platelet abnormalities encountered during the perioperative period are noted in Table

Box 22.5

AABB Summary of 2015 Platelet Transfusion Guidelines

Recommendations include evidence grade

1. Transfuse hospitalized patients with therapy-induced lymphoproliferative thrombocytopenia prophylactically, at risk for spontaneous bleeding, and a platelet count 10×10^9 cells/L or less. *Grade: Strong*
2. Prophylactic transfusion prior to elective central line placement with platelet count less than 20×10^9 cells/L. *Grade: Weak*
3. Prophylactic transfusion for patients with elective lumbar puncture with a platelet count less than 50×10^9 cells/L. *Grade: Weak*
4. Prophylactic transfusion for patients having major elective neuraxial surgery with a platelet count less than 50×10^9 cells/L.

Grade: Weak

5. Prophylactic transfusion for patients who exhibit perioperative bleeding, are thrombocytopenic, and having cardiopulmonary bypass. *Grade: Weak*
6. No recommendation for transfusion in patients receiving antiplatelet therapy who have an intracranial hemorrhage. *Grade: Uncertain*

From Kaufman RM, et al. Platelet Transfusion: A Clinical Practice Guideline from the AABB. *Ann Intern Med.* 2015;162:205–213.

Box 22.6

Suggested Minimum Platelet Counts Before Invasive Procedures

Very-High-Risk Procedures — 75,000/ μ L to 100,000/ μ L

- Neurosurgery
- Ocular surgery (except cataract extraction)
- Thyroid surgery
- Prostatectomy

Moderate-Risk Procedures — 50,000/ μ L

- Liver Biopsy
- Dental extraction
- Most surgical procedures

Low-Risk Procedures — 30,000/ μ L

- Endoscopy

- Bronchoscopy
- Lumbar puncture (with scrupulous technique)

Very-Low-Risk Procedures – No Platelet Transfusions Necessary

- Bone marrow biopsy
- Cataract extraction

From Abrams CS. Thrombocytopenia. In Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*. 25th ed. Philadelphia: Elsevier; 2016:1160.

TABLE 22.9

Common Platelet Abnormalities Encountered During the Perioperative Period

Reduction in Platelet Number	Reduction in Platelet Function
Drugs	Drugs
Heparin: heparin-induced thrombocytopenia	Aspirin: irreversible inhibition of cyclooxygenase
	Clopidogrel: adenosine Diphosphate-receptor antagonism
	Glycoprotein IIb/IIIa antagonists, e.g., abciximab, tirofiban
	Calcium channel blockers: reduced adhesion and aggregation
	Heparin: reduced adhesion
Chronic kidney/liver disease	Chronic kidney/liver disease
Trauma	Trauma
Cardiopulmonary bypass	Cardiopulmonary bypass
Sepsis: increased consumption, reduced production	Sepsis
	Metabolic
	Hypothermia
	Acidosis
Uremia	Uremia
	Myeloproliferative disorders
Myeloproliferative disorders	Myeloproliferative disorders

From Shah A, et al. Evidence and triggers for the transfusion of blood and blood products. *Anaesthesia*. 2015;70(Suppl 1):10–9, e3–e5.

Cryoprecipitate

Cryoprecipitate, a less frequently used blood component, contains 100 units of factor VIII and 200 mg fibrinogen, in addition to fibronectin and von Willebrand factor (vWF).^{20,43} Cryoprecipitate is

obtained by thawing FFP to 4°C and consolidating the white precipitate by centrifuge.^{20,34} Cryoprecipitate transfusion provides a concentrated version of coagulation factors found in FFP (10–20 mL versus 250 mL), and is recommended for treatment of patients with von Willebrand disease, and probable or documented deficits in fibrinogen (less than 80–100 mg/dL).^{10,11} Cryoprecipitate must be administered through a filter as rapidly as possible. The rate of administration should be at least 200 mL/hr, and infusion should be completed in less than 4 hours. Ten units of cryoprecipitate contain approximately 2 g of fibrinogen and will raise a patient's level by approximately 70 mg/dL.³⁴

Blood Storage

Benefits of transfusion include increased oxygen-carrying capacity and improved coagulation. Unfortunately, transfusion of blood and blood products is not without risk. Infectious and noninfectious complications are possible, and the risk of complications is increased by massive transfusion, as well as by transfusion of blood that has been stored for a prolonged period. Storage of blood as components has distinct advantages; however, banked blood undergoes undesirable changes during storage (Box 22.7).⁴⁴ During storage RBC energy sources are depleted, as is glucose 2,3-diphosphoglycerate and adenosine triphosphate (ATP), whereas potassium levels increase.⁴⁵ *Blood storage lesion* refers to red cell changes and membrane loss that occur over time. An observational study of nearly 6000 cardiac surgery patients found an association between transfusion of blood stored longer than 14 days and increased postoperative morbidity and mortality when compared with patients receiving blood stored for less than 14 days.⁴⁶ Similar findings were noted in intensive care units.^{47,48}

Changes in Banked Blood

- Depletion of 2,3-diphosphoglycerate (DPG)
- Depletion of ATP (adenosine triphosphate)
- Oxidative damage
- Increased adhesion to human vascular endothelium
- Acidosis
- Altered morphology of red blood cells (change in shape, decreased flexibility, membrane loss)
- Accumulation of microaggregates
- Hyperkalemia (as high as 17.2 mEq/L)

- Absence of viable platelets (after 2 days of refrigerated storage)
- Absence of factors V and VIII
- Hemolysis
- Accumulation of proinflammatory metabolic and breakdown products such as lysophospholipids

Complications of Blood Transfusion

Transfusion-related infections are less common than noninfectious complications. Acute complications occur within minutes to 24 hours of transfusion, whereas delayed complications may develop days, months, or even years later.⁴⁹ Serious complications of blood transfusion are most commonly the result of incompatibility. Hematologists from the United Kingdom and Ireland's Serious Hazards of Transfusion (SHOT) initiative reports transfusion reactions on an ongoing basis. The most recent report noted 300 serious transfusion reactions, 262 of which were “incorrect blood component transfused” incidents.^{33,50} *Immune-mediated* transfusion reactions encompass acute and delayed hemolytic reactions, febrile and allergic reactions, acute lung injury, posttransfusion purpura and immunomodulation.²⁰

Although very rare, *acute hemolytic reactions*, are a consequence of transfusion to an incompatible recipient. The resulting intravascular hemolysis is caused by the destruction of donor erythrocytes by recipient circulating antibodies.²⁰ Approximately half of all deaths from acute hemolytic reactions are caused by ABO incompatible transfusions resulting from procedural or administrative error. Volumes of donor blood as small as 10 mL may lead to hemolytic reactions in 20% to 60% of recipients.²⁸ The intraoperative view is complicated by the fact that general anesthesia may obscure symptoms associated with hemolytic reactions.¹⁰ Symptoms of acute hemolytic reaction typically present as unexplained hypotension, hemoglobinuria, or a hemorrhagic episode.²⁰

Delayed hemolytic reactions are more common and present with obscure symptoms. Obstetric patients are particularly at risk and may have symptoms such as jaundice, hemoglobinuria, and anemia.¹⁷ Patients with a history of delayed hemolytic reaction, may

Box 22.8 accept leuko-reduced blood components (**Box 22.8**).²⁰

Clinical Benefits of Leukoreduction

Proven Clinical Relevance

- Reduced frequency and severity of NHFTRs

- Reduced risk of CMV transmission
- Reduced risk of HLA alloimmunization and platelet refraction

Likely Clinically Relevant

- Reduced infectious risk associated with immunomodulation (TRIM)
- Reduced organ dysfunction and mortality
- Reduced direct risk of transfusion-transmission bacteria

Unproven Clinical Relevance

- Avoidance of vCJD transmission
- Avoidance of HTLV I/II, EBV, and similar viruses
- Reduced risk of GVHD

CMV, Cytomegalovirus; *EBV*, Epstein-Barr virus; *GVHD*, graft-versus-host disease; *HLA*, human leukocyte antigen; *HTLV*, human T-lymphotrophic virus; *NHFTRs*, nonhemolytic febrile transfusion reactions; *TRIM*, transfusion-related immunomodulation; *vCJD*, variant Creutzfeldt-Jakob disease.

From Blajchman MA. The clinical benefits for the leukoreduction of blood products. *J Trauma*. 2006;60(suppl 6):S83–S90; Friese RS, et al. The use of leukoreduced red blood cell products is associated with fewer infectious complications in trauma patients. *Am J Surg*. 2008;196(1):56–61; Phelan HA, et al. Prestorage leukoreduction abrogates the detrimental effect of aging on packed red cells transfused after trauma: a prospective cohort study. *Am J Surg*. 2012;203(2):198–204.

Nonhemolytic transfusion reactions are relatively common, occurring in 1% to 5% of all transfusions, and are associated with fever, chills, and urticaria. Similar to hemolytic reactions, these reactions are difficult to detect during general anesthesia.¹⁰ Although not usually life threatening, febrile nonhemolytic and allergic reactions can cause concern and may lead to interruption of the transfusion.²⁸ Antipyretics may be administered to relieve

fever.²⁰

The FDA has identified the most common causes of transfusion-related deaths as transfusion-related acute lung injury (TRALI), followed by hemolytic transfusion reaction, transfusion-associated sepsis, transfusion-related circulatory overload, babesiosis, anaphylaxis, and GVHD.⁵¹ TRALI and other transfusion related lung injuries come about as a result of alloantibodies, and are believed to occur as frequently as one in every 432 units of platelets, or as infrequently as one in every 7900 units of FFP.^{52,53} TRALI is likely underreported because the syndrome may be confused with other forms of acute lung injury (ALI), and was without a clear definition until 2005. Currently, TRALI is defined as ALI occurring within six hours of transfusion in individuals who were previously free of ALI, and without other risk factors for ALI.⁵² Clinically, presenting symptoms of TRALI include a spectrum of increased oxygen requirements to full blown adult respiratory distress syndrome, with varied onset.²⁰ Treatment is supportive and should include notifying the blood bank that a transfusion reaction suspected to be TRALI has occurred.⁵²⁻⁵⁴

Two theories have been proposed to describe TRALI syndrome. First, antibodies in donor plasma activate recipient neutrophils, leading to pulmonary capillary leakage. The second theory explains TRALI syndrome as a two-event model in which a physiologic stressor such as sepsis, leads to sequestration of neutrophils in the lungs. The transfusion of biologically active mediators (the second event) leads to activation of the neutrophils and capillary leakage.

Several undesirable effects of transfusions have been linked to the presence of leukocytes in allogeneic blood. Homologous transfusions, which invariably contain some leukocytes, have been implicated in immunosuppression of recipients, leading to early recurrences of cancer, and higher than expected rates of postoperative infection. This condition has been identified as transfusion-related immunomodulation (TRIM).^{10,43,55} Leukoreduction has been shown to significantly reduce transfusion immunomodulation.⁵⁶

Post transfusion purpura is a rare thrombocytopenic complication, which develops 7 to 10 days posttransfusion. Symptoms correlate with the lack of platelet antigen HPA-1a.²⁰

GVHD is another life-threatening complication seen in the context of transfusion in which donor lymphocytes incorporate themselves into the recipient tissues causing an immune system attack on the embedded lymphocytes and surrounding tissue. Rash, leukopenia, and thrombocytopenia are the most common outcomes.²⁸

Viral and Bacterial Risks

Despite enhanced safety of the blood supply, infectious complications remain a real, although perhaps overemphasized, possibility.⁵⁷⁻⁵⁹ Current rates of transmission of viral illness by transfusion are so low that mathematical models are now relied on to estimate risk.⁵⁵ Even with improved testing, transmission of viral disease can still occur during a window period when the donor blood is infectious, but screening tests used by blood banks are insensitive. Polymerase chain reaction assays have improved testing for antibodies, and shortened the window period to 11 days for human immunodeficiency virus (HIV), and 8 to 10 days for hepatitis C virus.⁶⁰

Newly emerging viral diseases in the United States threaten the safety of the blood supply. West Nile Virus is a recognized transfusion-related illness, but testing procedures have greatly reduced the risk of transmission by transfusion.⁶¹ Zika virus (ZIKV) is an arbovirus virus, which is carried by the *Aedes aegypti* mosquito, and transmitted through intrauterine, perinatal, and sexual contact. Zika virus was first isolated in 1947 from a rhesus monkey in the Zika Forest of Uganda. As of February 1, 2016, there was no confirmed blood transfusion transmission of ZIKV virus in the United States.⁶² In February 2016, the US Department of Health and Human Services Food and Drug Administration Center for Biologics Evaluation and Research published industry guidelines for the ZIKV transmission.⁶³ Variant Creutzfeldt-Jakob disease (vCJD) is thought to be contracted from blood donors who ingested beef from cattle infected with bovine spongiform encephalopathy (BSE). The infectious agent responsible for BSE, believed to be an abnormal prion protein, can be passed from blood donor to transfusion recipient and become manifest in the recipient as vCJD. BSE causes degeneration of the central nervous system. Measures to

protect the integrity of the blood supply include careful donor screening and leukodepletion (Table 22.10).⁶⁴

TABLE 22.10
Summary Risks and Side Effects of Allogeneic RBC Transfusion

Type of Risk	Incidence (Per Unit Transfused)
Infections	
Viruses	
Zika	United States: None
Human immunodeficiency virus (HIV)	1 : 1,500,000–1 : 2,000,000
Hepatitis B virus (HBV)	1 : 200,000–1 : 360,000
Hepatitis C virus (HCV)	1 : 1,000,000–1 : 2,000,000
Bacteria	
All	1 : 28,000–1 : 143,000
Parasites	
Malaria	1 : 4,000,000
Prions	
New variant Creutzfeldt-Jakob disease	No reported cases in the United States
Immunologic Reactions	
Hemolytic Transfusion Reactions (TR)	
Acute hemolytic TR	1 : 625,000
Delayed hemolytic TR	1 : 400,000
Alloimmunization	1 : 1600
Immunosuppression	1 : 1
Transfusion-related acute lung injury	1 : 8000
Mistransfusion	
All RBC mistransfusions	1 : 14,000–1 : 18,000
Anaphylactoid reactions	1 : 150,000
Fatalities	1 : 600,000

RBC, Red blood cell; TR, transfusion reaction.

Adapted from Spahn DR, et al. More on transfusion and adverse outcome: it's time to change. *Anesthesiology*. 2011;114(2):234–236; Glance LG, et al. Association between intraoperative blood transfusion and mortality and morbidity in patients undergoing noncardiac surgery. *Anesthesiology*. 2011;114(2):283–292; Goodnough LT. Transfusion medicine. In Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*. Philadelphia: Elsevier; 2016:1191–1198.

Bacterial contamination of blood remains a risk, and increases with the length of time the blood is stored. Contamination of platelets is of particular concern. Platelets are stored for a maximum of 5 days at room temperature, and carry a risk of bacterial contamination of 1 in 12,000.^{55,65}

Summary

Blood component therapy remains a strategic tool for treatment of demonstrated patient deficiencies in oxygen-carrying capacity, intravascular volume, and hemostasis. The anesthetist's role in assuring patient safety and wellbeing includes safeguarding the transfusion process. Communication with the blood bank and surgical care team to identify and anticipate hemodynamic alterations requiring transfusion, will facilitate better patient outcomes.

Although *blood substitute therapies* have evolved and improved over time, they have not demonstrated consistent reliability. Studies have focused on oxygen carrying substitutes, which avoid the vasoactive properties of early prototypes.^{66,67,68} Liposomal encapsulation of artificial Hgb, which transports oxygen to tissues without vasoconstriction, has benefited from advances in nanotechnology.⁶⁸ Long shelf half-life, and storage at room temperature are additional goals for future blood substitutes.^{67,68}

Positioning for Anesthesia and Surgery

Jennifer Lynn Thompson

The act of positioning a patient for surgery is a group endeavor that requires knowledge, teamwork, timing, and communication in order to protect against injury. The goal of patient positioning is to allow optimal surgical access while minimizing potential risk to the patient. Every surgical position carries some degree of risk that is magnified once an anesthetic is administered, which renders the patient unable to make necessary changes in positioning as needed. To prevent patient injury, clinicians must be knowledgeable about possible hazards associated with various surgical positions.

Physiologic Effects of Surgical Positions

Anesthesia providers are intimately involved in coordinating and directing patient positioning and are also continually monitoring and assessing the subsequent changes in the patient's physiologic status. Numerous factors have an effect on these changes: the surgical position; the length of time; the padding and positioning devices used; the type of anesthesia given; and the operative procedure. These changes most frequently involve (1) the cardiovascular system, (2) the respiratory system, (3) the nervous system, and (4) other vulnerable areas such as the skin, eyes, breasts, and genitalia.

Cardiovascular System

Cardiac output and blood pressure are generally decreased under general anesthesia in response to myocardial depression and vasodilation induced by anesthetic medications. As a result, blood pools in dependent body areas, reducing preload and decreasing stroke volume. Administration of neuromuscular blocking agents also contributes to decreased venous return because normal muscle tone is abolished. Additionally, opioids have the potential to slow the heart rate, further decreasing cardiac output and blood pressure. In healthy patients, mean arterial pressure (MAP) is maintained by compensatory increases in heart rate and systemic vascular resistance (SVR), but elderly patients and those with preexisting diseases are less adaptive to these hemodynamic changes. Compensatory mechanisms to increase heart rate when hypotension occurs are blunted by general anesthetics, rendering cardiac output and blood pressure more susceptible to gravitational forces.

With the patient under anesthesia, hemodynamic changes are usually minimal in the supine and lateral positions.^{1,2} However, cardiac output and blood pressure are often decreased in the sitting, prone, and flexed lateral positions, where the lower extremities are dependent.^{1,3} Although central venous pressure (CVP) is increased

in the prone position, left ventricular volume is reduced, probably due to decreased venous return and increased intrathoracic pressure.⁴ Cardiac index (CI) may be decreased^{5,6} or unchanged⁵ in the prone position compared with the supine; the effect may be frame dependent.⁶ In the lateral decubitus position with the kidney rest elevated, hypotension is likely because the legs are dependent, venous return is reduced by extreme flexion, and the kidney rest may compress the great vessels.^{1,3} Conversely, blood pressure may appear normal or higher in the lithotomy position, in which elevation of the legs above the trunk provides a gravity-dependent central redistribution of blood volume or autotransfusion.³

Mean arterial pressure increases or decreases by approximately 2 mm Hg per inch for each change in height between the heart and a body region.⁷ Therefore, regions elevated above the heart in the head-up, sitting, and lithotomy positions may be at risk for hypoperfusion and ischemia, particularly if hypotension occurs. The decrease in hemodynamic parameters depends on the degree of elevation of the torso. Hemodynamic changes are minimal if the patient is placed in a 45-degree, head-up sitting position, but cardiac output decreases 20% if the patient is raised to 90 degrees, because venous blood pools in the extremities. When the patient is in the seated position, as compared with supine, CI, CVP, and pulmonary capillary wedge pressure (PCWP) decrease significantly and SVR increases.⁸ In procedures in which the head is elevated and cerebral perfusion is a concern, invasive arterial blood pressure monitoring should be instituted, with the transducer placed at the level of the circle of Willis.⁹ Additionally, measuring cerebral oxygen saturation trends may be useful.¹⁰

Positioning devices and mechanical ventilation may contribute to decreased cardiac output and hypotension. In the lateral decubitus position, elevation of the kidney rest under the flank may cause vena cava compression. When the patient is in the lateral decubitus position, the kidney rest should lie under the dependent iliac crest.¹ Extreme flexion of the hips in some variations of the prone or lithotomy positions may occlude the femoral vessels and contribute to decreased venous return.¹¹ Large tidal volumes and positive end-expiratory pressure (PEEP) may generate high intrathoracic pressures, with a subsequent reduction in venous return, right

atrial filling, and cardiac output.¹²

A variety of methods have been suggested for attenuating the hemodynamic changes associated with surgical positioning. Slow assumption of the surgical position allows the cardiovascular system time to compensate for position-induced hemodynamic alterations. Because hemodynamic changes may be influenced by anesthetic technique, using a nitrous-narcotic technique or a lighter level of anesthesia (less than 0.5 minimum alveolar concentration) or gradually attaining a deeper level of anesthesia may attenuate position-induced hypotension.³ Intravascular volume loading before positioning can reduce or eliminate hypotension.^{1,6} However, volume replacement must be done judiciously because excessive fluid administration can lead to volume overload in susceptible individuals when the patient is returned to the supine position, or when the vasodilatory effects of general anesthetics are terminated.³

The Trendelenburg position is often used to treat hypotension, because it is assumed to increase venous return and MAP. When placed in a head-down position, normotensive individuals compensate for increases in CVP and pulmonary artery pressure (PAP) with vasodilation and a decrease in heart rate from stimulation of baroreceptor reflexes. However, hypotensive individuals may not respond in the same manner. Investigators have demonstrated variable effects of the Trendelenburg position on cardiovascular parameters. Changes in intrathoracic blood volume of 2% to 3% in unanesthetized normovolemic individuals are reported with the Trendelenburg position.¹³ CVP, mean PAP, and pulmonary artery occlusion pressure can be increased in the head-down position, but this increase may not reflect changes in CI, stroke volume, or MAP.^{13,14} Others have shown no increase in MAP, an increase in SVR, and a decrease in CI in hypotensive patients placed in the Trendelenburg position.¹⁵

Hypovolemia can be unrecognized in the lithotomy and Trendelenburg positions, because MAP can appear normal despite volume deficit. Volume replacement can be assessed as adequate until acute hypotension occurs when the patient is returned to the horizontal position. An additive effect can occur if the Trendelenburg position is used to supplement the lithotomy position.

Patients with comorbidities may be susceptible to the detrimental effects of various positions. The combination of the lithotomy position and a head-down tilt can have a detrimental effect on myocardial function in patients with coronary artery disease, because CVP, PAP, and PCWP are increased, whereas cardiac output is decreased.¹⁶ The Trendelenburg position may increase myocardial work by increasing central blood volume, cardiac output, and stroke volume. Individuals with very poor cardiac function can have decreased cardiac output if the increased central blood volume moves them to a worse position on the Frank-Starling curve. The lower extremities of individuals with peripheral vascular disease may be at risk of ischemia in the lithotomy and Trendelenburg positions because a relative state of hypoperfusion exists when the lower extremities are elevated above the heart. Additionally, when the extremities are elevated above the level of the heart, the patient may be at higher risk for compartment syndrome.

The prone and Trendelenburg positions may increase venous pressure in the head, with resultant swelling of facial, pharyngeal, and orbital structures. Intracranial pressure can be elevated when the head is dependent, because venous pressures are transmitted to the head and intracranial structures through the valveless jugular system. Cerebral blood flow can be decreased when inflow is limited by venous congestion in intracranial structures.¹⁷ Postoperative visual loss (POVL) may result from an increase in ocular venous pressures and concomitant decrease in ocular perfusion pressure. Facial edema, macroglossia, and airway edema are reported following the prone and head-down positions.¹⁸ When the patient is prone, positioning the head level or higher than the heart to minimize venous outflow obstruction may prevent the development of facial edema.¹⁹

Respiratory System

During spontaneous respiration in awake patients, contraction of the diaphragm and intercostal muscles causes expansion of the thoracic cavity in both an anterior-posterior and lateral direction. Downward displacement of the diaphragm generates a negative intrathoracic pressure and allows lung expansion as gas flows

inward. Lung elastance and chest-wall compliance affect the amount of pressure necessary to expand the alveoli for a given change in volume. Gravitational factors affect the distribution of ventilation and perfusion within the lung, as well as the shape of the thoracic cavity and movement of the diaphragm and abdominal contents.

Postural changes may significantly alter compliance, lung volumes, and the distribution of ventilation and pulmonary blood flow. Positioning devices may cause mechanical interference with movement of the belly wall and abdominal contents, the chest wall, or the diaphragm.²⁰ Therefore anesthetic-induced depression of ventilation may be worsened by the majority of surgical positions. Individuals with preexisting diseases that alter respiratory function may be more susceptible to the deleterious ventilatory effects of surgical positions.

Effective respiratory gas exchange depends on a balance of ventilation and perfusion throughout the lungs. Gravitational effects on gas and blood flow are thought to result in differences in ventilation and perfusion in different lung segments. In both awake and anesthetized patients, gravitational forces are theorized to create a gradient that favors perfusion in dependent portions of the lungs and ventilation in nondependent regions.^{21,22} However, new imaging techniques have identified a concentric pattern of blood flow in the lungs, with central regions receiving a greater proportion of flow than the periphery.^{23,24} The mechanism for this gradient has not been identified, but the diameters and branching patterns of pulmonary vessels and the distance blood must flow to reach a site are possible factors. Nongravitational factors such as cardiac output, pleural pressures, and lung volumes are also thought to play a factor in regional lung perfusion.^{21,24}

Positional changes may result in redistribution of ventilation and perfusion. These changes are less in the sitting position and more evident in the prone and lateral positions. In the prone position, changes in ventilation-perfusion (V/Q) ratios have been postulated as the cause of improved oxygenation.²¹ More lung volume is present posteriorly than anteriorly, where anterior mediastinal structures occupy significant space; as a consequence, posterior lung segments are better ventilated. Ventilation is more uniform

and V/Q matching is better in the prone position than in the supine position due to the alleviation of pressure from the anterior structures on the posterior lung tissue.²²

In the lateral decubitus position, ventilation and perfusion are greater in the dependent lung than in the nondependent lung in awake, spontaneously breathing patients.²⁴ V/Q mismatching in the lateral decubitus position may affect oxygenation, especially with procedures requiring one-lung ventilation. Hypoxic pulmonary vasoconstriction in the unventilated lung further redistributes blood flow to the dependent lung to improve oxygenation.²⁴

Changes in the elastance and resistance of the diaphragm and abdomen occur when shifting between positions. These changes have little effect on movement of the chest wall in healthy individuals but may have an effect in persons with conditions that predispose to abnormalities of lung function.²⁵ In the prone position, diaphragmatic excursion can be limited by the abdominal viscera if the abdomen is compressed by the weight of the body or positioning devices. If the abdomen hangs free, gravity allows the abdominal contents to shift, reducing interference with diaphragmatic movement.^{26,27} In the anesthetized patient in the lateral position, abdominal contents shift cephalad, moving the hemidiaphragm of the dependent lung upward, thereby decreasing ventilation in the dependent lung and reducing its compliance.²⁸ In the nondependent lung of the anesthetized patient, ventilation is greater and compliance is increased due to the caudal shift of the upper hemidiaphragm allowing unrestricted lung excursion (see [Chapter 30](#), Anesthesia for Thoracic Surgery).

Lung capacities are decreased with most position changes. In the supine position, functional residual capacity (FRC) and total lung capacity are significantly decreased compared with the sitting position due to the cephalad shift of the diaphragm caused by pressure of the abdominal viscera.^{20,25} Some investigators have found an increase in FRC with patients in the prone position, when the abdomen hangs free.^{21,29} Theories pose that better matching of ventilation and perfusion, rather than changes in lung volumes or capacities, cause improvements in oxygenation in the prone position.²⁰

In the awake patient in the lateral position, ventilation favors the

dependent lung during spontaneous respiration. With the addition of anesthesia, positive pressure ventilation, and paralysis, the upper lung becomes easier to ventilate. Displacement of the relaxed diaphragm by abdominal viscera and the downward gravity force of the mediastinum result in decreased compliance of the lower lung.^{24–26,28}

The lithotomy position has little effect on the compliance of the respiratory system in healthy, conscious volunteers.²⁰ However, extreme flexion of the thighs in the exaggerated lithotomy position compresses the abdomen, shifts the abdominal viscera cephalad, and limits diaphragmatic movement. As a result, compliance and tidal volume are reduced, and airway pressures and dead space/tidal volume ratios are increased.³⁰ This effect may be amplified in obese individuals.^{29,31}

The sitting position is more favorable for ventilation and has less effect on lung volumes than other positions. The more the torso is elevated, the smaller the effect on lung mechanics. Forced vital capacity and FRC are within normal parameters in the seated position.²⁶ The abdominal contents shift caudally and anteriorly, causing less interference with diaphragmatic movement and allowing greater expansion of dependent lung regions.²⁰ Compared with the supine position, in which the abdominal muscles are used for breathing, in the sitting position, the rib cage contributes more to ventilation.²⁶ However, respiratory benefits of the sitting position can be attenuated when the sitting position is modified to minimize cardiovascular effects. Flexion of the lower extremities at the hip and elevation of the legs can cause abdominal contents to shift cephalad against the diaphragm limiting diaphragmatic excursion and decreasing FRC and closing volumes.⁹

The Trendelenburg position exacerbates the deleterious ventilatory effects of the various positions. The diaphragm is displaced cephalad, and its excursion is limited by shifting of the abdominal contents, decreasing the FRC progressively as the degree of Trendelenburg position increases. Movement of the mediastinum toward the head may result in the tip of the endotracheal tube migrating into the right mainstem bronchus.^{32,33} This complication may also occur upon establishment of the pneumoperitoneum, in which the diaphragm is displaced in a cephalad direction by

pressurized gas.^{33,34}

Pathophysiology of Nerve Injury

Transection, compression and stretch are the primary mechanisms responsible for nerve injuries.^{35,36} Nerves may be transected by surgical maneuvers or by trauma. Compression can happen when a nerve is forced against a bony prominence or a hard surface such as an armboard or operating table. In the lateral position, for example, the weight of the superior leg pushes against the dependent extremity and may compress the common peroneal nerve of the dependent leg against the operating table. Stretch injuries occur where nerves such as the sciatic nerve or brachial plexus have a long course across many structures. Peripheral nerves have some laxity that allows a limited amount of elongation. However, excessive elongation or stretch may cause conduction changes, axonal disruption, or interruption of the nerve's vascular supply.^{37,38} Traction injuries can occur when a peripheral nerve is pulled over or under immovable structures.³⁸ For example, the femoral nerve can be kinked under the inguinal ligament when the thighs are flexed on the abdomen, as in the exaggerated lithotomy position.

A common component of all peripheral nerve injuries is ischemia. Intranural blood flow may be compromised by stretch, compression, or disruption of the nerve tissue itself.³⁸ Other causes include occlusion of major vessels, emboli, tissue edema, or inhibition of perfusion at the capillary level.³⁸ For example, pressure applied over a body surface may limit venous capillary outflow, causing a rise in venous capillary pressure and a decrease in the hydrostatic pressure gradient between interstitial tissues and the capillary.³⁹ Ultimately, tissue edema occurs as fluid is sequestered in the cells and interstitial space. As venous capillary pressure rises, the arterial-venous pressure gradient is reduced, decreasing flow to tissues along the capillary. As venous and tissue pressures continue to rise, arterial inflow is eventually obstructed and ischemia results. Low mean arterial blood pressure may augment the development of ischemic conditions.³⁵

Tissue metabolism continues even in the absence of blood flow. When ischemia ensues, adenosine triphosphate (ATP) production is decreased, causing failure of the transmembrane sodium-potassium

pump and accumulation of sodium within the cell. The resulting osmotic pressure gradient favors the movement of water into the cells. Intracellular volume is increased, and tissue edema occurs.⁴⁰ A vicious cycle of ischemia results as tissue pressures increase, preventing the movement of fluid and nutrients from the capillaries into the cells.

The susceptibility of peripheral nerves to ischemia may be partially due to their anatomic structure (Fig. 23.1). Peripheral nerves are composed of bundles of nerve fibers (fascicles) and their vascular supply is encased in protective connective-tissue coverings. Each nerve fiber is composed of one or more axons sheathed by Schwann cells (neurolemma) that are either myelinated or unmyelinated. The axons and neurolemma are covered by a loose connective tissue called the *endoneurium*. The perineurium is a tough connective tissue that binds the fascicles into identifiable structures. The epineurium consists of two layers: an inner epineurium that supports the fascicles and an outer epineurium that covers the external surface of the nerve.⁴¹ The quantity of these protective tissues varies between nerves and even along the same nerve. The entire nerve trunk is covered by a loose layer of connective tissue that allows it to slide across joints and other tissues.^{38,41}

FIGURE 23.1 Cross-section of a peripheral nerve trunk showing its components. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 9th ed. St Louis: Mosby; 2016:404.)

Peripheral nerves have an extensive microvascular supply. Blood vessels in the epineurium run parallel to the nerve and form numerous anastomoses with the perineurium. Collateral connections between the perineurium and the endoneurial capillaries run obliquely between the layers and thus may be more susceptible to compression by increases in tissue pressure. In addition, the endoneurial space lacks lymphatic vessels, so edema and fluid accumulation in this region may obstruct the microcirculation.³⁷

Factors Contributing to Nerve Injuries

Perioperative peripheral nerve injuries (PPNI) are frequently attributed to incorrect surgical positioning; however, current evidence indicates that the etiology of PPNI is multifactorial and involves patient predisposition, precipitating physiologic and mechanical factors.^{42,43} Perioperative factors that contribute to the development of nerve injuries include ancillary positioning devices, prolonged surgical procedures, and anesthetic technique. Patient-related factors include gender, advanced age, extremes in body habitus, and preexisting medical conditions such as diabetes mellitus, tobacco use, and hypertension. Intraoperative occurrences such as hypovolemia, hypotension, induced hypothermia, hypoxia and electrolyte disturbances have also been associated with nerve injury.⁴⁴ However, the precise mechanism of nerve injury is often unclear, suggesting that further investigation is needed to identify causative factors.^{42,45}

Positioning Devices

Controlled studies of complications related to specific positioning devices are largely nonexistent. Isolated case reports provide much of the evidence that is known about nerve injuries attributable to improper use of positioning devices. Ancillary positioning devices, such as tight padding or straps used to restrain the patient or an extremity, can cause skin breakdown or nerve injury if excessively tightened.^{46,47} For example, the lateral femoral cutaneous nerve in the thigh is susceptible to injury by tight table straps. Common peroneal nerve injury has been attributed to the improper use of stirrups. Brachial plexus injury has been caused by an armboard falling off the operating room (OR) table⁴⁸ or the improper use of shoulder braces with steep Trendelenburg position.⁴² Compression injury of the radial nerve has been reported after the intraoperative use of tourniquets and blood pressure cuffs and by compression between the humerus and a firm surface, such as a positioning device.^{49,50} Improper placement of an axillary roll may cause compression of neural and vascular structures of the brachial

plexus.⁵¹

Length of Procedure

Prolonged surgical procedures contribute to postoperative positioning complications. Postoperative visual loss, nerve injuries, and compartment syndrome have been associated with a variety of procedures and positions in which the common denominator was a duration of more than 4 hours.⁵²⁻⁵⁵ Rhabdomyolysis and acute renal failure also have been reported after lengthy procedures.^{56,57} One possible explanation is that during long procedures, the weight of the body causes external compression of dependent tissues and states of low perfusion.⁵⁷ The longer this situation persists, the higher the potential for development of edema and ischemic injury.

Anesthetic Techniques

Anesthetic techniques may contribute to the development of position-related injuries.⁵⁸ Patients receiving general anesthesia cannot move in response to painful stimuli generated by uncomfortable body positions. The constraints of the procedure or surgeon may limit movement even when patients are sedated. Muscle relaxation due to neuromuscular blocking drugs or volatile anesthetics may contribute to stretch injuries by allowing increased mobility of joints.⁴³ For example, limited elbow extension from tight biceps muscles can be overcome by neuromuscular blockade, allowing the arms to be extended flat and subsequently stretching the median nerve.³⁵ The hypotensive effects of general anesthetics may lower perfusion pressures below acceptable levels in patients who are hypertensive or have other comorbidities. The use of hypotensive techniques to reduce blood loss should be balanced against the risk of possible complications resulting from decreased perfusion pressures, particularly during prolonged procedures and in the sitting, lithotomy, and Trendelenburg positions, in which gravity affects blood flow.

Although neuraxial and peripheral nerve blocks are associated with both permanent and temporary nerve injuries, the majority of injuries are not related to positioning but to poor block technique, hematoma formation, and direct needle trauma.⁵⁹ However,

recognition of nerve injury may be delayed when providers attribute the patient's symptoms to the residual effects of regional blocks and local anesthetics.^{60,61} Anesthetists must have a high index of suspicion when return of function is delayed beyond what is expected for a particular technique or local anesthetic and when patients complain of severe pain in the presence of a seemingly adequate block.

Patient-Related Factors Contributing to Nerve Injuries

Body Habitus

Extremes of body habitus correlate with an increased incidence of positioning complications.^{54,56,57} Individuals who are underweight may develop decubiti or nerve damage due to lack of adequate adipose tissue over bony prominences.^{54,62} For example, thin patients may be at higher risk for sciatic nerve damage when the opposite buttock is elevated,³⁵ and thinner women (body mass index [BMI] less than 22) are more likely to develop ulnar neuropathy.^{59,62} Individuals with a muscular physique may also be at increased risk for compartment syndrome and ulnar nerve injury.^{36,63}

Obesity increases morbidity from positioning because large tissue masses place increased pressure on dependent body parts. Extreme abduction of the arms may cause stretch injuries to the lower roots of the brachial plexus, whereas the upper roots may be damaged by excessive rotation of the head to the opposite side. Ulnar neuropathy has been associated with an increased BMI.⁶⁴ Adipose tissue is poorly perfused and may contribute to this problem. For example, in the lateral position, a heavy superior extremity may interfere with perfusion by exerting substantial pressure on the inferior extremity.

Preexisting Conditions

Preexisting conditions appear to be associated with an increased risk of developing postoperative position-related injuries. Hypertension, diabetes mellitus, peripheral vascular disease, peripheral neuropathies, and alcoholism can exacerbate the physiologic effects of various positions.³⁸ Nerve injury and preexisting neuropathies are more common in patients with diabetes,³⁵ and diabetes is the most common metabolic cause of spontaneous isolated femoral neuropathy.⁶⁵ A history of smoking within 1 month of the surgical procedure has been identified as a

risk factor for nerve injury, as well as for delayed healing.^{54,66} Individuals with subclinical ulnar nerve entrapment, which may not be apparent to the patient or anesthetist, are also at risk for nerve injuries.^{67,68}

Box 23.1 highlights factors associated with position-related

Box 23.1

Factors Associated With Position-Related Injuries

Positioning Devices

- Table straps
- Leg holders and stirrups
- Axillary roll
- Bolsters
- Fracture table post
- Shoulder braces
- Positioning frames
- Headrests
- Ether screen

Length of Procedure

- Longer than 4–5 hr

Body Habitus

- Obesity
- Malnutrition

- Bulky musculature

Preexisting Pathophysiology

- Anemia
- Diabetes mellitus
- Peripheral vascular disease
- Liver disease
- Peripheral neuropathies
- Alcoholism
- Limited joint mobility
- Smoking

Anesthetic Technique

- General anesthesia
- Hypotensive techniques
- Neuromuscular blockade

Perioperative Neuropathies

In the awake patient, pain or discomfort from extreme body positioning would prompt optimization of position for the relief of symptoms. The induction of anesthesia renders a patient unable to make these changes and therefore susceptible to injury. The addition of muscle relaxants may allow body or extremity positioning that the awake patient would not otherwise tolerate, making the patient even more vulnerable to injury.³⁸ [Table 23.1](#) and [Box 23.2](#) identify specific nerve injuries associated with positioning and recommendations for prevention.

TABLE 23.1
Common Nerve Injuries: Etiology and Prevention

Nerve/Nerve Group Injured	Potential Cause	Positioning Recommendation
Brachial plexus	<i>Supine, Trendelenburg, Lithotomy</i>	
	Arm abducted more than 90 degrees on armboard	Do not abduct arm more than 90 degrees
	Arm falls off table edge and is abducted and externally rotated	Ensure arms are adequately secured
	Arm abduction and lateral flexion of the head to the opposite side	Support head to maintain neutral alignment
	<i>Trendelenburg</i>	
	Shoulder braces placed too medial or lateral	Place well-padded shoulder brace over the acromioclavicular joint Avoid use if possible
	<i>Lateral</i>	
	Thorax pressure exertion on dependent shoulder and axilla	Place roll caudad to the axilla supporting the upper part of the thorax
	<i>Prone</i>	
	Arms abducted more than 90 degrees	Abduct arms minimally
Ulnar nerve	Arm pronated on armboard	Supinate forearm on padded armboard
	Arms folded across abdomen or chest with elbows flexed more than 90 degrees	Do not flex elbows more than 90 degrees
	Arms secured at side with inadequate padding at the elbow	Place sufficient padding around elbow
	Arms inadequately secured at side, elbows extend over table edge	Draw sheet should extend above the elbow and be tucked between the patient and the mattress
Radial nerve or circumflex nerve	Arm pressed against vertical positioning or retractor post or pole securing ether screen	Place adequate padding between or ensure arm is not pressing against vertical posts or pole
Suprascapular nerve	Patient in lateral position rolls semi-prone onto dependent arm with shoulder circumduction	Stabilize patient in lateral position

Sciatic nerve	Malnourished/emaciated patient supine or sitting on inadequately padded table	Generous soft padding under buttock
	Legs straight in sitting position	Flex table at knees
	<i>Lithotomy</i>	
	Legs externally rotated with knees extended	Minimal external rotation of legs; knees should be flexed
Common peroneal nerve	<i>Lithotomy</i>	
	Fibular neck rests against vertical bar of lithotomy stirrup	Adequate padding between leg and stirrup
	Knees extended, legs externally rotated	Knees flexed with minimal external rotation
	<i>Lateral</i>	
	Undue pressure on downside leg	Padding under the fibular head
Posterior tibial nerve	<i>Lithotomy</i>	
	"Knee crutch" stirrups supporting posterior aspect of knees	Generous padding under knees Avoid use of this stirrup for prolonged procedures
Saphenous nerve	<i>Lithotomy</i>	
	Foot suspended outside vertical bar, leg rests on bar	Sufficient padding between legs and vertical bar
	Excessive pressure on medial aspect of leg from "knee crutch" stirrups	Sufficient padding between stirrup and leg
Obturator nerve	<i>Lithotomy</i>	
	Excessive flexion of the thigh at hip	Minimal hip flexion
Pudendal nerve	Traction of legs against perineal post or orthopedic fracture table	Generous padding between perineum and post

St. Louis: Elsevier; 2017:479–528; Heizenroth PA. Positioning the patient for surgery. In Rothrock JC. *Alexander's Care of the Patient in Surgery*, 15th ed. St. Louis: Elsevier; 2015:155–185.

Box 23.2

An Updated Report by the American Society of Anesthesiologists Task Force on Prevention of Perioperative Peripheral Neuropathies

Preoperative History and Physical Assessment

- When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.

- Body habitus, preexisting neurologic symptoms, diabetes mellitus, peripheral vascular disease, alcohol dependency, arthritis, and gender (e.g., male gender and its association with ulnar neuropathy) are important elements of a preoperative history.

Positioning Strategies for the Upper Extremities

Arm abduction in supine patients should be limited to 90 degrees. Patients who are positioned prone may comfortably tolerate arm abduction greater than 90 degrees.

- *Supine patient with arm on an armboard:* The upper extremity should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). Either supination or the neutral forearm position facilitates this action.
- *Supine patient with arms tucked at side:* The forearm should be in a neutral position. Flexion of the elbow may increase the risk of ulnar neuropathy, but there is no consensus on an acceptable degree of flexion during the perioperative period. Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided. Extension of the elbow beyond the range that is comfortable during the preoperative assessment may stretch the median nerve. Periodic perioperative assessments may ensure maintenance of the desired position.

Specific Positioning Strategies for the Lower Extremities

- *Stretching of the hamstring muscle group:* Positions that stretch the hamstring muscle group beyond the range that is comfortable during the preoperative assessment may stretch the sciatic nerve.
- *Limiting hip flexion:* Because the sciatic nerve or its branches cross both the hip and the knee joints, extension and flexion of these joints, respectively, should be considered when determining the degree of hip flexion. Neither extension nor flexion of the hip increases the risk of femoral neuropathy. Prolonged pressure on

the peroneal nerve at the fibular head should be avoided.

Protective Padding

- *Padded armboards*: Padded armboards may decrease the risk of upper extremity neuropathy.
- *Chest rolls*: The use of chest rolls in the laterally positioned patient may decrease the risk of upper extremity neuropathy.
- *Padding at the elbow*: Padding at the elbow may decrease the risk of upper extremity neuropathy.
- *Padding to protect the peroneal (fibular) nerve*: The use of specific padding to prevent pressure of a hard surface against the peroneal nerve at the fibular head may decrease the risk of peroneal neuropathy.
- *Complications from the use of padding*: The inappropriate use of padding (e.g., padding too tight) may increase the risk of perioperative neuropathy.

Equipment

The use of properly functioning automated blood pressure cuffs on the arm (i.e., placed above the antecubital fossa) does not change the risk of upper extremity neuropathy. The use of shoulder braces in a steep head-down position may increase the risk of perioperative neuropathies.

Postoperative Assessment

A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

Documentation

Documentation of specific perioperative positioning actions may be useful for continuous improvement processes, and may result in improvements by helping practitioners focus attention on relevant aspects of patient positioning, and providing information on

positioning strategies that eventually leads to improvements in patient care.

From Practice Advisory for the Prevention of Perioperative Peripheral Neuropathies: an updated report by the American Society of Anesthesiologists Task Force on prevention of perioperative peripheral neuropathies. *Anesthesiology*. 2011;114(4):741–754.

Ulnar Neuropathy

Ulnar neuropathy is one of the most frequently reported injuries after surgery and anesthesia, yet its causation is not completely understood.^{3,36,67} Damage to the ulnar nerve results in the inability to oppose the fifth finger and diminished sensation to the fourth and fifth finger and, if prolonged, can result in atrophy of the intrinsic muscles of the hand, creating a clawlike contracture.⁶⁹

The ulnar nerve traverses the length of the upper extremity from its origins as a branch of the medial cord of the brachial plexus to its terminal branches in the hand. In the upper arm, the ulnar nerve passes along the anterior aspect of the medial head of the triceps muscle and posterior into the groove between the medial epicondyle of the humerus and the olecranon ([Fig. 23.2](#)).⁷⁰ In this region, the nerve is sheathed in the cubital tunnel before exiting and passing between the two heads of the flexor carpi ulnaris. The cubital tunnel retinaculum (CTR) forms the roof of the cubital tunnel (see [Fig. 23.2](#)), a potential area for nerve compression because fibrous tissue and the elbow capsule form a semirigid canal that changes shape with flexion and extension of the forearm.⁵⁴ Direct pressure on the cubital tunnel from contact on an unpadded armboard or surgical table may cause nerve compression.^{70,71} When the elbow is flexed, the distance between the olecranon and medial epicondyle increases, stretching the CTR, decreasing the size of the tunnel, and can increase pressure on the nerve.^{36,72}

FIGURE 23.2 The ulnar nerve at the cubital tunnel. **A**, Medial view. **B**, Posterior view. Note cubital tunnel retinaculum over the ulnar nerve in the cubital tunnel. **C**, Posterior view with elbow tilted on medial side. Note the ulnar nerve compressed. (From Rothrock JC. *Alexander's Care of the Patient in Surgery*. 15th ed. St. Louis: Elsevier; 2015:162.)

Although excessive flexing of the elbow and direct compression of the ulnar nerve at the condylar groove may contribute to ulnar neuropathy, current consensus is that the cause is multifactorial and not always preventable.⁷¹ Ulnar neuropathy is more frequently associated with male gender,^{38,62,67} the presence of a preexisting asymptomatic neuropathy,⁶⁷ prolonged hospital stays,^{38,62} and extremes of body habitus.^{38,59} Anatomic variations, such as a larger coronoid process and less subcutaneous tissue over the ulnar region, are hypothesized to explain the gender difference findings.⁶² Although often blamed on intraoperative positioning, the prevalence of ulnar neuropathy is similar in medical and surgical patients and most often has a delayed onset (median of 3 days).⁷³

Recommendations for positioning to prevent ulnar nerve injury in anesthetized patients include the use of padding, placing the arms in either a supinated or neutral forearm position, and abducting the arms less than 90 degrees if armboards are used.^{71,74} If the arms are secured on armboards, the forearm should be supinated (palm up) or neutral, because pronation (palm down) may increase pressure over the ulnar nerve.⁷⁵ When the patient's arms are tucked at the side of the body, they should be in a neutral position with the palms facing inward (Fig. 23.3). Anatomic changes in the cubital tunnel with flexion and extension suggest that excessive flexion of the elbow should be avoided when the patient is in the lateral position or if the arms are secured across the chest. Evidence supports the conclusion that ulnar nerve palsy is not always a preventable complication despite the best efforts at careful positioning and padding.^{71,74,75}

FIGURE 23.3 **A**, Supine. Note the asymmetry of the base of the table, placing the patient's center of gravity over the base if positioned in the usual direction. **B**, Arm position on the armboard. Abduction of the arm should be limited to less than 90 degrees whenever possible. The arm is supinated, and the elbow is padded. **C**, Arm tucked at patient's side. Arm in neutral position with palm to hip. The elbow is padded, and one needs to ensure that the arm is supported. **D**, Lawn-chair position. Flexion of the hips and knees decreases tension on the back. **E**, Trendelenburg position (head tilted down) and reverse Trendelenburg position (head tilted up). Shoulder braces should be avoided to prevent brachial plexus compression injuries. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier; 2011:302.)

Brachial Plexus Injuries

The brachial plexus is vulnerable to injuries in almost every surgical position, particularly if the arms are abducted or the head is rotated (Fig. 23.4). When the patient is supine, abduction of the arms greater than 90 degrees stretches the plexus around the humeral head. Turning the head to the side with the arms abducted can cause stretching and compression of the contralateral brachial plexus beneath the clavicle.⁷⁶ Even tucking the arms next to the body is not without risk if the head is turned laterally and the shoulders are depressed. When the patient is prone, inadequate support of the shoulders allows them to sag anteriorly, causing traction on the plexus. Also in the prone position, extending the arms over the head may compress the plexus between the clavicle and first rib.⁷⁶

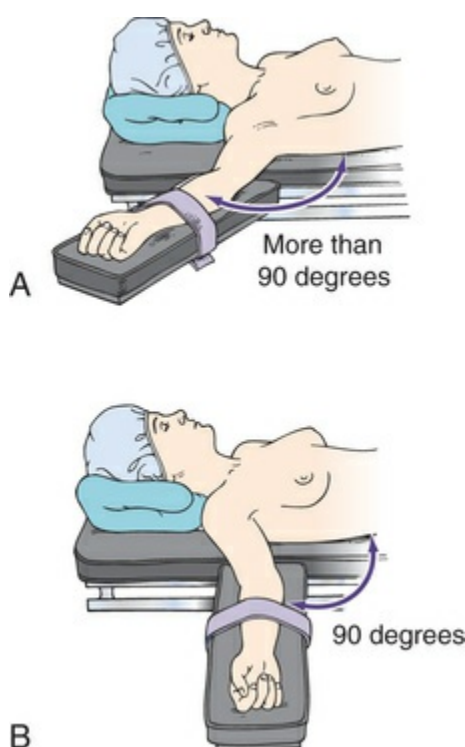

FIGURE 23.4 Position of arm on armboard should not exceed 90 degrees because otherwise injury to the brachial plexus may result. **A**, Incorrect positioning. **B**, Correct positioning. (From Phillips N. *Berry & Kohn's Operating Room Technique*. 13th ed. St. Louis: Elsevier; 2017:488.)

In the lateral decubitus position, brachial plexus injury is most commonly the result of excessive stretching, usually because of arm abduction greater than 90 degrees, external rotation, extension and lateral flexion of the head, and posterior shoulder displacement.³⁵ In the lateral position, the weight of the chest can compress the lower shoulder and axilla putting pressure on the axillary neurovascular bundle. An “axillary roll” can be placed just caudal to the dependent axilla to relieve this pressure.^{71,72}

Brachial plexus injuries are also associated with positioning devices. Injuries can be caused by an unsecured arm slipping off an armboard or an armboard falling off the OR table, causing excessive stretch of the plexus. Sometimes used during steep Trendelenburg position, shoulder braces placed too close to the base of the neck can compress neurovascular structures and cause brachial plexus neuropathy. Although best avoided, if used, shoulder braces are properly placed at the distal end of the clavicle over the acromioclavicular joint.^{48,77,78}

Spreading of the sternal retractor during cardiac surgery causes the clavicle to move posteriorly and the first rib to rotate upward, pinching the plexus between the two.⁷⁷ Dissection of the internal mammary artery requires wider, asymmetric chest retraction to allow adequate visualization and may predispose to brachial plexus neuropathy. To prevent brachial plexus injury during cardiac surgical procedures, caudad placement of the sternal retractor and avoidance of excessive and prolonged asymmetric chest wall retraction are recommended.^{79,80}

Spinal Cord Injury

Cheney et al.⁴² compared claims documented since 1990 to the outcome claims in the pre-1990 American Society of Anesthesiologists (ASA) closed-claims database and found that spinal cord injury claims had surpassed ulnar nerve injury claims. However, spinal cord injury claims were primarily associated with neuraxial blocks in anticoagulated patients and with blocks for acute and chronic pain management. Although rare, hemiparesis and quadriplegia are associated with surgical procedures performed in the sitting and prone positions.⁸¹⁻⁸³ Midcervical flexion myelopathy with temporary or permanent quadriplegia may occur when the head is flexed on the neck in the sitting or prone positions. When the head is flexed, the spinal cord moves anteriorly and may be compressed against the posterior vertebral body. Ischemia may result from a combination of compression and stretch, because the spinal cord lengthens with flexion. Like a rubber band, the cord becomes thinner as it stretches, and the caliber of the vessels supplying the cord can be reduced.⁸³ Increased vertebral venous pressure is also proposed as leading to postoperative spinal cord injury. The absence of valves between the central venous and epidural venous systems allows direct transmission of increased abdominal or intrathoracic pressure to the vertebral venous systems.⁸⁴ Congestion in the veins draining the spinal cord, coupled with hypotension, may result in decreased spinal cord perfusion and the onset of new neurologic deficits.⁸³ Hyperflexion of the head on the neck in any position may be avoided by allowing a minimum of two fingerbreadths between the sternum and mandible.³

Somatosensory evoked potentials (SSEPs) have been suggested as being useful in identifying position-related changes in spinal cord function.⁸⁵ However, neurologic defects have emerged postoperatively despite normal intraoperative SSEP readings.^{3,86,87} A study by Schwartz et al.⁸⁶ evaluated the role of transcranial electric motor-evoked potential (tceMEP) and its recommended use for the detection of not only spinal cord injury but also brachial plexus and ulnar nerve injury due to positioning.

Postoperative Visual Loss

Postoperative visual loss (POVL) is a rare but devastating complication of nonophthalmic surgery. It may occur in one or both eyes and refers to a variety of visual defects ranging from decreased visual acuity to total blindness.⁸⁸ Visual loss after nonophthalmic surgery is generally attributable to five causes: ischemic optic neuropathy (ION), central retinal artery occlusion (CRAO), central retinal vein occlusion, cortical blindness, and glycine toxicity.⁸⁹ Of these causes, patient positioning may be a contributing factor in the development of ION and CRAO. In the ASA POVL registry, ION and CRAO accounted for 81% of all cases, with ION accounting for 89% of POVL after prone spinal procedures.^{19,90}

As the name implies, ION is the result of ischemia in a portion of the optic nerve. The optic nerves may be susceptible to hypoperfusion. The central retinal and posterior ciliary arteries are end-arteries and lack anastomoses with other arteries⁹¹ (Fig. 23.5). Thus the structures supplied by these vessels are in a “watershed” region, meaning that the region receives a dual blood supply from the most distal branches of two arteries. Watershed areas are reportedly vulnerable to ischemia if a portion of the blood supply is interrupted.^{88,92} Although the ocular circulation lacks autonomic innervation, autoregulation does still occur in the ophthalmic and central retinal arteries.⁹¹ The limits of autoregulation in the ocular circulation are unknown. Preexisting diseases such as diabetes and hypertension that disrupt autoregulatory mechanisms may contribute to ischemic episodes during periods of hypotension.⁹³ ION is divided into two types: anterior ION (AION) and posterior ION (PION). AION is characterized by optic nerve injury occurring anterior to the lamina cribrosa, whereas PION results from optic nerve injury posterior to the lamina cribrosa.⁹⁴

FIGURE 23.5 Superior view of the orbital arteries and veins. a, Artery; v, vein.

A large case-control study on ION associated with spine surgery identified six independent and significant risk factors including male sex, obesity, Wilson frame use, longer operative times, greater blood loss, and a lower colloid to crystalloid ratio in the nonblood fluid administration.^{44,95,96} Significant risk factors found by other researchers include male sex, anemia from blood loss greater than 1 liter, surgery lasting over 5 hours, diabetes, hypertension, vascular disease, smoking, and intraoperative hypotension.^{44,95} Despite the association of various risk factors, ION has occurred in healthy patients and in the absence of these perioperative factors.^{44,95,97}

Whereas the exact cause of ION is still unclear, risk reduction strategies are aimed at avoiding both increased intraocular pressure and decreased optic nerve perfusion.^{44,88} Just as cerebral perfusion pressure equals MAP minus intracranial pressure, ocular perfusion pressure (OPP) is the difference between MAP and intraocular pressure (IOP).^{98,99} Intraoperative and anesthetic events that decrease MAP and thus reduce OPP include general anesthetics, hypotension, hemorrhage, and hypovolemia. Venous pressure and the ratio of aqueous humor production to absorption affect IOP. An increase in venous pressure may impede aqueous humor outflow into the venous system, causing a rise in IOP.⁹⁹ As IOP approaches MAP, OPP will decrease. During surgery, ocular venous pressure can be increased by a head-down tilt, increased abdominal and right atrial pressure, and obstruction of jugular venous return.⁹²

Both steep Trendelenburg position and beds such as the Wilson frame, where the head is positioned much lower than the heart, may exacerbate venous congestion and increase IOP. Unlike CRAO, ION does not seem to be associated with pressure on the globe, because ION has occurred in patients whose heads were secured with pin-type headrests.¹⁹

CRAO is a less common cause of POVL than ION and is caused by decreased blood supply to the entire retina. In 93 cases of POVL following prone spinal surgery, only 10 cases were attributed to CRAO.⁹⁰ The central retinal artery is one of the first branches of the internal carotid artery and nourishes the internal layer of the retina. The most common cause of CRAO is improper head positioning that result in external pressure on the eye.^{44,95} Other causes can include emboli, due to a hypercoagulable state, that migrates to the central retinal artery and cause unilateral blindness. Perioperative factors associated with CRAO are prone spine operations, cardiopulmonary bypass surgery, and head and neck procedures where injections are performed around the nose and eyes.⁹⁵ CRAO typically presents as severe unilateral vision loss immediately following surgery. Although many treatments are recommended for CRAO, few have proven efficacy and prognosis is poor.⁹⁹

General risk factors for central retinal vein obstruction syndrome include hypertension, cardiovascular disease, increased body mass index, open angle glaucoma, and sickle cell anemia. Because external pressure on the globe may cause central retinal vein obstruction, when the patient is placed prone for procedures on the head and neck, some suggest the use of three-pin headrests that securely immobilize the head rather than the horseshoe headrest.¹⁰⁰ Although the three-pin headrest avoids the potential for external ocular compression, POVL from ION has occurred despite its use.⁹⁰

A practice advisory for perioperative visual loss associated with spine surgery was developed in 2006 and updated in 2012, based on the synthesis and analysis of opinions of spine surgeons, neuroophthalmologists and anesthesiologists. A summary of practice points, including major considerations from the ASA practice advisory for the prevention of POVL, can be found in [Box 23.3](#)

Perioperative Blindness

- Providers should consider informing patients who are having spine surgery in the prone position with prolonged duration and/or substantial blood loss that they have a small but unpredictable risk of perioperative visual loss (POVL).
- POVL can be caused by direct pressure on the globe resulting in central retinal artery occlusion (CRAO).
- Ischemic optic neuropathy (ION) is the most common cause of POVL associated with prone spine surgery in adult patients.
- Factors that significantly and independently increase the risk of ION associated with spine surgery in the prone position include: male sex, obesity, use of Wilson frame, longer surgical duration, larger blood loss, and a lower percentage of colloid in the non-blood fluid administration.
- Risk reduction strategies include:
 - Avoid direct pressure on the eye.
 - Avoid the horseshoe headrest, which has a small margin of error, or any headrest that does not allow adequate assessment of the eyes during the procedure.
 - Perform and document periodic eye checks throughout the perioperative period.
 - Assess patient vision when the patient becomes alert.
 - An urgent ophthalmologic consultation should be obtained if there is concern for postoperative visual loss.

- Minimize venous pressure and congestion in the head.
- Keep the head in a neutral position at or above the heart level.
- Avoid using the Wilson frame if possible.
- Minimize bleeding.
- Avoid coagulopathy.
- Modify surgical technique.
- Decrease the duration of the prone position.
- Stage prolonged procedures if possible.
- Avoid significant hemodynamic changes as much as possible
- Closely monitor blood pressure.
- Monitor hemoglobin and hematocrit periodically throughout surgery.
- Use colloid along with crystalloid for non-blood fluid resuscitation.
- Resume normotension and normotension after turning patient supine unless medically

contraindicated.

- Prognosis is poor for POVL due to ION and CRAO and usually results in permanent visual loss.
- Consider magnetic resonance imaging to rule out intracranial causes of visual loss.
- Antiplatelet agents, steroids, or intraocular-lowering agents have not been shown to be effective for treatment of perioperative ION.
- Hyperbaric oxygen therapy treatment has been proposed for CRAO with the highest chance of significant improvement in visual acuity resulting when treatment is started within 6 hours of the onset of symptoms.

Adapted from American Society of Anesthesiologists Task Force on Perioperative Visual Loss. Practice advisory for perioperative visual loss associated with spine surgery: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Visual Loss. *Anesthesiology*. 2012;116(2):274–8; Kja KM, Lee LA. Perioperative visual loss. *Best Pract Res Clin Anaesthesiol*. 2016;30(1):69–77.

Much remains to be learned about POVL. Although factors such as hypertension, vascular disease, obesity, and smoking have been associated with POVL, specific methods for identifying at-risk patients are not available, and reasons that POVL occurs in patients without obvious risk factors are unknown. Patients at high risk of developing POVL include those undergoing lengthy procedures in the prone or steep Trendelenburg position, especially if surgery is accompanied by significant blood loss. During the preoperative interview, high-risk patients should be informed of the risk of POVL. Although periodic intraoperative monitoring of hemoglobin or hematocrit is suggested, safe lower limits for hematocrit are unknown. Deliberate hypotensive techniques to prevent blood loss

during spine surgery should be avoided in individuals with chronic hypertension or other factors that place them at risk for POVL.¹⁹ Avoidance of direct pressure over the eye is recommended to avoid CRAO. The prone patient's head should be placed in a neutral position (avoid excessive flexion) and level with or slightly elevated above the heart (10-degree head-up tilt) when possible⁹⁶ (Fig. 23.6). This prone position with the horseshoe adapter is the least preferred head support technique because of pressure on the eye and POVL (see Fig. 23.6 C,D).¹⁹ If necessary, it should only be used for short procedures. The foam head pillows with cutouts are preferred (see Fig. 23.6 A). A complete discussion of POVL associated with prone positioning for orthopedic procedures can be found in Chapter 45, Anesthesia for Orthopedics and Podiatry.

FIGURE 23.6 A, Prone position with Wilson frame. Arms are abducted less than 90 degrees whenever possible. Pressure points are padded, and chest and abdomen are supported away from the bed to minimize abdominal pressure and preserve pulmonary compliance. Foam head

pillow has cutouts for eyes and nose and a slot to permit the endotracheal tube to exit. Eyes must be checked frequently. **B**, Mirror system for prone position. Bony structures of the head and face are supported, and monitoring of eyes and airway is facilitated with a plastic mirror. **C**, Prone position with horseshoe adapter. Head height is adjusted to position neck in a neutral position. **D**, Prone position, face seen from below. Horseshoe adapter permits superior access to airway and visualization of eyes. Width may be adjusted to ensure proper support by facial bones. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier; 2011:307.)

Other Position-Related Injuries

Position-related injuries range from minor skin abrasions and backache to events with serious morbidity (Table 23.2).

Complications of these injuries can lead to tissue necrosis, infection, renal failure, paralysis, loss of limbs, and even loss of life. Although most individuals recover from minor position-related injuries without sequelae, more serious injuries may prolong a patient's hospital stay and recovery, cause psychological trauma, and perhaps even result in permanent disability. Anesthetists must not minimize the physical, psychological, social, and financial impact of transient injuries that resolve over hours, days, or months.

Permanent, disabling injuries are even more devastating to patients and providers.

TABLE 23.2

Potential Position-Related Injuries

Body System or Anatomic Location	Potential Injury
Head, eyes, ears, nose, and throat	Postoperative vision loss Corneal abrasion Facial edema Vocal cord edema
Cardiovascular	Vascular occlusion Deep vein thrombosis Ischemic injuries
Respiratory	Atelectasis Endobronchial intubation
Neurologic	Peripheral neuropathy Quadriplegia Decreased cerebral blood flow Increased intracranial pressure
Genitourinary	Myoglobinuria Acute renal failure
Musculoskeletal	Amputation Backache Compartment syndrome Rhabdomyolysis
Integumentary	Abrasion Alopecia Decubiti

Compartment Syndrome

Compartment syndrome is a rare but potentially life-threatening

complication that causes damage to neural and vascular structures from tissue swelling as a result of increased pressures and decreased tissue perfusion in muscles with tight, fascial borders. Because tissue swelling typically occurs when blood flow returns to a region after a period of ischemia, the syndrome has also been called a *reperfusion injury*. Increased compartmental pressure compromises arteriolar supply and results in ischemia with subsequent muscle and nerve infarction.^{51,101-104} Although compartment syndrome occurs most often in the lower extremities, it may also occur in the upper extremities or in the abdomen as a result of tight wound closures.¹⁰⁵ Compartment syndrome can be precipitated by intraoperative hypotension in conjunction with leg elevation that causes low-flow states. Because local arterial pressure decreases by 0.75 mm Hg per centimeter change in height above the right atrium, elevation of the legs puts the patient at greater risk.¹⁰¹

Long surgical duration with the patient in lithotomy position is the distinguishing characteristic of surgeries where patients develop lower extremity compartment syndrome.^{104,106} Compartment pressures increase over time in the lithotomy position, and the legs should be periodically lowered to the level of the body if the procedure lasts beyond 2 to 3 hours. Other risk factors that might contribute to the development of compartment syndrome include Trendelenburg position, advanced age, extremes of body habitus, patient history of nerve ischemia or neuropathy, connective tissue disease, anemia, hypotension, and the use of vasoconstrictive drugs.^{102,103,105} Although anesthetic technique has not been implicated as causing compartment syndrome, general and regional anesthesia can contribute to intraoperative hypotension and impaired blood flow.¹⁰⁵⁻¹⁰⁷

Unless the syndrome is promptly diagnosed and treated, permanent neuromuscular damage will occur. Fasciotomy is generally considered the definitive treatment because less-aggressive therapies will not release the constricted compartments. If untreated, the syndrome progresses to tissue necrosis with rhabdomyolysis and acute renal failure (crush syndrome). The need for amputation or even death can occur.¹⁰⁵

Venous Air Embolism

Venous air embolism (VAE) is a well-known consequence of surgery performed in the sitting position. However, VAE may occur in any position where a negative pressure gradient exists between the right atrium and the veins at the operative site.¹⁰⁸⁻¹¹¹ The precise incidence of VAE is unknown, but there is an increased incidence in surgeries performed in the sitting position.¹¹²⁻¹¹⁴ Air that enters the right side of the heart can limit gas exchange in the lungs as it displaces blood in the pulmonary vasculature. Complications of VAE are dependent on both the rapidity and volume of air entrainment. Physiologic effects range from no effect for minimal amounts of air to hypotension, arrhythmias, cardiac arrest, and death with larger volumes.¹¹¹⁻¹¹⁴ Another potential complication is that if air emerges through the left ventricle, disruption of blood flow to the heart or brain from micro-air emboli can result in an MI or CVA.

Paradoxical air embolism (PAE) can occur in the patient with a patent foramen ovale (PFO). Studies in vivo and in cadavers indicate that the incidence of PFO can be as high as 35% in the general population.^{109,112,113} In the patient with PFO, air can enter the systemic circulation when right atrial pressure is greater than left atrial pressure, a reversal of the normal pressure gradient. Very small amounts of air in the arterial system can result in severe cardiovascular and neurologic complications.

Because VAE and PAE carry the potential for serious consequences, identifying individuals at risk for these complications is important. Preoperative transesophageal echocardiograph (TEE) with contrast is the gold standard for detection of PFO in patients scheduled for surgery in the sitting position.^{110,114,115} The cost of TEE is thought to be justified because it is a low-risk, semi-invasive procedure and the sequelae of PAE are severe. However, PFO can be present and PAE can occur despite negative preoperative TEE.¹¹⁴ Because TEE is costly and has rare but serious complications, transcranial Doppler studies are recommended as an alternative, noninvasive approach with excellent diagnostic capability in detection of right-to-left shunting.^{114,116}

In addition to the use of standard anesthetic monitoring techniques, selection of appropriate monitoring for the detection of

air embolism is based on the sensitivity of each modality. TEE, precordial Doppler ultrasonography, capnography (ET_{CO_2}), end-tidal nitrogen (ETN_2) and pulmonary artery catheterization vary in their ability to detect intraoperative VAE. TEE is the gold standard as it is the most sensitive, having the ability to identify emboli less than 0.2 mL/kg, and can also be used to position right atrial catheters.^{113,117} Disadvantages to the use of TEE include: requires specialized training, requires considerable time, comes with risk to the patient, and may not provide a continuous monitor of cardiovascular events.

The precordial Doppler is often used to monitor for VAE when patients are in the sitting position. The probe is placed over the third to sixth intercostal spaces to the right of the sternum. The precordial Doppler is the most sensitive noninvasive monitor and is less expensive and cumbersome than TEE.^{111,114} However, it does not have the advantage of localizing entrained air within the cardiac chambers, it is sensitive to electrical interference from operating room equipment, and its effectiveness can be reduced by auditory fatigue in the anesthetist.^{111,113,117} Most frequently used for sitting cases, Doppler devices have not traditionally been advocated for management of VAE during procedures performed in the prone position because of the excessive pressure that it may exert on the chest wall.

VAE increases dead space and contains nitrogen; monitoring capnography will reveal a drop in end-tidal CO_2 and the presence of end-tidal nitrogen. A “mill-wheel murmur” is a characteristic of VAE that can be heard through the esophageal or precordial stethoscope.¹¹⁷ Air in the coronary arteries can cause ischemic electrocardiographic changes, and air in the pulmonary vessels can result in an increase in PAP and hypoxia. These signs occur later than changes detected by TEE, Doppler, or capnography and are indicative of PAE or large emboli.^{111,113}

Entrained air emboli can be removed from the circulation by aspiration through a multiorifice central venous catheter, although success rates of appreciable air aspiration are far from ideal.¹¹⁸ For patients undergoing surgery in the sitting position, the catheter is placed in the right atrium at the junction of the superior vena cava.^{110,117} Patients who are prone should have the CVP catheter

positioned at the junction of the inferior vena cava (IVC) and right atrium because air emboli from spinal surgery enter the venous circulation through the lumbar epidural veins and IVC.¹¹⁸ The risks of central venous catheter placement, the potential for VAE, and the cardiopulmonary risks of the position must be weighed against the benefits of fluid volume management and air recovery with a CVP catheter. See [Chapter 31](#), Neuroanatomy, Neurophysiology, and Neuroanesthesia for further discussion on detection and treatment.

Airway Complications of Surgical Positions

Anesthetized patients in various surgical postures are vulnerable to endotracheal tube displacement, airway edema, and passive regurgitation. The endotracheal tube may become dislodged, kinked, or disconnected when the patient is moved or upon position change. A right mainstem intubation may occur as a result of flexion of the neck or when the patient is placed in steep Trendelenburg position. With neck flexion, the endotracheal tube moves downward and may inadvertently enter the right mainstem bronchus.^{119,120} In the Trendelenburg position, pressure of the abdominal contents force the diaphragm cephalad and may cause a similar occurrence.³⁴

Extensive edema of the face, tongue, and oropharyngeal structures has been reported after procedures in the prone, head-down, and sitting positions.^{121,122} In the prone and head-down positions, gravitational forces or increases in hydrostatic pressures may restrict venous return from the head and neck. Excessive flexion of the head on the neck with patients in the sitting position may obstruct jugular venous return, resulting in macroglossia and airway edema. Oral airways, endotracheal tubes, and esophageal stethoscopes may compress the base of the tongue and limit lymphatic drainage. The endotracheal tube can become kinked with extreme degrees of flexion or may compress the arytenoids and epiglottis, resulting in postoperative supraglottic edema. Macroglossia or upper airway edema may necessitate leaving the patient intubated after surgery until the edema subsides.¹²² It may be prudent to verify an air leak around the endotracheal tube or examine the larynx via direct laryngoscopy before extubation in suspected patients.

Surgical Positioning

The Supine Position (Dorsal Decubitus)

The supine position is most frequently used for surgical procedures on the abdomen, head, neck, extremities, and chest, owing to the favorable exposure it allows. When positioning the patient supine, the head should be maintained in a neutral position on a small pillow or donut. The arms should be either comfortably positioned and secured alongside the trunk or positioned on padded arm boards.^{3,37,120} If the patient has severe arthritis, decreased mobility of the head and neck, or neuropathy of the upper extremities, it is best to position the patient to his or her preference prior to the induction of anesthesia. During prolonged procedures, the head should be repositioned at intervals and the occiput massaged to prevent alopecia due to prolonged pressure. Gel-type donuts may more evenly distribute pressure.⁴³

The ligaments of the vertebral column relax with anesthesia and can result in postoperative backache. Placing a pillow under the patient's knees or placing the table in a slight "lounge chair" position, with the patient's hips and knees flexed and the trunk slightly elevated increases patient comfort.^{3,120} The legs must remain uncrossed to avoid pressure from the superior extremity damaging the superficial peroneal nerve in the dependent leg and the sural nerve in the superior leg. If prolonged surgery is anticipated, the heels should be elevated off the mattress to prevent pressure sores; however, using too large a support to elevate the heels can cause hyperextension of the knees and pain postoperatively. Gel pads or mattresses more evenly distribute the patient's body weight and prevent reddened areas after lengthy procedures.³

If the arms are tucked, the elbow must not be allowed to hang over the edge of the operating table because ulnar nerve damage may occur. When tucked, the hands should be placed in a neutral position, the elbow padded, with the palms facing the hip^{73,75,76} (see Fig. 23.3) If the arms are secured on armboards, the forearm should be supinated; pronation may result in compression of the ulnar nerve against the armboard. The arms should be abducted less than

90 degrees, and the head should be maintained in a neutral position to avoid brachial plexus stretch injuries.^{73,75,76}

Trendelenburg/Reverse Trendelenburg Positions

Trendelenburg position (head-down position) is often used to increase venous return during episodes of hypotension and is also used to supplement the primary surgical position and improve surgical exposure. Physiologic alterations vary greatly depending on the degree of tilt and the primary position. An increase in central venous, intracranial, and intraocular pressures is observed with the Trendelenburg position and may contribute to edema of the face, tongue, oropharynx, and eyes.¹³⁻¹⁶ Various complications have been observed as outcomes of the Trendelenburg position and many are the result of positioning devices. Improperly positioned shoulder braces designed to prevent the patient from sliding when in a steep Trendelenburg position can injure the brachial plexus and should not be used when the arm is extended on an armboard. Placement of the shoulder brace in a position that is placed too medial can result in depression of underlying bony structures and compression of the plexus. Braces placed too lateral may result in a stretch injury of the brachial plexus. The brace should be placed over the acromioclavicular joint and should be avoided if at all possible because nerve injury can still occur despite proper placement.^{14-16,75,123} The arms are vulnerable to injury in the Trendelenburg position, particularly if they are positioned on armboards and inadequately restrained. The arms can slip off, hyperextend, and abduct above the level of the shoulder, stretching the plexus.^{3,14,75}

The reverse Trendelenburg position (head-up position), often used in laparoscopic surgeries, can also predispose patients to injury. The positioning of the head higher than the heart reduces perfusion pressure to the brain and should be monitored closely. When too tight, table straps used to prevent the patient from sliding in the reverse Trendelenburg position have resulted in lower-extremity neuropathies and pressure ulcers¹⁴ (see [Fig. 23.3](#)). The use of a foot board is preferable to the overzealous tightening of the

table strap if a steep reverse Trendelenburg position is necessary.

The Lithotomy Position

The lithotomy position is used for surgical procedures that require access to any perineal structure. In the typical lithotomy position, the legs are held in flexion and abduction above the level of the torso by a leg-holding device⁴³ (Fig. 23.7). The level of lithotomy position needed is dependent on the type of surgery and surgical access (Fig. 23.8). In low lithotomy position, the legs are almost level with the torso, whereas in exaggerated lithotomy position, the legs are suspended with boots or stirrups so that the feet are well above the body. A hemilithotomy position, with one leg elevated, is also used for some orthopedic procedures.^{14,43,120}

FIGURE 23.7 **A**, Lithotomy position. Hips are flexed 80 to 100 degrees with the lower leg parallel to the body. Arms are on armrests away from the hinge point of the foot section. **B**, Lithotomy position with “candy cane” supports. **C**, Lithotomy position with correct position of “candy cane” stirrups away from lateral fibular head. **D**, Improper

position of arms in lithotomy position with fingers at risk for compression when the lower section of the bed is raised.

(From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier; 2011:304.)

FIGURE 23.8 Four basic types of lithotomy position with progressively increasing leg elevation. **A**, Low. **B**, Standard. **C**, High. **D**, Exaggerated. (From Rothrock JC.

Alexander's Care of the Patient in Surgery. 15th ed. St. Louis: Elsevier; 2015:177.)

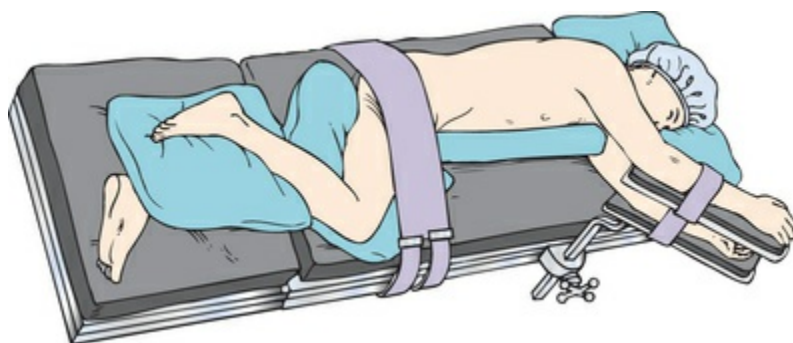

The arms are usually positioned either tucked at the sides or abducted on armboards. In the hemilithotomy position, one arm may be secured across the chest. The same cautions for positioning the upper extremity apply as in the supine position. Strict attention must be paid to the fingers, if the arms are tucked at the sides, to avoid a potentially disastrous crush injury or amputation if they become trapped when the foot section is raised.^{3,75,120} (see [Fig. 23.7,D](#)) Many neurovascular complications can occur in the lithotomy position because of the position of the leg and hip. Both legs should be elevated and lowered simultaneously when they are placed in a leg-holding device; raising and lowering the legs separately can cause hip dislocation, spinal torsion, or postoperative back pain.^{43,75} Acute abduction and external rotation

of the hips can also cause femoral nerve or lumbosacral plexus stretch injuries. Flexion of the hips more than 90 degrees in the lithotomy position can cause neural damage by stretching the sciatic and obturator nerves or by direct pressure of femoral neurovascular structures under the inguinal ligament, with subsequent arterial or venous occlusion and nerve palsy.^{43,75,123,124} Leg holders that support the leg under the knee can compromise vascular structures in the popliteal space.¹²³

Peroneal nerve injury is frequently associated with the lithotomy position because of its anatomic course.³⁵ The nerve crosses the knee joint laterally and wraps around the fibular head before traveling down the lower leg. Depending on the type of leg holder used, the nerve can be injured by compression against the upright bar or against the supporting cradle of the leg holder. The saphenous nerve courses down the medial aspect of the lower leg and is also at risk for compression in the leg holder. Care must be taken to adequately pad any points of potential compression.⁷⁵

The Lateral Decubitus Position

The lateral decubitus position is often used for surgeries involving the thorax and kidneys when the supine position cannot provide sufficient exposure. Orthopedic procedures involving the hips, shoulders, or extremities can also require this position for better access to the surgical site. When a nephrectomy is performed using a lateral approach, exposure of the kidney can be facilitated by elevating the kidney rest beneath the dependent iliac crest and flexing the operating table so that the operative flank is higher than the upper torso or legs^{3,43,75} (Fig. 23.9).

FIGURE 23.10 Proper alignment of spinal column in lateral position. (From Phillips N. *Berry & Kohn's Operating Room Technique*. 13th ed. St Louis: Elsevier; 2017:497.)

Once the patient is in the lateral position, flexing the knee and hip of the dependent leg stabilizes the patient. The nondependent leg remains straight and is supported by a pillow placed between the lower extremities. Positioning the legs in this manner prevents bony prominences of the legs from resting on each other and reduces compression of the inferior leg by the superior extremity (see [Fig. 23.9A](#)). Padding should be placed along the lateral aspect of the dependent leg, extending from the knee to the heel to protect the peroneal nerve from external pressure against the table or beanbag.

The dependent arm is positioned on a padded armboard perpendicular to the torso and flexed less than 90 degrees at the elbow.^{35,71} The nondependent arm is placed to avoid interference with surgical exposure—usually parallel to the dependent arm and level with the shoulder on a well-padded arm-holding device. Alternatively, both arms may be positioned on a single armboard with adequate padding between them. Perfusion to the upper extremities, especially the dependent arm, should be periodically assessed by palpating the radial artery and checking capillary refill.^{3,35}

The dependent shoulder and upper extremity are susceptible to compression in the lateral position. A small roll (axillary roll) is placed under the dependent thorax, slightly caudad to, but not directly in the axilla, to lift the thorax and relieve pressure exerted on the shoulder, axillary vessels, and brachial plexus of the

dependent arm.^{3,125} It is useful to obtain blood pressures in the nondependent arm because of potential for neurovascular compression in the dependent arm from the blood pressure cuff.³ It is important to recognize the potential for inaccuracy in blood pressure readings if the arm is not level with the right atrium.¹²⁶

Ancillary positioning devices such as beanbags, pillows, sandbags, braces, and adhesive tape aid in securing the patient and preventing rotation of the trunk. If tape or straps are used to stabilize the torso, they should be placed just caudal to the axilla to reduce the risk of brachial plexus injury.⁴³ Placement across the ribs can impair ventilation. Soft tissue injury may occur if straps or tape is overly tight.

Rhabdomyolysis has been reported after use of the lateral decubitus position.^{127,128} Prolonged operating time, hypotension, and pressure of the operating table against gluteal and flank muscles have been described as contributory factors. The anesthetist, as well as the entire operating team, should ensure that the operating table is well padded and that positioning devices are properly placed. Furthermore, prolonged or excessive hypotension should be avoided to ensure adequate tissue perfusion.

The Sitting Position

The term *sitting position* commonly refers to any position in which the torso is elevated from the supine position and is higher than the legs. A true sitting position in which the torso is elevated at 90 degrees to the legs is rarely used. The modified sitting position, in which the torso is elevated 45 degrees, the head is flexed, and the legs are elevated and flexed is more commonly used. This position is variously described as the *lounging*, *lawn chair*, or *beach chair* position.⁴³ Although its use is reportedly decreasing in popularity, some neurosurgeons favor the sitting position for posterior fossa and cervical spine procedures because this position allows excellent visualization of intracranial structures and facilitates drainage of blood and cerebral spinal fluid from the wound. During shoulder arthroplasty and arthroscopy, the sitting position reduces brachial plexus stretch and aids surgical exposure and manipulation of the arm and shoulder.¹²⁹

Placement of the patient in the sitting position involves flexion of

the operating room table, elevation of the backrest and legs, and sometimes head-down rotation. For neurosurgical procedures, a three-pin head holder is generally used to secure the head. The device provides better head stabilization compared with other headrests, but jugular venous obstruction can occur if the head is excessively flexed on the neck. At least two fingerbreadths of space should be allowed between the neck and mandible (Fig. 23.11).^{8,9,110,111}

FIGURE 23.11 A, Sitting position with Mayfield head pins.

The patient is typically semirecumbent rather than sitting because the legs are kept as high as possible to promote venous return. Arms must be supported to prevent shoulder traction. Note that the head holder support is preferably attached to the back section rather than the thigh section of the table so that the patient's back may be adjusted or lowered emergently without first detaching the head holder. **B**, Sitting position adapted for shoulder surgery. Note the absence of pressure over the ulnar area of the elbow. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier; 2011:309.)

A horseshoe headrest is often used to support the head for shoulder procedures performed in the sitting position. Straps or adhesive tape secure the head to the headrest. Vigorous surgical manipulation of the arm and shoulder can move the patient's body toward the operative side of the table. If the head is firmly secured to the headrest, excessive traction or stretch can be placed on the neck and brachial plexus. If the restraining straps are loose, the head can become partially or completely dislodged from the headrest, introducing the potential for cervical spine injury. Accidental extubation can occur if the endotracheal tube is secured by a supporting device and the head is displaced.

Serious complications associated with the sitting position are among the reasons that the position is falling out of favor. VAE is the most feared complication, but pneumocephalus, quadriplegia, and peripheral nerve injuries are also possible. Profound hypotension and bradycardia from activation of the Bezold-Jarisch reflex may occur when shoulder surgery is performed in the sitting position under an interscalene block.^{119,129}

The Prone Position

The prone position provides optimal exposure for a variety of procedures performed on the spine, certain orthopedic procedures, and some rectal procedures. The prone position has also been advocated for intracranial procedures, owing to the decreased risk of venous air embolism compared with the sitting position.¹¹⁰ Many modifications of the prone position exist (Fig. 23.12). Anesthetists must become familiar with the various methods of securing the

patient in the prone position and recognize the potential hazards of each variation or device.

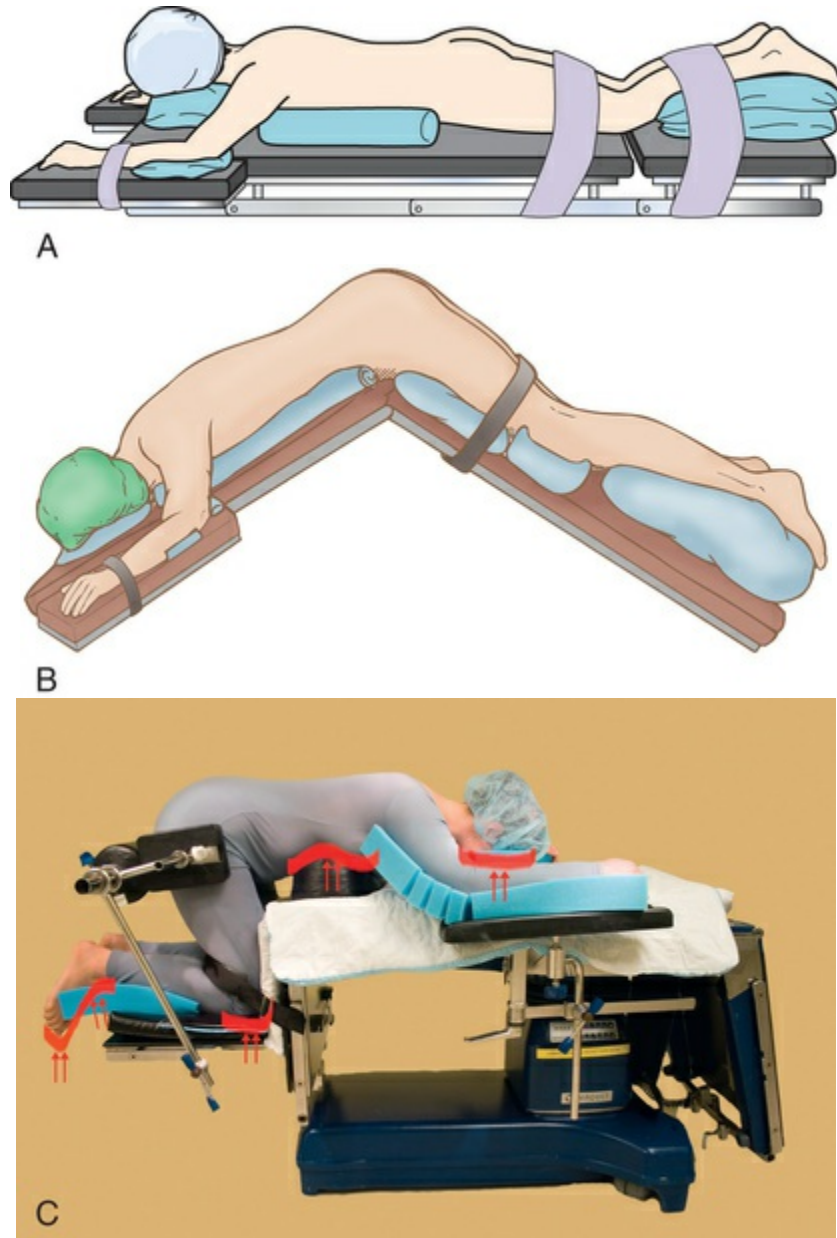

FIGURE 23.12 Variations of the prone position. **A**, Classic prone position with the torso supported on chest rolls. **B**, Jackknife position. **C**, Knee-chest position. (A, From Phillips N. In the prone position, the torso is typically supported on a frame

or with rolls that extend from the shoulders to the iliac crests. Alternatively, supports can be placed crosswise at the pelvis and shoulders. The lower legs are supported with pillows, and the upper extremities may be tucked at the sides or supported on armboards with the arms flexed at the shoulders and elbows. Care must be taken to pad pressure points at elbows, knees, and ankles. Breasts and genitalia must be positioned to limit pressure on them.^{71,75}

When a posterior approach is planned and the prone position is necessary, the patient is anesthetized on the gurney and then log-rolled onto the bed, frame, or rolls with good body alignment maintained. Thoughtful planning of monitor placement allows turning without removal of monitors during this critical period and avoids delays. Typically, the patient is disconnected from the breathing circuit to avoid accidental extubation. The anesthetist should control the airway, head, and neck, as well as coordinate the turn.

Head, neck, shoulder, and arm mobility must be assessed preoperatively; arm placement can be limited by ankylosis of shoulder or elbow joints. Depending on the surgeon's preference, the arms may be tucked parallel to the sides with a draw sheet or supported on armboards. If tucked, the arms should be secured in a natural position with the palms facing the thighs. Plastic or metal arm "sleds," with sufficient padding, can be used to protect the arms and vascular access sites from compression by the bodies of the surgical team. If the arms are not tucked at the sides, they should be carefully rotated into position. The preferred arm placement is flexed, slightly abducted, and with the forearms and hands lower than the shoulders and adequately supported.^{38,71} The arms should rest at a comfortable height on the armboards and should not support the weight of the shoulders. Padding should be placed under the shoulders to prevent sagging of the shoulders and stretching of the brachial plexus.^{38,71,75}

Particular care must be taken to maintain alignment of the head and neck in the prone position. The head should be supported in a neutral position with a head-holding device. Hyperextension or lateral rotation of the neck should be avoided, because either may compromise spinal cord blood flow, especially in elderly

individuals with narrowing of the spinal canal due to osteoarthritis.⁷¹ Stretch injuries of the brachial plexus may also occur with lateral head rotation.^{43,71,86}

A primary goal of positioning a patient prone is to avoid pressure on the abdomen, which can impede venous return, increase venous pressures, and interfere with ventilation by inhibiting movement of the diaphragm.^{3,38} Valves are not present in the intervertebral veins that drain the vertebral and spinal cord venous plexuses into the lumbar veins. External abdominal pressure is transmitted to the vena cava and communicated to the lumbar epidural veins.^{38,43} Positioning devices that allow the abdomen to hang freely are associated with greater decreases in inferior vena cava pressures than those that compress the abdomen and therefore prevent engorgement of spinal venous plexuses.⁴³ Engorged epidural veins are fragile and easily traumatized, and the ensuing blood loss will decrease surgical exposure and contribute to hypotension. Studies suggest that in the prone position, the degree to which pulmonary mechanics are altered depends on the positioning device used, not on body habitus.^{3,38} The Jackson table resulted in the smallest change in pulmonary compliance and peak airway pressures when compared with the Wilson frame and chest rolls. The investigators hypothesized that the Jackson table allows the abdomen to hang freely, permitting better diaphragmatic excursion and lower intraabdominal and intrathoracic pressures.³

Meticulous attention must be paid to protection of the eyes, because corneal abrasions and POVL are complications of the prone position.⁹⁰ Several devices, including three-point skull fixation, the horseshoe headrest, and foam cushions, allow the head to be placed in a neutral position while the eyes are kept free of pressure. However, the head may slip or rotate on the horseshoe headrest, allowing pressure to be applied over the globe and placing the patient at risk of POVL. Although three-point skull fixation is often recommended for securing the head and protecting the eyes in the prone position, POVL has occurred despite the use of this device.⁹⁰

Closed-Claims Studies

Surgical positions are associated with numerous potential complications that can be detrimental to a patient's short- and long-term outcomes. Although the potential for various complications is generally well known, the precise incidence and cause of position-related injuries are often difficult to determine. Because the frequency of these events is low, contributing causes are frequently multifactorial, and uniform reporting does not exist. Position-related injuries are thought to be underreported in the scientific literature.^{42,58} Fear of litigation or damage to one's professional reputation may prevent anesthesia providers from reporting such events. However, case reports, closed-claims studies, and retrospective analyses of databases can provide insight into position-related injuries and shed light on precipitating causes and outcomes.

Both the American Association of Nurse Anesthetists Foundation (AANA-F) and the ASA have conducted studies of closed malpractice claims from professional liability insurance companies. These studies provide a rich source of data about position-related complications. The ASA Closed Claims Project (ASA-CCP) was initiated in 1985.^{130,131} Because the ASA-CCP involves primarily anesthesiologists, the AANA-F conducted a similar study to examine outcomes of care provided by CRNAs. Dental claims are excluded from both the AANA-F and ASA-CCP studies.^{130,132}

An analysis of the ASA-CCP revealed that death (26%), nerve injuries (22%), and permanent brain damage (9%) were the major causes of liability.⁵⁸ Nerve damage included injuries to both the peripheral nervous system and spinal cord but not to the brain. Nerves most commonly affected were the ulnar (28%), brachial plexus (20%), lumbosacral nerve root (16%), and spinal cord (13%). Injuries to all other nerves accounted for only 8% of the nerve damage claims. Although claims for nerve injury have remained constant over time, claims for ulnar nerve injury have decreased whereas those from spinal cord injury have increased.^{42,58}

Specific causative factors could not be identified in the majority of claims in the ASA-CCP. When the association of anesthetic

technique with nerve injury was examined, regional anesthesia was more frequently associated with nerve-injury claims—particularly of the spinal cord and lumbosacral nerve root—than general anesthesia. However, 85% of ulnar nerve injuries were associated with general anesthesia. The quality of anesthesia care was judged as appropriate in 66% of all nerve injury claims, as compared with 42% of non-nerve-damage cases. However, care was deemed appropriate in only 46% of spinal cord damage claims. Other factors associated with nerve damage included positioning and positioning devices, intraoperative trauma, and paresthesias during regional block performance.⁴²

The AANA-F closed-claims study compared 151 claims (68%) in which a CRNA was judged to have contributed to the adverse outcome (CRNA-related) with 72 claims (32%) in which the CRNA was judged not to have contributed to the adverse event (non-CRNA related).¹³³ Death (32%), nerve injury (12%), brain injury (12%), and eye injury (10%) were the primary outcomes of CRNA-related claims. No significant difference in the type of outcome was found between CRNA-related claims and non-CRNA-related claims. Reviewers evaluated the appropriateness of care and found care inappropriate in 52% of CRNA-related cases, appropriate for 30%, and impossible to assess in the remaining cases.¹³⁴

The AANA-F and ASA-CCP studies highlight the importance of following standards of care and properly documenting perioperative activities. Standards for nurse anesthesia practice identify thorough, complete, and accurate documentation as an expectation of nurse anesthesia practice.¹³⁵ In the event of a malpractice claim, thorough documentation assists reviewers in determining the quality of care provided.

Several limitations are inherent in closed-claims studies. First, the purpose of data collected by professional liability insurance companies is to investigate malpractice claims, not to improve patient safety. Not all anesthesia-related injuries result in a liability claim. Therefore, data from closed-claims studies are not a random or even representative sample, because only those cases in which a claim was filed and subsequently closed are included. Second, the incidence of various outcomes cannot be described because the total number of cases performed by insured providers is unknown.¹³³ For

these two reasons, closed-claims data are not suitable for calculation of risk. However, analysis of closed-claims data can identify issues confronting practitioners and suggest methods for improving practice or making changes in systems.^{133,136}

Other factors limit the conclusions that can be drawn from closed-claims data. Many cases that might be included in the database are eliminated because of inadequate documentation. In addition, closed-claim studies and quality assurance data categorize claims by type of injury rather than cause. Inadequate documentation and inability to determine the role played by various factors can limit the ability of reviewers to determine the cause of injury.⁵⁸ Finally, reviewers' knowledge of patient outcomes may bias their opinions on the quality of care provided.¹³²

In both studies, monetary awards were higher in those cases resulting in more severe outcomes and when anesthesia care was determined to be less than appropriate. Although some suggest that position-related nerve injuries are largely preventable,³⁸ the ASA analysis of nerve injury claims revealed that payouts were frequently made even when anesthesia care was judged appropriate.⁴² This suggests that current knowledge of methods for preventing nerve injury is inadequate and that further research into mechanisms of nerve injury is needed.

Summary

Surgical positioning alters normal cardiovascular and respiratory physiology. These positional changes can be augmented by anesthetic techniques, patient pathophysiology, and body habitus. The implications of physiologic changes associated with each position should be considered when the procedure is planned, when positioning is initiated, and when the patient is returned to the supine posture. Anesthetists must recognize and anticipate both the publicized complications and the potential for damage inherent in each surgical position. Prevention is the best method for decreasing both the incidence of position-related injuries and the associated physical, psychological, and economic costs to the patient.

Airway Management

Jeremy S. Heiner

Effective airway management is a cornerstone of safe anesthesia practice, and it is an essential skill for all anesthesia providers. Nurse anesthetists are responsible for managing the airway in the operating room (OR) and in many other health care settings. The maintenance of ventilation and oxygenation are primary goals during airway management for both difficult and routine (nondifficult) airways. Effective preparation for the management of a difficult airway occurs through knowledgeable and regular management of normal airways. Therefore it is important that anesthesia providers be familiar with appropriate decision-making strategies and methods for providing adequate ventilation during airway management. These strategies and methods pertain not only to routine airways but also to anticipated difficult airways, unanticipated difficult intubations or ventilations, failed airways, patients at risk for aspiration of gastric contents, and patients who present with any other type of airway compromise.

An understanding of airway anatomy and appropriate airway assessment techniques facilitates the development of a comprehensive airway management plan. Complete and thorough airway assessments guide airway management plans, which may involve placing an airway while the patient is awake or after the induction of anesthesia, using any one of a variety of airway adjuncts. Familiarization with the different airway adjuncts is important so that anesthesia providers may become comfortable with their use in a variety of airway management situations and to facilitate safe practices for the establishment of a protected airway.

Removal of an airway management device should be incorporated as part of the overall airway management plan. Consideration should be given to patient, surgical, and anesthetic risk factors before removing any airway adjunct. Ultimately, the

removal of an airway is determined by the patient's ability to meet extubation criteria and maintain adequate spontaneous ventilation and oxygenation. Finally, the risk factors and complications of airway management are important to understand in order to develop the most appropriate and safe airway management plan for the patient.

Anatomy and Physiology of the Airway

The airway is divided into upper and lower sections. Anatomic structures above the level of the cricoid cartilage constitute the upper airway and include the nose, mouth, pharynx, hypopharynx, and larynx. Anatomic structures below the level of the cricoid cartilage constitute the lower airway and include trachea, bronchi, bronchioles, terminal bronchioles, respiratory bronchioles, and alveoli. This section reviews primary structures, innervation, blood supply, and normal and abnormal function of the upper airway structures.

Developmental Anatomy

Upper Respiratory Tract

Unlike the structures of the lower respiratory tract, the upper respiratory tract arises from bony structures of the head. Endochondral bone is preformed in cartilage. The bones form initially from the optic, olfactory, and otic capsules. These capsules merge with the midline cartilaginous structures to form the embryologic vestiges of the ethmoid, the sphenoid, the petrous portion of the temporal bone, and the base of the occipital bone. Direct ossification of membranous tissue known as the *mesenchyme* occurs during early embryologic development to form membranous bone. The membranous bones include the temporal bone, the parietal bone, the frontal bone, and portions of the occipital bones and the pharyngeal arches. The pharyngeal arches are complex structures also known as the *branchial arches* that extend anterior to posterior. Development of these structures begins at day 22 (week 4 after fertilization).¹

Embryologically, there are six arches that develop from five structures. Arches one through four and six go on to develop the airway structures, and the fifth arch disappears with fetal development. The arches all contain a covering of tissue that will eventually become the nerves, muscles, and cartilage of the airway.

These will become the tissues of the oropharynx, the middle ear, the hyoid bone, and the laryngeal cartilages. Arch one becomes the jaws; arch two becomes the facial structures and the ears; arch three becomes the hyoid bone and structures of the upper pharynx; arches four and six become the structures of the larynx and the lower pharynx; and arch five disappears. The tongue is formed from the mesoderm of multiple arches. The anterior two-thirds of the tongue is developed from the first arch. The mesoderm of the third and fourth arches comprises the posterior third of the tongue. Spaces found between the arches are known externally as *clefts* and internally as *pouches*. The cleft between the first two arches becomes the external auditory meatus. The internal pouch between the first and second arches forms the majority of the tympanic cavity and the Eustachian tubes. The other clefts disappear as the fetus develops. The pouches contribute to the development of the glandular structures of the head and neck. The palatine tonsils arise from pouch two; the inferior parathyroid glands and the thymus arise from pouch three; the superior parathyroid glands arise from pouch four; and the ultimobranchial structures arise from the inferior portion of pouch four.¹

Nose.

The nose and mouth are the external openings to the respiratory tree. The large surface area of the nasal mucosa warms and humidifies inspired air but also provides almost two-thirds of the resistance to breathing. The nose is the primary passage by which air enters the lungs. Because of the surface area over the turbinates and the sinuses, the nasal passages are well-suited for the humidification of air and primary filtration. As air passes through the nose, it meets the turbinates, which cause directional changes in the airflow. Branches of three arteries (e.g., the maxillary [sphenopalatine], ophthalmic, and facial [septal]) provide a rich supply of blood to the nasal mucosa. The innervation of the nose is from the nasopalatine and ethmoidal branches of the facial nerve. These nerves also supply the nasopharynx, nasal septum, and palate. Sensory nerve supply to the nasal mucosa is from the ophthalmic and maxillary divisions of the trigeminal nerve. Parasympathetic innervation arises from the seventh cranial nerve

and the pterygopalatine ganglion. Sympathetic innervation is derived from the superior cervical ganglion. Sympathetic stimulation results in vasoconstriction and shrinkage of the nasal tissue. Depression of the sympathetic nervous system, as occurs with general anesthesia, may cause engorgement of the nasal tissues, increasing the bleeding potential during manipulation of nasal airways or endotracheal tubes (ETTs).

Mouth.

The oral cavity is separated from the nasal passages by the hard and soft palates. The hard palate is stationary and remains in the same position. The soft palate covers the posterior third to half of the oral cavity. The soft palate rises during eating to prevent food and liquids from passing from the mouth into the nose, and thereby decreases the chance of aspiration. With age, obesity, and other conditions, this structure may stretch and become more movable. When an individual is asleep or paralyzed, as with general anesthesia, this structure can fall back against the nasal passages, blocking air movement and causing symptoms of sleep apnea. The tongue is a large muscular organ that fills most of the oral cavity and is involved in the tasting and ingestion of food. It relaxes when the individual is either asleep or paralyzed, which increases the potential for airway obstruction. The uvula protects the passageway from the oral cavity into the oropharynx. This pendulous piece of tissue extends from the posterior edge of the middle of the soft palate into the oral cavity. If swollen, enlarged, or injured, it can be a cause of airway obstruction. The tonsils are walnut-shaped structures that sit on both sides of the posterior opening of the oral cavity. They are partially buried in the soft tissue at the base of the tongue, and are protected by the anterior and posterior tonsillar pillars. Underdevelopment of the tongue, maxilla, and/or mandible can result in upper airway obstructive disorders such as Pierre-Robin sequence, Apert syndrome, and Treacher Collins syndrome. Other disorders, such as Beckwith Wiedemann syndrome and Down syndrome, can result in airway obstruction as a result of macroglossia.²

Pharynx.

The pharynx is divided into three compartments: the nasopharynx, oropharynx, and hypopharynx (laryngopharynx). The pharynx extends from the base of the skull to the level of the cricoid cartilage. The nasopharynx lies anterior to C1 and is bound superiorly by the base of the skull and inferiorly by the soft palate. The openings to the auditory (Eustachian) tubes and the adenoids are found in the nasopharynx. Sensory innervation of the mucosa is derived from the maxillary division of the trigeminal nerve. The oropharynx lies at the C2 to C3 level and is bound superiorly by the soft palate and inferiorly by the epiglottis. It opens into the mouth anteriorly through the anterior and posterior tonsillar pillars. The hypopharynx lies posterior to the larynx and is bound by the superior border of the epiglottis and the inferior border of the cricoid cartilage at the C5 to C6 level. The upper esophageal sphincter lies at the lower edge of the hypopharynx and arises from the cricopharyngeus muscle. This muscle acts as a barrier to regurgitation in the conscious patient.

Numerous nerves supply motor and sensory fibers to the airway. The glossopharyngeal, vagus, and spinal accessory nerves share nuclei in the medulla, and innervate all the muscles of the pharynx, larynx, and soft palate. Afferent (sensory) stimuli elicited when the posterior wall of the pharynx is touched are carried by the glossopharyngeal nerve to the medulla, where they synapse with nuclei of the vagus nerve and the cranial portion of the spinal accessory nerve. The efferent response returns primarily through the vagus nerve, resulting in the gag reflex as the muscles of the pharynx elevate and constrict.

Two branches of the vagus nerve innervate the hypopharynx: the superior laryngeal nerve and the recurrent laryngeal nerve (RLN) (Fig. 24.1). The superior laryngeal nerve divides into the internal and external branches. The internal branch of superior laryngeal nerve provides sensory input to the hypopharynx above the vocal folds (cords), which includes the base of tongue, epiglottis, aryepiglottic folds, and arytenoids. The external branch provides motor function to the cricothyroid muscle of the larynx.

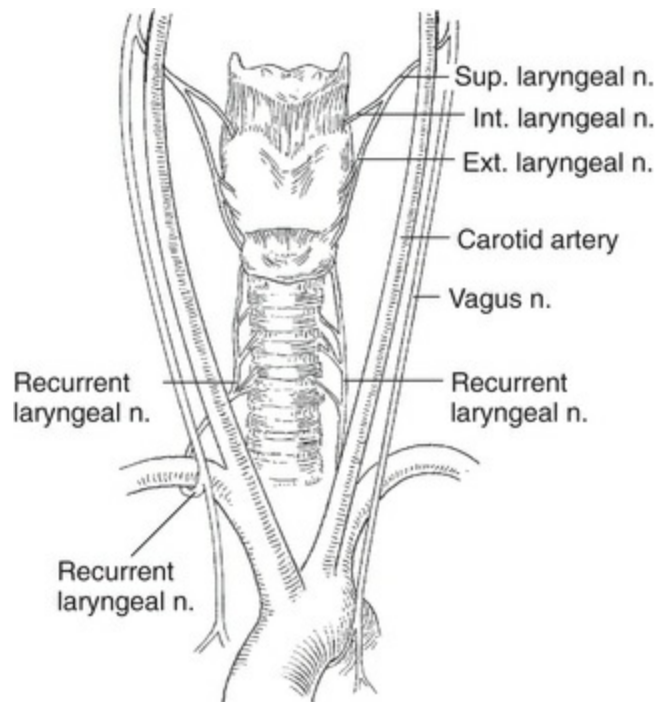

FIGURE 24.1 Anatomy of the right and left, superior and recurrent laryngeal nerves. *ext*, External; *int*, internal; *n*, nerve; *sup*, superior.

The RLN provides sensory innervation to the subglottic area and the trachea. The RLN is so named because it recurs (loops around) other structures. The right RLN branches from the vagus nerve and recurs (loops) around the brachiocephalic (innominate) artery, and the left RLN branches from the vagus nerve and recurs (loops) around the aorta. Traction on either of these structures during thoracic surgery can cause injury to the RLN, causing hoarseness or stridor. The motor component of the RLN provides motor function to all the muscles of the larynx except the cricothyroid muscle.

The superior laryngeal nerve and the RLN may be damaged by surgery, neoplasms, and neck trauma. Dissecting aortic arch aneurysms and mitral stenosis place traction on the RLN, causing hoarseness. Unilateral injury to the RLN usually results in hoarseness, but does not compromise respiratory status. The vocal cords compensate by shifting the midline toward the uninjured side. In the acute phase of bilateral injury to the RLN, unopposed tension and adduction of the vocal cords result in stridor, which may deteriorate into severe respiratory distress and possibly death. Patients with chronic injury develop compensatory mechanisms that allow for normal respiration and gruff or husky speech. Injury

to the superior laryngeal nerve does not usually cause respiratory distress.

Larynx.

The larynx begins with the epiglottis and extends to the cricoid cartilage. The larynx is composed of (1) three single cartilages (e.g., thyroid, cricoid, and epiglottis), (2) three paired cartilages (e.g., arytenoid, corniculate, and cuneiform), and (3) intrinsic and extrinsic muscles (Figs. 24.2 and 24.3). These structures function in an intricate manner to provide (1) protection to the lower airway from aspiration, (2) patency between the hypopharynx and trachea, (3) protective gag and cough reflexes, and (4) phonation. In the adult, the larynx begins between the third and fourth cervical vertebrae and ends at the level of the sixth cervical vertebra (e.g., cricothyroid muscle). The anterior and lateral larynx is formed by the thyroid cartilage. Anteriorly, the thyroid cartilage fuses and forms the thyroid notch. Posteriorly, the thyroid cartilage rises toward the hyoid bone at the base of the tongue as the posterior cornu. The thyroid cartilage is connected to the hyoid bone by the thyrohyoid fascia and muscles of the larynx.

FIGURE 24.2 A, Posterior view of the pharyngolaryngotracheal region showing the close relationship between the pharynx, larynx, esophagus, and trachea. (a) Epiglottis. (b) The inferior pharyngeal constrictor muscle protects the posterior pharyngeal wall.

(c) The esophagus is in close contact with the (e) posterior tracheal wall. (d) The recurrent laryngeal nerves ascend in the tracheoesophageal groove on each side after branching off the vagus nerve. **B**, Superior and internal view of the pharynx and larynx showing the laryngeal cartilages covered by the mucosa (*h, i, and j*) in the anterior pharyngeal wall, (*l*) the posterior pharyngeal wall, and (*k*) the pyriform recess. (From Tarrazona V, Deslauriers J. Glottis and subglottis: a thoracic surgeon's perspective. *Thorac Surg Clin.* 2007;17:561–570.)

FIGURE 24.3 Posterior view of the larynx showing the laryngeal muscles.

The posterior portion of the cricoid cartilage forms the posterior border of the larynx. Internal to the larynx are the epiglottis and three paired cartilages. The epiglottis exists as a single leaf-like cartilage. The epiglottis rests above the glottic opening, where it closes the glottic aperture during swallowing. The superior vallecula is formed by the space between the epiglottis and the base of the tongue. The inferior vallecula is formed by the space between the inferior edge of the epiglottis and the true vocal cords.

The intrinsic muscles of the larynx control the tension of the vocal cords, as well as the opening and closing of the glottis (Table 24.1). In contrast, the extrinsic muscles of the larynx connect the larynx, hyoid bone, and neighboring anatomic structures (Box 24.1). The primary function of the extrinsic muscles is to adjust the position of the larynx during phonation, breathing, and swallowing.

TABLE 24.1**Intrinsic Muscles of the Larynx**

Role	Muscles Involved	Main Function
Respiration	Posterior cricoarytenoids	Abduction of vocal cords
Phonation	Lateral cricoarytenoids	Adduction of vocal cords
	Lateral thyroarytenoids	Shortening and adduction of vocal cords
	Medial cricoarytenoids	Shortening of vocal cords
	Cricothyroids	Lengthening and increasing tension of vocal cords
Sphincteric function	Interarytenoid	Closing of posterior commissure of the glottis
	Arytenoepiglottics	Closing of laryngeal vestibule

From Tarrazona V, Deslauriers J. Glottis and subglottis: a thoracic surgeon's perspective. *Thorac Surg Clin.* 2007;17(4):561–570.

Box 24.1**Extrinsic Muscles of the Larynx****Muscles That Elevate the Larynx (Elevators)**

- Stylohyoid
- Digastric
- Mylohyoid
- Geniohyoid
- Stylopharyngeus
- Thyrohyoid

Muscles That Depress the Larynx (Depressors)

- Omohyoid
- Sternohyoid
- Sternothyroid

From Tarrazona V, Deslauriers J. Glottis and subglottis: a thoracic surgeon's perspective. *Thorac Surg Clin.* 2007;17(4):561–570.

Blood supply to the larynx originates from the external carotid, which branches into the superior thyroid artery. The superior

thyroid artery eventually gives rise to the superior laryngeal artery, which supplies blood to the supraglottic region of the larynx. The inferior laryngeal artery, a terminal branch of the inferior thyroid artery, supplies the infraglottic region of the larynx.

Lower Respiratory Tract

As the fetus develops, the respiratory system evolves into complex developmental interactions between the endodermal-derived epithelium and the mesoderm. Both contribute to lung development. The lungs and airways develop through a five-stage process. These include the embryonic, pseudoglandular, canalicular, and terminal sac phases, and maturation.³

During the embryonic phase, the endodermal respiratory diverticulum (laryngotracheal groove) develops. This occurs during week 4 through week 7. The laryngotracheal groove develops from the ventral surface of the foregut. During this period, fibroblast growth factor (FGF-10) causes stimulation and proliferation of cells that will eventually express fibroblast homologous factor (FHF). As the laryngotracheal groove grows and develops, it becomes the primitive lung bud. By day 28, it has grown caudally to the splanchnic mesoderm. It divides into the right and left bronchial buds. This then progresses through the development and expression of the epithelial lining of the lower respiratory system. Cartilage, muscle, and connective tissue arise from the same tissues that form the smooth muscle of the blood vessels. The bronchopulmonary segments appear by day 42 of fetal development.

During the pseudoglandular stage, there is rapid growth and proliferation of the peripheral airways. This occurs during week 6 through week 16. Repeated branching of the distal ends of the epithelial tubes results in 16 or more generations of the bronchial tubes and the development of the terminal bronchioles. The airways are filled with liquid at this time. The cellular structure is characterized by tall columnar epithelium.

The next phase of development is known as the *canalicular stage*. This occurs most often during week 16 through week 26. At this time, the airways widen and lengthen. This space will eventually become the large volume of air space in the expanded lung after

birth. Terminal and respiratory bronchioles and terminal saccules develop. Cuboidal cells of the terminal sacs differentiate into alveolar type II cells. Secretion of surfactant begins at this time. Type II alveolar cells that are adjacent to a vessel flatten and differentiate into type I cells. As the type II and type I cells develop, vascularization appears. The vascularization is associated with the development of the respiratory bronchioles and the alveoli necessary for air exchange after birth. Along with other growth factors, vascular endothelial growth factor participates in the formation of blood vessels that will surround the alveoli. At the end of this phase, air exchange is possible, though inefficient.

The terminal sac phase occurs during week 24 through week 36. Branching of the respiratory bud continues, and further development of the terminal buds is expressed as primitive alveoli. Capillaries begin to develop around the terminal buds, and proliferate at the same time as the primitive alveoli develop. Cells further differentiate throughout this period, and by week 26, a primitive blood-gas barrier has developed.

By week 36, mature alveoli are seen. This requires fibroblast growth factor (FGF) and platelet-derived growth factor. Development of alveoli will continue for approximately 3 years after birth. A change in the relative relationship of parenchyma to total lung volume contributes to lung growth until the second year of life. From the third year of life until adulthood, lung growth continues.³

Trachea.

The trachea originates at the inferior border of the cricoid cartilage and extends to the carina (Fig. 24.4). It is approximately 10 to 20 cm long in adults. The cricoid cartilage is the only cartilage of the trachea that is a complete cartilaginous ring. The remainder of the trachea is composed of 16 to 20 C-shaped cartilaginous rings. The posterior side of the trachea lacks cartilage, thereby accommodating the esophagus during the act of swallowing. The cartilaginous rings and plates continue until the bronchi reach 0.6 to 0.8 mm in size. At this point, the cartilage disappears, and the bronchi are termed *bronchioles*. The function of the bronchi is to provide humidification and warming of inspired air as it passes to the alveoli.

FIGURE 24.4 Principal features of the larynx and trachea. Anterior view. Tracheobronchial angles vary widely. The angle of the right mainstem bronchus is approximately 25 to 30 degrees, whereas the angle of the left mainstem bronchus is 45 degrees. (From Minnich DJ, Mathisen DJ. Anatomy of the trachea, carina, and bronchi. *Thorac Surg Clin.* 2007;17:571–585.)

The angle of bifurcation of the right mainstem bronchus is approximately 25 to 30 degrees. The bifurcation to the right upper lobe is approximately 2.5 cm from the carina. The angle of the left mainstem bronchus is 45 degrees. The left mainstem bronchus is approximately 5 cm long, before it bifurcates into the left superior and inferior lobe bronchi.

The tracheobronchial trees receive sympathetic innervation from the first through fifth thoracic ganglia. Parasympathetic innervation is derived from branches of the vagus nerve. The carina is richly innervated, making it sensitive to sensory stimulation.

Diaphragm

The diaphragm arises from four structures: (1) the septum transversum, (2) the dorsal esophageal mesentery, (3) the

pleuroperitoneal folds, and (4) the body wall mesoderm. The diaphragm develops in the cephalic region and descends into position between the abdominal and pleural cavity contents as the embryo develops. The nerve supply for the diaphragm arises from the cords of the third, fourth, and fifth cervical nerves, and travels with the descending diaphragmatic structure as the phrenic nerve. Owing to this process of descent, the phrenic nerves lie within the pericardium as the fetus matures and after birth. Because of the development of the diaphragm in the cephalic position and the merging of four structures, drugs that impair fetal development can result in many potential congenital deformities, including diaphragmatic hernia.³

Airway Evaluation

Evaluation of the airway is central to any airway management plan. A proper airway evaluation should be conducted in a thorough and systematic fashion for every patient to determine potential problems. A substantial amount of research has been conducted over the past 20 years and has identified how individual airway examinations can be poor and unreliable predictors of difficulty. Currently, no single examination consistently demonstrates high sensitivity and specificity with minimal false-positive or false-negative reports.^{4,5} Instead, many researchers have advocated for a more comprehensive airway management plan that involves the use of multiple airway assessments to identify a difficult airway.⁶⁻⁸ One area of airway management that may now render some airway examinations obsolete is the advent of video laryngoscopy (VL). Ultimately, an appropriate airway management plan considers multiple airway examinations, the availability of equipment, and presence of experienced personnel.

Current recommendations concerning evaluation of the airway are to employ several assessments (Table 24.2).⁸⁻¹¹ In order to recognize possible difficult airway conditions and to make “sensible airway management decisions,” these assessments should be tailored to the patient, the operative procedure, and the situation in order to formulate a comprehensive airway management plan.^{11,12}

TABLE 24.2
Components of the Preoperative Airway Physical Examination*

Airway Examination Component	Indication of Airway Difficulty
Length of upper incisors	Relatively long
Relation of maxillary and mandibular incisors during normal jaw closure	Prominent “overbite” (maxillary incisors anterior to mandibular incisors)
Relation of maxillary and mandibular incisors during voluntary protrusion (ULBT)	Inability to protrude mandibular incisors anterior to maxillary incisors
Interincisor distance	Less than 3 cm
Visibility of uvula	Not visible when tongue is protruded with patient in sitting position (e.g., Mallampati class III or greater)
Shape of palate	Highly arched or very narrow
Compliance of mandibular space	Stiff, indurated, occupied by mass, or nonresilient
Thyromental distance	Less than three ordinary fingerbreadths

Length of neck	Short
Thickness of neck	Thick (greater than 43 cm in circumference)
Range of motion of head and neck	Patient cannot touch tip of chin to chest or patient cannot extend neck

*This table displays some findings of the airway physical examination that may suggest difficulty with laryngoscopy and intubation. The decision to examine some or all of the airway components shown in this table depends on the clinical context and judgment of the practitioner. The table is not intended as a mandatory or exhaustive list of the components of an airway examination. The order of presentation in this table follows the “line of sight” that occurs during conventional oral laryngoscopy.

ULBT, Upper lip bite test.

From Berkow LC. Strategies for airway management. *Best Pract Res Clin Anaesthesiol.* 2004;18(4):531–548.

There is no system that reliably and consistently predicts airway difficulty with 100% certainty.¹³ Instead of focusing on conditions that affect the ability to intubate only, a more all-encompassing assessment of the airway has been described.¹⁴ The following four areas of airway management focus the airway assessment on conditions that could lead to difficulty with:

1. bag mask ventilation (BMV);
2. direct laryngoscopy (DL) and video laryngoscopy (VL) with tracheal intubation (TI);
3. supraglottic airway ventilation; and
4. cricothyrotomy airway placement (e.g., needle or surgical).

A series of acronyms was developed to facilitate a thorough and systematic assessment of airway features (Box 24.2) that may lead to difficulty with hand mask, supraglottic device, ETT, and cricothyrotomy airway ventilation and placement.¹⁴

Four Areas of Airway Management With Factors Associated With Difficulty

Indication of Difficulty With Bag Mask Ventilation

- Mask seal impeded by beards, altered anatomy, or nasogastric tubes
- Obstruction of the upper or lower airway
- Obesity with redundant upper airway soft tissue and greater chest and abdominal mass compressing the lungs
- Age greater than 55 related to loss of upper airway tissue elasticity
- No teeth, leading to improper facial structure for the bag mask
- Stiff lungs (e.g., increases in airway resistance and decreases in pulmonary compliance)
- Sleep apnea or snoring

Indication of Difficulty With Direct and Video Laryngoscopy With Tracheal Intubation

- Look externally (if it looks difficult it probably is)
- Evaluate the 3-3-2 rule*
- Mallampati score (classes III and IV indicating increased difficulty)
- Obstruction of the upper airway
- Obesity with increased neck circumference and redundant soft tissue
- Scarring, radiation, or masses on the neck
- Neck mobility that is impaired by disease of immobilization (direct laryngoscopy)
- Operator experience

Indication of Difficulty With Supraglottic Airway Device Placement and Ventilation

- Restricted mouth opening
- Obstruction of the upper airway
- Distortion of airway anatomy preventing an adequate seal
- Stiff lungs (e.g., increases in airway resistance or decreases in pulmonary compliance)

Indication of Difficulty With Cricothyrotomy Airway Placement

- Distortion of neck anatomy (e.g., hematoma, infection, abscess, tumor, scarring from radiation)
- Obesity or a short neck limiting cricothyroid identification
- Trauma in or around the cricothyroid area
- Impediments causing limited access to the neck (e.g., halo device, fixed flexion abnormality)
- Surgery causing limited access to anatomic landmarks

*3-3-2 rule = three fingerbreadths between incisors; three fingerbreadths between tip of the chin (mentum) and chin-neck junction (hyoid bone); two fingerbreadths between chin-neck junction (hyoid bone) and thyroid notch.

Adapted from Walls RM, Murphy MF. In: Walls R, Murphy M, eds. *Manual of Emergency Airway Management*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2012:8–21.

In addition to an airway examination, a history of a difficult airway is a strong indication for current airway difficulties. Therefore, an evaluation of the patient's anesthetic history should be included in the airway assessment.¹⁵ A careful review of prior anesthetic records and information obtained directly from the

patient or family members can reveal past difficulties and offer insight concerning specific techniques used to previously manage the patient's airway. Clues that may indicate a history of difficult airway management may include chipped or broken teeth, bruised lips, previous sore throat after general surgery, past postoperative dysphonia, a memory of TI, an unexpected admission to an intensive care unit (ICU), or a pharyngeal, esophageal, or tracheal perforation.^{15,16} Weight gain or loss can influence airway anatomy, and the patient may not necessarily present with the same airway conditions as in the past. Furthermore, pathologies or conditions such as an airway tumor or hematoma, which may have previously caused difficulty, but have since been treated or removed, may not influence the current airway to the same degree they once did.

Multiple airway assessments exist that help the anesthetist predict difficulty with BMV, DL and VL with TI, supraglottic airway ventilation, and cricothyrotomy airway placement (see [Box 24.2](#)). The following sections consider airway evaluations specific to each of the four areas of airway management.

Bag Mask Ventilation Assessment

Adequate BMV skills are important for effective airway management. A sufficient seal between the facemask and the patient's face is imperative. Proper BMV can be achieved by placing the left thumb and index finger around the collar of the facemask at both the mask bridge and chin curve, while compressing the left side of the mask onto the face with the palm of the left hand ([Fig. 24.5](#)). The middle and ring fingers can then be placed on the bony part of the mandible to help compress the mask to the patient's face and to raise the chin. The fifth finger can be placed at the angle of the mandible to provide an anterior jaw-thrusting maneuver. Mask retaining straps can be placed behind the patient's head and then be connected to the collar of the mask to apply pressure at various angles and promote a better mask seal.

FIGURE 24.5 Suggested hand technique for facemask ventilation. **A**, The thumb, index finger, and thenar eminence of the palm encircle the collar, while the hypothenar eminence extends below the mask. **B**, One-handed mask technique. The thumb and index fingers encircle the collar of the mask, while the middle finger grasps the mental protuberance (chin), and the ring and little fingers grip the body of the mandible in order to pull the mask securely onto the face while gently extending the head. **C**, Jaw thrust with one-handed mask technique. Middle and ring fingers grasp the mandible and pull upward into the mask, while the little finger is moved to the angle of the jaw and pulls backward and upward to maintain subluxation (jaw thrust). (From Hagberg CA. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Elsevier; 2013:335.)

If BMV is believed to be inadequate, then a series of steps can be performed ([Box 24.3](#)) to facilitate ventilation. First, the patient's head and neck can be repositioned into a sniffing position. Second, if the tongue or airway soft tissue is thought to be the cause of obstruction, then the placement of an oropharyngeal airway (OPA) may help bypass the obstruction. However, the placement of an

OPA can be considered prior to any attempt at BMV. Third, if BMV continues to remain inadequate, then place both thumbs on either side of the facemask bridge with both index fingers on either side of the mask chin curve on the body of the mask. The middle fingers can then be placed on either side of the mandible at the chin, the ring fingers on the bony part of the mandible, and the fifth fingers on each angle of the mandible to provide a jaw-thrust while a second provider inflates and depresses the anesthesia bag.

Alternatively, a second provider may stand at the side of the bed to provide the mask seal while the provider at the head of the bed inflates the anesthesia bag in preparation for intubation (Fig. 24.6).

Fig. 24.7 depicts the placement of a two-provider orientation for airway management. If ventilation continues to remain inadequate, then a supraglottic airway device (SAD) may be placed while the decision to awaken the patient is considered. In the event that all these maneuvers fail, then a cricothyrotomy should be considered.

Box 24.3

Proper Sequence for Bag Mask Ventilation When Difficulty Is Encountered

1. Assure proper positioning of the patient that avoids compression of the airway.
2. Attempt ventilation with one (left) hand (can consider use of mask strap on opposite side of mask [right] to improve mask seal).
3. Reposition the head into a sniffing position.
4. Place oropharyngeal airway (may consider earlier placement).
5. Proceed with two-handed mask ventilation.
6. Consider placement of a supraglottic device and consider awakening the patient.
7. Proceed with cricothyrotomy access if ventilation and intubation becomes impossible.

FIGURE 24.6 Two-handed mask technique. **A**, Provider above patient. The thumb and index finger of both hands encircle the collar of the mask to create a seal to the face, while the middle and ring fingers grasp the mandible, pulling from below and assisting with the jaw thrust maneuver. The little fingers of both hands grip the angles of the mandible to complete the jaw thrust. **B**, Provider holding mask below and to the side of patient. The thumbs hold the rim of facemask to create a seal to the face, while the index fingers grip the angles of the mandible to perform a jaw thrust. This technique allows the provider above the patient to prepare for airway manipulation (e.g., laryngoscopy, fiberoptic intubation, etc.). (From Hagberg CA, ed. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Elsevier; 2013:336.)

FIGURE 24.7 **A**, Two-person mask ventilation effort with second provider providing a jaw thrust. **B**, Two-person mask ventilation effort with primary provider maintaining a mask seal and performing a jaw thrust while second provider squeezes the anesthesia bag. (Redrawn in Miller RD, Pardo M, eds. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011.)

The incidence of difficult BMV has been described as being between 0.9% and 7.8%, and the incidence of impossible BMV as 0.15%.¹⁷⁻²¹ Difficulty with BMV can result from problems in establishing an appropriate mask seal (such as with the presence of a beard). Inadequate ventilation during BMV is evidenced by (1) minimal or no chest movement; (2) inadequate or deficient exhaled carbon dioxide (e.g., lack of condensation and spirometric reading); (3) reduced or absent breath sounds; and (4) a decreasing oxygen saturation (e.g., less than 92%).^{11,18} If difficulty is believed to be a possibility with BMV, positioning can be improved by elevating the shoulders, neck, and head, which is known as *ramping* the patient (Fig. 24.8). Multiple factors have been identified as predictors for difficulty with BMV (see Box 24.2); these include mask seal impediments, upper airway obstructions, obesity, elderly patients, Mallampati scores of III or IV, a short thyromental distance, snoring, and poor lung compliance.^{17,18,20,21}

FIGURE 24.8 Example of a ramp created using blankets to improve positioning. Optimal positioning is observed when an imaginary horizontal line can be drawn from the sternal notch and extending just anterior to the ear on the face or to the tragus of the ear. Arrows pointing up indicate blanket ramp, arrow pointing down indicates imaginary line

between the ear and sternal notch (From Chestnut DH, et al., eds.
Chestnut's Obstetric Anesthesia: Principles and Practice. 5th ed.
Philadelphia: Elsevier; 2014:693.)

Mask seal impediments such as facial hair, altered facial anatomy, lack of teeth causing the face to cave inward, or a nasogastric tube can cause air leakage out of the mask and prevent adequate positive pressure ventilation. Some of these factors can be modified, such as shaving the patient's beard, delaying removal of dentures, and removing the nasogastric tube. Although shaving a beard may be undesirable, and removal of a gastric tube may cause a buildup of gastric secretions in the stomach, these interventions do allow for a better mask seal and more effective positive pressure ventilation upon induction of anesthesia.

Obstruction may occur in the upper or lower airway, and can severely limit the effectiveness of BMV. Upper airway obstructions should be considered an emergency, recognized early, and managed with extreme care because of the potential to become total airway obstructions. The hallmark signs of an upper airway obstruction in the unanesthetized patient include a hoarse or muffled voice, difficulty swallowing secretions, stridor, and dyspnea. Stridor and dyspnea are ominous signs of severe respiratory obstruction in the hypopharyngeal and/or laryngeal area.¹⁴ There are several potential causes of an upper airway obstruction (Boxes 24.4 and 24.5). The relative management of these conditions is discussed later in this chapter (see [Management of the Difficult and Failed Airway](#)). It is important to treat the airway with care because these conditions have the potential to severely impair ventilation and oxygenation, as well as cause difficulty with

[Box 24.4](#) Laryngoscopy and TI.

Causes of Upper and Lower Airway Obstruction

Upper Airway Obstruction

Facial

- Burns

- Congenital abnormalities
- Trauma

Oropharyngeal

- Abscesses (e.g., peritonsillar)
- Ludwig angina
- Sleep apnea
- Tongue

Pharyngeal and Laryngeal

- Angioedema
- Foreign bodies
- Epiglottitis
- Hematomas
- Hemorrhage
- Laryngospasm
- Laryngotracheobronchitis (croup)
- Subglottis stenosis
- Tumors or lesions

Lower Airway Obstruction

Trachea

- Angioedema
- Aspirated foreign bodies

- Hematoma
- Hemorrhage
- Tumors or lesions

Bronchial and Alveolar

- Acute respiratory distress syndrome (ARDS)
- Aspiration pneumonia
- Asthma
- Bronchospasm
- Chronic obstructive pulmonary disease (COPD)
- Pulmonary edema

Extrapulmonary

- Morbid obesity (BMI greater than 30 kg/m²)
- Pregnancy
- Trauma

From Berkow LC. Strategies for airway management. *Best Pract Res Clin Anaesthesiol.* 2004;18(4):531–548.

Box 24.5

Congenital and Acquired Conditions Associated With Difficult Airway Management

Conditions With Associated Pathology Relating to Airway Difficulty

Congenital

- *Pierre Robin syndrome*: Retrognathia, micrognathia, glossoptosis cleft palate
- *Treacher Collins syndrome*: Mandibular hypoplasia, micrognathia, facial bone hypoplasia, choanal atresia, cleft palate
- *Goldenhar syndrome*: Hemifacial microsomia, mandibular hypoplasia; vertebrae may be incomplete, fused, or missing
- *Mucopolysaccharidosis*: Macroglossia, odontoid hypoplasia, dental anomalies, sleep apnea
- *Klippel-Feil syndrome*: Short neck, fusion of two or more cervical vertebrae, limited range of neck motion
- *Down syndrome*: Macroglossia, flattened nose, cervical spine abnormalities, obstructive sleep apnea, dental anomalies

Acquired

- *Morbid obesity*: Thick neck with redundant airway tissue, obstructive sleep apnea
- *Acromegaly*: Macroglossia, prognathism, vocal cord swelling
- *Ludwig angina*: Infection at the floor of the mouth, trismus
- *Abscesses (oral, retropharyngeal)*: Distortion or stenosis of the airway tissues, trismus
- *Laryngeal Papillomatosis*: Viral infection causing tumors or papillomas within the larynx
- *Epiglottitis*: infection causing swelling of the epiglottis, laryngeal edema
- *Croup*: infection causing laryngeal edema and subglottic edema

- *Rheumatoid arthritis*: Limited cervical spine range of motion, temporomandibular joint ankylosis, cricoarytenoid arthritis
- *Ankylosing spondylitis*: Cervical spine ankylosis, decreased chest expansion
- *Tumors involving the airway*: Distortion or stenosis of the airway, fibrosis with fixation from irradiation
- *Trauma (airway, cervical spine)*: Distortion, edema, hemorrhage of the airway

Lower airway obstructions typically manifest with high peak airway pressures, low tidal volumes, and impaired ventilation. These conditions can be caused by pathologic, congenital, or acquired causes (see [Boxes 24.4](#) and [24.5](#)), and should be managed in a way that provides optimal ventilation and oxygenation for the patient.

Obstructive sleep apnea (OSA) and snoring were recognized as predictors of difficult mask ventilation.^{17,18,20} Studies have revealed that patients with a history of snoring and sleep apnea are more likely to have obstruction and difficulty with BMV.^{17,18,22} An obstructive tongue, as well as posterior oropharyngeal soft tissue collapse, is thought to be the cause of difficulty and obstruction. Patients with a history of OSA should be encouraged to bring their positive pressure device (e.g., continuous positive airway pressure [CPAP] or biphasic positive airway pressure [BiPAP] machine) from home to the hospital for use in the postanesthesia care unit.²²

Significant obesity (body mass index greater than 30 kg/m²) has been identified as a potential risk factor for difficult BMV.^{17,18,21} Difficulty with BMV may be the result of excessive weight from both chest and abdominal tissues causing compression on the lungs, especially in the supine and head down positions. Pregnant patients in the third trimester may also be difficult to ventilate because the gravid uterus can compress the lungs, creating elevated airway resistance. Furthermore, obese patients tend to have decreased functional residual capacities (FRCs), which predisposes them to desaturate more quickly, even after appropriate preoxygenation periods. One study reported that the time to reach

a preoxygenation end-tidal oxygen value of 85% or greater was similar in both obese and lean patients. However, the authors observed that apnea-induced desaturation occurred more quickly, and hypoxemia was more profound, in the obese population.²³ Time to desaturation should be considered in the overall airway management plan because any time delay after the induction of anesthesia in the obese population may result in significant hypoxemia.

Redundant tissue of the upper airway may be another factor that leads to difficulty with BMV, because excessive soft tissue in the oropharyngeal and pharyngeal cavities can cause resistance to airflow during positive pressure ventilation.^{14,24} Therefore, ideal positioning (e.g., ramping the patient), adequate preoxygenation, a secondary airway management plan with alternative airway adjuncts readily available, and assistance from other anesthesia professionals should be considered prior to the induction of anesthesia in the obese patient.

Researchers have also identified obesity as a risk factor for difficult laryngoscopy and TI, because excessive upper airway soft tissue may inhibit direct visualization of the glottis.^{17,23} However, some researchers concluded that an increased body mass index (greater than 35 kg/m²) had no effect on difficulty with laryngoscopy, leaving this a somewhat controversial subject.^{25,26}

Apneic oxygenation is a strategy used to provide a patient with oxygen during times of apnea, and more specifically during intubation of the trachea. Even without lung expansion and diaphragmatic movements, alveoli will continue to receive oxygen if a higher concentration gradient exists in the upper respiratory areas. Approximately 250 mL/min of oxygen diffuses from the alveoli into the blood stream during apnea, whereas only 8–20 mL/min of carbon dioxide is transferred into the alveoli. This difference is the result of blood gas solubility and hemoglobin's affinity for oxygen, and causes the alveoli's net pressure to become slightly subatmospheric, facilitating gas to flow from the pharynx into the alveoli. Apneic oxygenation can sustain a patient's partial pressure of arterial oxygen (PaO₂) for significant amounts of time without ventilation. However, hypercapnia and acidosis are probable if either spontaneous or assisted breaths are not

administered within a reasonable amount of time. The process of providing apneic oxygenation during an intubation procedure requires a patent upper airway and a nasal cannula. Initially, the nasal cannula can be placed under an anesthesia facemask during preoxygenation, and is then set to a high flow rate (15 L/min) during apnea in order for oxygen to reach the hypopharynx and become entrained in the trachea. The effects of such high nasal cannula flows on airway tissues can be minimized as long as this technique is utilized for short-term apneic episodes. Apneic oxygenation may be considered for use in obese patients who require intubation or in other similar populations at risk for rapid desaturation during apnea.²⁷

Advanced age (greater than 55 years) is associated with difficult BMV.^{17,18} Older patients may have decreased upper airway muscle tone as a result of inelastic or aged tissue. In addition, elderly patients commonly have loose teeth, missing teeth, or are edentulous, all of which can cause the airway soft tissue to sink inward. These factors contribute to a poor mask seal and the inability to perform adequate BMV. Anesthesia practitioners may consider leaving dentures in place (as long as they are easily removable) in the edentulous patient prior to instrumentation of the airway. This may be done to conserve the facial structure and facilitate a better mask seal.

Decreases in lung compliance can contribute to ineffective BMV because of the inability to effectively move ventilated gases into the alveoli. Conditions such as bronchospasm, pulmonary edema, acute respiratory distress syndrome, or pneumonia (see [Box 24.4](#)) can cause peak airway pressures to rise and compliance to decrease, resulting in ineffective BMV and poor oxygenation of the patient. If severe enough, these conditions may necessitate an abortion of the surgical procedure and require intubation and/or intensive care monitoring. Therefore it is important for the anesthetist to recognize potential upper and lower airway problems and realize the time limitations during inadequate ventilation.

Direct and Video Laryngoscopy With Tracheal Intubation Assessment

DL, VL, and TI are different procedures. DL is the process of airway instrumentation with a laryngoscope to acquire a direct line of sight with the laryngeal opening and supporting structures. VL is an indirect procedure for viewing the laryngeal opening using an airway device with a camera linked to a video monitor. TI is the process of placing an ETT into the trachea proximal to the carina and can be done utilizing either direct or indirect laryngoscopy. Usually, when anesthesia professionals perform a DL or VL, it is with the intent of completing TI, and as a result laryngoscopy and intubation are generally performed together in sequence. Airway assessments specific to DL, VL, and TI are therefore discussed together in this section.

A primary goal during airway evaluation is to determine factors that predispose a patient to difficulty with DL, VL, and TI. The distinction between these procedures has not always been clear in the literature, and the definition of difficulty can vary. However, the incidence of difficult TI has been described to be between 1.5% and 8.5%, and the incidence of failed TI has been estimated to be between 0.3% and 0.5%.^{6,28-30} As described earlier, individual airway assessments have not demonstrated an ability to reliably and consistently predict difficulty. Therefore the use of multiple airway evaluation techniques is prudent when assessing potential airway difficulty.

Different combinations of difficult airway assessments have been used with varying degrees of predictive success.^{8,28,31-33} Responsible airway management goals are to formulate primary, secondary, and even tertiary airway management plans. If an airway turns out to be less difficult than previously anticipated, then the decision to err on the side of patient safety is certainly the better choice.

A significant concern when performing the different airway assessments is the variation in measurements.⁶ Interpractitioner variability while performing airway evaluation techniques alters the validity of findings between studies. Therefore, it is important that airway evaluations are conducted the way they were intended every time. The most commonly cited airway assessments used to evaluate the airway include: (1) the modified Mallampati classification; (2) thyromental distance (TMD); (3) interincisor gap distance; (4) atlanto-occipital joint mobility and cervical range of

motion; (5) mandibular protrusion test; (6) evaluation for obstruction of the upper airway; and (7) measurement of neck circumference (specifically for obese patients).

Mallampati Classification

The Mallampati classification is a commonly used technique of assessing the mouth opening, size of the tongue, size of the oral pharynx, and posterior oropharyngeal structures. First developed by Rao Mallampati, this classification originally described three classes.³⁴ Later, Samsoon and Young³⁵ added a fourth class, which is now often referred to as the *modified Mallampati test* (MMT) (Fig. 24.9 and Table 24.3). When performing the assessment, the patient is instructed to sit upright, extend the neck, open the mouth as much as possible, protrude the tongue, and avoid phonation. The MMT uses a classification system to evaluate tongue size relative to the oropharyngeal space, and is categorized as follows:

Mallampati Classification

FIGURE 24.9 Modified Mallampati classification. Performed with the patient sitting up and maximally protruding his/her tongue; visibility of the soft palate, fauces, tonsillar pillars, and uvula are noted. Class I describes full visualization of all structures. Class II allows visualization of the soft palate, fauces, and uvula. Class III allows visualization of the soft palate and the base of the uvula. With class IV, only the hard palate is visible. (Courtesy Cleveland Clinic.)

TABLE 24.3

Mallampati Airway Classification

Classification	Description of Visualized Structures
I	Soft palate, fauces, uvula, pillars visible
II	Soft palate, fauces, uvula visible
III	Soft palate, base of uvula visible
IV	Hard palate visible only

From Berkow LC. Strategies for airway management. *Best Pract Res Clin Anaesthesiol.* 2004;18(4):531–548.

- *Class I:* Full visualization of the entire oropharynx, including soft palate, uvula, fauces (archway between oral and pharyngeal cavities), and tonsillar pillars
- *Class II:* Visualization of the soft palate, fauces, and uvula
- *Class III:* Visualization of the soft palate and base of the uvula
- *Class IV:* Visualization of the hard palate only

Ezri et al.³⁶ suggested adding a class “zero” to the MMT, which is the ability to see any part of the epiglottis on mouth opening and tongue protrusion, and found a 1.2% incidence. However, most researchers, and likely most clinical practitioners, use the Samsoon and Young I to IV modification of Mallampati's classification.

Evaluations of the MMT have shown some correlations with difficulty when either class III or IV is measured.^{35,36} However, by itself, the MMT has been unreliable at consistently predicting the presence or absence of a difficult airway.^{37,38} Variability in the administration of the MMT and practitioner subjectivity of assessment can result in the assessment of different classifications between similar patients. Nevertheless, when used in combination with other airway assessments, the MMT can help increase the predictive ability of both laryngoscopic and intubation difficulties. For example, the combination of high Mallampati classification levels of III or IV and a large neck circumference (greater than 43 cm, as measured at the thyroid cartilage) were predictors of intubation problems.^{12,25} Other researchers identified the combination of high Mallampati classifications, decreased TMDs, and limited interincisor openings as strong predictors of both laryngoscopic and intubation troubles.^{6,28,33}

Cormack and Lehane Grading System

An objective scoring system that is frequently used by researchers and clinicians to describe laryngoscopic difficulty is the Cormack

and Lehane grading scale (Fig. 24.10). This scale offers an objective assessment of the pharyngeal structures, glottic structures, and glottic opening during laryngoscopy, and is rated as follows³⁹:

FIGURE 24.10 Cormack and Lehane grading system. Grade I is visualization of the entire glottic opening. Grade II is visualization of only the posterior portion of the glottic opening. Grade III is visualization of the epiglottis only. Grade IV is visualization of the soft palate only. (From Cormack RS, Lehane J. Difficult tracheal intubation in obstetrics. *Anaesthesia*. 1984;39(11):1105–1111.)

- *Grade I*: Most or full view of the glottic opening
- *Grade II*: Only the posterior portion of the glottic opening can be visualized; anterior commissure not seen
- *Grade III*: Only the epiglottis can be visualized; no portion of the glottic opening can be seen
- *Grade IV*: Epiglottis cannot be seen; only view is of the soft palate

Cormack and Lehane grades I and II are generally associated with easier intubations, whereas grades III and IV correspond with higher degrees of intubation difficulty.³⁹ A modification of the

Cormack and Lehane grading scale was developed by Koh et al., and includes a Grade IIA (partial view of the vocal cords) and a Grade IIB (arytenoids and epiglottis visualized only) criteria. Grade IIB was associated with significantly more difficulty than Grade IIA.⁴⁰ Other authors have focused on an assessment to quantify the percentage of glottic visualization in an effort to limit the subjectivity and ambiguity that exists between Cormack and Lehane grades I and II. The percentage of glottic opening (POGO) is what the clinician performing laryngoscopy sees when looking at the glottic opening, and is defined as the linear span from the anterior commissure to the interarytenoid notch. A 100% POGO score is a full view of the glottis, and includes the anterior commissure to the interarytenoid notch. A POGO score of 0% signals that no portion of the glottic opening (including the interarytenoid notch) is seen. Objective scoring between 0% and 100% is dependent on the judgment of the person performing the laryngoscopy, and POGO scoring has been shown to provide good intra- and interobserver reliability.⁴¹

Thyromental Distance

The TMD is a measurement of the thyromental space. This space is an available pliable compartment, directly anterior to the larynx, where the tongue can be displaced during laryngoscopy to improve direct line of site with the glottic opening. The tongue is a malleable structure that can be displaced within the oropharyngeal and pharyngeal compartments. The thyromental space is bordered laterally by the neck, superiorly by the mentum, and inferiorly by the semifixed hyoid bone. The TMD is measured from the thyroid notch to the lower border of the mentum (at the chin) when the patient's head is extended and the mouth is closed (Fig. 24.11B). A TMD less than 6 cm, or three ordinary fingerbreadths, is associated with a higher incidence of difficult intubation. Research has indicated that the thyromental space should accommodate most tongue sizes, but that a small space would only facilitate a relatively small tongue.^{32,42} Some conditions, such as radiation or pathologic factors (e.g., tumors), may render the thyromental space noncompliant, hindering tongue placement and causing it to protrude into the pharyngeal space. A malplaced tongue that does

not fit into the thyromental space can obstruct the line of site to the glottic opening during DL.

FIGURE 24.11 3-3-2 Rule. **A**, Oral access: mouth opening (three fingerbreadths) between upper and lower teeth. **B**, Mentum and hyoid bone, otherwise known as the *thyromental distance* (three fingerbreadths). **C**, Thyroid notch and hyoid bone (two fingerbreadths). (Courtesy Cleveland Clinic.)

Another condition affecting tongue placement into the thyromental space is known as *mandibular hypoplasia*. This condition results in a TMD of less than three fingerbreadths, and may cause difficulty with DL and TI because the tongue cannot be displaced into the small submandibular space. Furthermore, the larynx may be tucked underneath the tongue or be positioned relatively anterior to the base of the tongue in the pharyngeal space, causing difficulty with laryngoscopic views. This condition is commonly called an *anterior larynx*, and unless the tongue can be pulled anterior away from the pharyngeal space, little can be done to improve the direct line of site view. In contrast, VL has shown to provide improved laryngeal visualization in patients with difficult direct line of site views.^{43,44}

The assessment of a long TMD (greater than 9 cm) may also indicate a potentially difficult laryngoscopy and intubation. The

indication for difficulty is due to a large hypopharyngeal tongue, caudal larynx, and longer mandibulohyoid distance (MHD). The MHD measures the vertical distance from the angle of the mandible to the hyoid bone, and is usually assessed by radiograph. A long TMD and MHD may position the glottic opening caudally in the neck and beyond the visual horizon. If the larynx is more caudally situated in the pharyngeal compartment, then the tongue is also likely to be positioned lower because the tongue muscle is hinged to the hyoid bone.^{45,46} This can lead to both a greater distance to the glottic opening during laryngoscopy and an obstructed view caused by a greater amount of tongue mass in the hypopharyngeal space. In addition, a history of sleep apnea and snoring can provide further evidence of a possible hypopharyngeal tongue, which has been shown to cause difficulty with both mask ventilation and intubation.^{46,47} Similar to other airway assessment tests, researchers have found limited predictability when the TMD test was used by itself, and therefore recommend that it be used as part of a multivariable airway assessment.^{25,30}

The 3-3-2 rule has been described by some authors as a nonscientifically based test to ensure that upper airway geometry is adequately assessed.⁴⁸ The 3-3-2 rule is an assessment that evaluates various airway proportions using fingerbreadths as a measurement (see [Fig. 24.11](#)). It is a combination of different geometric dimensions that relate mouth opening and the size of the mandibular space to the position of the larynx in the neck.¹⁴ The first “3” estimates oral access (the interincisor gap distance), which should accommodate at least three fingerbreadths. The second “3” assesses the mandibular length (TMD) from the tip of the mentum to the mandible-neck junction, and gauges the ability of the tongue to displace within the submandibular space during laryngoscopy. The “2” is a modification of the MHD, which is a nonradiographic measurement from the mandible-neck junction to the tip of the thyroid notch, and assesses the position of the larynx (glottic opening) in relation to the base of the tongue. More than two fingerbreadths indicates that the larynx may be positioned too far down the neck and could be difficult to visualize. Less than two fingerbreadths indicates that the larynx may be tucked under the base of the tongue, which would be indicative of an anterior larynx.

This combination of airway assessments allows the anesthetist to perform multiple airway measurements in a rapid and sequential manner.

It may be worth mentioning the sternomental distance (SMD), although it has been described as a poor predictor of airway difficulty (even when used as part of a multivariable assessment). The SMD is measured from the sternal notch to the lower border of the mentum at the chin, with the head extended and the mouth closed. A normal SMD is greater than 12 cm. Distances of less than 12.5 cm have been described as a preoperative predictor for a difficult to intubate patient.³²

Interincisor Gap

As discussed previously, the interincisor gap is important to assess when performing a DL or VL because the size of the mouth opening can affect the ability to introduce a laryngoscope device and to create a direct line of sight with the laryngeal opening.¹⁵ The challenge with a narrow mouth opening is placing both the laryngoscope blade's 2-cm flange and the ETT into the mouth while maintaining good visualization of the vocal cords. An adequate interincisor opening is at least two to three fingerbreadths, or a minimum of 4 cm.⁴⁹ An increase in maxillary incisor length can reduce the interincisor gap and create a sharper angle between the oral and glottic openings. Furthermore, prominent incisors or "buck teeth" increase the risk of dental damage from any hard device used to manipulate the airway. Finally, loose or awkward teeth can either impede the placement of a laryngoscope blade, videolaryngoscope device, and ETT, or create an obstruction if a tooth is dislodged and falls posteriorly into the laryngeal opening or trachea.

Atlanto-Occipital Joint Mobility

The full range of neck flexion and extension varies from 90 to 165 degrees, and decreases approximately 20% between ages 16 and 75. The atlanto-occipital joint provides the highest degree of mobility in the neck, with a normal head extension of up to 35 degrees. Proper atlanto-occipital joint mobility is required for an adequate sniffing

position. The sniffing position is important because it helps to improve direct laryngoscopic views by promoting displacement of the tongue by better aligning the oral, pharyngeal, and laryngeal axes (Fig. 24.12). Evaluation of atlanto-occipital joint extension is conducted with the patient seated upright in a neutral face-forward position; the patient is then asked to lift the head back with the chin up as far as possible. When extension is reduced to 23 degrees, visualization may become difficult.⁵⁰ If the patient demonstrates substantial or complete immobility of the atlanto-occipital joint, then significant compromise with DL should be anticipated. Furthermore, cervical spine diseases such as cervical pathology (e.g., degenerative disease, rheumatic disease, neurologic pathology, trauma, or previous surgical intervention) or spinal abnormalities (e.g., Down syndrome) may lead to difficult laryngoscopy and difficult airway management in general. VL has been shown to be an effective method for placing an ETT in patients with limited cervical spine mobility, or in patients where the cervical spine requires minimal or no movement.⁴³ One study demonstrated no difference in laryngoscopic views between the C-MAC (Karl Storz GmbH, Germany) video laryngoscope and the flexible fiberoptic scope (using the eyepiece view only), and a faster time to intubation with the C-MAC in patients that required cervical spine immobilization.⁵¹

FIGURE 24.12 Oral axis (OA), pharyngeal axis (PA), and laryngeal axis (LA) for intubation. **A**, Nonaligned position. **B**, Head resting on a pad causes flexion of the neck and aligns the PA and LA. **C**, Head resting on pad causes flexion of the neck, and neck extension into the sniffing position aligns the OA, PA, and LA. **D**, Extension of the neck without head elevation aligns PA and LA, but not the OA. (From Miller RD, Pardo MC, eds. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier; 2011:226.)

Mandibular Protrusion Test

The mandibular protrusion test, also known as the *upper lip bite test* (ULBT), is an evaluation technique that demonstrates the patient's ability to extend the mandibular incisors anterior past the maxillary incisors. The purpose of this airway test is to first assess the patient's maxillary incisor length (e.g., presence of buck teeth), and then to assess the mobility of the patient's temporomandibular joint function and forward subluxation of the jaw. The presence of these indicators can lead to problematic oral airway placement, noneffective relief of soft tissue obstruction from poor mandibular movement, difficulty introducing the laryngoscope blade into the mouth, and an obstructive view of the glottic opening caused by

malplacement of the tongue. Difficulty with laryngoscopy arises when the patient is unable to protrude the mandibular incisors anterior past the maxillary incisors (Fig. 24.13). The test has three classifications⁵⁰:

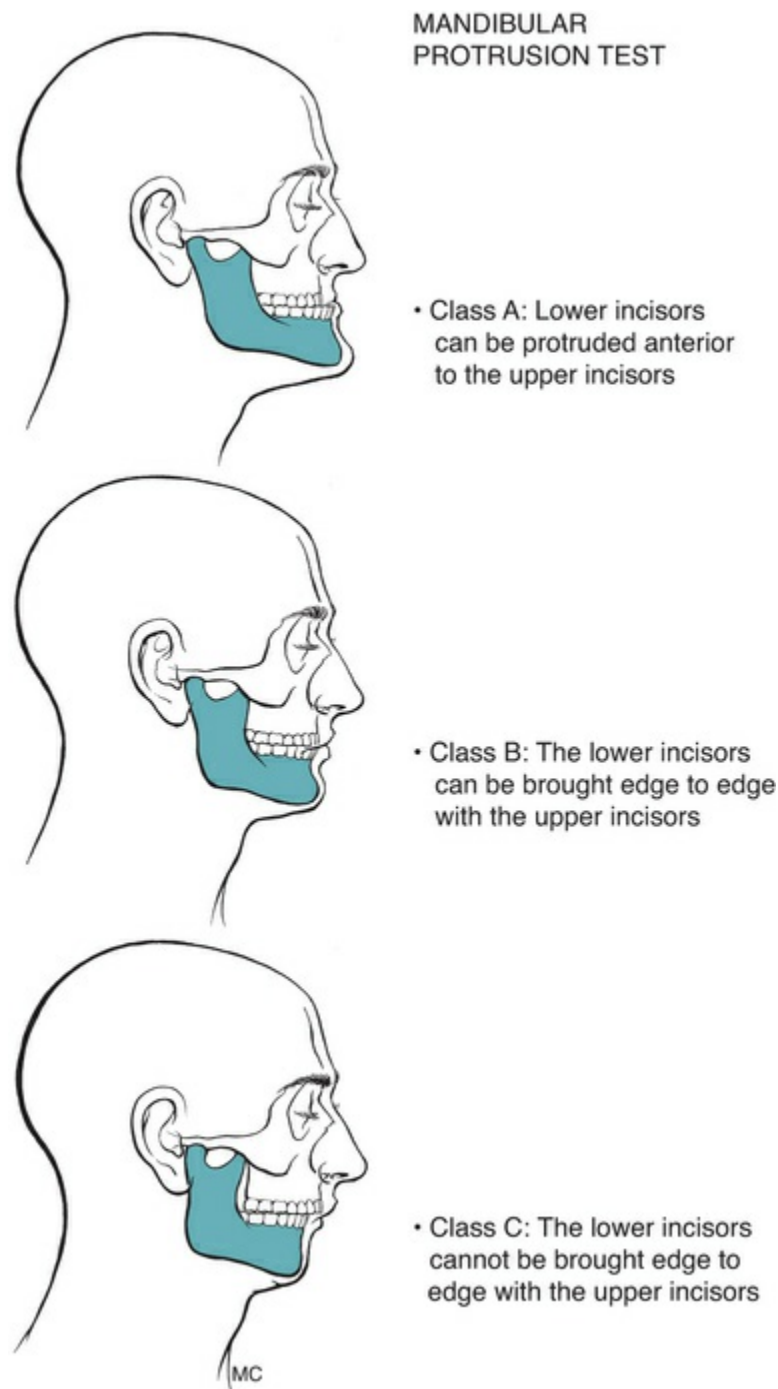

FIGURE 24.13 Mandibular protrusion test classes A, B, and C (also known as the *upper lip bite test*). (Redrawn from Munnur U, et al. Airway problems in pregnancy. *Crit Care Med*.)

- *Class A:* Patient can protrude the lower incisors anteriorly past the upper incisors and can bite the upper lip above the vermilion border (line where the lip meets the facial skin).
- *Class B:* Patient can move the lower incisors in line with the upper incisors and bite the upper lip below the vermilion border, but cannot protrude lower incisors beyond.
- *Class C:* Lower incisors cannot be moved in line with the upper incisors, and cannot bite the upper lip.

Assessment of an ULBT class C indicates a potential difficult laryngoscopic view, whereas class A indicates a good view using conventional laryngoscopy.⁵²

The ULBT was found to be a valuable assessment tool for the prediction of difficult ventilation when used in combination with other assessment techniques such as increased neck circumference and a history of snoring.⁵³ Furthermore, the ULBT has shown to be useful in the assessment of temporomandibular joint function and the prediction of difficult laryngoscopies when used in combination with the modified Mallampati classification.^{5,54} However, the ULBT has been shown to be an unreliable assessment technique when used in the edentulous population, and has demonstrated poor predictability when used as a single screening test for the assessment of laryngoscopic difficulty.⁵⁵

Supraglottic Airway Assessment

Supraglottic airway ventilation may be the primary means of managing an airway, or it can be used for rescue ventilation in the event that facemask ventilation is difficult or fails. Similar predictors related to difficulty with mask ventilation, laryngoscopy, and intubation can also be used to indicate difficulty in placing and ventilating with a supraglottic airway device (SAD). These predictors include a restrictive mouth opening, a distortion in the upper airway anatomy, and both upper and lower airway obstruction (see [Box 24.2](#)).

The interincisor gap is an important assessment to consider when introducing any airway adjuncts into the mouth. As identified

earlier, an assessment of less than three fingerbreadths or less than 4 cm indicates a restricted oral access that can make some SADs difficult to introduce into the mouth.¹⁵ Furthermore, some researchers have indicated that reductions in atlanto-occipital joint movement due to conditions such as ankylosing spondylitis and rheumatoid arthritis may cause difficulty with some SAD placements, such as the laryngeal mask airway (LMA).^{56,57}

Obstruction at the level of the larynx, trachea, or below can reduce or completely block ventilation from a SAD (see [Box 24.4](#)). In addition, fixed upper airway lesions, such as oropharyngeal tumors or a disruption or distortion in the upper airway anatomy, may make SAD placement difficult and lead to ineffective ventilation from a compromised “seat and seal.”^{48,58}

Finally, conditions affecting the lower airways resulting in decreases in pulmonary compliance or increases in airway resistance can cause peak airway pressures to rise, which may also make supraglottic airway ventilation difficult. For example, bronchospasm or acute respiratory distress syndrome require higher ventilatory pressures to facilitate adequate gas exchange within the lungs. Severe obstruction or restriction as a result of lung pathophysiology may limit the amount of ventilation that can be accomplished with an SAD, and even allow for the possible risk of vomiting and pulmonary aspiration.^{58,59}

Cricothyrotomy Airway Assessment

An assessment of the neck is part of any comprehensive airway examination, and should be conducted with the intent of identifying factors that may indicate difficulty with cricothyrotomy placement. The need for an invasive airway usually occurs on an emergency basis. An invasive airway consists of a needle cricothyrotomy, surgical cricothyrotomy, or a tracheotomy. Because surgeons are more likely to perform a tracheotomy, rather than anesthesia personnel, the primary focus here will be on assessments aimed at identifying factors that lead to difficulty with both the needle and surgical cricothyrotomy procedures.

Even though there is no absolute contraindication for the placement of an emergency cricothyrotomy, there are conditions that make performing this procedure difficult or even impossible

(see [Box 24.2](#)). Murphy and Walls¹⁴ described using the mnemonic *SHORT* as a means for remembering *surgery, hematoma, obesity, radiation, and tumors*, which are conditions associated with difficult cricothyrotomy placement. Any condition that causes a distortion of the airway, such as trauma, surgery, infection, tumors, or physical impediments in or around the cricothyroid area, may cause difficulty with invasive airway access. A hematoma from surgery (e.g., carotid endarterectomy), an infection of the soft tissue around the airway (e.g., Ludwig angina), an oral or pharyngeal abscess, a tumor in or around the neck, or radiation causing scarring of the neck tissue can distort the neck anatomy, making a cricothyrotomy neck incision and tube placement into the trachea challenging. However, none of these factors should be considered a contraindication when emergency airway access is required. In addition, recent or past neck trauma or surgery can alter neck anatomy and cause scarring or acute bleeding, again making cricothyrotomy procedures difficult. Finally, neck impediments such as a halo device or a rigid cervical collar may impede emergency access or make the procedure technically difficult, and should be removed whenever possible.

Patient physical conditions indicating cricothyrotomy difficulty include a short neck, obesity, scarring, or fixed flexion abnormality. Both a short neck and excessive soft tissue around the neck can make finding the cricothyroid membrane and surrounding anatomic landmarks challenging. When performing the preoperative airway assessment on patients who exhibit any of these characteristics, practitioners should consider marking the cricothyroid membrane, prior to airway manipulation, to save time locating the membrane in the event of an emergency. Furthermore, the appropriate equipment, such as an emergency cricothyrotomy kit or necessary equipment and personnel, should be readily available in order to save time when and if emergency airway access is indicated.

Radiologic and Ultrasonographic Imaging

Imaging technologies such as magnetic resonance imaging (MRI) and computed tomography (CT) can identify pathologies and alterations in airway anatomy and increase the predictive value of

anticipated difficulty. These technologies can help anesthesiologists formulate appropriate airway management plans. Advantages of the CT scan include the ability to accurately depict pathology involving bones and soft tissues and the ability to view images in the sagittal, coronal, axial, and three-dimensional views. Furthermore, CT scans have become the gold standard for ruling out fractures of the cervical spine.⁶⁰

Whereas CT scans can image both bone and soft tissue, an MRI offers detailed information on soft tissues only. An MRI can help assess the impact that pathologic processes have on soft tissue, such as the altered patency of an airway caused by a tumor in the neck. However, CT and MRI tests are not currently used on a routine basis because of the economic costs and time-delaying factors associated with their use, especially if there is no indication to perform them.

Ultrasonography has been shown to be useful as a predictor for difficult laryngoscopies. Excessive pretracheal soft tissue, as assessed by ultrasound, in combination with a large neck circumference and a history of sleep apnea were all positive predictors for difficult laryngoscopy in an obese population.⁶¹ Furthermore, the use of ultrasound demonstrated real-time noninvasive and repeatable bedside imaging of airway anatomy, including the cricoid cartilage and vocal cords.⁶² As such, ultrasonography may be a useful technique for the identification of the cricoid cartilage in an obese individual or to determine proper placement of an ETT. Other researchers have shown that the quantification of soft tissue using ultrasonography fails to predict difficult laryngoscopy in the obese population.⁶³ The effectiveness of ultrasonography as an airway assessment tool has yet to be determined. However, as it is used with more frequency, it may emerge as a useful adjunct in the assessment of the difficult airway.

When assessing the airway and preparing for manipulation, the anesthesiologist should perform a multivariable assessment. This assessment is based on patient, surgical, and situational requirements, and is crucial for the identification of factors that are associated with difficult BMV, DL and TI; difficult SAD placement and ventilation; and difficult cricothyrotomy placement.

Tracheal Intubation

TI remains a cornerstone of traditional airway management. TI may be performed by various methods (e.g., DL, fiberoptic intubation, intubating LMA, VL). The technique chosen for TI is dependent on the patient's history, physical examination (including airway assessment), and previous anesthetic history (e.g., difficult intubation). Indications for TI can be found in [Table 24.4](#).

TABLE 24.4

Indications for Tracheal Intubation

Condition	Indication
Anesthesia and surgical	High risk of aspiration of blood (e.g., head and neck trauma, bleeding into respiratory tract) or gastric contents (e.g., severe gastroesophageal reflux disease, inadequate gastric emptying, gastrointestinal obstruction) Predicted difficult airway Intraoperative patient positioning that may impede access to the airway (e.g., prone, lateral decubitus) Ineffective oxygenation or ventilation with supralaryngeal airway (e.g., mask ventilation, laryngeal mask airway)
Surgical	Airway access shared with surgeon (e.g., otolaryngologic and head-neck surgery) Surgery requiring paralysis by neuromuscular blocking medications (e.g., intraabdominal surgery) Surgical procedures affecting ventilation and perfusion (e.g., cardiothoracic surgery) Prolonged surgical time
Medical	Inadequate airway protection or suppressed airway reflexes (e.g., Glasgow coma scale less than 10) Ineffective oxygenation or ventilation (e.g., noninvasive positive pressure respiratory assist device, mask ventilation, laryngeal mask airway) Critical illness (e.g., inadequate respiratory function, acute respiratory distress syndrome, sepsis) Controlled management of arterial carbon dioxide content (e.g., prevention of hypercapnea for increased intracranial pressure)

Modified from Henderson J. Airway management in the adult. In Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2009:1573–1610.

The TI procedure is preceded by careful attention to optimal head and neck positioning for laryngoscopy. Flexion of the neck and extension of the atlanto-occipital joint, or sniffing position, allows for proper alignment of the oral, pharyngeal, and tracheal axis (see [Fig. 24.12](#)). This can be accomplished using pillows, towels, blankets, or the OR table's positioning functions ([Fig. 24.14](#)).

Furthermore, elevation of the shoulders, head, and neck, known as *ramping* (see [Fig. 24.8](#)), in an effort to align the tragus of the ear with

the sternum may help in patients identified as potentially difficult to intubate. Manipulation of the head and neck must be used with caution in patients with decreased cervical range of motion caused by degenerative disease, rheumatic disease, neurologic pathology, trauma, or previous surgical intervention (Fig. 24.15).

(From Chi JH, et al. Complex deformities of the cervical spine. *Neurosurg Clin N Am.* 2007;18(2):295–304.)

Sufficient preoxygenation may help to delay arterial desaturation prior to the induction of anesthesia and during subsequent apneic situations. Effective preoxygenation increases the oxygen content and eliminates much of the nitrogen (approximately 79% of room air) from the FRC and can theoretically provide oxygen to the blood for up to 8 minutes in a healthy individual. However, without preoxygenation, the oxygen reserve in the FRC is limited, leading to a decrease in the time an anesthetist has to secure the airway. Preoxygenation should include 100% inspired oxygen, a tight mask seal, instructing the patient to breathe at normal tidal volumes for 3 to 5 minutes, and providing a minimum fresh gas flow of at least 5 L/min. Signs of adequate preoxygenation are a respiratory bag that moves with each inspiration/expiration, a well-defined end-tidal

CO₂ waveform, and a fraction of expired oxygen that increases to 90% or greater. If time is limited, there is some evidence that supports a patient taking eight vital capacity breaths within 60 seconds, before the induction of anesthesia, with equivalent results to 3 minutes of tidal volume breathing.⁶⁴ Finally, as discussed earlier, the concept of apneic oxygenation using a nasal cannula with flows reaching 15 L/min to insufflate oxygen into the pharyngeal airway may help to delay desaturation during apnea in a patient with a patent airway.

The technique for DL is dependent on the type of laryngoscope blade used for the procedure, but the premise of control/displacement of the tongue from right to left and elevation of the epiglottis remains the same for both techniques. The use of the curved (e.g., Macintosh) laryngoscope blade requires the anesthetist to (1) place the tip of the laryngoscope in the vallecula and (2) apply tension to the hyoepiglottic ligament using a gentle lifting force, which promotes (3) indirect elevation of the epiglottis. In contrast, the use of the straight (e.g., Miller) laryngoscope blade requires the anesthetist to (1) place the tip of the laryngoscope posterior to the epiglottis and (2) apply gentle force to directly lift the epiglottis. Levering action should never be applied to the patient's dentition. Such action risks dental damage and diminishes the quality of the laryngoscopic view. A technique known as *Backwards-Upwards-Rightwards-Pressure* ("BURP") has been demonstrated to improve visualization of the vocal cords, and can be achieved by the clinician manipulating the larynx at the neck with his/her right hand during laryngoscopy.⁶⁵

If an adequate laryngoscopic view cannot be achieved after DL, then strategies and algorithms for the difficult or failed airway should be followed. Maintenance of adequate oxygenation and ventilation is of the utmost priority during TI, and can be facilitated by the use of various adjunctive airway equipment and techniques.

Management of the Difficult and Failed Airway

Management of the difficult airway is a multifaceted process that begins with the airway assessment, considers decision-making strategies suggested by the various difficult airway algorithms, continues with a primary airway management plan, and is then flexible with an understanding of how to proceed when initial airway management plans fail. Part of a thorough airway management plan is the consideration of patient characteristics and conditions that predispose the patient to difficulty with facemask ventilation, supraglottic airway use, laryngoscopy, TI, and cricothyrotomy. As discussed in previous sections, multiple patient characteristics and conditions are associated with difficult airway management. Therefore, an important aspect of airway management is obtaining the competency and knowledge to deal with the identified difficult airway and the less common unexpected failed airway.

The unexpected failed airway, also termed the *unanticipated difficult airway*, consists of an airway that has previously been evaluated as having no external identifiers indicating difficulty. In other words, the anesthesia provider does not expect or anticipate difficulty with facemask ventilation, laryngoscopy, intubation, or other airway management techniques. However, after the patient is anesthetized, difficulty then occurs with ventilation, intubation, or both. Although rare, a common cause of an unanticipated difficult intubation has been shown to be enlarged lymphoid tissue at the base of the tongue (i.e., lingual tonsil hyperplasia), which cannot be evaluated externally.^{66,67} Instead, this condition is discovered during laryngoscopy by a failure to visualize the glottic opening and a description of a grade III or IV airway. In one case series and review of literature, lingual tonsil hyperplasia was found to be the most common cause of unanticipated difficulty with the airway. Although lingual tonsil hyperplasia is often asymptomatic, there are indicators that may alert the anesthetist to the presence of this potential obstruction, which include sore throat, dysphagia, globus

sensation, snoring, palpation of a lump in the throat, and OSA.⁶⁷

Definition of a Difficult and Failed Airway

The definition of a difficult airway varies within the existing literature, making it challenging to identify the true incidence. However, in broad terms, a difficult airway has been described as a clinical situation in which a trained anesthetist experiences difficulty with facemask ventilation, laryngoscopy, intubation, or all these.¹¹ A significant amount of subjectivity is possible between observers when performing the different airway assessments, leading to various interpretations of predicted airway difficulty. Ultimately, it is not enough to simply identify a difficult airway; instead, it is important to also possess the knowledge and skills that guide intervention after difficulty has been identified, or when unanticipated difficulty is encountered. Knowing what to do when an airway proves difficult will ensure that proper ventilation is provided in a timely manner.

There are four strategies to facilitate a patent upper airway and effect ventilation and thus oxygenation of the tissues. The methods of providing ventilation are as follows:

1. Mask ventilation with an appropriate mask seal with or without a jaw thrust maneuver
2. Placement of an SAD such as an LMA
3. Placement of an ETT into the trachea
4. Placement of an invasive airway such as a cricothyrotomy tube

Problems or indications of complexity with one or more of these four methods of providing ventilation would suggest a difficult airway.

When managing an airway, the signs that indicate difficulty must be recognized in a timely manner. Indications of difficult facemask ventilation include (1) gas flow leaks out of the facemask and increasing use of the oxygen flush valve; (2) poor chest rise; (3) absent or inadequate breath sounds; (4) gastric air entry; (5) poor

carbon dioxide return and an altered capnographic waveform; (6) a decreasing oxygen saturation of less than 92%, as measured by pulse oximetry using a 100% inspired oxygen concentration; and (7) necessity of using an oral or nasal airway and performing a two-handed mask ventilation technique.^{18,68} Difficult laryngoscopy and TI have been consistently identified in the literature as the inability to visualize any portion of the vocal cords (e.g., Cormack and Lehane grade III or IV) after multiple attempts using a standard laryngoscope. In addition, difficulty with laryngoscopy and intubation has been described as requiring multiple operators in the presence or absence of tracheal pathology. Furthermore, evidence of a failed intubation was identified as an inability to place an ETT after multiple laryngoscopic attempts.¹¹ Difficulty with a supraglottic device may also be apparent when placement requires multiple attempts or more than one airway practitioner. Furthermore, objective indications of difficulty with supraglottic ventilation are similar to those described for facemask ventilation earlier, as well as a leak pressure less than 10–15 cm H₂O and a poor expired tidal volume.¹⁶ Finally, difficulties with invasive airway device placement, such as a cricothyrotomy, are apparent with bleeding at the site of insertion, an inability to identify the correct anatomic structures, or with trouble accessing the cricothyroid membrane and puncturing through into the trachea.

Incidence of a Difficult and Failed Airway

Adverse events related to difficulty with airway management continue to occur within the OR, and researchers agree there is continued room for improvement.⁶⁹ In 2008, the Royal College of Anaesthetists in the United Kingdom and the Difficult Airway Society (DAS) gathered information from the administration of 2.9 million general anesthetics in an attempt to identify the incidence of major complications related to airway management. The major complications identified were death, brain damage, emergency surgical airway placement, and unanticipated ICU admission. They found that a major complication occurred at a ratio of 1 : 22,000 general anesthetics, with a mortality rate of 1 : 180,000.⁶⁹ Other researchers have focused strictly on the occurrence of a difficult

airway, such as a laryngoscopic view grade II or III, and have reported a 1% to 18% incidence. The incidence of failed TI is relatively uncommon, and has been reported as 0.045% to 0.35%, with the high end of this range relating to obstetric patients and other surgical patients with known difficulties.^{68,70} As previously mentioned, the incidence of difficult facemask ventilation has been described between 0.9% and 7.8%, with the variation in results occurring as a result of different study parameters.

Finally, researchers have reported an SAD failure rate of 0.19% to 1.1%, mostly caused by an inadequate seal from improper placement, surgical table rotation, poor dentition, male gender, and increased body mass index.^{71,72}

The incidence of difficult intubation and ventilation is much higher in patients with neck or mediastinal pathology, previous surgery, or radiation. For example, one study evaluated 181 patients with pharyngolaryngeal disease and found that 50 (28%) were difficult to intubate, and four (2.8%) were impossible to intubate.⁷³ Other researchers performed a retrospective analysis on patients with deep neck infections, such as Ludwig angina, and found a 3.8% incidence of failure to intubate, necessitating a tracheostomy.⁷⁴ The true incidence of situations in which practitioners cannot intubate and subsequently cannot ventilate or oxygenate is difficult to assess because of the failure to consistently and accurately report these occurrences. However, some authors have reported an incidence of 1 : 2250 in nonparturients and as high as 1 : 300 in parturients, whereas another researcher reported four cases of impossible mask ventilation and intubation in 53,041 cases involving anesthetics.^{13,21,75}

When assessing the frequency of emergency cricothyrotomy placement, the Fourth National Audit Project reported an occurrence of 1 : 2500-50,000 general anesthetic cases.⁶⁹ Other researchers explained that the incidence of emergency cricothyrotomy placement is strongly influenced by the clinical situation and contributing patient factors.⁷⁶ For example, the incidence of emergency cricothyrotomy placement resulting from failed TI in the emergency department (ED) has been reported as 0.3% to 0.8%, increasing to 1.4% in trauma patients, and was reported to be as high as 11% in the prehospital setting. Other

research also concluded that difficult airways may be encountered more frequently outside of the OR.⁷⁷⁻⁷⁹ The Fourth National Audit Project from the United Kingdom reported that airway-related adverse events, which led to death or brain damage, were 30 to 60 times more likely to occur in the ED or ICU.⁸⁰

Difficult Airway Algorithms

When considering how to approach airway management, certain issues should be considered prior to the induction of anesthesia. The following are five questions, termed “the airway approach algorithm,” which may initially help in the development of an airway management plan:¹⁵

1. Is airway management necessary?
2. Will DL and TI be straightforward?
3. Can supralaryngeal ventilation be used?
4. Has the risk for aspiration been minimized, or is the stomach empty?
5. In the event of airway failure, will the patient tolerate an apneic period?

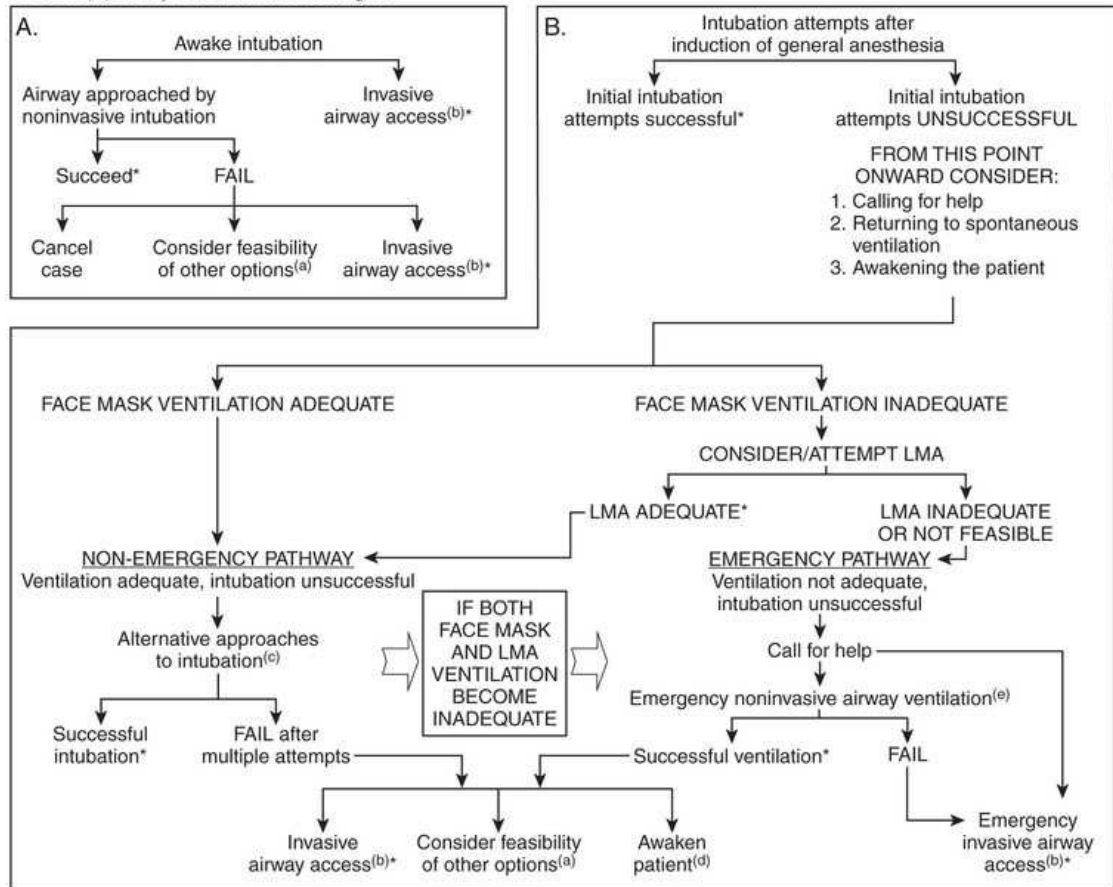

If the answer to each of these questions is “yes,” then the airway is deemed manageable by conventional means, and the anesthetist may proceed with the induction of anesthesia followed by muscle relaxation to provide optimal conditions for laryngoscopy and intubation. If, however, the answer to any question is “no,” then the anesthetist should either abandon airway management altogether and proceed with an alternative anesthetic option (e.g., monitored anesthesia care, regional anesthesia), or follow the guidelines set forth by various professional associations for the management of anticipated airway difficulty.

Difficult airway management is multifactorial and necessitates an awareness of the interactions between the patient's condition, the clinical setting, and the anesthesia provider's experience and skill level. Each of these factors alone or in combination can contribute to

poor outcomes during airway manipulation, and must be considered when developing airway management strategies. Tools that help the anesthetist formulate plans for safe airway care in the face of both known and unanticipated difficulties are known as *difficult airway algorithms*. Multiple difficult airway algorithms exist, such as the American Society of Anesthesiologist's (ASA) difficult airway algorithm (Fig. 24.16) and the DAS's difficult intubation guidelines (Fig. 24.17). An important fact to keep in mind is that many of the guidelines suggested in difficult airway algorithms are based on the opinions of experts in the field of airway management, but lack empirical evidence. Reasons given have included the significant challenges with the design of randomized controlled trials, the infrequency of certain difficult airway events (e.g., failed airway or cricothyrotomy), and an inability to account for confounding variables such as individual practitioner experience.⁸¹ However, the widespread distribution of the different guidelines has resulted in a reduction in airway-related critical accidents.^{81,82} Overall, it is important to remember that difficult airway algorithms are simply guidelines that provide structure for decision-making and tools for use when managing difficult airways, but they do not preclude personal responsibility and sound clinical judgment.

1. Assess the likelihood and clinical impact of basic management problems:
 - A. Difficult ventilation
 - B. Difficult intubation
 - C. Difficulty with patient cooperation or consent
 - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:
 - A. Awake intubation vs Intubation attempts after induction of general anesthesia
 - B. Noninvasive technique for initial approach to intubation vs Invasive technique for initial approach to intubation
 - C. Preservation of spontaneous ventilation vs Ablation of spontaneous ventilation

4. Develop primary and alternative strategies:

*Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO₂.

- a. Other options include (but are not limited to) surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the emergency pathway.
- b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.
- c. Alternative noninvasive approaches to difficult intubation include (but are not limited to) use of different laryngoscope

- blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.
- d. Consider re-preparation of the patient for awake intubation or canceling surgery.
- e. Options for emergency noninvasive airway ventilation include (but are not limited to) rigid bronchoscope, esophageal-tracheal Combitube ventilation, or transtracheal jet ventilation.

FIGURE 24.16 The American Society of Anesthesiologists Difficult Airway Algorithm. (From Caplan RA et al. ASA Task Force on Management of the Difficult Airway: practice guidelines for management of the difficult airway: an updated report.

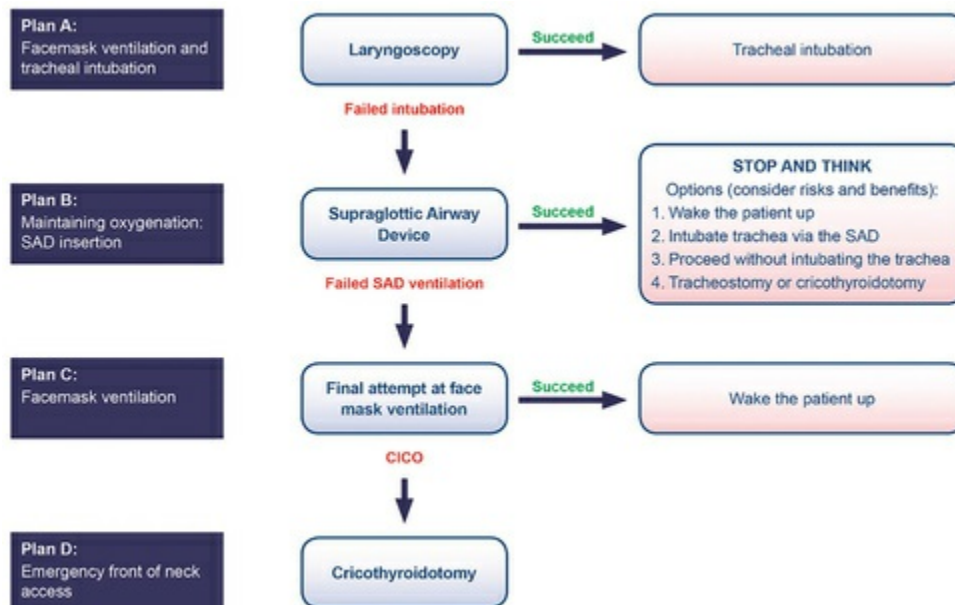

FIGURE 24.17 The Difficult Airway Society's (DAS) Difficult Intubation Guidelines. (From Frerk C, et al. Difficult Airway Society 2015 guidelines for management of unanticipated difficult intubation in adults. *Br J Anaesth.* 2015;115(6):827–848.)

ASA Difficult Airway Algorithm

The difficult airway algorithm, established in 1991 by the ASA, gave anesthesia practitioners the first standardized approach for the management of the anticipated or unanticipated difficult airway. The practice guidelines were updated in 2003 and again in 2013 to reflect current management strategies.¹¹ The algorithm provides guidelines for dealing with difficult facemask ventilation, difficult laryngoscopy, difficult TI, and failed intubation. Assessment of the airway and use of the difficult airway algorithm provide the practitioner with four end-points: (1) intubation awake or asleep, (2) adequate or inadequate facemask ventilation or LMA ventilation, (3) approach to intubation by special means, and (4) surgical or nonsurgical emergency airway access. Each of these end-points entails using specific airway equipment and techniques to facilitate ventilation (Table 24.5). According to the algorithm, an

organized plan should be initiated when a difficult airway is encountered. In essence, the philosophy of the ASA difficult airway algorithm has been explained by the following⁸³:

TABLE 24.5
Airway Adjuncts and Alternative Airway Techniques*

LMA, Laryngeal mask airway; *LT*, laryngeal tube; *LTS-D*, disposable laryngeal tube with gastric access; *PLA*, perilaryngeal airway.

1. Plan ahead, and be prepared for failed attempts at intubation.
2. If you are suspicious of airway trouble, intubate awake.
3. If you get into trouble and can still ventilate the patient, wake him or her up.
4. When making intubation choices, do what you do best

DAS Difficult Intubation Guidelines

The primary focus of the DAS difficult intubation guidelines is the unanticipated difficult airway with TI (see Fig. 24.17). These guidelines promote a simplified plan, "A, B, C, and D," within a single page algorithm. Emphasis is placed on airway assessment, preparation, positioning, preoxygenation, prioritizing oxygenation,

and limiting the number of airway interventions in an effort to limit the amount of trauma and complications during management.⁸³ The importance of recognition and declaration of the difficult airway during management is stressed, as is the request for assistance. The developers of the guidelines highly recommend that, each time an airway plan fails, the airway manager verbalizes the failure and then the option of moving to the next plan in an effort to inform the entire perioperative team of the situation. The guidelines also highlight the importance of planning for failure during the preinduction briefing. Other pertinent suggestions about each airway plan contained within the guidelines include⁸³:

- *Plan A*: Maximize success of TI on the first attempt (e.g. preparation, preoxygenation, positioning). Limit laryngoscopy attempts to no more than three total. Declare failed intubation and verbalize implementation of plan B.
- *Plan B*: Emphasis is maintenance of oxygenation using an SAD. Second generation SADs are recommended because of their reliability for first-time placement, high seal pressure capabilities, separation of the gastrointestinal and respiratory tracts, and compatibility with fiberoptic video devices. Video- or fiberoptic-guided TI is recommended instead of blind techniques using bougie stylets or through SADs because blind techniques may cause significant trauma. Cricoid pressure should be removed during SAD placement. Maximum of three attempts. Declare failed SAD placement and verbalize implementation of plan C.
- *Plan C*: Attempt to oxygenate using a facemask. If facemask ventilation is possible, awaken the patient. Provide complete paralysis if facemask ventilation fails. Declare failed mask ventilation and verbalize implementation of plan D.
- *Plan D*: Declare cannot intubate and cannot ventilate/oxygenate, proceed with cricothyrotomy. Attempts to oxygenate the patient should continue (e.g. facemask, SAD, and nasal cannula). Surgical cricothyrotomy using a scalpel for access is the preferred rescue technique. DAS guidelines recommend regular practice with this technique.

There are similarities between the ASA difficult airway algorithm and other airway algorithms. For example, in the event of failed

intubation, the ASA difficult airway algorithm reverts to facemask ventilation, and if that proves inadequate, moves to ventilation with an LMA. The DAS's algorithm suggests using the LMA as means for ventilation and oxygenation immediately after a failed intubation, and then if the LMA fails, suggests reverting back to facemask ventilation. Both the ASA and DAS algorithms advocate for awakening the patient if initial attempts at intubation fail but subsequent ventilation attempts succeed. Furthermore, both recommend the placement of a cricothyrotomy if intubation has failed and both facemask and LMA ventilation have proven to be inadequate, although the DAS guidelines promote the surgical cricothyrotomy approach.^{11,83}

It is worth noting the important role of the SADs within the difficult airway algorithms. SADs are used for rescue ventilation at two points in the ASA difficult airway algorithm: first, in the anesthetized patient whose trachea cannot be intubated but who can be ventilated with a facemask (anesthetized nonemergency limb); and second, in the anesthetized patient whose trachea cannot be intubated and whose lungs cannot be conventionally ventilated (anesthetized emergency limb). The DAS algorithm recommends using an SAD device if initial TI fails. Comparable uses can also be found in other national recommendations from Germany and Italy.^{84–86}

The number of laryngoscopic attempts and the total procedural duration for intubation are quantifiable objective measurements used by multiple airway management guidelines as indications of airway difficulty. Most airway management guidelines allow two to four laryngoscopic attempts and 5 to 10 minutes of total procedural time before they classify the airway as a failed laryngoscopic intubation.^{75,81,87} The number of laryngoscopic attempts is limited to prevent excessive airway instrumentation leading to airway trauma and increased difficulty. When an unanticipated difficult intubation is encountered, the first attempt is usually the “awareness” look or view, and the second attempt should be performed under the best possible conditions (e.g., proper head and neck extension, head and shoulders elevated, experienced practitioner). If subsequent attempts are performed, alternative approaches should be considered (e.g., blade change,

introducer usage, video laryngoscope, etc.), and possibly performed by a different clinician.⁸⁸

Many of the airway algorithms advocate for the use of different difficult airway adjuncts and strategies, including awake intubation, as long as ventilation is adequate and time permits. The choice of which adjunct to use is based on clinical judgment, which again should consider the patient's condition, the clinical setting, and the anesthesia provider's experience and skill level.

Frequent training in the clinical setting, at workshops, or during simulation scenarios can help increase familiarity with difficult airway management strategies and the use of different airway adjuncts, and may play a role in decreasing complications associated with difficult airway management.^{89,90} Ultimately, the primary goal of difficult airway management is to maintain ventilation and oxygenation, and each airway algorithm has been developed to assist in achieving this objective.

Difficult Airway Cart

A dedicated difficult airway cart or box is very useful during management of difficult airway situations. There is no definitive list of equipment, and the contents of the difficult airway cart should be decided on by the anesthesia department personnel based on the likely caseload and department budgets. The recommended basic elements of the difficult airway cart are devices for (1) standard laryngoscopy, (2) intubation by alternative means, and (3) tube position control; and (4) equipment for anesthetizing the airway (Box 24.6).⁸¹ Some difficult airway carts may also contain video and fiberoptic laryngoscopy devices.

Suggested Components of the Difficult Airway Cart

Standard Airway Equipment

- Oral and nasal airways of various sizes
- Tongue blades

- Flexible stylets
- Endotracheal tubes (cuffed and uncuffed) from size 2.5 to 8.0
- Miller laryngoscope blades sizes 0, 1, 2, 3, and 4
- Macintosh laryngoscope blades sizes 2, 3, and 4
- Extra laryngoscope batteries and bulbs
- Magill forceps
- Salem sump—16 and 18 French
- Suction catheters—10, 12, and 14 French
- Oxygen mask
- Nasal cannula
- Oxygen with 15 L/min regulator
- Ambu bag

Alternative Airway Equipment Options

- Supraglottic airway devices of different sizes (e.g. laryngeal mask airways—sizes 3, 4, and 5)
- Intubating supraglottic airway device
- Combitube or King Laryngeal Tube
- Lighted stylet (e.g., Trachlite)
- Eschmann stylet (e.g., gum elastic bougie)
- Tube exchanger—small, medium, and large
- Ventilating stylet

- Needle cricothyrotomy set
- Retrograde intubation set
- Melker percutaneous dilational cricothyrotomy set
- Transtracheal jet ventilator

Tube Position Control

- Stethoscopes
- CO₂ detectors
- Esophageal detector device

Topical or Infiltration Anesthesia

- Syringes—3, 5, 10, and 20 mL (three or four of each size)
- Angiocatheters—14, 16, 18, and 20 gauge (three each)
- Xylocaine jelly (2%)
- Lidocaine—4% topical, 2% for injection
- Surgilube
- Nebulizer
- Atomizer
- 4×4 gauze pads

Video Laryngoscope Options

- Airtraq
- C-MAC
- GlideScope

- McGrath Mac or Series 5

Fiberoptic Bronchoscopy Equipment

- Tongue clamp
- Light source
- Endoscopy mask
- Flexible fiberoptic compatible oral airway (e.g. Ovassapian intubating airway)

Awake Intubation

When airway management is anticipated to be difficult, and the clinical scenario is such that the patient should remain spontaneously breathing, many airway guidelines suggest awake video- or fiberoptic-guided TI. There are several benefits to awake intubation, the first being that the patient will maintain his or her own ventilation. In addition, the size of the pharynx may be improved because, due to the patient's inherent muscle tone, the tongue will have a more forward placement in the pharyngeal area and sufficient lower esophageal sphincter tone should persist. Because the patient will maintain spontaneous ventilation and pharyngeal/laryngeal muscle tone during airway management, regional anesthesia (e.g., airway blocks) provides an increased margin of safety and can help to facilitate both the viewing of airway structures and the placement of an ETT.²⁹ Anesthetizing an airway can be a time-consuming endeavor, and may need to be abandoned if the patient is unwilling or unable to cooperate in an elective situation. However, in an emergency, there is no absolute contraindication to awake intubation if it is considered the safest option for TI.

Sedative medications can be used to help the patient better tolerate an awake intubation. Agents that have been used include midazolam, propofol, etomidate, ketamine, fentanyl, remifentanyl, and dexmedetomidine.⁹¹ Dexmedetomidine has been shown to be effective as the sole sedative agent for awake TI in patients with

local anesthetic allergies.⁹² However, if permitted, local anesthetics and other agents are generally used to prepare the airway. Agent selection depends on the clinical situation (e.g., an emergency that requires immediate airway access versus an anticipated difficult airway for a scheduled surgery), availability of the medication, and the provider's familiarity with the sedative agent. In addition, combinations of these medications are frequently used in clinical practice to reduce the total amount of any one drug given, especially as most cause respiratory depression in a dose-dependent fashion.

Caution should be exercised in patients with any degree of respiratory compromise or who are at risk for developing respiratory failure, because even small doses of sedative medications may induce apnea. Furthermore, sedative and opioid analgesic agents decrease both pharyngeal and laryngeal muscle tone, which can lead to a total obstruction of the airway. Finally, deep sedation, or sedation levels that approach general anesthesia, defeat the purpose of performing an awake intubation and increase the risk for loss of airway reflexes, upper airway obstruction, and airway failure.⁹¹

Awake Intubation Techniques

An awake intubation is the placement of an ETT into the trachea in situations where the patient is not under the influence of general anesthesia. "Awake" is somewhat of a misnomer, because, owing to inherent airway reflexes, it is very challenging to place an ETT without the use of local anesthesia, sedation, or both. However, the patient is awake in the sense that they are cooperative and ventilating spontaneously. Awake intubation is an essential component of difficult airway management, and should be a primary option any time abolishment of spontaneous ventilation is contraindicated. There are two awake techniques that can be considered after the patient has been prepared and the airway has been anesthetized:

1. Perform laryngoscopy with a standard or video laryngoscope to (a) facilitate TI, or (b) diagnostically determine whether the patient is truly difficult to intubate.

2. Perform flexible fiberoptic-guided bronchoscopy with a preloaded ETT that can be passed into the trachea.

The use of awake laryngoscopy to diagnostically determine difficulty with TI may help with the decision to proceed with video- or fiberoptic-guided techniques (while the patient is awake) or with anesthesia induction and paralyzation to optimize airway conditions. Another option to determine airway difficulty is the use of preoperative endoscopic airway examination. The purpose of this technique is viewing the airway anatomy to determine airway difficulty through an endoscope using minimal sedation and local anesthesia topicalization prior to entering the OR. It has been shown to reduce the need for awake intubation, and can help identify airway lesions that would otherwise not be seen in traditional external airway assessments.⁹³

When performing an awake fiberoptic-guided intubation, either an oral or a nasal ETT can be used. The nasal route often has a direct line of sight to the laryngeal opening; however, this route may carry an increased risk of hemorrhage or soft tissue damage. Examples of situations where an awake intubation would be necessary include patients with previous airway difficulty, unstable neck fractures, halo devices, small or limited oral openings, upper airway impingement by a mass, and patients in the critical care setting.

Patient Preparation

For maximum patient cooperation, the awake procedure must be clearly explained, and consent must be obtained. It is difficult, if not impossible, to proceed if the patient is uncooperative or unwilling to participate. Depending on the situation and the patient's condition, judicious use of anxiolytics and narcotics may be considered, as previously discussed. Examples of medications that may be considered when anesthetizing the airway are shown in [Table 24.6](#). Administration of an antisialagogue (such as atropine 0.5–1 mg intravenous [IV] or intramuscular [IM] or glycopyrrolate 0.2–0.4 mg IV or IM) can help dry secretions and maximize the view of the laryngeal structures. Furthermore, an antisialagogue will decrease the secretion of saliva, allowing topical local anesthetics to

penetrate the mucosa to a greater degree and enhancing anesthesia of the oral cavity, tongue, oropharynx, and hypopharynx. However, 20 minutes is usually required to effectively decrease secretions.

TABLE 24.6

Medication Considerations for Awake Intubation

	Medication	Indication
Intravenous Medications	Antisialagogue (glycopyrrolate or atropine)	Dry secretions in the airway
	Propofol Midazolam Ketamine Etomidate Dexmedetomidine Fentanyl Remifentanyl	Provides sedation and anxiolysis, and assists with patient cooperation <i>Caution with respiratory depression and decreased muscle tone</i>
	Bicitra Metoclopramide Histamine 2 antagonist (e.g., famotidine, ranitidine, cimetidine)	Aspiration prophylaxis
Topical or Infiltration Medications	Phenylephrine (1%)	Vasoconstrictors for nasal intubation
	Lidocaine (2%, 4%, 5%)	Topical local anesthesia
	Cetacaine	Topical local anesthesia
	Benzocaine (20%)	Topical local anesthesia
	Cocaine (4%)	Topical local anesthesia and vasoconstrictor
	Lidocaine (2%)	Infiltration nerve block

The risk of aspiration must always be considered when the airway reflexes have been anesthetized. Therefore, medications that decrease stomach acid production and promote gastric emptying should be considered. Vasoconstriction of the nasal passages reduces the risk of mucosal damage and hemorrhage. Solutions containing 0.05% oxymetazoline (Afrin) or phenylephrine (Neo-Synephrine) can be sprayed into the nose 2 to 3 minutes prior to application of the local anesthetic. Cocaine (4%) has the benefit of local anesthetic action, as well as promoting vasoconstriction.

The most widely used local anesthetic for anesthetizing the airway is lidocaine in various forms (liquid, gel, and ointment) and concentrations. Cocaine (4%), benzocaine (20%), and tetracaine are also effective anesthetics. Peak serum lidocaine levels are highest 30 minutes after instillation. Use of lidocaine within the recommended dosage keeps serum lidocaine levels below toxic levels.^{94,95} The evidence regarding the maximum safe dose for the topical administration of local anesthetics is controversial. However, an

estimate of the maximum safe dose of local anesthesia should be calculated prior to any administration (e.g., lidocaine 4–5 mg/kg). Finally, clinical judgment of the situation is required, and the anesthetist should continually assess for signs and symptoms of toxicity.

Airway Blocks

Anesthesia for the airway can be provided by topical anesthesia, infiltration, or a combination of the two. The anesthetic requirements for the airway include sensory inhibition of the nasal, oral, pharyngeal, laryngeal, and tracheal mucosae. Specific branches of three cranial nerves need to be anesthetized to perform an awake oral or nasal intubation. The three cranial nerves include the trigeminal, glossopharyngeal, and vagus nerves (Fig. 24.18). Both the ophthalmic and maxillary divisions of the trigeminal nerve provide sensory innervation to the nasal septum and lateral wall. In addition, the mandibular division of the trigeminal nerve forms the lingual nerve, which provides sensation to the anterior two-thirds of the tongue. The glossopharyngeal nerve provides sensory innervation to the posterior third of the tongue, the soft palate, and the oropharynx. Finally, the vagus nerve provides sensory innervation to the hypopharynx, larynx, and trachea via the superior laryngeal nerve (SLN) and the recurrent laryngeal nerve (RLN). The internal laryngeal branch of the SLN provides sensation above the vocal cords, and the RLN provides sensation below the vocal cords (Fig. 24.19).

Topical Anesthesia

Anesthesia to the nasal septum, nasal wall, and nasopharynx blocks the anterior ethmoidal, nasopalatine, and sphenopalatine nerves that originate from the ophthalmic and maxillary divisions of the trigeminal nerve. These areas can be anesthetized by insertion of 5 mL of viscous lidocaine down each naris. The solution then liquefies to a greater degree and may coat the back of the throat. The nasal and oral cavities, as well as the nasopharynx and oropharynx, may also be anesthetized by adding 4–10 mL of 4% lidocaine with 1 mL of 1% phenylephrine to either a handheld nebulizer or a nebulizer attached to a facemask.⁹¹ As the patient breathes through the nose and mouth, small droplets of local anesthetic are deposited on the mucous membranes. This method is

also effective for anesthetization of subglottic tissue. However, this procedure requires a minimum of 10 to 20 minutes, and may necessitate additional topical anesthesia during the awake procedure.

An alternative approach to nebulization is providing topical anesthesia by atomization using a mucosal atomization device. Atomization produces larger droplets than nebulization, resulting in an increase of medication raining onto the upper airway mucosa and producing a denser block. The technique requires the patient take five to eight deep breaths on the atomizer through both the mouth and nose, which helps the fluid follow the same path as ventilated gases. Like nebulization, a similar dose of 4% lidocaine and 1% phenylephrine can be used for atomization.

Anesthetizing the mouth and oropharynx decreases the gag and coughing reflexes associated with awake intubations. Local anesthesia to this region blocks nerve transmission originating from the trigeminal (anterior two-thirds of the tongue) and glossopharyngeal nerve. Topical sprays provide effective anesthesia to the anterior portion of the tongue and mouth. Benzocaine 20% (Hurricane) spray is a topical anesthetic with a quick onset and short duration. A half-second spray delivers approximately 0.15 mL (30 mg), which is estimated to be approximately one-third of the toxic dose (100 mg). Cetacaine spray contains benzocaine (14%), tetracaine (2%), butyl aminobenzoate (2%), benzalkonium chloride, and cetyl dimethyl ethyl ammonium bromide. The combination of these medications shortens the onset time and increases the duration of action.⁹⁶ Methemoglobinemia is associated with the use of benzocaine, and has been reported after the use of these topical sprays. Therefore, only conservative amounts of these sprays should be used. An alternative method for providing anesthesia to the mouth and tongue is to have the patient swish and gargle for 2 minutes with 2% or 4% lidocaine solution. The patient should then spit out the solution.

Topical anesthesia for the oropharynx and posterior tongue may alternatively be provided using a "lidocaine lollipop," which can be made by coating the tip of a tongue blade with lidocaine ointment and then pulling the tongue forward while placing the lidocaine ointment on the back of the tongue. The tongue blade should be

held in place for 1 to 2 minutes to allow the lidocaine ointment to liquefy and coat the oropharynx. Additionally, either nebulization or atomization using lidocaine can provide effective topical anesthesia, if adequate time is allowed.

Topical anesthetization of the vocal cords may be accomplished by instilling local anesthetic directly onto the cords. This can be accomplished in one of two ways. After the nasal cavity has been anesthetized, a nasal airway or ETT is passed and positioned in close approximation to the vocal cords. The patient is instructed to take a deep breath. On inspiration, 5 mL of 2% lidocaine is inserted down the lumen of the nasal airway. This causes the patient to cough, indicating that local anesthetic was deposited on the vocal cords. Another option is using a fiberoptic bronchoscope (FOB) or video laryngoscope. After visualization of the vocal cords is achieved, local anesthetic solution can be deposited directly onto the vocal cords through the injection port of the fiberoptic scope or by using a laryngeal tracheal anesthesia device. An alternative option for deposition of local anesthetic using the fiberoptic scope is to place an 18-gauge epidural catheter through the suction channel. This allows precise topical injection of local anesthesia onto visualized airway structures.⁹⁷

Topical anesthetization of the upper airway can be achieved quickly and safely, provided the anesthetist prepares the patient, calculates the appropriate toxic dose of local anesthetic to be used, and becomes familiar with these and other topical anesthesia techniques. Alternative upper airway anesthesia approaches, which can be used alone or in combination with topical anesthesia techniques, are infiltration nerve blocks. Both topical and infiltration techniques have demonstrated acceptable conditions for awake TI.^{98,99}

Glossopharyngeal Block

The lingual branch of the glossopharyngeal nerve supplies sensory innervation to the posterior third of the tongue. To block the lingual branch, the practitioner first anesthetizes the tongue with topical anesthesia and then has the patient open his or her mouth and protrude the tongue forward. The anesthetist then displaces the tongue to the opposite side with a tongue blade, resulting in the

formation of a gutter (Figs. 24.20 and 24.21). Where the gutter meets the base of the palatoglossal arch, a 23- or 25-gauge spinal needle is inserted approximately 0.25 to 0.5 cm and aspirated for air. If air is obtained on aspiration, the needle has been placed too deeply and should be withdrawn until no air is aspirated. If blood is obtained, the needle must be withdrawn and repositioned more medially. This is important as intracarotid injection is a possible complication. After correct positioning, 1 to 2 mL of 2% lidocaine is injected, and the block is then repeated on the opposite side.^{91,96}

FIGURE 24.20 Glossopharyngeal nerve block.

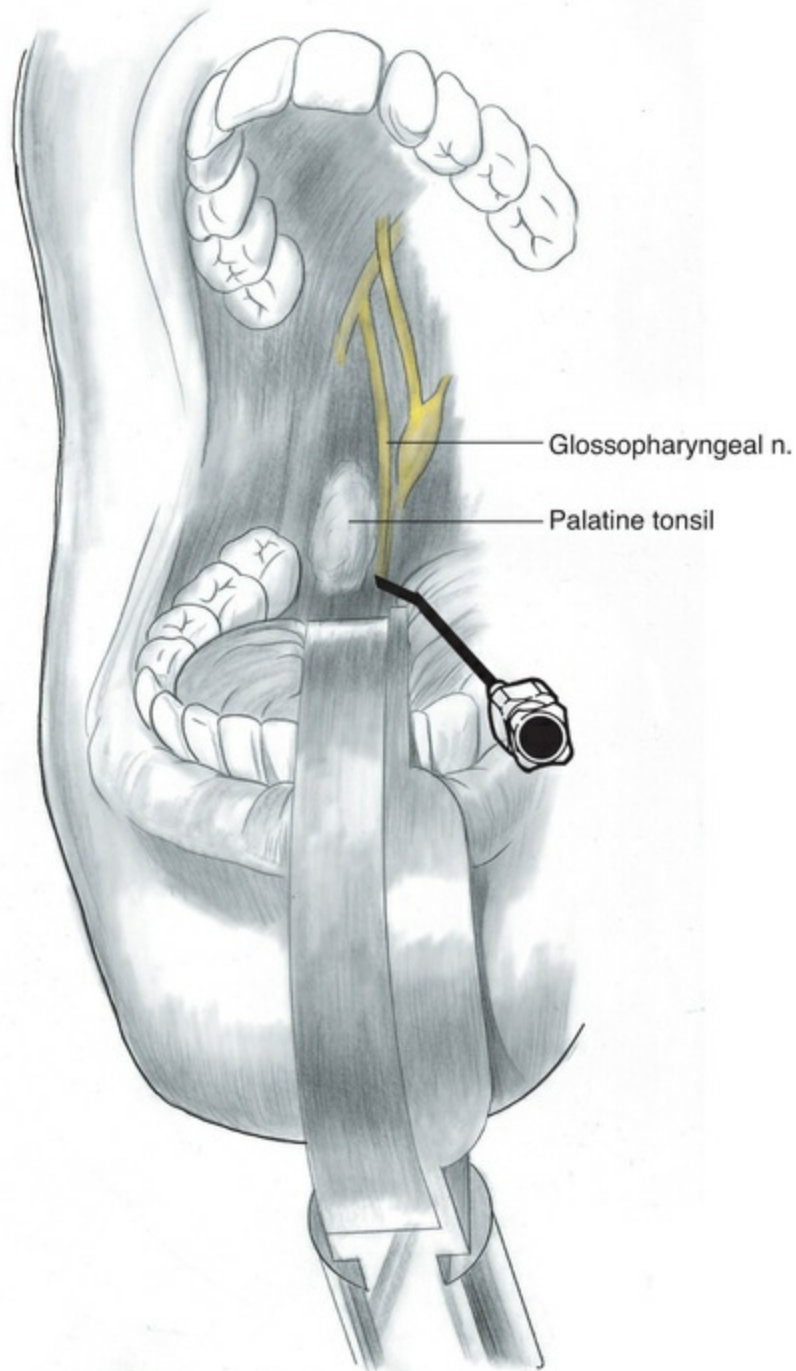

FIGURE 24.21 Glossopharyngeal nerve block anatomy and technique. *n*, Nerve. (From Brown DL, et al., eds. *Atlas of Regional Anesthesia*. 5th ed. Philadelphia: Elsevier; 2017.)

Superior Laryngeal Nerve Block

The superior laryngeal nerve block provides a dense block of the supraglottic region. To perform the block, the practitioner locates

the greater cornu of the hyoid bone, which lies beneath the angle of the mandible and can be palpated with the thumb and index finger on either side of the neck as a rounded structure (Fig. 24.22). The hyoid bone is then displaced toward the side that is being injected to help stabilize the bone and facilitate identification of structures and injection of the local anesthetic. The needle is inserted perpendicular to the skin to make contact with the inferior border of the greater cornu (Fig. 24.23). The needle is then “walked off” the caudal edge of the hyoid bone where it then meets the thyrohyoid membrane. Resistance may be appreciated as the tip of the needle may be felt to “bounce” on the thyrohyoid membrane.¹⁰⁰ This site approximates the area where the superior laryngeal nerve pierces the thyrohyoid membrane. Aspiration should confirm there is no air or blood, and 1 mL of local anesthetic (e.g., 2% lidocaine) is deposited above this membrane. The needle is then advanced an additional 2 to 3 mm through the membrane, and 2 mL of local anesthetic is deposited. The block is then repeated on the other side. Again, aspiration is performed before the injection of the local anesthetic. If air is aspirated, the needle has been placed too deep and is in the pharynx, and the tip of the needle should be withdrawn and repositioned. The same should occur if blood is aspirated.

FIGURE 24.22 Superior laryngeal nerve block anatomy and technique. *n*, Nerve. (From Brown DL, et al., eds. *Atlas of Regional Anesthesia*. 5th ed. Philadelphia: Elsevier; 2017:14.)

FIGURE 24.23 Superior laryngeal nerve block.

Transtracheal Block

The transtracheal block is accomplished by injecting local anesthetic through the cricothyroid membrane (Fig. 24.24). To administer the block, first palpate the cricothyroid membrane with the index and middle fingers (Fig. 24.25) and localize the skin. Then attach a 22-gauge needle or a 24-gauge angiocatheter to a syringe containing 3 to 5 mL of 2% lidocaine. Place the needle midline and puncture in a caudad direction through the cricothyroid membrane while aspirating continuously. When air bubbles are aspirated through the solution, the tip of the needle is in the tracheal lumen. If using an angiocatheter, the catheter is advanced into the tracheal lumen and the needle withdrawn, which may produce coughing.¹⁰⁰ The patient is then instructed to take a deep breath. On inspiration, the local anesthetic is injected into the tracheal lumen. This will cause the patient to cough, spraying the local anesthetic onto the vocal cords. Care must be taken to stabilize the needle so as not to tear the tracheal mucosa when the patient coughs. Use of the softer angiocatheter may decrease trauma.

FIGURE 24.24 Transtracheal injection. *n*, Nerve.

Cricoid Pressure

British anesthetist Brian Arthur Sellick first described cricoid pressure in 1961 as the posterior displacement of the cricoid cartilage against the cervical vertebrae with the patient in a 20-degree head-up position to prevent regurgitation and possible aspiration of stomach contents during the induction of general anesthesia. As such, cricoid pressure (e.g., the Sellick maneuver) has remained a mainstay of anesthetic practice, particularly in patients at risk for aspiration who receive rapid-sequence induction for general anesthesia. The optimal amount of force necessary to effectively occlude the esophagus without obstruction of the trachea is between 30 and 44 Newtons (N). It is recommended that 10–20 N (e.g., 2 kilogram-force) cricoid pressure be applied prior to loss of consciousness, and that the pressure be increased to 30–40 N (e.g., 4 kilogram-force) after loss of consciousness (Fig. 24.26).¹⁰¹ This pressure is equivalent to a firm pressure or a pressure that would cause discomfort if applied to the bridge of the nose.

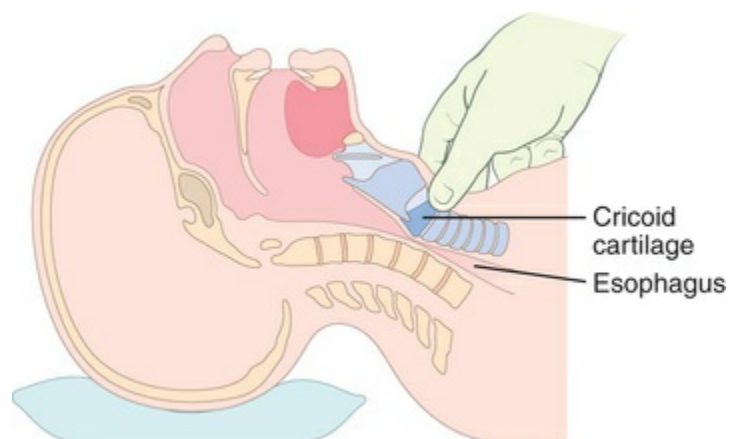

FIGURE 24.26 Application of cricoid pressure. (From Miller RD, Pardo MC, eds. *Basics of Anesthesia*. 6th ed. Philadelphia: Elsevier; 2011:229.)

The efficacy of cricoid pressure as an intervention to decrease the incidence of gastric aspiration and occlude the esophagus has been questioned on the grounds that initial studies researching cricoid pressure's effectiveness to prevent aspiration were conducted using

cadavers.^{102,103} There are also reports that cricoid pressure can interfere with visualization of the patient's airway during laryngoscopy and induce relaxation of the lower esophageal sphincter.^{103,104} Furthermore, MRI has demonstrated that the esophagus can be found lateral to the cricoid ring in more than 50% of patients. This proportion may increase to 90% after the application of cricoid pressure, theoretically hampering esophageal occlusion during posterior displacement of the cartilaginous cricothyroid ring.¹⁰⁵ However, there continues to be debate, claiming that the anatomic location and movement of the esophagus during the application of cricoid pressure is irrelevant to the efficiency of the Sellick maneuver because it is the hypopharynx that is compressed. In a cohort of unsedated volunteers, MRI showed that compression of the alimentary tract occurs with both midline and lateral displacement of the cricoid cartilage relative to the underlying vertebral body.¹⁰⁶

The application of cricoid pressure is not a benign procedure. Cricoid pressure of 44 N applied to the awake individual has been associated with laryngeal discomfort and retching. Furthermore, holding cricoid pressure during active vomiting may result in rupture of the esophagus and should be released immediately if vomiting occurs.¹⁰⁷ The application of pressure during rapid-sequence induction has been shown to decrease upper and lower esophageal sphincter tone.^{101,108} Other complications attributed to the use of cricoid pressure include (1) airway obstruction (e.g., partial or complete), (2) difficult laryngoscope placement, (3) glottic visualization impediments during laryngoscopy, (4) difficulty with facemask and supraglottic device ventilation, and (5) trouble with TI.^{102,103} However, the use of cricoid pressure is widespread and has value in the right circumstances.¹⁰⁹ The decision to use cricoid pressure should consider the potential benefits against the potential complications, and should be made based on the clinical situation.

Adjunct Airway Equipment and Techniques

Over the past two decades, multiple adjunctive airway devices have been developed for use in both routine and difficult airway management situations. Airway adjuncts include ETT guides, lighted stylets, rigid laryngoscopes, indirect rigid fiberoptic laryngoscopes, flexible FOBs, supraglottic ventilation devices, video scopes, and any device or piece of equipment that supports airway management. Techniques used for difficult intubation and ventilation may include any one or a combination of airway adjuncts. To improve proficiency, frequent use of adjunctive airway equipment should be considered in nonemergent or simulated practice situations.^{89,90} Ultimately, the selection of an airway adjunct for airway management is based on familiarity and skill with the device, as well as (1) the need for airway control; (2) the ease of laryngoscopy; (3) the ability to use supralaryngeal ventilation; (4) aspiration risk; and (5) the patient's tolerance for apnea.¹⁵ It is beyond the scope of this chapter to review all adjunctive equipment related to airway management as many airway tools and management devices exist. What follows is a review of the more established airway devices and pieces of equipment.

Supraglottic Airway Devices

SADs consist of those airway adjuncts that provide ventilation above the glottic opening. Different terminology has been used to describe these devices depending on where they are placed. For example, devices that sit above or surround the glottis (e.g., LMA, facemask) are truly supraglottic. In contrast, those devices that pass behind the larynx and enter the upper esophagus (e.g., Combitube, King LT [laryngeal tube] airway) are known as *retroglottic* or *infraglottic devices*. However, because ventilation with all these devices is performed superior to the glottic opening, SAD is the preferred terminology. The choice of an SAD is dependent on the clinical situation and preference of the provider. Indications for these devices include (1) rescue ventilation for difficult mask

ventilation and failed intubation; (2) an alternative to endotracheal intubation, in appropriately selected patients, for elective surgery in the OR; and (3) as a conduit to facilitate endotracheal intubation.¹¹⁰ SADs have proven to be valuable tools for airway management, especially in the patient who is difficult to ventilate and/or intubate. These devices are well-tolerated by patients because they follow the same inherent pathway as the airway, and unlike laryngoscopy, require minimal tissue distention in the hypopharyngeal space.

Laryngeal Mask Airway

Since its introduction into clinical practice in 1981, the LMA has been used extensively in airway management. Its development has been hailed as one of the most significant advances in airway management since the ETT.¹¹¹ The LMA can be used as the primary airway device during appropriate surgical procedures, and is considered a valuable airway tool when managing a difficult airway. A great deal of literature exists that reports the successful use of the LMA as a primary airway device and as a conduit for intubation of the trachea.¹¹¹⁻¹¹³

The LMA Classic (Fig. 24.27) was used extensively in Europe, primarily in England, before its introduction in the United States in 1989. Today, the LMA Unique (Fig. 24.28) is more ubiquitous in everyday practice because it is single-use only. Several variations of the LMA exist, including the Flexible, ProSeal, Supreme, and Fastrach models (all from Teleflex, Wayne, PA). In daily clinical use, the LMA can be used in place of BMV during general anesthesia. An appropriately sized LMA is generally based on patient kilogram weight (Table 24.7). Laryngeal mask insertion is usually accomplished using the classic technique, which is fully deflating the cuff and placing a water-soluble lubricant on its posterior surface. The practitioner inserts the LMA midline into the mouth with the posterior surface pressed flat against the palate of the mouth and then advances with the index finger along the palatopharyngeal curve. Reports have indicated between an 88% and 95% success rate on the first attempt with an experienced provider.¹¹⁴ If initial attempts at LMA placement are difficult, then the LMA should be removed and intubation should be attempted with the patient in a proper sniffing position. In addition, if the

LMA encounters resistance when it reaches the posterior pharyngeal wall, it is many times due to the distal tip having folded back as a result of aggressive posterior pressure, and the airway simply needs to be retracted and advanced again, applying a more upward pressure toward the top of the patient's head. If continued resistance occurs, then the operator can place the right index finger between the superior portion of the LMA and the palate and “flip the tip” back into normal position while advancing the device with the opposite hand. When properly placed, final resistance denotes placement of the LMA's tip in the hypopharynx, and the black line on the tubing will be even with the upper lip. The cuff is then inflated, sealing the airway over the larynx. Intracuff pressure should not exceed 60 cm H₂O. The esophageal opening at the base of the hypopharynx has no seal. If the cuff is overinflated, it can open the upper esophageal sphincter, or potentially cause posterior cricoarytenoid muscle fatigue.¹¹⁵

TABLE 24.7

Appropriate LMA Sizing Based on Patient Weight With Maximum Cuff Inflation Volumes

LMA Size	Patient Weight* (kg)	Maximum Cuff Inflation (Air) LMA Classic, Unique, Proseal, Flexible, & Fastrach	Maximum Cuff Inflation (Air) – Maximum OG Size LMA Supreme
1	Less than 5	Up to 4 mL	Up to 5 mL–6 French OGT
1.5	5–10	Up to 7 mL	Up to 8 mL–6 French OGT
2	10–20	Up to 10 mL	Up to 12 mL–10 French OGT
2.5	20–30	Up to 14 mL	Up to 20 mL–10 French OGT
3	30–50	Up to 20 mL	Up to 30 mL–14 French OGT
4	50–70	Up to 30 mL	Up to 45 mL–14 French OGT
5	70–100	Up to 40 mL	Up to 45 mL–14 French OGT
6 (LMA Classic only)	> 100 kg	Up to 50 mL	

*The Classic, Unique, Proseal, Supreme, Flexible, and Fastrach model sizes are based on similar patient weights.

LMA, Laryngeal mask airway; OG, orogastric; OGT, orogastric tube.

From Teleflex, Wayne, PA.

Alternative techniques and maneuvers can be used for LMA placement. The LMA can also be introduced into the mouth with the opening initially facing the palate. It is then advanced until the LMA reaches the oropharynx, when it is rotated 180 degrees

counterclockwise and advanced into its final position. Another technique is to partially or fully inflate the LMA cuff with air before insertion. Finally, guided techniques using an Eschman stylet (bougie) or a laryngoscope to facilitate placement have been reported.¹¹⁶ The LMA Flexible is a variation of the LMA Classic that utilizes a smaller diameter wire-reinforced barrel. Indications for use include surgeries on the mouth, pharynx, face, or jaw, or any other procedure in which the head may be moved, when heavy drapes cover the patient's face and head, or if the barrel cannot be secured at the midline.

Second Generation Supraglottic Devices

Compared to original SAD designs, second generation SDAs (1) attempt to reduce the risk of aspiration by incorporating a channel for gastric decompression and suctioning of secretions; (2) have reinforced tips that prevent folding; (3) incorporate improved cuff designs to help create a better cuff seal with higher ventilation pressures; and (4) are more rigid in their design to prevent rotation and to facilitate easier insertion.^{59,117} Indeed, current difficult airway algorithms support the use of these second generation SADs for the previously mentioned reasons.⁸³ Several different types of second generation devices exist including, but not limited to, the LMA ProSeal (PLMA) and LMA Supreme (Teleflex, Wayne, PA), i-gel (Intersurgical, Wokingham, UK), and the AuraGain (Ambu, Glen Burnie, MD). A significant amount of research and discussion is available describing the use of and comparing second generation SADs.^{118–123} The King LTS-D (Ambu, Glen Burnie, MD) is considered a second-generation SAD; however, its use is primarily in the prehospital setting, and it is not suitable as a conduit for TI. Ultimately, because these devices have all been proven to be effective for ventilation, the selection of an SAD will most likely be a result of the clinical situation and the airway provider's experience and comfort level.

The PLMA was introduced in 2000 as an alternative SAD to the LMA Classic, and comes in the same sizes ([Fig. 24.29](#)). Modifications compared to the LMA Classic include: (1) a larger and deeper bowl with no grille; (2) posterior extension of the mask cuff; (3) a gastric drainage tube running parallel to the airway tube

and existing at the mask tip; (4) a silicone bite block; and (5) an anterior pocket for seating an introducer or finger during insertion.^{123,124} The PLMA was designed with a second posterior cuff, which, when inflated, helps to separate the respiratory and gastrointestinal tracts, and a second tube developed for the insertion of a gastric tube into the esophagus without passing through the hypopharynx. The addition of this esophageal gastric drain tube allows the practitioner to identify misplacement and decompress the patient's stomach of air or solid contents, and may vent regurgitated stomach contents.

FIGURE 24.29 ProSeal LMA. (Courtesy Teleflex Inc.)

Compared to the LMA Classic, insertion of the PLMA takes an additional few seconds, but the overall success is equivalent. In addition, the airway seal is improved by 50%, allowing a peak ventilation pressure up to 28–30 cm H₂O (versus the 20 cm H₂O with the LMA Classic).^{117,119} The PLMA has been used in laparoscopic surgery (though this is controversial), as well as in the obese, intensive care, trauma, and difficult airway populations.¹²⁵ A disposable version of the PLMA, named the LMA Supreme (Fig. 24.30), has a fixed curve design for easier insertion, a gastric access port superior to the ventilation channel, and an integrated bite

block. Peak ventilation pressures were slightly lower when compared to the PLMA (e.g., 26–28 cm H₂O), although first-time insertion success rates were slightly higher with the LMA Supreme. Finally, the LMA Supreme has demonstrated similar capabilities as a ventilation and oxygenation device in challenging cases.^{120,122,126}

FIGURE 24.30 LMA Supreme. (Courtesy Teleflex Inc.)

The i-gel, first marketed in 2007, is a single-use second generation SAD designed for anesthesia and airway rescue (Fig. 24.31). Instead of an inflatable cuff, the i-gel mask is made of a medical grade thermoplastic elastomer which is soft, gel-like, and transparent. The device occupies the entire hypopharynx and laryngopharynx, is designed to create a noninflatable anatomical seal of the perilaryngeal structures while avoiding compression trauma, and relies on contact with these anatomical structures to create an effective seal for ventilation. The channel of the device can be used as a conduit for intubation under fiberoptic guidance. The i-gel incorporates a gastric channel to provide an early warning of regurgitation, allow for the passing of a nasogastric tube to empty the stomach contents, and facilitate venting. It also has an integral bite block to reduce the possibility of airway occlusion, and a buccal cavity stabilizer to aid with insertion and reduce the potential for

rotation. The tip of the i-gel mask is blunt to prevent it from flexing either forward or backward. Recent evidence suggests that proper placement of the device provides both a good seal and effective ventilation.¹²⁷ Clinical trials focused on the i-gel have demonstrated relative ease of insertion, high seal pressures, and a lower incidence of sore throat when compared with other SADs.^{121,123}

FIGURE 24.31 i-gel. (From Hagberg CA, ed. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Elsevier; 2013:495.)

The Ambu AuraGain is a preformed anatomically curved single-use SAD that includes a gastric access port, as well as intubating capabilities (Fig. 24.32). The device includes an integrated bite block, and comes in both pediatric and adult sizes. Limited data exist regarding use of the AuraGain, however, when compared to other SADs. It appears to have similar capabilities with respect to airway leak pressures, ease of insertion, and successful insertion when used in children.¹²⁸

The King LT differs from other SADs in that it does not have a mask that covers the laryngeal opening. Instead, this device is a one-time use, double lumen tube with a large oropharyngeal balloon and a smaller esophageal balloon. Ventilation ports are situated anteriorly between both balloons. A single pilot balloon is used to inflate both balloons when the device is situated in the airway. The larger oropharyngeal balloon isolates both the oropharynx and nasopharynx from above, and when inflated, lifts the base of the tongue anteriorly while providing stabilization of the device. The distal esophageal balloon sits at the esophageal inlet and isolates the esophagus from below, providing a high-pressure esophageal seal. The newer King LTS-D model (Fig. 24.33) is disposable, and includes a gastric vent posterior to the airway tube that accommodates an 18-French nasogastric suction tube for suctioning air and gastric secretions. The LTS-D is designed for blind insertion during emergency airway management, but is not suitable as a conduit for intubation. The King LT model has the capacity to achieve a ventilatory seal of 30 cm H₂O or higher. Scant data are available regarding the use of the LTS-D model when compared to other SADs; however, emerging data suggest that it is

popular in the prehospital environment because of its ease of insertion.^{112,129} Several other SADs have been introduced for single airway use. Examples include the Cobra perilaryngeal airway, which is a single lumen tube with a circumferential distal cuff just proximal to a distal adaptor that looks like a cobra head and is intended to expand hypopharyngeal tissue. Similar to the i-gel, the streamlined liner of the pharynx airway does not have an inflatable cuff, but does have the capacity to ventilate, and contains a reservoir to capture regurgitated material.

Intubating Supraglottic Airway Devices

Intubating SADs offer the ability to ventilate and then to attempt either a blind or fiberoptic-guided endotracheal intubation through a barreled channel. There are several types of intubating SADs, including the LMA Fastrach (Teleflex Inc., Wayne, PA), the air-Q (Mercury Medical, Clearwater, FL), and the Aura-I (Ambu, Glen Burnie, MD). A common indication for an intubating SAD is when difficulty with facemask ventilation or with TI occurs. Intubating SADs allow for continued ventilation and provision of anesthesia until TI is accomplished.

Perhaps the most well-known intubating SAD is the LMA Fastrach (Fig. 24.34), also known as the *intubating LMA*, which was released in 1997 and was specifically designed for use in anticipated and unanticipated difficult airway situations.¹³⁰ The LMA Fastrach has been used successfully in the “cannot intubate and cannot ventilate” scenario, in situations where a difficult intubation is anticipated, and in prehospital emergency airway situations where intubation is not possible by DL.¹³¹

FIGURE 24.34 Fastrach LMA. (Courtesy Teleflex Inc.)

The rigid curved design of the LMA Fastrach allows the mask aperture to align with the glottis vestibule. The primary distinguishing features, as described by the Fastrach inventor, Dr. Archie Brain, include: (1) an anatomically curved 13-mm internal diameter rigid airway tube that can accommodate an 8.5-mm ETT; (2) an integrated guiding handle at the proximal end to facilitate insertion; (3) a vertically-oriented semirigid epiglottic elevating bar; and (4) a guiding ramp built into the floor of the mask aperture.¹³² The device comes in sizes 3, 4, and 5. A description of the steps required for placing an LMA Fastrach can be found in [Box 24.7](#). After successful ETT placement, the rigid LMA Fastrach should be removed to avoid sustained pressure on the hypopharyngeal

tissues. An adaptation of the Fastrach is the C-Trach intubation device. This device was introduced in 2004, and added a fiberoptic cable and monitor screen (magnetically mounted) to the handle, but **Box 24.7** is no longer available.

LMA Fastrach and Endotracheal Tube Placement

Initial Preparation

1. Confirm integrity of LMA and ETT cuff (may use Fastrach reusable silicon-tipped ETT or standard prewarmed polyvinylchloride ETT) and then deflate cuffs.
2. Lubricate ETT with water-soluble lubricant at distal end and pass through to Fastrach lumen to lubricate inside the channel.
3. Lubricate anterior and posterior surfaces of LMA Fastrach cuff with water-soluble lubricant.
4. If using fiberoptic guided approach, prepare fiberoptic device and lubricate channel of fiberoptic scope.

LMA Fastrach Placement for Supraglottic Ventilation

1. Hold device by the metal handle in dominant hand and open the airway.
2. Insert cuff into mouth with mask tip in contact with the palate (metal tube portion will be near the chin).
3. Maintain firm upward pressure with the palate and posterior pharynx while advancing the LMA Fastrach into place until resistance is felt or handle meets face (only metal end of silicone-coated tube will protrude from mouth).
4. Inflate the cuff.
5. Confirm adequate ventilation (ventilation confirmation should

indicate consistent end tidal CO₂ waveform, positive change in color on CO₂-detecting devices, and equal bilateral breath sounds).

6. May manipulate device gently using handle until ventilation is optimized.

ETT Placement Through LMA Fastrach

1. Remove 15-mm connector from ETT and set aside (may place on ventilator circuit for easy placement back onto ETT postintubation).
2. Place ETT through Fastrach LMA lumen until it reaches the 15-cm marking. At this position the ETT is about to push the epiglottic elevating bar up, moving the epiglottis out of the way.
3. **Blind Approach:** Use the Fastrach handle to lift anteriorly, blindly insert ETT into trachea (should not encounter resistance), and inflate ETT cuff balloon.
 - a. **Fiberoptic-Guided Approach:** Insert fiberoptic through ETT channel and visualize glottis opening. Advance fiberoptic scope into trachea and then advance ETT over fiberoptic. Can confirm placement by carinal and tracheal ring visualization.
4. Finish by placing ETT connector back on ETT and attempt ventilation (ventilation confirmation should indicate consistent end tidal CO₂ waveform and equal bilateral breath sounds).

Remove Fastrach LMA

1. Remove ETT connector and set aside (may place on ventilator circuit for easy placement back onto ETT postintubation).

2. Deflate ETT balloon and Fastrach LMA balloon.
3. Place Fastrach stylet on the end of the ETT and provide countertraction caudally as the LMA Fastrach is removed.
4. When the ETT is visualized below the Fastrach cuff at the level of the mouth, hold ETT, remove stylet so that the ETT balloon cuff can pass through the LMA Fastrach barrel, and then remove the LMA Fastrach completely.
5. Replace ETT connector and reconfirm correct ETT placement in trachea (ventilation confirmation should indicate consistent end tidal CO₂ waveform and equal bilateral breath sounds).

ETT, Endotracheal tube; *LMA*, laryngeal mask airway.

Physician-inventor Daniel Cook developed an oval-shaped laryngeal mask that allows ventilation through the device and intubation with a standard ETT. The masked laryngeal airway known as the *air-Q* (Fig. 24.35) comes in a reusable and disposable form. The *air-Q* device is nonrigid and does not contain an epiglottic elevating bar, but does come with a removal stylet which provides stabilization of the ETT while the device is being removed. The *air-Q* was primarily designed as a routine SAD with intubating capabilities using standard ETTs, and unlike the LMA Fastrach, provides pediatric sizes. The device has proven to be a safe and effective conduit for intubation in the pediatric population, utilizing the fiberoptic-guided technique.¹³³ The Ambu Aura-i (see Fig. 24.32) is a disposable SAD primarily suited for conditions where intubation is not needed, but has the capability to facilitate standard ETT passage for TI. The device has a built-in anatomically correct curve, incorporates a bite-resistant connector block, and comes in pediatric and adult sizes that are each color-coded. As with all adjunctive airway equipment, intubating SADs should be used in routine cases to ensure familiarity with the device and technique before its use is attempted in an emergent situation.

FIGURE 24.35 Intubating laryngeal airway or air-Q.
(Courtesy Mercury Medical.)

Several new LMAs have recently been developed that have intubating capabilities. The LMA Unique EVO (Teleflex, Wayne, PA) is a one-time use SAD with a preformed curve to facilitate placement. It has an integrated bite block, a silicone cuff, and an integrated color-coded cuff pressure monitoring system. The Unique EVO comes in adult sizes only, and can accommodate a 7–8-mm ETT. The LMA Protector (Teleflex, Wayne, PA) is a single-use SAD with a preformed rigid curve design that incorporates a dual gastric channel. The Protector is designed to channel high-volume, high-pressure gastric contents away from the airway, and allows for the ability to suction secretions or gastric contents out of the airway upon removal of the device. The cuff and airway tube are made of silicone. The Protector also contains an integrated color-coded cuff pressure monitoring system, as well as an elongated cuff purported to create a more secure esophageal seal. This SAD comes in adult sizes and allows a 6.5–7.5-mm ETT and a 16–18-French gastric tube.

Supraglottic Tubes

Several supraglottic tubes (also known as *retroglottic* or *infraglottic tubes*) have been developed over the past several years. Devices in

this class include the Combitube, King LT airway, Rusch Easy Tube, and LaryVent. These devices are placed blindly through the mouth and positioned into the esophagus. These tubes have a distal balloon to occlude the esophagus, as well as a larger proximal balloon to occlude the posterior oropharynx. Between the two balloons is a ventilation port at approximately the level of the trachea. These devices can be used for both rescue and routine management, as well as for prehospital difficult airway situations.

The Combitube (Fig. 24.36) is a double-lumen airway device that is inserted blindly into the hypopharynx. The Combitube can be considered a secondary rescue device in the event of intubation, gum elastic bougie, and LMA failure.¹³⁴ This device contains an esophageal lumen and a tracheal lumen. The esophageal lumen has a blocked distal port and perforations at the pharyngeal level, whereas the tracheal lumen has only an open distal end. Regardless of tracheal or esophageal placement, the lungs may be ventilated. The usual placement of the tube is into the esophagus. If the tube is placed in the esophagus, the side ports of the esophageal lumen between the pharyngeal and tracheal cuffs allow for tracheal ventilation. This blind insertion is easily accomplished, and the patient's head can be kept in the neutral position. To successfully insert the Combitube, cricoid pressure should be released while the mandible and tongue are lifted anterior. After insertion, the cuffs of both lumens are inflated, and ventilation is first attempted with the esophageal lumen and assessed for verification. If there are no breath sounds and air is auscultated over the stomach, then it is probable that the tube was inserted into the trachea, and the tracheal lumen is then used for ventilation. Bilateral breath sounds and the presence of consistent end-tidal CO₂ should be confirmed to indicate successful placement. The Combitube may offer some protection from aspiration due to the distal cuff occluding the esophagus. The Combitube is a supraglottic device, and pathology at or below the laryngeal level may make the Combitube ineffective. Reported complications include esophageal rupture.

FIGURE 24.36 Combitube. (From Hagberg CA, ed. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Elsevier; 2013:571.)

Supraglottic Device Considerations

Familiarity with the different SAD models, their ease and speed of insertion, and their high likelihood of success in difficult airway situations make them an extremely valuable airway rescue devices. A significant concern with the use of SADs is the possibility of aspiration during insertion and ventilation. Inflation of the stomach, regurgitation, or aspiration of gastric contents can occur with SAD use; however, the incidence of aspiration has proven to be small, at 1–2 per 10,000 cases.¹³⁵ Furthermore, with the use of second generation SADs, the risk of aspiration may be further reduced. These devices can also be malpositioned or cuffs overinflated, resulting in failure to ventilate the patient. Malpositioning of the LMA in the airway and overinflation of the cuff may result in a disruption of the seal over the glottis, could disrupt the function of the gastric drainage port, or may create additional pressure to the sidewalls of the pharynx and posterior wall of the larynx. If this occurs, the epiglottis can be folded back against the glottic opening, obstructing the airway. Pathology at or below the laryngeal level may render SADs ineffective as a ventilation device. Indeed, LMA failures have been reported with both obstructions within the hypopharynx and obstructions below the hypopharynx, such as subglottic obstructions (e.g., tracheal thrombosis, tracheal stenosis, tumors), obstetric patients, aspiration, or severe rheumatoid arthritis.^{15,136} In obstetric anesthesia, the LMA

is used when TI has failed and ventilation with a facemask is difficult or impossible. In the cannot intubate and cannot ventilate scenario, the LMA, or another SAD of choice, should be attempted prior to a cricothyroidotomy. Finally, SAD use in nonsupine positions should be used with caution and evaluated on a case-by-case basis according to the situation. Insertion of an SAD is different in the lateral and prone positions than in the supine position, and may lead to failed placement or failed ventilation.

Intubation Stylets

Trachlite Lighted Stylet

The Trachlite (Laerdal Medical,) (Fig. 24.37) is a lighted stylet that uses transillumination of the neck to accomplish endotracheal intubation. As the light source enters the glottis opening, a well-defined circumscribed glow is noticed below the thyroid prominence, and can be readily seen on the anterior neck. Placement of the Trachlite in the esophagus results in a much more diffuse transillumination of the neck without this circumscribed glow. The Trachlite utilizes a bright light source that does not require low ambient light for optimum performance. In addition, a retractable stylet helps to increase intubation success.

FIGURE 24.37 Trachlite lighted stylet.

The device is less affected by anterior placement of the larynx, is

less stimulating than conventional laryngoscopy, and may be associated with a lower incidence of sore throat. The Trachlite is indicated in patients with a small oral opening or minimal neck manipulation, and can be used in both the anticipated and the unanticipated difficult airway when conventional laryngoscopy has failed.

The risk of injury or failure is increased when the device is used in patients with any upper airway anomaly, such as foreign body, tumor, polyps, or soft-tissue injuries. If these anomalies exist, other airway adjuncts should be used. Furthermore, it may be more difficult to accurately place the Trachlite in patients with short, thick necks or redundant soft tissue. Since the advent of fiberoptic stylets, the use of transillumination to facilitate intubation has declined. In 2009, Laerdal decided to cease production of the Trachlite stylet and tracheal lightwand.

Eschmann Stylet (Gum Elastic Bougie)

The Eschmann stylet ([Fig. 24.38](#)) is a 15-French flexible stylet that is 60 cm in length with a 40 degree bent distal tip. The stylet is used when the glottic opening is difficult to visualize (e.g., Cormack and Lehane grade II or III). Placement first involves visualization of the epiglottis or posterior arytenoid cartilages. The stylet is advanced behind the epiglottis and placed into the glottic opening. Feeling the stylet “bounce” along the tracheal rings as it is advanced into the trachea confirms placement, but is not always felt. The stylet should be advanced until the 25-cm marking is at the lip, where the stylet is then held in place. An ETT is inserted over the stylet and slid into the trachea. If resistance is felt, the ETT can be rotated 90 degrees to the left and then advanced. An alternative technique is to advance the ETT over the tracheal-placed Eschmann stylet until the ETT is in the oropharynx. DL or VL is then performed while an assistant holds the stylet in place. The ETT is then advanced through the glottic opening and into the trachea. Care should be taken not to advance the Eschmann stylet further into the trachea and risk a bronchial or distal tracheal puncture. The Eschmann stylet or bougie may be utilized during several potential clinical scenarios, including (but not limited to): (1) aiding advancement of an ETT during VL; (2) guiding ETT placement during difficult TI;

(3) during tracheal extubation, when it can be left *in situ*; and (4) during open surgical cricothyrotomy, when it can facilitate tracheal tube placement.

FIGURE 24.38 Eschmann stylet or gum elastic bougie.

Airway Exchange Catheters

Airway exchange catheters (AECs) facilitate interchanging an ETT and/or extubating the trachea. These catheters are capable of gas exchange using either jet ventilation or oxygen insufflation from an adapter and bag mask (Fig. 24.39). The AEC is introduced through the existing ETT with the distal tip placed proximal to the carina.¹³⁷ The ETT can then be removed and the new ETT placed over the AEC, which acts as a stylet guide into the trachea. If the new ETT encounters resistance or a “hang-up” during advancement, withdrawing the ETT 2–3 cm and rotating it 90 degrees may facilitate passage. An alternative technique is to place the new ETT over the AEC, advance until the ETT is in the oropharynx, and perform a similar technique as described previously with the Eschmann stylet using a laryngoscope. The AEC also can be left in the trachea after the extubation of a difficult airway, in the event that the patient requires reintubation. Care should be taken not to advance the AEC distally into either of the mainstem bronchi or to exert excessive force, which could result in a tracheal or bronchial perforation. If jet insufflation is used with the AEC, then muscle paralysis should be considered to prevent glottic closure. An oral airway device (or other airway device that promotes airway opening) can assist with maintenance of an open airway and gas egress.

FIGURE 24.39 Cook airway exchange catheter. (From Cook Medical Incorporated, Bloomington, Indiana.)

Flexible Scopes and Fiberoptic Stylets

Scopes can be either flexible or rigid and assist with the placement of ETTs through visual confirmation. These devices can be used during routine airway management, but are more frequently employed when the airway is expected to be difficult or during management of an unanticipated difficult airway.

Flexible Bronchoscope

Flexible bronchoscopes can be used to evaluate the airway, facilitate intubation in a patient with a difficult airway, check ETT placement, change an existing ETT, and perform postextubation evaluations. The flexible fiberoptic laryngoscope consists of multiple strands of tiny glass fibers that transmit light. These fibers are bound together inside a rubberized coating that allows for flexibility. Within the scope are working channels that can carry oxygen, act as suction ports, or be used to instill local anesthetic. The handle contains an eyepiece for viewing and a lever for controlling the distal end of the scope through one plane (either up or down). The second plane is navigated using side-to-side rotation of the scope by the operator's hand. Light is supplied by an external

light source or by battery. Newer models eliminate the fiberoptic components and instead incorporate a small camera at the distal end of the flexible tip that transmits images to an external screen for viewing. For simplicity, all flexible bronchoscopes will be referred to here as FOBs (fiberoptic bronchoscopes).

The limitations of fiberoptic laryngoscopy should be considered prior to performing this procedure, but ultimately the decision to proceed is based on the anesthetist's clinical judgment. Limitations of fiberoptic laryngoscopy include the following:

- Impaired viewing due to fogging, especially if the FOB is cold. Soaking the scope in warm saline, using an antifog liquid, or placing the scope in the buccal mucosa below the patient's lip for 5 seconds before use may help prevent fogging.
- Viewing can be limited when multiple fiberoptic strands are broken or damaged. The scope should never be banged or dropped, and should always be stored flat in a protective case or cart.
- Copious secretions or blood can obstruct the operator's view. This may be prevented with the instillation of oxygen at 10–15 L/min through one of the side channels or with effective suctioning.
- The FOB should be used with extreme caution in patients with epiglottitis, laryngotracheitis, or bacterial tracheitis, because aggressive contact with inflamed tissue may cause a partial obstruction that can convert into a total airway obstruction.
- Caution should be strictly exercised in patients with airway burns because of the restricted size and the hyperirritability of the airway.
- The use of the FOB is very limited in airway trauma. The presence of blood, tissue, and mucus in the airway may obscure the lens and make visualization impossible. If significant soft-tissue trauma is present, edema of the tissues can prevent adequate visualization of the larynx and trachea.
- Lack of patient cooperation may make awake FOB difficult, if not impossible.
- In hypoxic situations where both intubation and ventilation have failed and immediate airway access is required, it may be prudent to attempt a different airway technique because of time

constraints.

Indications for fiberoptic intubation of the patient include the following:

- *An anticipated difficult airway.* These patients usually have a history of intubation difficulty and upper airway obstructions such as angioedema, tumors, abscesses, hematomas, Ludwig angina, or lingual hyperplasia.
- *Cervical spine immobilization.* For example, patients with traumatic cervical injuries, an unstable cervical spine, or a cervical spine with a severely decreased range of motion.
- *Anatomic abnormalities of the upper airway.* Patients with a restricted mouth opening or hypoplastic mandible or who are morbidly obese may fall into this category.
- *Failed intubation attempt, but ventilation possible with a mask or SAD.* In these unanticipated difficult airway situations, the operator has time to set up and perform the fiberoptic technique using either an endoscopy mask or SAD as a conduit for the FOB.

The FOB can be used for oral or nasal intubation, with the patient either awake or asleep. An awake FOB intubation is most commonly performed for an anticipated difficult airway. Preparation for an awake FOB intubation includes educating the patient regarding what to expect, removing or drying up secretions, anesthetizing the patient's airway, and providing adequate sedation.

Topical anesthesia, nerve blocks, or a combination of the two can be used to anesthetize a patient's airway. Several drying agent and sedation options exist. Radiation can cause fibrosis and loss of mucus-producing glands, so drying of the airway can be extensive with the use of an antisialagogue in this patient population. Either atropine or glycopyrrolate may be administered 5 to 20 minutes before the procedure. Another option is to use suction and gauze to dry up existing secretions immediately prior to anesthetizing the airway. Administration of light sedation may help reduce the patient's stress and provide for a calmer environment. Several options exist, including fentanyl, midazolam, ketamine, or dexmedetomidine. However, carefully titrated amounts using small bolus doses should be considered whenever control of the airway is

in doubt. A short-acting titratable opioid such as remifentanyl is an alternative that can be used during the stimulating portion of fiberoptic intubation.¹³⁸

Preparation for fiberoptic intubation is important. A Yankauer suction device must be accessible whenever the FOB is used. Medications should be readily available, and include local anesthetics, resuscitation drugs, induction agents, and muscle relaxants. If the equipment is to be used outside of the OR, the appropriate monitors should be placed in the difficult airway cart. This cart can become the central location for all emergency airway devices, including invasive airway equipment and SADs.

Success with the FOB is dependent on familiarity with the device and skill in its use. This may be accomplished by continued training with intubation manikins, high-fidelity patient simulators, or during routine airway management in the clinical setting.¹³⁹ With oral intubations, a fiberoptic guide (such as the Williams, Berman, or Ovassapian airway) facilitates placement of the scope into the pharyngeal area, and can also help prevent damage to the shaft of the scope if the patient were to bite down (Fig. 24.40). The operator can either perform the technique at the head of the bed with the patient in the supine position, or from the side using a frontal approach with the patient in a sitting position (Fig. 24.41). The latter technique may help prevent tissues from falling against the posterior pharynx (impeding fiberoptic views), may help decrease anxiety in an awake patient, and has been used in patients with upper airway masses that compress the airway.¹⁴⁰

FIGURE 24.40 Ovassapian (*left*) and Williams (*right*) airways.

FIGURE 24.41 Fiberoptic intubation technique (frontal approach).

An ETT is first loaded onto the fiberoptic scope and is then inserted through either the mouth or nose and advanced to the posterior pharynx. The larger the ratio between the FOB shaft and the internal diameter size of the ETT, the more the potential for hang-up of the ETT on airway structures. The scope can be manipulated in two planes by adjusting the lever on the handle up or down and by rotating the scope laterally with the wrist. The

dominant hand holds the handle with the arm bent and resting on the operator's shoulder, or positioned to look through the eyepiece on the handle, while the other hand holds the distal portion of the scope to keep it taut (see [Fig. 24.41](#)). Care must be taken to keep the scope in the midline while the tip is advanced toward the epiglottis. The operator should be able to visualize the different airway structures (if not using a fiberoptic guide) as the scope is advanced through the oropharyngeal, pharyngeal, and laryngeal spaces. If at any point the view is lost, and the operator is unsure of the scope's location in the airway, it should be retracted until identifiable airway anatomy is visualized. Insufflation of oxygen through the suction port not only aids in the oxygenation of the patient, but also helps keep the optics clear. The tip of the scope is delivered through the glottic opening and advanced until the tracheal rings come into view. The ETT is then advanced downward, with the scope used as a stylet through the cords into the trachea. If a hang-up is encountered, the ETT should be slightly retracted, rotated 90 degrees, and then advanced. The ETT should never be forced into the airway because this may cause airway trauma. After the ETT is advanced into the trachea, the operator can verify placement by visualization of the carina.

Suctioning is difficult through the suction port. A more advantageous use of this channel is to provide the patient with supplemental oxygen. A 2–4 L flow through this port can provide additional oxygen to the patient and keeps debris from collecting on or near the port and lens. The administration of local anesthesia through the port or through an epidural catheter threaded down the port is another use of this channel.

All personnel who will be using the device should be trained in its care and cleaning. The bronchoscope should be handled with care because the fibers are very fragile, and bending, curling, or any other type of kinking could break them. After use, the scope should be flushed with warm sterile water, and all the channels cleaned thoroughly with the appropriate solutions and equipment. Manufacturers recommend specific detergents and sterilizing solutions. Instructions regarding solution, dilution, soak times, and rinsing must be closely followed to ensure the integrity and longevity of the equipment.

Rigid and Semirigid Fiberoptic Stylets and Laryngoscopes

Rigid and semirigid fiberoptic stylets and laryngoscope devices can be used in difficult airways situations, when intubation has failed, or during routine airway management.^{141,142} These devices provide the operator with an indirect view of the glottic opening through a transmitted image via a fiberoptic bundle that is enclosed in a preformed design. The use of both rigid and semirigid fiberoptic stylets allows the operator to see around the tongue, which makes them suitable for patients with limited cervical spine mobility. Trauma to the airway and a limited mouth opening are other indications for these devices. Examples of semirigid fiberoptic stylets include the Shikani optical stylet (SOS) and the Levitan First Pass Success (LFPS) scope. Rigid stylets include the Bonfils Retromolar Intubation Fiberscope (Karl Storz Endoscopy, Tuttlingen, Germany), the airway rigid intubation fiberscope laryngoscope (RIFL), and the Bullard laryngoscope. Indications and limitations with the use of these devices are similar to those described for the FOB.

Shikani Optical Stylet and Levitan FPS.

The SOS (Fig. 24.42) is a malleable, semirigid, intubating fiberoptic stylet that is useful in both adult and pediatric populations. It features a battery-operated light source with a high-resolution eyepiece on the handle that is then attached to a stylet. The SOS also has the ability to insufflate oxygen into the pharynx via an oxygen port connector. The malleable distal end allows configuration for varying intubation angles; this can be particularly useful for patients with a rigid or unstable cervical spine. The SOS can be used alone or in conjunction with DL.¹⁴³ The LFPS is similar to the SOS, but is intended to be used with a standard laryngoscope. Laryngoscopy is first performed with a standard laryngoscope. If the glottis opening is visualized, the LFPS can be used as a stylet to directly intubate the trachea. However, if only the epiglottis is visualized, the LFPS is placed into the airway below and posterior to the epiglottic edge. The operator then looks through the FPS eyepiece in order to visualize airway structures and advance the

stylet through the vocal cords. This semirigid scope has a malleable stylet to facilitate passage into the trachea. The stylet is 30 cm in length with a 5-mm diameter. Similar to the SOS, the LFPS has an oxygen port for insufflation.

FIGURE 24.42 Shikani optical stylet. (From Marx JA, et al., eds. *Rosen's Emergency Medicine*. 8th ed. St Louis: Elsevier; 2014:19.)

Bonfils Retromolar Intubation Fiberscope and RIFL.

These devices have a rigid anatomic shape with a fiberoptic bundle that affords an indirect view of the vocal cords. The rigid anatomic shape allows for visualization and intubation of the airway without aligning the oral, pharyngeal, and tracheal axes. These devices can be used on either an awake or an anesthetized patient. Because they do not require the sniffing position, they are ideal for patients with limited range of motion of the neck, such as those in cervical collars. Most have a channel for insufflation of oxygen while performing intubation and a small combination battery pack that permits portability.

The Bonfils fiberoptic stylet has a rigid shaft that is 40 cm long, has an anterior bend of approximately 45 degrees, and is meant to be advanced in the airway using a retromolar approach. Advancement of the ETT occurs after the stylet has passed through the vocal cords.

The RIFL is a hybrid rigid design incorporating a rigid stylet that ends with a flexible tip. This scope can be adjusted up to 135 degrees with the use of a trigger on the handle as the device is

advanced into the airway. The distal tip is manipulated as the operator slowly advances the stylet until it passes through the vocal cords, where the ETT is then advanced over the RIFL and placed into the trachea.

Video Laryngoscopy

VL has been described as the most significant advancement in the way intubation is performed since the development of the laryngoscope in the 1940s.¹⁴⁴ VL devices include illumination and a microvideo camera on the laryngoscope blade, which enables the transmission of video images to an external viewing screen. Glottic visualization is indirectly accomplished, and TI is performed while the operator views the external monitor. VL is a popular choice for anticipated difficult airways and as a rescue strategy when unexpected difficulty occurs. Indeed, some authors have found that video-assisted laryngoscopy provides improved visualization of the larynx over standard laryngoscopy.^{75,145} VL can be learned quickly, and has several advantages^{145,146}:

- Magnification of the airway allows the operator to visualize airway structures in greater detail.
- Blade design and anterior angulation, along with placement of the video camera on the distal portion of the blade, permit the operator to visualize structures that would otherwise be difficult or impossible to see under DL.
- The external monitor allows other practitioners to visualize airway anatomy and understand current airway conditions.
- The recording capabilities allow for education, documentation, and research.

Disadvantages of VL include cost, which can be as high as approximately \$10,000 or more. As with other optic devices, blood and secretions can obscure the viewing of airway structures. Pharyngeal injuries, such as anterior tonsil pillar, soft palate, or palatopharyngeal arch perforation, can occur from indirect ETT advancement and stylets.^{147,148} In addition, indirect placement of the ETT into the glottic opening while viewing an external monitor can prove difficult. No specific device is recommended over another;

however, speed, simplicity, reliability, and efficiency are desirable characteristics to be considered.¹⁴⁹ Finally, with the advent of this new technology, a debate exists regarding whether direct or video (indirect) laryngoscopy is better. Ultimately, this is dependent on the provider's experience and competency, and many researchers recommend maintaining proficiency with both DL and VL techniques.¹⁵⁰

GlideScope Video Laryngoscope

The GlideScope (Fig. 24.43) is perhaps the most widely used video laryngoscope, and provides a laryngoscopic view equal to or better than that of DL without manipulation of the head into a sniffing position.^{151,152} The device is made of medical grade plastic that is curved with a distal 60-degree anterior bend and is 18 mm wide. A camera is located in the middle part of the blade and transmits a signal via a video cable to a separate external liquid crystal display (LCD) monitor. The GlideScope features an antifog system that heats the lens around the video camera, preventing fogging of the device during laryngoscopy. Multiple models have been developed, such as the portable GlideScope Ranger intended for prehospital and military field use and the GlideScope Cobalt, which incorporates a disposable one-time use blade over a lighted video baton.

FIGURE 24.43 GlideScope AVL Single Use in airway.
(Used with permission, Verathon. Inc.)

When performing video-assisted laryngoscopy with this device, the blade should be inserted midline, and as soon as the tip of the blade is past the teeth, the operator should begin viewing the LCD monitor to identify the different airway structures and navigate to the glottic aperture. The blade should ultimately be placed into the vallecula, followed by a gentle tilt of the handle to allow visualization of the vocal cords. An accompanying rigid stylet is recommended with the use of the GlideScope to facilitate ETT delivery into the trachea. An alternative method is to bend the ETT and regular stylet at a right angle just proximal to the cuff. The ETT is inserted into the right side of the mouth by direct visualization and is advanced to the oropharynx. The operator should then view the monitor and slowly introduce the ETT using gentle forward semicircular rotation to align the tip of the ETT with the glottic opening. Once aligned, the ETT should be advanced through the vocal cords under video visualization.¹⁴⁶ At this point, the stylet may be withdrawn to help assist with the advancement of the ETT. The GlideScope should be cleaned before each use following the manufacturer's recommendations.

Karl Storz C-MAC Video Laryngoscope

The C-MAC video laryngoscope (Fig. 24.44) uses a blade design similar to a standard Macintosh blade, but unlike the GlideScope, uses a less sharp anterior curve. The insertion and technique of the device is similar to DL, with the added benefit of VL, if needed. The device includes illumination and a distally placed microvideo camera that resists fogging and provides an enhanced field of view. In addition, the C-MAC incorporates a video recording system that can be used for education and documentation. Because the angle of the blade is less acute than that of the GlideScope, the ETT can be formed into a shape consistent with regular DL. The C-MAC has proven to be a useful airway adjunct in patients with predicted difficult airways.¹⁵³

FIGURE 24.44 The C-MAC video laryngoscope with option for fiberoptic bronchoscope addition. (Photo courtesy of KARL STORZ Endoscopy-America, Inc. ©2016.)

McGrath Video Laryngoscope

The McGrath video laryngoscope is a portable device that was initially released into clinical practice in 2007. The McGrath Series 5 video laryngoscope (Fig. 24.45) requires a AA battery, whereas the newer McGrath Mac requires a proprietary 3.6V lithium battery pack for self-contained power. Both include a rotational color LCD screen attached to the handle. A one-time use disposable laryngoscope blade sleeve fits over the light source. With the Series 5, the sleeve is adjustable to three different positions. The McGrath blade is a modification of the Macintosh blade, and, like the GlideScope, has a similar distal anterior angle. In addition, similar to the GlideScope, a semirigid or rigid stylet is recommended to assist with the placement of an ETT. The McGrath does not have an antifog mechanism, but does incorporate a hydrophilic optical surface coating to minimize condensation on the light. The device is extremely portable, and can be transported out of the OR easily as both the camera and monitor are built into the device.

FIGURE 24.45 McGrath Series 5 scope. (Courtesy LMA North America.)

Channel Scope Devices

The Pentax Airway Scope, the Res-Q-Scope II, and the King Vision (Fig. 24.46) incorporate a small video screen into the handle of each device. All use disposable blades with a near 90-degree distal bend. All allow for the preloading of an ETT prior to airway manipulation. These devices can be used in patients with limited or no cervical spine mobility, in prehospital situations where space around the patient is limited, or during difficult airway management. None incorporate antifog capabilities, although the plastic material is purported to limit (but not eliminate) fogging. These devices are less expensive alternatives than the previously mentioned video laryngoscopes; however, lens contamination by fogging and blood or secretions severely limits their viewing capabilities. Several reports support their use in difficult airway situations.^{154,155}

FIGURE 24.46 King Vision. (Courtesy Ambu.)

The Airtraq (Fig. 24.47) is an optically enhanced laryngoscope that uses a series of mirrors, prisms, and lenses to magnify and enhance the laryngeal view. Like other channel and video laryngoscope devices, the Airtraq is designed to provide a view of the glottic opening without manipulating the neck into a sniffing position. The blade of the Airtraq has two channels. The first channel has a lighted, heated lens, and the second channel is for passage of an ETT up to a diameter of 8.5 mm. The Airtraq has a unique system that provides antifogging when the LED light is on for at least 30 seconds. There is an optional video camera that clips onto the viewfinder. When compared to standard laryngoscopy, the Airtraq was successful in achieving faster TI times, a reduced number of intubation attempts, and fewer hemodynamic changes.¹⁵⁶

Subglottic Interventions and Emergency Front of Neck Access

With the advent of SADs, VL, and other effective airway rescue devices, the need for invasive airway access, such as a cricothyrotomy, has decreased. However, regular training and practice in emergency front-of-neck access and subglottic airway techniques is important.^{69,83} This is particularly true with failed intubation and subsequent failed ventilation situations. When this occurs, the anesthesia provider must be familiar with and avoid any delay in performing emergency subglottic airway access such as surgical cricothyrotomy or needle cricothyrotomy with transtracheal jet ventilation. An elective cricothyrotomy can be considered in situations where access to the upper airway is limited, such as in patients with trauma or obstructive tumors.

Cricothyrotomy techniques are performed by perforating the cricothyroid membrane and establishing airflow into the trachea. The cricothyroid membrane is a fibroelastic membrane located inferior to the thyroid cartilage and superior to the cricoid cartilage.

Needle Cricothyrotomy With Transtracheal Jet Ventilation

Percutaneous transtracheal jet ventilation (PTJV) can be attempted after the placement of a needle cricothyrotomy through the cricothyroid membrane. The procedure is performed using a needle (e.g., 18-gauge or Ravussin needle) or a venous or arterial angiocatheter. Caution should be taken when using intravenous angiocatheters because these devices are at risk of kinking; consideration should be given to using more kink-resistant catheters. Ventilation through a catheter requires a jet injector powered by an oxygen source (Fig. 24.48). Needle cricothyrotomy with PTJV may be considered in cannot intubate and cannot ventilate situations; however, in the adult patient, a surgical cricothyrotomy can be performed quickly and provides a more secure airway with better ventilation. Instead, PTJV should be reserved for those airways where the anatomy is less favorable for placement of a surgical cricothyrotomy (e.g., small children younger than 12 years old) or as a temporary means of ventilation.¹⁵⁷

FIGURE 24.48 Transtracheal jet ventilation system assembly: (1) intravenous angio-catheter, (2) small-bore tubing assembly with Luer-lock fitting, (3) manual on/off valve, (4) pressure gauge (e.g., psi), (5) adjustable pressure regulator, and (6) high-pressure hose assembly,

with Diameter Index Safety System oxygen fitting (not shown).

The procedure can be accomplished quickly using a large-bore catheter inserted through the cricothyroid membrane (see Fig. 24.25) in a caudad direction (Fig. 24.49). The lungs are ventilated using a high-pressure oxygen source and a regulating valve to control oxygen flow through noncompliant tubing attached to the percutaneous catheter.

FIGURE 24.49 Insertion of needle for transtracheal jet ventilation.

Barotrauma is a concern because high-pressure oxygen is delivered through central wall outlets and high-flow (50–100 psi) tank regulators. Therefore, vigilant monitoring of psi pressures and a focus on longer expiratory times should occur during PTJV.¹⁵⁸ Most jet ventilators have a regulator to allow for a decrease in the inspiratory pressure. Inspiratory pressures should not exceed 50 psi on the regulator, and in most instances, 20–25 psi is sufficient. A 1-sec inspiration at 25 psi with a rate of 20 breaths per minute delivers a 285-mL tidal volume or 5.7 L/min ventilation. Exhalation occurs passively through the upper airway. Obstructions to passive exhalation or excessively large tidal volumes result in hyperinflation and incomplete exhalation of CO₂, and have been shown to be a common occurrence with needle cricothyrotomies.¹⁵⁸

Placement of bilateral nasal airways or an oral airway may facilitate exhalation and the egress of ventilated gases. Use of an in-line pressure gauge and inspiration:expiration ratios of 1 : 3 or 1 : 4 help decrease the incidence of barotrauma. High tracheal pressures created from PTJV can potentially stent open the glottis, making DL and identification of airway structures easier.

Complications associated with the use of PTJV include barotrauma, subcutaneous emphysema, pneumothorax, pneumomediastinum, hypercarbia, esophageal puncture, airway mucosal damage, blood or mucus obstruction, catheter kinking, and inadvertent removal.^{82,157} Bilateral breath sounds and bilateral chest rise should be confirmed frequently to rule out pneumothorax or dislodgement of the catheter.

Surgical Cricothyrotomy

A surgical cricothyrotomy is accomplished by cutting through the cricothyroid membrane and placing a cuffed tracheostomy tube or an ETT. Most airway algorithms and strategies recommend this procedure as a means of providing ventilation for patients who cannot be intubated or ventilated with a facemask or an SAD. The use of a cricothyrotomy kits allows this procedure to be performed in approximately 1 to 2 minutes.¹⁵⁹ Indications for cricothyrotomy include (but are not limited to) (1) failed airway (e.g., cannot intubate and subsequently cannot ventilate), (2) traumatic injuries of maxillofacial, cervical spine, head, or neck structures that make intubation through the nose or mouth difficult to impossible or too time-consuming, (3) immediate relief of an upper airway obstruction, and (4) the need for a definitive airway for neck or facial surgery, assuming intubation is not possible.

Absolute contraindications are rare; however, the anesthetist should consider avoiding surgical cricothyrotomy in favor of needle cricothyrotomy and PTJV in infants and small children younger than 12 years of age. The child's larynx is small, pliable, and movable, which can make cricothyrotomy very difficult in this population. Relative contraindications for cricothyrotomy include preexisting laryngeal or tracheal diseases such as tumors, infections, or abscesses in the location of the cricothyroid membrane, distortion of neck anatomy (e.g., hematoma), bleeding

diathesis, and history of coagulopathy.¹⁵⁷

Complications related to the placement of a surgical cricothyrotomy are similar to those listed under the placement of a needle cricothyrotomy. Identification of the cricothyroid membrane can be difficult in some patients, resulting in malplacement (e.g., inferior or superior to the cricothyroid membrane). In addition, perforation of the posterior tracheal wall can occur as a result of the surgical technique.⁷⁶ The use of ultrasound as a means to correctly locate the cricothyroid membrane has shown promise,¹⁶⁰ and may be considered in those patients with anticipated difficult airways prior to any airway manipulation. Several cricothyrotomy kits are available, such as the Melker, the Quicktrach II, the Pertrach, or the Portex cricothyrotomy kit (PCK). The tracheostomy tube is placed percutaneously using these kits either by a cannula over a trocar or by the Seldinger method. Both the Quicktrach II and PCK devices have a tracheostomy tube loaded over a trocar. The sequence of placing these devices over the trocar is as follows: (1) check the tube cuff for air leaks; (2) palpate the cricothyroid membrane and stabilize it between the first two fingers (see [Fig. 24.25](#) for palpation of the cricothyroid membrane); (3) insert the trocar/tube through the cricothyroid membrane in a caudad direction; (4) aspirate air and then advance the tracheostomy tube into the trachea; (5) remove the trocar and inflate the tube cuff; and (6) secure the tube with a tracheotomy tie and confirm ventilation.

The Melker Universal Emergency Cricothyrotomy Catheter Set (Cook Critical Care, Bloomington, IN) ([Fig. 24.50](#)), is a commonly used cricothyrotomy kit that contains equipment for both open surgical and Seldinger techniques. The Melker kit comes in 3.5-, 4.0-, and 6.0-mm internal diameter (ID) cuffed and uncuffed tube sets. Each kit has a tracheal cannula that is fitted internally with a curved dilator. A 15-mm circuit adaptor is located at the end of the cannula and allows attachment to a bag valve mask or anesthesia circuit. A scalpel, a syringe, an introducer needle with and without a catheter, a stiff guide wire, a tracheal hook, forceps, and tie tapes for securing the cricothyrotomy tube complete each kit.

FIGURE 24.50 Melker cricothyrotomy set. (From Cook Medical Incorporated, Bloomington, Indiana.)

The sequence of steps for placing a surgical cricothyrotomy using the Seldinger technique is as follows:

1. Place the patient's head in a neutral position.
2. Open the proper tray and place it in a position that is comfortable and within reach for the person inserting the device. First, prepare the kit by inserting the dilator into the cricothyrotomy tube.
3. Palpate the cricothyroid membrane and then, using the introducer needle with the syringe attached, puncture the neck in a caudad direction while aspirating with the syringe. Once air is aspirated, stop advancing the needle, and thread the catheter fully into the trachea. Attach the syringe to the catheter and again aspirate air (Fig. 24.51).

FIGURE 24.51 Needle inserted through cricothyroid membrane in caudad direction with aspiration of air for confirmation of proper placement.

4. Insert the flexible end of the guide wire through the catheter until it is approximately 2 inches beyond the tip of the catheter ([Fig. 24.52](#)).

FIGURE 24.52 Guide wire threaded through catheter in

neck.

5. Using the enclosed scalpel, incise the neck with a single insertion along the guide wire, with the sharp end of the blade away from the guide wire (Fig. 24.53).

FIGURE 24.53 Neck incised with scalpel along guide wire.

6. Thread the cricothyrotomy dilator/tube over the exposed guide wire and advance to the incision. Apply steady pressure by pushing on the dilator. Once there is a loss of resistance, usually preceded by a “pop” as the catheter penetrates the cricothyroid membrane, advance the cricothyrotomy tube off the dilator until it rests firmly against the neck. Remove the dilator and wire and assess for appropriate ventilation (Fig. 24.54).

FIGURE 24.54 Airway catheter/dilator threaded over guide wire, through cricothyroid membrane, and into the trachea.

7. Using sutures or the tape ties, secure the tube onto the neck while continuously ventilating the patient (Fig. 24.55).

FIGURE 24.55 Dilator and guide wire removed, allowing connection to a ventilation device.

An alternative surgical cricothyrotomy technique, known as the *scalpel-finger-tube*¹⁶¹ or *scalpel-finger-bougie*¹⁶² technique, uses equipment found in most ORs (i.e., scalpel, bougie stylet, 6.0 Shiley

tracheal tube, or a 6.0–6.5-mm ETT). The procedure is depicted in Fig. 24.56. If the cricothyroid membrane is difficult to palpate, then a vertical cut-down incision from the chin/neck junction extending caudad several centimeters should allow palpation of the cricothyroid membrane. Once found with digital palpation, a transverse incision through the membrane is performed, and the inside of the cricothyroid cartilage is palpated. A bougie is then advanced into the trachea with verification of correct placement by the operator's finger. The tube is then passed over the bougie and into the trachea.¹⁶² A potential serious complication with this technique is false passage of the bougie and/or tube through a dissected pretracheal fascial layer of tissue. Verification of correct placement should be performed, and can be accomplished with visual bilateral chest rise and auscultation, sustained positive end-tidal CO₂, and/or with visual confirmation through the tube of the tracheal rings and carina using an FOB or another optical device (i.e., LFPS).

FIGURE 24.56 Surgical cricothyrotomy technique with

cricothyroid membrane palpable: Scalpel technique; “stab, twist, bougie, tube.” **A**, Identify cricothyroid membrane. **B**, Make transverse stab incision through cricothyroid membrane. **C**, Rotate scalpel so that sharp edge points caudally. **D**, Pulling scalpel caudally to open up incision, slide coude tip of bougie down scalpel blade into trachea. **E**, Railroad 6.0 mm Shiley tracheal tube or 6.0–6.5 mm endotracheal tube over bougie into trachea. (From Frerk C, et al. Difficult Airway Society 2015 guidelines for management of unanticipated difficult intubation in adults. *Br J Anaesth*. 2015;115(6):827–48. Used with permission.)

The decision to place a cricothyrotomy should not be delayed when indications are present.⁷⁶ Indeed, a review of closed claims data for injuries related to invasive airway access suggested that failure to apply the technique early enough, and before significant hypoxia developed, resulted in death or brain damage in two-thirds of the claims reviewed.⁸² Furthermore, current airway algorithms suggest preparing for the possibility of cricothyrotomy early, and promote verbalization of the failed airway and transition from one airway plan to the next in an effort to promote team situational awareness.⁸³ Most researchers advocate for regular training and practice in an effort to maintain proficiency with this critical skill.^{83,163,164}

Retrograde Intubation

A retrograde wire-guided intubation may be considered in situations where intubation has failed but ventilation is possible. Indications can include impaired visualization of the vocal cords from blood, secretions, or anatomic anomalies, airway tumors, an unstable cervical spine, or upper airway trauma. A commercial kit is available for retrograde intubation, or the practitioner can choose to insert either a “J-wire” or #2 Mersilene suture thread via a cricothyrotomy and pass the device cephalad into the oropharynx. This procedure is performed by inserting a 14- to 18-gauge IV catheter or a Cook needle through the cricothyroid membrane and directing it cephalad. After aspiration of air is confirmed, a wire or suture is then inserted through the needle and passed cephalad until it can be visualized in the posterior pharynx. It is then either

advanced through the mouth or retrieved using Magill forceps. The distal end of the wire is secured with a clamp at the neck to prevent the wire from being pulled into the trachea prematurely. An ETT is then directed over the wire and passed into the trachea. As the tube enters the larynx, tension is increased on the wire or suture. Once the ETT is through the larynx and cannot pass further, the distal wire is removed at the level of the skin, and the ETT is advanced further into the trachea. Placement should be confirmed and the tube secured in place. The time required for completion and the potential difficulty of wire or suture retrieval and ETT passage limit the usefulness of this technique.

Tracheotomy

An additional surgical airway technique is the surgical tracheotomy. However, this surgical intervention has limited use in an emergency, and is generally performed by a surgeon. Potential complications with this procedure include RLN trauma, damage to large vessels in the neck, and posterior tracheal wall perforation with esophageal trauma. In emergency situations with significant airway compromise, a surgical cricothyrotomy should be the invasive airway technique of choice. The standard tracheotomy is performed at the level of the fourth to sixth tracheal ring, and below the isthmus of the thyroid gland. This procedure can take up to 30 minutes.

Tracheal Extubation

Tracheal extubation and continued control of the airway during recovery are cornerstones of perioperative airway management. Tracheal extubation remains a logical corollary of TI, in that almost all intubations are performed with the prospect of tracheal extubation at some point during the course of a hospitalization.¹¹ During the perioperative period, the plan for tracheal extubation should be considered to (1) minimize alterations in cardiopulmonary physiology; (2) decrease the risk of respiratory infection and complications; and (3) reduce the postoperative length of stay while decreasing cost and resource utilization.

Tracheal extubation is not a benign procedure, and is associated with significant complications (Box 24.8).¹⁶⁵ Every tracheal extubation is a trial to determine whether a patient's spontaneous ventilation effort is adequate to support cardiopulmonary function. There is no guarantee that tracheal extubation will be tolerated, especially in patients with marginal cardiopulmonary reserve. Standard criteria for tracheal extubation can be divided into two categories: global and respiratory (Box 24.9). It is often impossible and impractical to fulfill the criteria in their entirety. However, the decision to extubate a patient should be based on a methodical and comprehensive evaluation of patient-, surgical-, and anesthetic-related risk factors for extubation failure (Box 24.10). Patients who require postoperative mechanical respiratory support should remain intubated until standard extubation criteria are met and risk factors for extubation failure are minimized.

Complications of Tracheal Extubation

Respiratory

- Airway obstruction
- Breath holding
- Inadequate clearance of secretions

- Coughing and straining
- Hypercarbia
- Hypoxemia
- Laryngeal cartilage damage
- Laryngospasm
- Negative-pressure pulmonary edema
- Postextubation laryngeal edema
- Pulmonary aspiration
- Stridor
- Subglottic or supraglottic edema
- Tracheomalacia
- Vocal cord damage (e.g., edema, paralysis, or dysfunction)

Cardiovascular

- Cardiac dysrhythmias
- Tachycardia
- Hypertension
- Left ventricular failure
- Myocardial infarction
- Myocardial ischemia

Neurologic

- Cervical spine injury

- Increased intracranial pressure
- Increased intraocular pressure

Other Considerations

- Damage to dentition or other airway structures
- Inadvertent removal of equipment (e.g., nasogastric tube)
- Self-extubation
- Unintentional extubation

Box 24.9

Standard Extubation Criteria

Global Criteria

- Acceptable hemodynamic status
- Normothermia
- Ability to maintain patent airway

1. Return of laryngeal and cough reflexes

2. Appropriate level of consciousness

- Adequate muscular strength

1. Reversal of neuromuscular blockade as indicated by train-of-four ratio greater than 0.9, tetanic response to 100 Hz for 5 seconds, and double-burst stimulation without fade

2. Head lift for more than 5 seconds with constant strong hand grip

- Acceptable metabolic indicators

1. Electrolytes within acceptable limits

2. Acid-base balance within acceptable limits

- Acceptable hematologic indicators

1. Hemoglobin level consistent with adequate oxygen delivery

- Adequate analgesia for optimal respiratory effort

Respiratory Criteria

- Adequate respiratory mechanics

1. Vital capacity greater than 15 mL/kg

2. Maximal negative inspiratory force greater than -20 cm H₂O

3. Adequate tidal volume of at least 4–5 mL/kg

- Ability to maintain adequate oxygenation (with FiO₂ less than 50%)

1. SpO₂ greater than 90%

2. PaO₂ greater than 60 mm Hg

- Ability to maintain adequate alveolar ventilation

1. PaCO₂ less than 50 mm Hg

- Acceptable spontaneous respiratory rate (breaths/minute)

FiO₂, Fraction of inspired oxygen; *PaO₂*, partial pressure of oxygen in arterial blood; *PaCO₂*, partial pressure of carbon dioxide in arterial blood; *SpO₂*, blood oxygen level.

Box 24.10

Risk Factors for Difficult Tracheal Extubation

Patient Risk Factors

- Comprehensive airway evaluation indicating possible difficult reintubation or extubation
- Current and past medical illnesses that affect extubation tolerance (e.g., cardiopulmonary disease)
- Difficult intubation or ventilation (e.g., vocal cord paralysis or dysfunction, morbid obesity, obstructive sleep apnea)
- Generalized airway edema (e.g., tissue trauma, drug or systemic reactions, angioedema, anaphylactic or anaphylactoid reactions, sepsis, inhalation injury, burns, SIRS)
- Limited cervical spine mobility injury (e.g., hard cervical collar or halo fixation, ankylosing spondylitis)
- Tracheomalacia

Surgical Risk Factors

- Airway surgery (e.g., uvulopalatopharyngoplasty, laryngeal or

tracheal surgery, tracheal resection, or reconstruction)

- Head and neck surgery (e.g., maxillofacial surgery, carotid surgery, thyroid surgery, facial and deep neck infections)
- Neurosurgical (e.g., cranial surgery, posterior fossa surgery, stereotactic brain procedures, and cervical fusion)
- Orthopedic surgery (e.g., close proximity to airway)
- Impingement of head and neck venous drainage
- Postsurgical injury (e.g., hematoma, hemorrhage, nerve injury)
- Prolonged surgical duration and intubation
- Prone or Trendelenburg position

Anesthesia Risk Factors

- Depressed neurologic status, muscular strength, or respiratory effort
- Difficult or traumatic intubation (e.g., failure to visualize glottis, intubation requiring multiple attempts or alternative techniques)
- Excessive head and neck movement during procedure
- Excessive volume resuscitation
- Intubation injury causing laryngeal incompetence or arytenoid dislocation
- Lack of cuff leak
- Laryngotracheal edema (e.g., caused by oversized endotracheal tube or dual-lumen tube, excessive cuff pressure, traumatic suctioning)

SIRS, Systemic inflammatory response syndrome.

Tracheal Extubation Techniques

The same vigilant care taken to secure the airway should be exercised when control of the airway is returned to the patient. Complications of tracheal extubation (e.g., laryngospasm) are increased when extubation is performed during Guedel stage II of anesthesia (e.g., the excitatory plane). Tracheal extubation should be performed with the patient in a surgical plane of anesthesia (e.g., deeply anesthetized or Guedel stage III) or fully awake. Advantages and disadvantages of deeply anesthetized versus fully awake extubation can be found in [Table 24.8](#). Patients with a history of difficult intubation or who are at high risk of aspiration should be extubated when airway reflexes return and the patient can ventilate spontaneously without difficulty. Increased cardiovascular stimulation during awake tracheal extubation can be minimized using β -blockers, calcium channel blockers, and vasodilators. Furthermore, coughing and straining can be attenuated by the judicious use of local anesthetics (e.g., intravenous, topical, intracuff lidocaine) and opioids (caution with hypoventilation).

TABLE 24.8

Tracheal Extubation Techniques

	Anesthetized	Awake
Advantages	Decreased cardiovascular stimulation Decreased coughing and straining	Return of airway reflexes Decreased risk of aspiration Airway reflex return Spontaneous ventilation
Disadvantages	Absent or obtunded airway reflexes Increased risk of aspiration Airway obstruction Hypoventilation	Increased cardiovascular stimulation Increased coughing and straining

Tracheal Extubation of the Difficult Airway

The American Association of Nurse Anesthetists and the ASA's closed claims analysis of perioperative difficult airway management revealed that claims for death or brain damage have decreased from initial closed claim reviews.^{82,165} The development of difficult airway guidelines and new airway adjuncts (e.g., SADs and VL) has greatly improved the safety of airway management

during anesthesia induction. Of particular interest is the fact that a significant portion of airway emergencies (up to one-third) happen upon extubation and recovery from anesthesia.⁶⁹ This may be attributed to the paucity of literature and guidelines regarding techniques for tracheal extubation of the difficult airway. Therefore, a preformulated airway management plan, based on extubation strategies or algorithms (Fig. 24.57), may be helpful in decreasing complications during or after extubation.^{82,165}

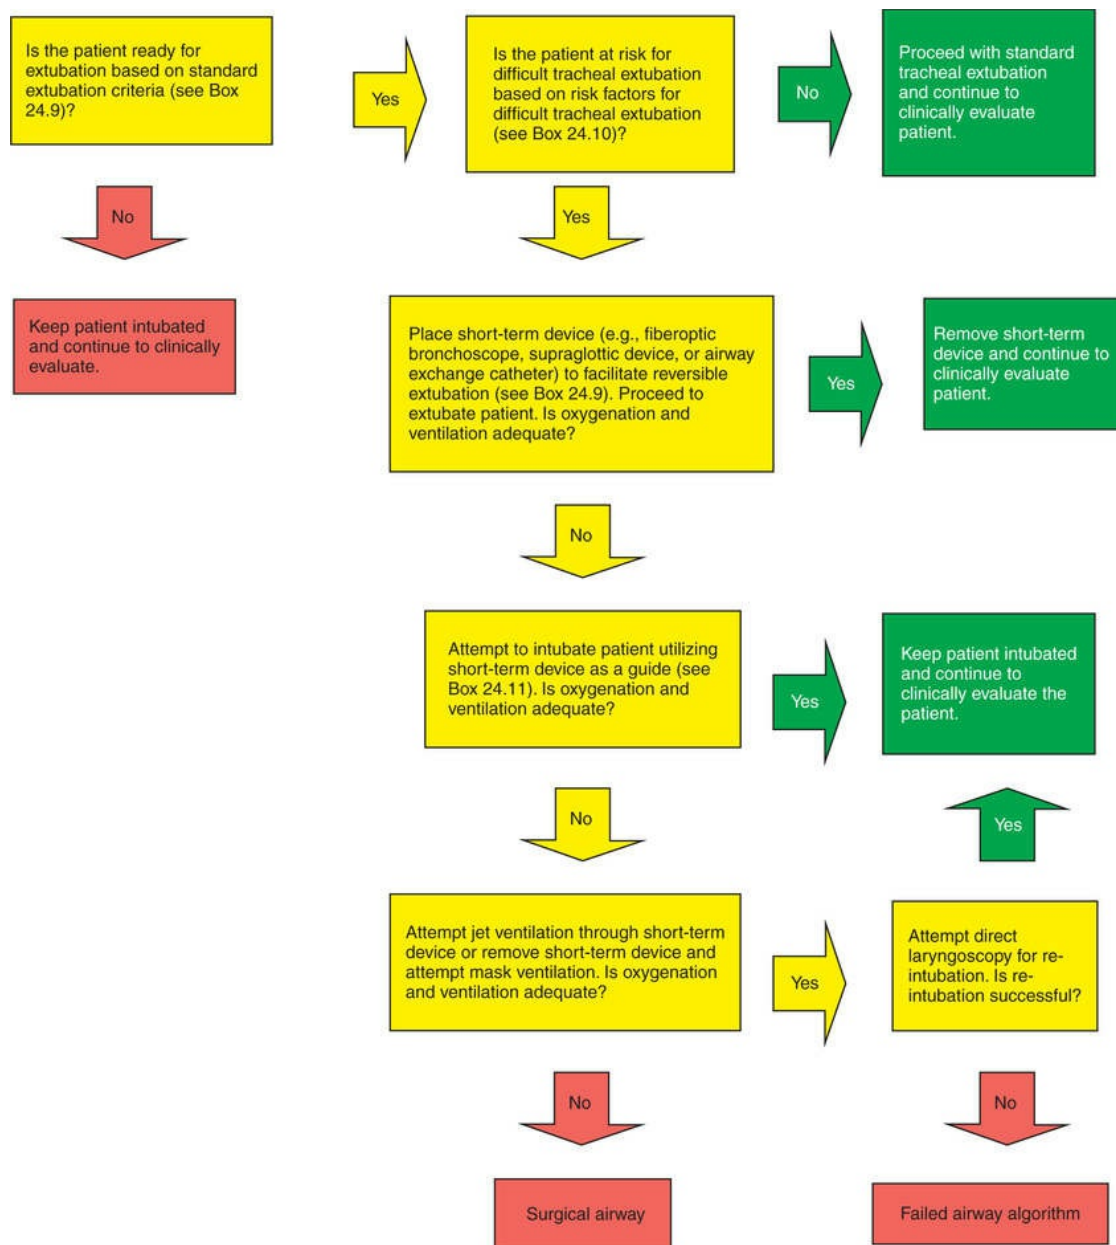

FIGURE 24.57 Extubation algorithm for the difficult airway, using an airway exchange catheter. Note: Short-term device refers to fiberoptic bronchoscope, supraglottic airway device, or airway exchange catheter.

Effective strategies for tracheal extubation in high-risk patients include: (1) extubation over a flexible FOB; (2) extubation followed by placement of a supraglottic airway (e.g., LMA); (3) use of an AEC; or (4) simply leaving an ETT in place until extubation criteria are met and it is safe to remove. The placement of these short-term devices serves as a guide for expedited reintubation in the event that oxygenation or ventilation proves inadequate after extubation

(e.g., reversible extubation). Advantages, disadvantages, and methods for both extubation and reintubation using these devices are discussed in [Table 24.9](#). Antisialagogues (e.g., glycopyrrolate) and/or sedative analgesics (e.g., dexmedetomidine) may help facilitate the placement and management of these devices. Prior to extubation of a difficult airway, a discussion with the OR team regarding subsequent airway plans (in the event of initial extubation failure) should occur, just as it should when initially managing a difficult airway. These plans can include the use of SADs, VL, and cricothyrotomy.⁸³

TABLE 24.9

Tracheal Extubation of the Difficult Airway

	Flexible Fiberoptic Bronchoscope	Supraglottic Airway	Airway Exchange Catheter (AEC)
Advantages	Useful method to evaluate pharyngeal and laryngeal function, injury, pathology, and obstruction	Facilitates fiberoptic bronchoscope evaluation of airway through mask orifice Associated with decreased cardiovascular stimulation, coughing, and straining	Maintains continual access to the airway Lumen allows for ventilation, oxygenation, tracheal suctioning, administration of medication, and carbon dioxide monitoring
Disadvantages	Requires experience and skill to properly manipulate device May offer only a brief evaluation of the airway May cause carinal irritation	Restricted evaluation of supraglottic and pharyngeal structures if fiberoptic bronchoscope used Periglottic obstruction will impair gas exchange through supraglottic airway	Dislodgement of AEC can occur any time during procedure Complications include trauma from deep placement, barotrauma or pneumothorax with jet ventilation, and carinal irritation Ventilation and oxygenation may not be effective
Method for extubation	Placement of fiberoptic-guided oral airway (e.g., Williams or Ovassapian airway) over existing endotracheal tube Tracheal extubation Insertion of bronchoscope with prefitted endotracheal tube Fiberoptic evaluation of airway Bronchoscope is left in place within the trachea and removed when deemed	Tracheal extubation Insertion of laryngeal mask airway (LMA) LMA is left in place and removed when deemed appropriate	Placement of AEC through endotracheal tube to predetermined depth (e.g., not to exceed 25–26 cm) Tracheal extubation over AEC Confirm depth and tracheal placement of AEC by standard methods, secure with tape AEC is left in place and removed when deemed appropriate

	appropriate		
Method for reintubation	Visual confirmation of bronchoscope within trachea Appropriately sized endotracheal tube is passed over bronchoscope Bronchoscope removed Placement of endotracheal tube confirmed by standard methods	Appropriately sized endotracheal tube passed through supraglottic airway tube, blindly or aided by fiberoptic bronchoscope Placement of endotracheal tube confirmed by standard methods	Remove tape and maintain depth of AEC Perform laryngoscopy to aid endotracheal tube advancement Appropriately sized endotracheal tube passed over AEC AEC removed Placement of endotracheal tube confirmed by standard methods

The AEC offers several benefits over the Eschmann stylet or gum elastic bougie (Box 24.11). There are three AECs currently available on the market: (1) the Endotracheal Ventilation Catheter (CardioMed Industries), (2) the Sheridan Tracheal Tube Exchanger (Hudson Respiratory Care), and (3) the Cook Airway Exchange Catheter (Cook Medical) (see Fig. 24.39). For adult patients, 11-French (external diameter: 3.7 mm) and 14-French (external diameter: 4.7 mm) AECs are generally well-tolerated and allow spontaneous breathing, phonation, and the clearance of secretions. After confirmation of placement and depth, the AEC may be secured in place until it is determined that reintubation will not be required. It is important to verify that the internal diameter of the reintubation ETT approximates that of the external diameter of the AEC as much as possible to prevent the leading edge of the ETT from catching and impinging on airway structures, causing trauma, and preventing passage through the glottis. A laryngoscope can be used to lift and move supraglottic tissue; this minimizes the angle of approach and facilitates ETT passage through the glottis. If the ETT encounters an obstruction at the glottic opening, slight retraction and manual rotation 90 degrees counterclockwise can be used prior to advancement to avoid arytenoid or vocal cord impingement.

Benefits of the Airway Exchange Catheter

- Exchangeable 15-mm external diameter connector for manual ventilation and Luer-lock adaptor for jet ventilation
- Facilitates removal of endotracheal tube while still maintaining continual access to the airway

- Lumen allows for ventilation, oxygenation, tracheal suctioning, administration of medication (e.g., local anesthetic), and carbon dioxide monitoring
- Lumen and side ports ensure adequate airflow, while blunt tip decreases trauma to airway (see [Fig. 24.39](#))
- Radiopaque and depth (cm) markers
- Sufficient length and rigidity guides replacement endotracheal tube into position (e.g., Seldinger technique)

Complications After Tracheal Extubation

Residual Neuromuscular Blockade

Residual neuromuscular blockade is a potential problem in the postoperative period, and can affect tracheal extubation. Complications of residual neuromuscular blockade include: (1) upper airway obstruction from pharyngeal muscle weakness; (2) hypoxemia; (3) increased risk of aspiration; (4) decreased ventilatory response to hypoxia; (5) unpleasant muscle weakness; and (6) delay in tracheal extubation.¹⁶⁶ Vigilant monitoring of neuromuscular function and correct administration of neuromuscular blocker reversal and binding agents can help to mitigate complications. Sugammadex is a cyclodextrin-based binding agent that contains a hydrophilic periphery and a lipophilic core. This agent is able to trap either rocuronium or vecuronium in a very strong cyclodextrin-target bond, effectively removing the blocking agent from the synaptic gap and rendering it inert.

Laryngospasm

Laryngospasm is the involuntary protective reflex that causes contraction of the laryngeal musculature (see [Table 24.1](#)). Bradycardia, pulmonary edema, pulmonary aspiration, and desaturation with accompanying hypoxemia are potential problems when a laryngospasm occurs, with a desaturation rate reported in up to 60% of patients. Laryngospasm is believed to occur as a result of sensory stimulation of the vagus nerve via the internal branch of

the SLN. Afferent responses causing spasm and closing of the vocal cords occur from the external branch of both the SLN and the RLN. The manner in which a laryngospasm occurs includes both the tensing of the cords by the cricothyroid muscles (stimulated by the SLN) and the adduction of the cords by the thyroarytenoid and lateral cricoarytenoid muscles (stimulated by the RLN).

Laryngospasm can be caused by a number of factors, such as airway manipulation, noxious stimuli (e.g., water, blood, or mucus) within the pharynx, or stimulation of the larynx during inadequate anesthetic depth. Tracheal extubation should therefore be performed with the patient in a surgical plane of anesthesia (e.g., deeply anesthetized or Guedel stage III) or fully awake to minimize the risk of laryngospasm. See [Box 24.9](#) for standard extubation criteria.

Laryngospasm has been described as having two mechanisms. During “glottis shutter closure,” intrinsic laryngeal muscles mediate vocal cord adduction, causing partial airway obstruction. In contrast, during “ball valve closure,” extrinsic laryngeal muscles cause contraction of the false vocal cords and supraglottic soft tissue, resulting in complete airway obstruction. If left untreated, laryngospasm can result in hypoxia, negative-pressure pulmonary edema, and cardiovascular derangements (e.g., cardiac arrhythmias, tachycardia, bradycardia, and cardiac arrest). Treatment of laryngospasm can be found in [Box 24.12](#). The Larson maneuver, also termed the *laryngospasm notch*, can be applied while performing a vigorous jaw thrust using bilateral firm pressure on the styloid process behind the posterior ramus of the mandible and anterior to the mastoid process. This technique has not been studied, but instead has shown anecdotal evidence for breaking a laryngospasm. Finally, when a laryngospasm occurs and rapid desaturation is observed, then paralysis with succinylcholine should not be delayed.¹⁶⁷

Treatment for Laryngospasm

1. Remove stimulus (e.g., suction the pharyngeal space)
2. Administration of 100% oxygen

3. Provide an open and clear airway (e.g., placement of an oral airway)
4. Perform a jaw thrust (e.g., Larson maneuver or pressure on the laryngospasm notch)
5. Apply positive-pressure ventilation (e.g., 10–30 cm H₂O pressure—beware of gastric insufflation)
6. Consider deepening the anesthesia with propofol (e.g., 0.5 mg/kg IV)
7. Administer succinylcholine (e.g., 0.2–2 mg/kg IV or 4–5 mg/kg IM)

Laryngotracheobronchitis

Laryngotracheobronchitis, or croup, involves inflammation and edema of the airway below the level of the vocal cords. Subglottic edema may manifest as stridor, which is the high-pitched inspiratory and expiratory sound caused by turbulent airflow through a partially obstructed upper airway. A “barking” cough is another distinctive symptom of croup. Croup can occur in adult and pediatric patients. However, pediatric patients are more vulnerable because of the narrow caliber of their airways. Because inflammation greatly increases airway resistance, respiratory failure can occur rapidly. Croup can be caused by (1) postintubation edema around the glottic and subglottic regions, (2) multiple intubation attempts, (3) an inappropriately large ETT causing laryngeal and tracheal capillary compression, or (4) excessive head and neck movement. Croup can occur anytime during the postoperative period, but typically occurs within 3 hours of extubation. Treatment of croup is aimed at decreasing inflammation and edema using (1) humidified supplemental oxygen, (2) racemic epinephrine (e.g., 0.5 mL of a 2.25% solution in 2.5 mL of normal saline), and (3) dexamethasone (e.g., 0.1 to 0.5 mg/kg). Other treatment modalities include the use of a helium-oxygen mixture to facilitate oxygen delivery through narrowed airways.

Complications of Airway Management

Complications related to TI include: (1) airway trauma; (2) aspiration; (3) esophageal intubation; (4) endobronchial intubation; and (5) ETT complications. Whereas individual treatments may vary, vigilant care and recognition of problems remain primary interventions if an airway complication occurs.

Airway Trauma

Trauma to the airway is a well-recognized complication related to airway management.¹⁶⁸⁻¹⁷⁰ Structures damaged and sites of injury noted in the analysis included the dentition, pharynx, larynx, esophagus, and trachea.¹⁶⁸ Of the anesthesia-related malpractice claims, dental injury is the most common.^{82,165,168} The majority of dental injuries occur during laryngoscopy and intubation, with the maxillary central incisors most at risk. However, dental injury can also occur after emergence and extubation. Risk factors for dental trauma include: (1) preexisting dental pathology (e.g., carious teeth, periodontitis, paradentosis, or fixed dental work) and (2) one or more indicators of difficult laryngoscopy and intubation (e.g., upper incisor protrusion).

Pharyngeal injury to the airway includes: (1) pharyngeal perforation, laceration, or contusion; (2) localized infection; (3) macroglossia; and (4) edema and necrosis of the uvula.^{168,169} The cause of pharyngeal injury is often the result of (1) direct trauma (e.g., laryngoscopy or blind pharyngeal suctioning), (2) prolonged mechanical compression and ischemia by an ETT or oral pharyngeal airway, or (3) pressure-induced nerve injury (e.g., lingual, recurrent laryngeal, or hypoglossal nerve). A malpositioned, oversized, or overinflated LMA may also cause trauma to delicate mucosa.^{168,169} Lastly, obstruction of the submandibular duct by extreme head flexion, surgical manipulation/trauma, or impingement via an ETT or bite block can cause massive tongue swelling in extreme cases. The incidence of sore throat after intubation is approximately 40% to 65% when blood is observed on the instruments (e.g., laryngoscope) after

airway manipulation. Fortunately, pain on swallowing usually lasts no more than 24 to 48 hours.

Trauma to the larynx can be subcategorized into (1) vocal cord paralysis, (2) granuloma formation, and (3) arytenoid dislocation and subluxation. Most susceptible to mechanical injury are the posterior half of the vocal cords, the arytenoids, and the posterior tracheal wall. Unilateral or bilateral vocal cord paralysis can most often be attributed to nerve or mechanical injury, and may manifest as partial or complete airway obstruction. Hoarseness or airway obstruction noted in the immediate postoperative period should be evaluated for possible emergent reintubation or tracheotomy. Granuloma or polyp formation can occur at the vocal process of the arytenoids, as well as the posterior wall of the trachea (Figs. 24.58 and 24.59), both of which come into intimate contact with the ETT. The degree of injury and granuloma formation increases with increasing ETT diameter and duration of intubation. Arytenoid dislocation (e.g., complete disruption of the cricoarytenoid joint, or malpositioning of the arytenoid cartilages) can be caused by the mechanical force of an ETT against the arytenoids or by forceful ETT placement.

FIGURE 24.58 Fiberoptic view of vocal cord polyps.

FIGURE 24.59 Fiberoptic view of granuloma.

Esophageal laceration or perforation can occur with any attempt at intubation, especially in patients with a difficult airway or after multiple attempts. Esophageal laceration or perforation may manifest as neck erythema, edema, pneumothorax, and subcutaneous emphysema. Mediastinitis associated with esophageal injury correlates with a high degree of morbidity and mortality despite aggressive treatment with surgical drainage and antibiotics.

Tracheal laceration or perforation may be caused by overinflation of the ETT cuff, overdistention of the ETT cuff by nitrous oxide, multiple intubation attempts, the use of an intubating stylet, repositioning of the ETT without cuff deflation, or the use of an inappropriately large ETT. The risk of tracheal injury is increased with tracheal distortion (e.g., neoplasm or enlarged lymph nodes), membranous trachea weakness, corticosteroid therapy, and chronic obstructive lung disease.

Aspiration

Pulmonary aspiration has two components: the movement of gastric contents from the stomach to the pharynx, followed by the movement of gastric contents from the pharynx into the lungs. Clinically significant aspiration is an uncommon complication of general anesthesia, with a reported incidence of 1 per 35,000 anesthetics.¹⁰² Less than half of all aspirations lead to pneumonia. An analysis of the ASA Closed Claims Project (CCP) indicated that aspiration pneumonitis was present in 3% of claims.^{82,168} Patient,

anesthetic, and pathologic risk factors for gastric aspiration are reviewed in [Box 24.13](#). The development of pneumonia, with subsequent ventilation perfusion abnormalities, is dependent on (1) the type of aspirate (e.g., contaminated, acidic, particulate, or nonparticulate), (2) the volume of aspirate, and (3) the patient's comorbid conditions. Aspiration pneumonitis can be divided into two phases: phase 1 (direct chemical injury) and phase 2 (inflammatory mediator release).¹⁰² Acute gastric aspiration can occur whenever the patient's laryngeal reflexes are inhibited. Gastric aspirate contamination into the lungs causes (1) chemical destruction of pulmonary tissue, (2) alveolar capillary membrane edema and degeneration, (3) alveolar type II pneumocyte destruction, and (4) microhemorrhage, leading to hypoxia. Management of this condition includes positive pressure ventilation and intensive physiologic support.

Risk Factors for Gastric Aspiration

Patient-Related Risk Factors

- Ascites
- Cardiac arrest
- Emergency surgery
- Full stomach
- Nausea and vomiting
- Obesity
- Scleroderma
- Severe hypotension
- Trauma or stress

Anesthesia-Related Risk Factors

- Cricoid pressure
- Difficult airway management
- Inadequate depth of anesthesia
- Opioids

Gastrointestinal Pathology

- Decreased esophageal sphincter tone
- Diabetic gastroparesis
- Gastroesophageal reflux disease (GERD)
- Gastrointestinal obstruction
- Hiatal hernia
- Increased gastric pressure
- Peptic ulcer disease

Neurologic Pathology

- Decreased airway reflexes
- Decreased level of consciousness
- Head injury
- Seizures

From Nagelhout JJ. Aspiration prophylaxis: is it time for changes in our practice? *AANA J.* 2003;71(4):299–303.

A number of mechanical and pharmacologic measures can be taken to minimize the risk of gastric aspiration. During airway management and mask ventilation, limiting peak airway pressures to less than 15 to 20 cm H₂O helps minimize gastric insufflation. If

higher peak airway pressures (e.g., greater than 25 cm H₂O) are necessary for ventilation, then gastric insufflation may occur. Realistic adherence to fasting guidelines should be instituted, and these guidelines should include consideration of the type of liquid or food consumed, patient age and characteristics, type of anesthesia and surgical procedure planned, and the presence of risk factors for gastric aspiration.

The application of cricoid pressure during rapid-sequence induction may be beneficial in preventing gastric aspiration, provided that it is performed properly and does not impede effective airway management. However, the use of cricoid pressure and its efficacy have been questioned, as primary studies were done on cadavers and have not been reproduced. Furthermore, it has been demonstrated that the esophagus is not directly posterior to the trachea in a significant portion of the population, causing it to move laterally during cricoid pressure application. Finally, lateral displacement and compression of the airway can occur during cricoid pressure, artificially causing difficulty with visualization of the glottic opening.^{171,172} However, there is evidence that esophageal occlusion does occur during correct application of cricoid pressure with 30 N of force, and it continues to be used for patients at risk for aspiration.¹⁷³

Pharmacologic methods that decrease the acidity and volume of gastric contents may reduce the risk of gastric aspiration. The administration of nonparticulate antacids (e.g., 30 mL of sodium citrate) 10 to 20 minutes before the induction of anesthesia effectively raises the gastric pH. A histamine-blocking agent (e.g., famotidine [20 mg IV], cimetidine [300 mg IV], or ranitidine [50 mg IV]) administered at least 45 to 60 minutes preoperatively is also effective in reducing stomach acid production and raising the gastric pH. Proton pump inhibitors, such as omeprazole, may also be administered the night before surgery to help reduce acid production. The administration of a gastroprokinetic agent (e.g., metoclopramide [10 mg IV]) 20 to 30 minutes before the induction of anesthesia accelerates gastric emptying.

Esophageal Intubation

Esophageal intubation may occur during any intubation procedure. However, during difficult intubation where inadequate visualization of the glottis occurs, the possibility of inadvertently placing the ETT into the esophagus increases significantly. Unrecognized esophageal intubation can lead to severe hypoxia and catastrophic complications, up to and including death. An analysis of the ASA-CCP indicated that a significant portion of respiratory-related claims involved esophageal intubation.⁸² Indeed, the results of the United Kingdom's fourth National Audit Project demonstrated that esophageal intubation and the lack of appropriate recognition of this complication still occurs.⁶⁹ It is imperative that confirmation of ETT placement within the trachea is verified with end-tidal capnographic CO₂ monitoring. Fiberoptic bronchoscopy is another sensitive method for confirming ETT placement, although its use may not be practical after every intubation. It is important to recognize that other traditional methods of confirming ETT placement, such as equal bilateral breath sounds, symmetrical chest wall movement, epigastric auscultation, and observation of tube condensation, lack specificity and are potentially misleading. Esophageal perforation, retropharyngeal abscess formation, subcutaneous emphysema, and pneumothorax have been documented after esophageal intubation. Mediastinitis is a potentially lethal consequence after esophageal intubation, with a mortality rate of 50%.¹⁶⁸

Endobronchial Intubation

Endobronchial intubation may occur during any intubation procedure, and is sometimes difficult to identify. This type of postintubation problem can contribute to high peak airway pressures, atelectasis, and inadequate ventilation. Endobronchial intubation occurs most commonly within the right mainstem bronchus. It occurs more commonly in infants and children because of the relatively short distance between the glottis and the carina. Signs and symptoms of endobronchial intubation include: (1) increased peak inspiratory pressures; (2) asymmetrical chest expansion; (3) unilateral breath sounds; and (4) hypoxemia. Endobronchial intubation may occur after initial placement of an

ETT or following extreme flexion of the neck. The tip of the ETT can move an average of 3.8 cm (up to 6 cm) toward the carina when the neck is moved from full extension to full flexion. When endobronchial intubation is discovered, the ETT cuff should be deflated and the tube carefully withdrawn into the trachea. The cuff should then be reinflated, after which the lungs should be hyperinflated sufficiently to expand any atelectatic areas.

Endotracheal Tube Complications

Complications regarding the ETT can occur any time during the administration of general anesthesia. In particular, partial or complete obstruction of the ETT may occur during a surgery of prolonged duration or in a patient with predisposing abnormalities of the airway anatomy. ETT obstruction may be caused by (1) mechanical factors (e.g., sharp bend, kinking, or biting), (2) foreign material (e.g., mucus, blood, tissue, foreign bodies, or lubricant), or (3) the ETT cuff. The expansion of gas bubbles within the ETT cuff by nitrous oxide or overinflation of the cuff may cause partial or complete airway obstruction. Wire-reinforced ETTs may be used to decrease the risk of mechanical obstruction in patients or during surgeries at risk for this complication.

To clear a partially obstructed ETT, a suction catheter or an FOB should be placed down the lumen of the ETT. If the ETT is totally obstructed, passage of a stylet or AEC should be attempted. Total obstruction that cannot be treated quickly requires removal of the ETT, followed by reintubation.

Summary

Airway management is a critical component of anesthesia practice. Knowledge of airway anatomy, physiology, and pathophysiology will aid in the formulation of appropriate airway management plans. In addition, the recognition of patient signs or symptoms and situations that indicate airway difficulty may help to develop effective airway management strategies. Adherence to established standards and protocols, including difficult airway algorithms, can minimize complications and assist the airway provider during both anticipated and unanticipated airway difficulty. Familiarization with airway equipment and competence with a variety of airway management skills and techniques will facilitate appropriate management when a situation involving a difficult airway occurs.

Cardiovascular Anatomy, Physiology, Pathophysiology, and Anesthesia Management

Sass Elisha

Cardiovascular System

A thorough knowledge of anatomy and physiology of the cardiovascular system is essential to anesthesia practice. Every anesthetic agent has either a direct or an indirect effect on the cardiovascular system. There are near-instantaneous and continuous changes in the cardiovascular response to surgical stimulation, physiologic alterations during surgery (e.g., blood loss), and variations in anesthetic depth. Therefore, whether the clinical concern includes decreased blood pressure during neuraxial blockade or myocardial depression during administration of an inhalation anesthetic agent, a thorough understanding of these effects and their implications with regard to human physiology is critical.

The cardiovascular system is composed of the heart and the vasculature that carries blood that provides oxygen and cellular substrate to all cells in the body. At the center of this network is the heart. The heart pumps deoxygenated blood to the lungs and then supplies oxygenated blood to all parts of the body. This chapter describes the anatomic and physiologic characteristics, as well as pathophysiologic changes associated with the cardiovascular system.

Heart

Gross Anatomy

The heart is bound anteriorly by the sternum and the costal cartilages of the third, fourth, and fifth ribs and inferiorly by the diaphragm. It is positioned with the apex of the heart projecting anteriorly and inferiorly toward the left fifth intercostal space at the midclavicular line. At this location, the pulsation from the cardiac apex may be palpated. This is known as the *point of maximal impulse*. The first heart sound (S_1) is best auscultated in this area. A third (S_3) or fourth (S_4) heart sound, if present, can also be heard in this location. Heart sounds are generated from the vibrations caused by the closure of the atrioventricular (AV) (e.g., S_1) and semilunar

(e.g., S2) valves.¹

Cardiac Silhouette

The superior aspect of the cardiac silhouette is formed by the transverse and ascending aorta. The right lateral border is composed of the right atrium (RA), and the mass of the right ventricle (RV) constitutes most of the inferior border. The left ventricle (LV) comprises the majority of the apex and the lower left lateral border. The left atrial appendage lies superior to the LV and to one side of the pulmonary artery. On X-ray, it is located between the LV and the pulmonary outflow tract. The heart is rotated on its base such that the anterior surface is almost entirely composed of the RV. The base of the heart is the most superior portion of the cardiac silhouette.

Pericardium

The heart is situated within the mediastinum and surrounded by a fibrous, double-walled sac called the *pericardium*, which envelops the heart and the roots of the great vessels. It consists of a visceral portion, which is in intimate contact with the outer surface of the heart (epicardium), and an outer parietal portion that adheres to the fibrous pericardium (Fig. 25.1).

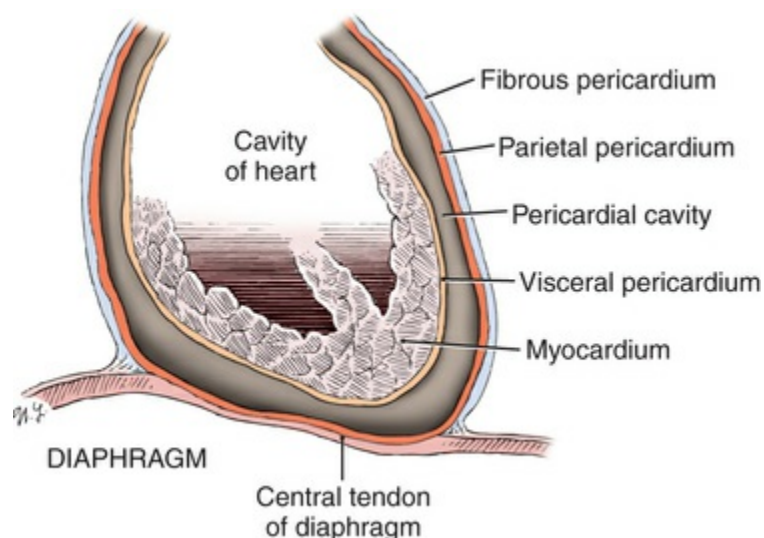

FIGURE 25.1 The pericardium.

The fibrous pericardium is pierced superiorly by the aorta, the pulmonary trunk, and the superior vena cava. The base of the fibrous pericardium is fused with the central tendon of the diaphragm. The visceral pericardium and parietal pericardium are separated by a thin potential space known as the *pericardial cavity*. This space normally contains approximately 10 to 25 mL of serous fluid, which provides lubrication for the free movement of the heart within the mediastinum. In disease states, the pericardial space can fill with blood and or serosanguinous fluid, compress the heart, and decrease cardiac output (CO). In acute cardiac tamponade, the volume rapidly increases, producing myocardial dysfunction. In contrast, in chronic cardiac tamponade, the degree of pressure exerted on the heart increases slowly because the pericardial sac stretches over time to accommodate the blood that accumulates.² However, the pressure may eventually increase as much as tenfold before symptoms associated with cardiac tamponade occur.³

The pericardium receives its arterial blood supply from the branches of the internal thoracic arteries and through the bronchial, esophageal, and superior phrenic arteries. Venous drainage from the pericardium occurs through the azygos system and the pericardiophrenic veins, which anastomose with the internal thoracic veins. Nervous innervation to the pericardium is derived from the vagus nerve, the phrenic nerves, and the sympathetic trunks.

Surface Anatomy

The atria are separated from the ventricles by the coronary sulcus (AV sulcus), as seen in [Fig. 25.2A](#). The right coronary artery (RCA) travels within this sulcus. The circumflex artery arises from the left coronary artery and travels in the coronary sulcus until it branches posteriorly. The RV and LV are separated by the interventricular sulci, which descend from the coronary sulcus to the apex. The interventricular sulci are composed of an anterior interventricular sulcus and a posterior interventricular sulcus. The anterior interventricular sulcus contains the left anterior descending (LAD) artery, which courses over the interventricular septum and continues into the posterior interventricular sulcus.

FIGURE 25.2 **A**, Surface anatomy of the heart (anterior view). **B**, Surface anatomy of the heart (posterior view). *a.*, Artery; *v.*, vein.

The crux of the heart is the place at which the coronary and the posterior interventricular sulci meet. Internally, it is where the atrial and ventricular septa meet (see [Fig. 25.2B](#)). This anatomic crux is important for determining coronary artery dominance.

Cardiac Skeleton

Essential to a discussion of the chambers of the heart is a description of the fibrous skeleton, the annulus fibrosus ([Fig. 25.3](#)). Tough fibrous rings surround the AV valves and act as points of attachment for the valves. Two additional fibrous annuli develop in relation to the bases of the aorta and the pulmonary trunk. The aortic fibrous annulus is connected to the pulmonary annulus by a fibrous band called the *tendon of the conus*. The aortic annulus is connected to the AV annuli by the small left fibrous trigone, and the larger right fibrous trigone is also called the *central fibrous body*. The four annuli and their interconnections constitute the fibrous cardiac skeleton.

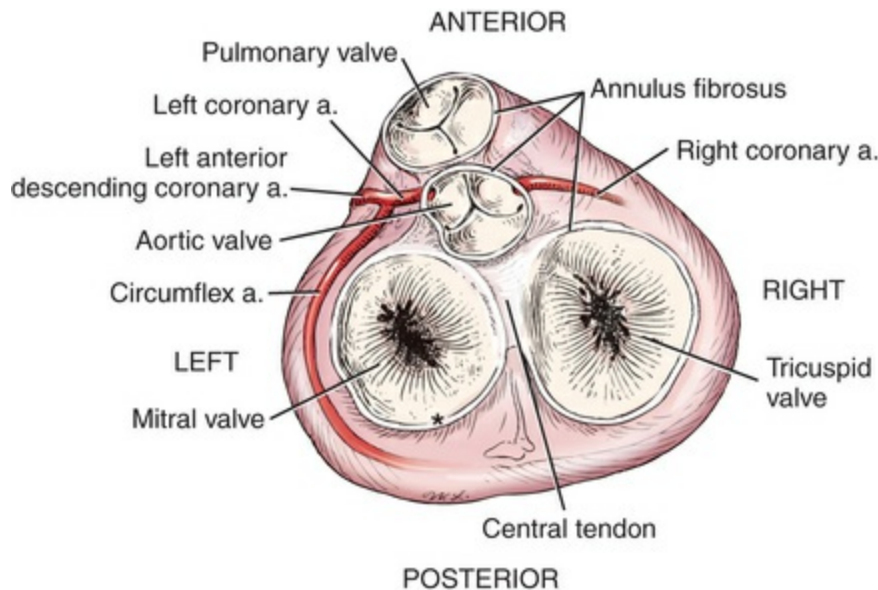

FIGURE 25.3 The annulus fibrosus. a., Artery.

The annulus fibrosus is the fixation point for the cardiac musculature, and it plays an important role in the structure, function, and efficiency of the heart. The annulus acts as an insulator to prevent aberrant electrical conduction from the atria to the ventricles so that AV conduction moves through one pathway only: the AV node to the AV bundle which is also known as the *bundle of His*. This element increases the electromechanical efficiency of the heart and helps to prevent dysrhythmias.

Chambers of the Heart

Right Atrium.

The atria act as the priming chambers for the ventricles. As such, the RA acts as a reservoir for the RV and has unique anatomic characteristics. It has a muscle wall thickness of approximately 2 mm. The RA receives blood from several sources: the superior vena cava, the inferior vena cava, and the coronary sinus (Fig. 25.4). The RA consists of two parts: an anterior, thin-walled trabeculated portion and a posterior, smooth-walled portion called the *sinus venarum*. The sinus venarum receives blood from the vena cava and the coronary sinus. The auricle projects to the left from the root of the superior vena cava and overlaps the root of the ascending aorta.

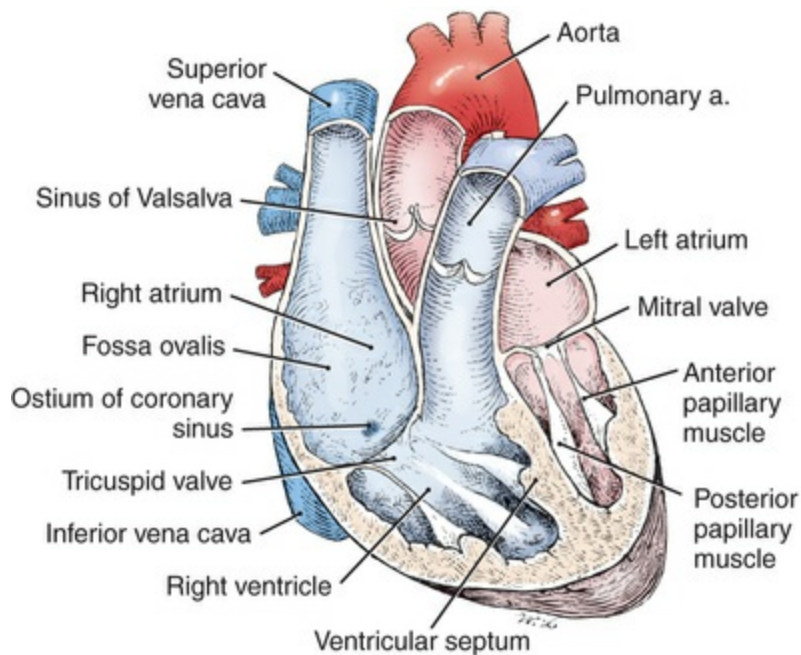

FIGURE 25.4 Internal anatomy of the heart chambers. a., Artery.

The superior vena cava returns blood to the RA from the upper body. The inferior vena cava returns blood to the RA from the lower body. The entrance of the inferior vena cava into the RA is protected by a rudimentary valve called the *eustachian valve*.⁴

The entrance from the coronary sinus into the RA is located between the AV orifice and the valve of the inferior vena cava. This opening is protected in part by a rudimentary valve of the coronary sinus called the *thebesian valve*.⁵ Other distinguishing structures within the RA include the interatrial septum and the fossa ovalis cordis, which is the remnant of the fetal foramen ovale located within the septum.

Right Ventricle.

The RV ejects blood into the pulmonary arterial system for oxygenation and removal of carbon dioxide by the lungs. The RV communicates with the RA through the AV orifice, which is separated by the tricuspid valve. The RV also communicates with the pulmonary outflow tract through the pulmonary orifice, which is guarded by the pulmonic valve (see Fig. 25.4).

The walls of the RV are much thicker (4 to 5 mm) than those of the RA because of the increased pressures required to generate forward blood flow into the pulmonary artery. The superior portion

of the RV as it approaches the pulmonary orifice has a conical appearance and is called the *conus arteriosus* or *infundibulum*.⁶

The inner wall of the conus is smooth, but the remainder of the right ventricular wall has a rough appearance because of the presence of several irregular muscular bundles called the *papillary muscles* and the *trabeculae carneae*. One of the trabeculae carneae (the moderator band) crosses the cavity of the ventricles and carries the right branch of the AV bundle. The papillary muscles have attachments to the ventricular walls and to the chordae tendineae. The chordae tendineae are attached to the cusps of the tricuspid valve; together with the papillary muscles, they help prevent eversion of the tricuspid valve into the RA during ventricular systole.⁷

Left Atrium.

The left atrium (LA) acts as a reservoir for oxygenated blood as it receives blood from the four pulmonary veins and also serves as a pump during atrial systole. It provides a 20% to 30% increase in left ventricular end-diastolic volume (LVEDV), which is known as the *atrial kick*. A person who has normal myocardial performance does not rely on this increase in ventricular filling to achieve adequate CO. However, in certain cardiovascular or respiratory pathologic conditions, compromised patients do rely on this atrial kick to maintain an adequate CO. The LA is located superiorly and posteriorly to the other cardiac chambers. The walls of the LA are slightly thicker (3 mm) as compared to the RA. The LA connects to the LV through the left AV orifice, which contains the mitral valve. The atrial septum is smooth but may contain a central depression that corresponds to the location of the fossa ovalis cordis.

Left Ventricle.

The apex of the LV is positioned within the mediastinum in an anterior and inferior orientation. The LV receives blood from the LA and ejects it into the aorta. Left ventricular wall thickness is approximately 8 to 15 mm, or two to three times the thickness of the RV. This additional muscle mass is required to overcome the systemic vascular resistance (SVR), or afterload, and to maintain stroke volume (SV).

The ventricular septum separates the right and left ventricular cavities.⁸ The upper third of the septum is smooth endocardium. The remaining two-thirds of the septum and the rest of the ventricular wall are covered with trabeculae carneae.

Two large papillary muscles are present within the LV. The anterior papillary muscle attaches to the anterior part of the left ventricular wall, and the posterior papillary muscle arises from the posterior aspect of the inferior wall. The chordae tendineae of each muscle are attached to the cusps of the mitral valve and prevent eversion of the valve during LV systole.

Myocardium

The cardiac musculature is arranged in three distinct layers: an outer epicardium, a middle muscular myocardium, and an inner endocardium. The epicardium is composed of mesothelium, connective tissue, and fat. The middle muscular myocardium consists of two muscle layers, a superficial and a deep layer. These layers are arranged in a spiral fashion and appear on cross section to run at right angles to each other. It has been postulated that the superficial and deep layers of the myocardium are not two separate layers but one tortuous and continuous layer. The arrangement of the muscle layers provides strength during contraction of the myocardium and efficient propulsion of blood toward the semilunar valves. The endocardium consists of endothelium and a layer of connective tissue.

Heart Valves

The cardiac valves increase the heart's efficiency by ensuring unidirectional flow of blood through the circuit. They open and close in response to pressure gradients that exist above (atrium) or below (ventricles) the valves. These valves may be categorized as AV which exist between the atria and ventricle or semilunar (pulmonary artery or aorta).

One of the most accurate ways to determine the presence of valvular pathology is by calculating the valvular area. The standard method for determining valvular area is during cardiac catheterization. Echocardiography is a noninvasive method of

determining valve area and it is used to estimate the presence and degree of valvular heart disease. The use of echocardiography is discussed later in this chapter. A cardiologist is able to determine valve gradients using the Gorlin formula or its correction, which can provide information regarding the degree of pathology that exists

$$\text{Valve Area (cm}^2\text{)} = \frac{\text{Cardiac Output (liters/min)} \times 1000}{(\text{K}) (\text{HR}) (\text{SEP}) \sqrt{\text{Mean valve gradient}}}$$

K is a hydraulic pressure constant, heart rate (HR) (beats per minute), systolic ejection period (SEP) expressed in seconds, and square root of mean valve gradient expressed in mm Hg.⁹

Atrioventricular Valves

Tricuspid Valve.

The tricuspid valve is positioned inferiorly to the right AV annulus, which lies between the RA and the RV. The tricuspid leaflets are well defined, thinner and more translucent than those of the mitral valve. Three leaflets of unequal size exist: the anterior, septal, and posterior leaflets. The leaflets are attached to the chordae tendineae, which are anchored to the papillary muscles. This structure prevents eversion of the valve leaflets into the RA.¹⁰ The normal tricuspid valve area is approximately 7 cm². Symptoms associated with tricuspid valve stenosis typically occur when the valve area is less than 1.5 cm².

Mitral Valve.

The mitral valve is situated inferiorly to the left AV annulus between the LA and the LV. Two major leaflets, the anteromedial leaflet and the posterolateral leaflet, are connected by commissural tissue. The normal mitral valve area is 4 to 6 cm². When the surface area of the valve is decreased by half, clinical symptoms may appear. Like the tricuspid valve, the mitral valve has papillary muscles and chordae tendineae attached to the leaflets to prevent eversion of the valve during ventricular systole.¹¹

Semilunar Valves.

The configuration of the aortic and pulmonary valves is similar. The cusps of the aortic valve are slightly thicker because it is subjected to greater pressures, which are created by left ventricular ejection. The semilunar valves are situated within the outflow tracts of their corresponding ventricles. Each valve is composed of three cusps. Above the aortic valve is a dilation known as the *sinus of Valsalva*, which allows the valve to open efficiently without occluding the coronary ostia or openings that communicate with the coronary arteries. Eddy currents form behind the valve leaflets and prevent contact between the valve leaflets and the walls of the aorta. Normal aortic valve area is 2.5 to 3.5 cm². Reduction of the valve area by one-third to one-half is associated with an increase in the symptoms caused by aortic stenosis.

Coronary Circulation

The heart is a highly aerobic organ that depends on a constant supply of oxygen to meet its high metabolic demand. It requires an elaborate arterial and venous network to ensure that myocytes are adequately supplied with oxygen and substrate to create cellular energy. The arterial system consists of epicardial and subendocardial vessels. The epicardial vessels are located superficially and most commonly become obstructed at areas of bifurcation where the blood flow is turbulent rather than laminar. Significant obstruction (50% to 70% reduction in luminal diameter) can result in myocardial ischemia or infarction because of increased resistance to flow across the stenotic areas.

Coronary Arteries.

The left and right coronary arteries originate from the ascending aorta within the anterior and left posterior sinuses. The coronary ostia are the entrance points by which blood flows through the coronary circulation, and they are located behind the aortic cusps near the superior part of the sinus of Valsalva. The ostium of the left coronary artery is superior and posterior to the right coronary ostium. The coronary arteries act as end arteries, and each supplies blood to its respective capillary bed¹² (Fig. 25.5).

FIGURE 25.5 The coronary arterial circulation. a., Artery.

Left Main Coronary Artery.

The left main coronary artery travels anteriorly, inferiorly, and leftward from the left coronary sinus to emerge from behind the pulmonary trunk. The caliber of this artery is greater than the right main coronary artery reflecting the increased metabolic needs of the myocardium in the left ventricle. Within 2 to 10 mm of its emergence, the left main coronary artery divides into two or more branches of near-equal diameter. The branches include the LAD artery, the left circumflex coronary artery, anterior interventricular (descending) artery and possibly the diagonal artery.

Left Anterior Descending Coronary Artery.

The LAD is a continuation of the left main coronary artery. The branches of this vessel include the first diagonal branch, the first septal perforator, the right ventricular branches (not always observed), other septal perforators, and other diagonal branches. The LAD provides blood flow to the anterior two-thirds of the interventricular septum, the right and left bundle branches, the anterior and posterior papillary muscles of the mitral valve, and the anterior lateral and apical walls of the LV. The LAD also provides collateral circulation to the anterior wall of the RV.

Left Circumflex Coronary Artery.

The left circumflex artery arises from the left main coronary artery at an obtuse angle, and it is directed posteriorly as it travels around the left side of the heart within the left AV sulcus. Branches are variable and may include the sinus node artery (40% to 50% of the population), the left atrial circumflex artery, the anterolateral marginal artery, the distal circumflex artery, one or more posterolateral marginal arteries, and the posterior descending artery (10% to 15% of the population). The circumflex artery supplies blood to the left atrial wall, the posterior and lateral LV, the anterolateral papillary muscle, the AV node in 10% of the population, and the sinoatrial (SA) node in 40% to 45% of the population.

Right Coronary Artery.

The RCA supplies blood to the SA and AV nodes, the RA and RV, the posterior third of the interventricular septum, the posterior fascicle of the left bundle branch, and the interatrial septum. In approximately 90% of the population, the RCA leaves the right coronary sinus and descends in the right AV groove. At the crux, the RCA courses inferiorly in the posterior AV groove and terminates as a left ventricular branch.

The branches of the RCA include the conus artery, the sinus node artery (50% to 60% of the population), several anterior right ventricular branches, the right atrial branches, the acute marginal branch, the AV node artery (90% of the population), the proximal bundle branches, the posterior descending artery, and the terminal branches to the LA and LV.

Coronary Artery Dominance.

Dominance of one coronary artery is determined by the location of the coronary artery that crosses the crux and provides blood flow to the posterior descending artery. The dominant coronary artery in 50% of the general population is the right coronary. In addition, 10% to 15% of the general population are left coronary dominant, and 35% to 40% of the general population have mixed right and left dominance.

Venous Drainage.

An extensive venous system exists within the heart. The three major systems include the coronary sinus, the anterior cardiac veins, and the thebesian veins (Fig. 25.6).

FIGURE 25.6 The coronary venous system. v., Vein.

The coronary sinus is located in the posterior AV groove near the crux. It collects approximately 85% of the blood from the LV, and for this reason it is catheterized when metabolic studies of the LV are performed. It may also be cannulated during cardiopulmonary bypass to deliver cardioplegia. The coronary sinus receives blood from the great, middle, and small cardiac veins; the posterior left ventricular veins; and the left atrial vein of Marshall.

Two to four anterior cardiac veins drain the anterior right ventricular wall. These veins may enter the RA directly, or they may empty into the coronary sinus.

The thebesian veins traverse the myocardium and drain into the various cardiac chambers, especially the RA, the RV, and to a lesser extent the LV. The thebesian veins may carry up to 40% of the blood that is returned to the RA.

Cardiac Innervation

The autonomic nervous system is divided into the sympathetic and the parasympathetic nervous systems. Efferent impulses are transmitted from the brainstem and hypothalamus to numerous

body systems, including the heart. The neurologic innervation to the heart originates from the autonomic nervous system, as well as from sensory fibers. The myocardium also has a specialized conduction system that is further discussed in this chapter.

Increased sympathetic nervous system tone increases heart rate (chronotropic), force of myocardial contraction (inotropic), and rate of AV node discharge (dromotropic). Sympathetic nervous system activation results in the mobilization of myocardial fat-free acids and glycogen for energy use by the myocardial cells. The preganglionic sympathetic nervous system fibers originate from the cells in the intermediolateral columns of the higher thoracic segments of the spinal cord and synapse at the first through the fourth or fifth thoracic paravertebral ganglia. These spinal cord segments are known as the *cardioaccelerator fibers*. The postganglionic fibers then travel as the superior, middle, and inferior cardiac nerves and the thoracic visceral nerves. These fibers form an epicardial plexus and are distributed over the entire ventricular myocardium. There is greater distribution of sympathetic nerves that innervate the ventricles, resulting in increased ventricular contractility, as is shown in [Fig. 25.7](#). Catecholamines released during sympathetic stimulation bind with adrenergic receptors on the heart (primarily β_1) and change the biochemical properties within the myocyte. This process is further discussed in this chapter.

FIGURE 25.7 Distribution of sympathetic and parasympathetic innervation to the heart. AV, Atrioventricular; SA, sinoatrial.

Some of these postganglionic sympathetic fibers also join with the postganglionic parasympathetic fibers from the cardiac plexus and primarily innervate the SA and AV nodes and the atrial myocardium. Suppression or blockade of this thoracic portion of the spinal cord by regional anesthesia causes bradycardia and hypotension as a result of the blockade of these sympathetic ganglia exhibiting parasympathetic nervous system predominance.

The preganglionic parasympathetic fibers originate in the dorsal motor nucleus of the medulla. Short postganglionic fibers primarily innervate the SA and AV nodes and the atrial muscle fibers as shown in [Fig. 25.7](#). For this reason, increased parasympathetic tone decreases HR. The function of the parasympathetic nervous system is primarily to slow the HR and secondarily to decrease contractility. In fact, maximal vagal (parasympathetic) stimulation reduces contractility by only 30%, whereas maximal sympathetic stimulation increases contractility by 100%. Acetylcholine is the neurotransmitter of the parasympathetic nervous system. Acetylcholine binds to muscarinic receptors on the heart and decreases the rate of sinus node discharge slowing conduction velocity through the AV node. The physiologic effects of parasympathetic nervous system stimulation occur because of increased permeability of cardiac muscle cell membranes to potassium, resulting in hyperpolarization. As a result, SA and AV node cells are less excitable.

Sensory innervation to the heart originates in the nerve endings in the walls of the heart, the coronary artery adventitia, and the pericardium. These nerve endings synapse with ascending fibers in the posterior gray columns of the spinal cord, where the fibers synapse with second-order neurons. From these neurons, the fibers ascend in the ventral spinothalamic tract and terminate in the posteroventral nucleus of the thalamus.

Cardiac Conduction System

Within the myocardium lies the specialized conduction system

whose purpose is to automatically initiate and coordinate the cardiac rhythm. The cells of this system differ from the other myocardial cells because they are more variable in shape, contain fewer myofibrils, and have a characteristic pale staining of the cytoplasm. The conductive system consists of the following components: the SA node, the internodal tracts, the AV node, the AV bundle, and the Purkinje system (Fig. 25.8).

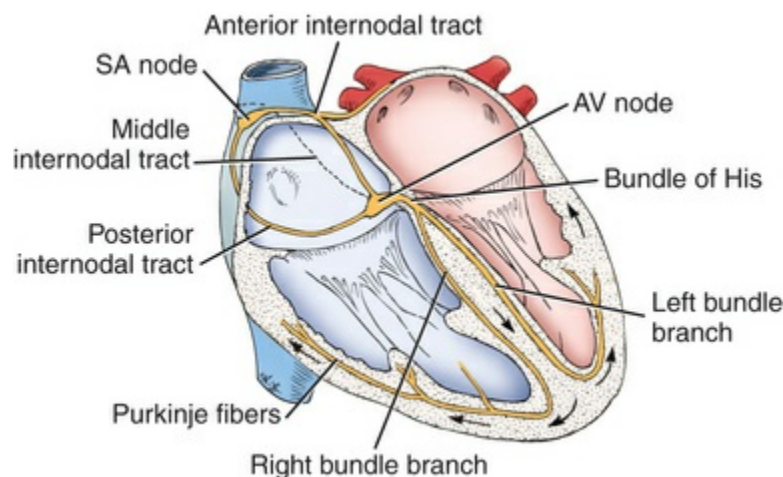

FIGURE 25.8 The cardiac conduction system. AV, Atrioventricular; SA, sinoatrial.

Sinoatrial Node.

The SA node (the Keith-Flack node) is a small collection of specialized cells and collagenous tissue located along the epicardial surface at the junction of the superior vena cava and the RA. It has a prominent central artery that is a branch of the RCA. The SA node is derived from the junction of the right horn of the sinus venosus and the primitive atrium. The SA node consists of two cell types: P cells (pacemaker cells), which are pale and ovoid with large round nuclei, and intermediate or transitional cells, which are elongated. These transitional cells are intermediate between ovoid and ordinary cells. They conduct impulses within and away from the SA node. Intrinsic rate of the SA node is 60 to 100 beats/min. The speed of conduction to adjacent cells within the SA node is 0.5 m/sec.

Internodal Tracts.

The internodal tracts are located within the atria and are the preferential conduction pathways between the SA and the AV nodes. They are composed of a combination of closely packed parallel myocardial fibers and large pale-staining cells with a perinuclear clear zone. They have large nuclei and sparse myofibrils that resemble the Purkinje cells. Like the SA node, the internodal tracts contain P cells and transitional cells.

Three major internodal tracts exist: the anterior, middle, and posterior internodal tracts. The anterior internodal tract, or Bachmann bundle, extends into the LA and then travels downward through the atrial septum to the AV node. The middle internodal tract, or Wenckebach tract, curves behind the superior vena cava before descending to the AV node. Finally, the posterior internodal tract, or Thorel's pathway, continues along the terminal crest to enter the atrial septum and then passes to the AV node.

Atrioventricular Node.

The AV node is located beneath the endocardium on the right side of the atrial septum, anterior to the opening of the coronary sinus. The AV node is supplied by an abundance of nerve endings, as well as vagal (ganglionic) cells. The AV node causes a delay in the transmission of action potentials. This delay may be attributed to several factors, such as the size of the AV nodal cells (smaller than the surrounding atrial cells), a decreased distribution of gap junctions between cells, a resting membrane potential that is *more negative* than the normal resting membrane potentials of the surrounding cells, and thus the paucity of gap junctions. Greater resistance to the transmission of an action potential exists within the AV node. Impulse conduction is considerably slower as compared to any other region within the normal cardiac conduction system (0.05 m/sec). This delayed speed allows for sufficient time for atrial depolarization and contraction (systole) prior to ventricular depolarization and contraction.

Atrioventricular Bundle.

The AV node is a group of cells located on the posterior aspect of the right atrium behind the tricuspid valve and near the opening of the coronary sinus. There are three functional regions that are

divided according to the action potentials generated and the tissues response to electrical and chemical stimulation: atrionodal (upper region), nodal (middle region) and the nodal-His (lower region). The nodal-His is where the inferior portion of the AV node merges with the AV bundle (bundle of His). The intrinsic pacemaker cells in the AV node are capable of depolarization at a rate of 40 to 60 beats/min. The AV bundle extends from the lower end of the AV node and enters the posterior aspect of the ventricle and the Purkinje system. This AV bundle is the preferential channel for conduction of the action potential from the atria to the ventricles. Conduction velocity from the Bundle of His into the left and right bundle branches along the interventricular septum is rapid (2 m/sec).

Purkinje System.

The Purkinje system consists of the bundle branch system and its terminal branches. The left bundle branch extends outward under the endocardium and forms several fascicles, which innervate various parts of the LV. The anterior fascicle innervates the anterolateral wall of the LV and the anterior papillary muscle. The posterior fascicle innervates the lateral and posterior ventricular wall and the posterior papillary muscle. The anterior and posterior fascicles join to form the septal fascicle, which innervates the lower ventricular septum and the apical wall of the LV. The right bundle branch travels under the endocardium along the right side of the ventricular septum to the base of the anterior papillary muscle. The Purkinje fibers have pacemaker cells capable of firing at a rate of 20 to 40 beats/min. There is rapid velocity of impulse conduction (4 m/sec) through the Purkinje fibers which allows for rapid depolarization of ventricular myocytes.

Structural and Regulatory Proteins.

The myocardium has characteristics of both skeletal and smooth muscle. Like smooth muscle, cardiac muscle fibers are interconnected (syncytium), which allows for an action potential to rapidly spread to adjacent cells. Due to this characteristic of cardiac muscle fibers, action potential propagation and muscle contraction occur as an “all-or-none” response.

The myocardial cell is similar to skeletal muscle in that it is composed of sarcomeres (Fig. 25.9). These sarcomeres contain all the microfilaments and structures that are consistent with the skeletal muscle sarcomere. The sarcomere stretches from Z line to Z line. The A bands consist of the actin filaments, which contain a bilayer filament of F-actin and tropomyosin. Along the actin filament, many active sites exist that can attach to the head of the myosin molecule. A troponin complex is necessary to inhibit actin and myosin from interacting and initiating muscle contraction. The other microfilament in the cardiac muscle is the myosin molecule. This molecule is composed of two major parts: a light meromyosin chain and a heavy meromyosin chain. The heavy meromyosin chain consists of two hinged ends and a head that plays a role in the “ratchet theory” of muscle contraction (Fig. 25.10).¹

FIGURE 25.9 The myocardial sarcomere.

FIGURE 25.10 Interaction between actin and myosin that initiates cardiac muscle contraction.

During sympathetic nervous system stimulation, catecholamines (primarily epinephrine and norepinephrine) are released from the central nervous system (CNS) and the adrenal medulla. Increased cardiac conduction velocity, increased force of contraction, and increased heart rate are primarily mediated by beta₁ (β₁)-adrenergic receptors. When catecholamines interact with β₁ receptors, they stimulate intracellular G protein activation. Adenyl cyclase activity increases and catalyzes the formation of cyclic adenosine monophosphate. A specific protein kinase is formed, and phosphorylation occurs, increasing myocardial cell permeability to calcium and sodium. Threshold potential is reached, and depolarization occurs, which increases the concentration of calcium from the sarcoplasmic reticulum and the transverse tubular system. Calcium interacts with the troponin tropomyosin complex to initiate cardiac contraction. The force of myocardial contraction is dependent on the quantity of calcium present within the cardiac cell.

The troponin-tropomyosin complex inhibits the binding of the heads of the myosin filaments with the active sites on the actin molecule (Fig. 25.11). During the initiation of contraction, calcium is released from the sarcoplasmic reticulum. Calcium binds to the troponin-tropomyosin complex and causes a conformational change so that the active binding sites on the actin filaments become exposed. The myosin cross bridges bind to the active filament and move along the actin filament by alternately attaching and detaching from the active sites, thereby causing shortening of the Z lines (Fig. 25.12). This is known as the *sliding filament theory*. When the actin filaments and myosin cross bridges intermingle, muscle contraction occurs. Inhibition of calcium influx into cardiac muscle cells is the proposed mechanism whereby the inhaled anesthetic agents cause depression of myocardial contractility. Cellular energy or adenosine triphosphate (ATP) is required for this process, known as *excitation-contraction coupling*, to occur, as shown in Fig. 25.13. For muscle contraction to conclude, calcium reuptake into the sarcoplasmic reticulum occurs as a result of active transport. As intracellular calcium concentrations decrease, the troponin-tropomyosin complex reinhibits the interaction between

actin and myosin. The process of myocardial excitation-contraction coupling reoccurs within milliseconds and throughout the myocardium. This is the primary reason for the heart's high metabolic demands (see Fig. 25.13). With a limited supply of oxygen and substrate (primarily fatty acids), such as with patients with coronary artery disease or an increased energy demand caused by tachycardia from sympathetic nervous system stimulation, myocardial ischemia and infarction can occur.

FIGURE 25.11 Arrangement of actin and myosin in cardiac muscle.

FIGURE 25.12 Phases of cardiac muscle contraction. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate.

FIGURE 25.13 Letter A (*dotted line*) indicates that the troponin tropomyosin complex blocks the active binding site and inhibits contraction. Letter B (*solid line*) indicates that when calcium interacts with troponin, there is a conformational change. The troponin tropomyosin complex is displaced, and interaction between actin and myosin initiates muscle contraction. Note that ATP is used during the binding, the power stroke, and the unbinding process. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate.

Similar length-force relationships exist within the myocardium and in skeletal muscle. The resting sarcomere length at which the muscle cell is most efficient is 2.0 to 2.4 μm . At greater lengths, the interdigitation of the actin and myosin is compromised, and at shorter lengths the sarcomere is unable to generate an efficient contraction.

Clinically, this concept is demonstrated by having the ideal filling pressure of the LV necessary to achieve adequate CO. Filling pressures are used to reflect the filling volumes of the ventricles and (indirectly) the amount of stretch on the ventricular muscle at rest. Filling pressures are measured by the use of the pulmonary capillary wedge pressure (PCWP) or the pulmonary artery diastolic pressure. It has been demonstrated that at excessively high filling pressures (as in congestive heart failure) and at excessively low filling pressures (as in hypovolemia), the CO can be compromised as a result of either excessive or inadequate stretch of the left

ventricular myocardium. The greater the degree of stretch of myocardial muscle fibers, the greater the number of actin filaments and myosin cross bridges that are more completely approximated. This will result in an increase in the force of cardiac contraction, as shown in [Fig. 25.14](#). This concept is the basis for the Frank-Starling law of the heart, which is discussed later in this chapter.

FIGURE 25.14 Greater alignment of actin binding sites and myosin cross bridges causes increased myocardial contractility.

Comparison-Skeletal and Cardiac Muscle Cells.

Several differences exist between myocardial muscle cells and skeletal muscle cells (see [Fig. 25.9](#)). At the junctions between the fibers in the myocardial muscle mass, many branching, interconnected fibers are intercalated disks and gap junctions, or nexi. Areas of low resistance facilitate the conduction of the action potential from one myocardial cell to another.

The myocardial sarcomeres also contain increased concentrations of mitochondria due to the heart's high metabolic rate. Skeletal muscles can function both aerobically and anaerobically.

The myocardial sarcomere system has a rich capillary blood supply (one capillary per fiber) that allows for efficient diffusion and perfusion. The T-tubular system and the sarcoplasmic reticulum are extensive within the cardiac sarcomere. This situation allows for the rapid release and reabsorption of calcium from the

cells. It also serves to highlight the important role extracellular calcium plays in the contractile process of the myocardial cell.

Generation of Membrane Potentials

Resting Membrane Potentials.

The myocardial sarcomere is not merely a contractile entity. It also possesses properties common to neural tissue, such as the generation of a resting membrane potential, the ability to generate an action potential, and the conduction of the action potential from one sarcomere to the next.

The resting cell membrane is relatively permeable to potassium and relatively impermeable to both sodium and calcium. The resting membrane potential is caused by a chemical force, an electrostatic counterforce, and the sodium-potassium active transport pump.

The chemical force relies on the potential difference in ion concentration between the intracellular and extracellular environment. The ions primarily responsible for this force are sodium, potassium, and calcium.¹³ The electrostatic counterforce results from the negative potential generated by the ion difference of the interior of the cell and can pull ions into the cell, especially potassium.

The sodium-potassium pump requires an energy source (active transport) and involves the magnesium-dependent enzyme adenosine triphosphatase located in the cell membrane. Three molecules of sodium are pumped out of the cell into the extracellular fluid for every two molecules of potassium pumped into the intracellular fluid.

Calculation of the equilibrium potential (E_m , measured in millivolts [mV]) has been accomplished by examining the concentration of an ion inside the cell versus outside the cell (see the Nernst equation that follows). [Table 25.1](#) lists the equilibrium potentials of the most physiologically important ions. The ion most responsible for the resting membrane potential is potassium.

TABLE 25.1

Equilibrium Potential of Various Ions

Ion	Intracellular Concentration (mmol)	Extracellular Plasma Concentration (mmol)	Equilibrium Potential E_m (mV)
Na ⁺	10	145	60
K ⁺	135	4	-94
Cl ⁻	4	114	-97
Ca ²⁺	10 ⁻⁴	2	132

$$E_m = (-RT/zF) \times \log[K]_i/[K]_o$$

R is a gas constant, T is temperature in Kelvin, F is Faraday's constant, $[K]_i$ is the intracellular concentration of potassium, and $[K]_o$ is the extracellular concentration of potassium.

If a temperature of 310°K is assumed for a living human, the Nernst equation reduces to the following in a human heart:

$$E_m = (-61.5/zF) \times \log[K]_i/[K]_o$$

The Nernst potential is useful only in discussions of a single ion. The membrane potentials are generated because the cell membrane is permeable to several different ions. Three factors affect the calculation of the effect of these different ions on the resting membrane potential: the electric charge of each ion, the permeability of the membrane to each ion, and the concentration gradient across the membrane. The following equation, the Goldman-Hodgkin-Katz equation, is a modification of the Nernst equation that accounts for these factors.

$$EMF = 61.5 \times \log\left(\frac{[Na]_i P_{Na} + [K]_i P_K + [Cl]_o P_{Cl}}{[Na]_o P_{Na} [K]_o P_K [Cl]_i P_{Cl}}\right)$$

$[K]_i$ is the intracellular ion concentration of potassium, $[K]_o$ is the extracellular ion concentration of potassium, P_{Na} is the membrane permeability of sodium, P_{Cl} is the membrane permeability of chlorine, and P_K (when calculated) is the membrane permeability of potassium.

Ventricular Muscle Fiber Action Potential

Gate Theory.

The functioning of electrostatic gates have been determined for the various ions. These gates open (activated) and close (inactivated), depending on the electrical potential of the cell membrane. An electrostatic gate exists for each of the major cardiac ions (sodium, potassium, calcium, and chloride).

Phases of the Action Potential.

The action potentials of the various parts of the conduction system vary according to their locations and functions.¹⁴ The action potential of ventricular muscle fibers is separated into five phases (Fig. 25.15).

FIGURE 25.15 The ventricular muscle action potential. A to B, Absolute refractory period; B to C, relative refractory period; 0, depolarization; 1, overshoot; 2, plateau; 3, repolarization (rapid); 4, repolarization (complete).

Phase 0, or upstroke, is represented by depolarization and involves the fast sodium channels. The fast sodium channel activation gates (M gates) open between -70 and -65 mV (threshold potential). At 0 mV, both the activation and the inactivation gates (H gates) are open. The rapid upstroke velocity of phase 0 gives a relative indication of the conductivity of the myocardial cell. Local

anesthetics such as lidocaine have an inhibitory effect on phase 0 by decreasing the influx of sodium. [Table 25.2](#) describes the phases and events of a cardiac action potential.

TABLE 25.2
Cardiac Action Potential

Phase	Name	Cation Movement	Effect
0	Upstroke	Na ⁺ , ECF to ICF	Sodium channels open Potassium permeability decreased
1	Initial repolarization	K ⁺ , ICF to ECF	Sodium channels close Potassium channels open
2	Plateau	Ca ²⁺ , ECF to ICF	Calcium channels open
3	Final repolarization	K ⁺ , ICF to ECF	Calcium channels close Potassium channels open
4	Resting potential	K ⁺ , ICF to ECF Na ⁺ /Ca ²⁺ ECF to ICF	Resting membrane permeability restored, sodium and potassium leak to ICF to increase threshold potential

ECF, Extracellular fluid; ICF, intracellular fluid.

During *phase 1* (early rapid repolarization, +2 mV to +30 mV), the sodium gates close, the rapid influx of sodium stops, and the slower influx of calcium begins. In addition, potassium gates open and potassium moves out of the interior of the cell into the extracellular fluid.

Phase 2 (plateau phase), represents one of the characteristics of the action potential that is unique to ventricular muscle. The plateau phase exists because the slow calcium channels open at -30 to -40 mV and allow an influx of calcium. This inward calcium flux delays repolarization and prolongs the absolute refractory period. Toward the end of phase 2, a decreased permeability to potassium occurs that accounts for a small outward leakage of potassium, balanced by the calcium and sodium influx, that maintains a membrane potential near 0 mV. Calcium channel blockers exert their pharmacologic effect during phase 2. The physiologic effects include decreased contractility, decreased heart rate, and decreased cardiac conduction velocity.¹⁵

Phase 3 (terminal repolarization phase), is initiated as the slow calcium channels become inactivated. This phenomenon is sustained by an accelerated potassium efflux. These events return

the transmembrane potential to its resting membrane value.

During *phase 4* (diastolic repolarization phase), the sodium-potassium pump, which is dependent of ATP, reestablishes the proper intracellular-to-extracellular ionic concentrations. Phase 4 lasts from the completion of repolarization to the next action potential. Lidocaine lengthens the duration of phase 4 by decreasing the cardiac cell membrane's permeability to potassium ion, thereby decreasing the efflux of potassium and delaying the onset of the resting membrane potential.¹⁵

The cardiac glycoside digoxin inhibits the sodium-potassium ATP-dependent pump, decreasing sodium efflux into the extracellular fluid. As intracellular sodium concentrations increase, the exchange between sodium and calcium is decreased. The result is a higher concentration of calcium remains within the cardiac cell, and this effect is believed to be responsible for the increased inotropic effect.¹⁵

Refractory Periods.

The extended duration of the action potential of the myocardial cell protects it against premature excitation. This period of quiescence is known as the *refractory period* and it can be divided into effective or absolute and relative refractory periods. The refractory periods are a result of the properties of the sodium channels during the action potential.

The term *effective or absolute refractory period* is used to describe the time during which a conducted action potential may not be evoked, even if an active response is elicited by a stimulus at the cellular level. This period lasts from phase 0 to the middle of phase 3, when the membrane potential drops below -60 mV. The relative refractory period is the time during the action potential when a second stimulus can result only in an action potential with decreased amplitude, upstroke velocity, and conduction velocity. The relative refractory period extends from this middle part of the phase 3 range to the beginning of phase 4, when the membrane potential ranges from -60 to -90 mV. This information can be clinically related to synchronized cardioversion. When in a synchronized mode, a shock will not be delivered during the T wave on the electrocardiogram (ECG), which represents ventricular

repolarization. The relative refractory period occurs during the T wave, and electricity delivered to the chest during this time can cause electrical disorganization in cardiac cells, resulting in ventricular tachycardia or ventricular fibrillation.

Sinoatrial Node Action Potential.

The myocardium has among its characteristics contractility, automaticity, and conductivity. Various portions of the myocardium have their own intrinsic automaticity and rate of action-potential initiation. The SA node is the primary pacemaker of the heart and has several unique characteristics (Fig. 25.16). As a result of its higher resting membrane potentials, the SA node membrane is more permeable to sodium than other atrial myocardial cells. This “leakiness” gradually raises the membrane potential closer to threshold potential (–55 to –60 mV), at which time an action potential may be initiated. Therefore, the action potential originating within the SA node differs from the action potential generated within the ventricular muscle mass. For this reason, the SA node is the primary pacemaker of the heart. The intrinsic rate of the SA node is 60 to 100 beats/min. The SA node and the other automatic cells exhibit only phase 4, phase 0, and phase 3 of the action potential. As rapid depolarization is absent, phase 1 or phase 2 (plateau phase) does not occur.

FIGURE 25.16 The sinoatrial (SA) nodal action potential.

If the SA node fails, the area of the heart with the next highest intrinsic rate, the AV node, replaces the SA node as the pacemaker

of the heart. The intrinsic firing rate of the AV node is 40 to 60 beats/min. If both the SA and the AV nodes fail, the Purkinje fibers within the ventricle have pacemaker cells capable of firing at a rate of 20 to 40 beats/min. Cardiac conduction velocity is influenced by the autonomic nervous system (sympathetic-increase, parasympathetic-decrease), myocardial ischemia (decreased within the affected cells), and medications (adrenergic-increase, cholinergic-decrease).

Physiology of the Heart

Cardiac Cycle.

To understand the cardiac cycle, one must have a firm understanding of the basics of the anatomy of the heart and the pressures and volumes generated within the various chambers during the cardiac cycle. An appreciation for the valves and their positions during the phases of the cycle is essential (Fig. 25.17). Additionally, notice that the ECG impulse generation precedes the mechanical action of the heart. This delay between the electrical impulse and the mechanical event occurs because time is needed for the wave of depolarization to spread across the myocardium before contraction can begin. In relation to the ECG, the P wave represents atrial systole, the QRS complex signifies ventricular systole, and the T wave represents ventricular repolarization.

FIGURE 25.17 The cardiac cycle.

The cardiac cycle extends from one ventricular contraction to the next. It may be divided into two main phases, systole and diastole. The cardiac cycle is usually described in relation to the left side of the heart. However, similar conclusions about the function of the right side of the heart may be drawn in the absence of cardiopulmonary pathology.

Diastole.

During ventricular systole, the atria fill and blood returns from the venous system to the right side of the heart and from the pulmonary circulation into the left side of the heart. The first phase

of diastole is the period of isovolumetric relaxation. The ventricular muscle mass relaxes, and the aortic and mitral valves are closed as long as the ventricular pressure remains higher than the atrial pressure. The true filling phase is divided into three periods: (1) rapid inflow, (2) reduced inflow (also known as *diastasis*), and (3) atrial systole. Once the ventricular pressure drops below atrial pressure, the mitral valve opens, and the period of rapid inflow to passively fill the ventricle begins. The second period of diastole is diastasis, in which minimal changes occur in volume and in pressure as passive ventricular filling is nearly complete.

Atrial systole provides the final period of rapid filling and is commonly referred to as the *atrial kick*. This active process increases ventricular volume by approximately 20% immediately before ventricular systole. In patients who have severe mitral stenosis, the atrial kick may be responsible for up to 40% of the ventricular filling. Once left atrial systole and closure of the mitral valve occurs, this volume is known as *LVEDV*. During periods of strenuous exercise or in patients with many pathologic conditions such as shock or congestive heart failure, the additional ventricular filling is critical to maintaining SV.

Systole.

After left atrial systole and closure of the mitral valve, the isovolumetric phase, or isovolumetric contraction begins and this period is associated with the beginning of left ventricular contraction. The ventricular myocardial fibers shorten, and pressure is increased within the ventricle. As the pressure in the left ventricle exceeds the pressure in the left atrium, the mitral valve closes. During this period, an increase in left ventricular pressure occurs without a change in ventricular diastolic volume. Isovolumetric contraction begins with closure of the mitral valve and lasts until opening of the aortic valve.

Systolic ejection begins with the opening of the aortic valve and occurs when the left ventricular pressure exceeds the aortic pressure. This phase of the cardiac cycle is divided into two periods, with the *period of rapid ejection* accounting for the first third of systole and the *period of reduced ejection* comprising the remaining two-thirds of systole. During rapid ejection, left ventricular systolic

pressure peaks, and the largest amount of volume is ejected. Therefore, systole is composed of isovolumetric contraction, rapid ejection, and reduced ejection. The dicrotic notch or incisura on the arterial pressure tracing occurs within the period of isovolumetric relaxation. This segment represents retrograde blood flow back into the LV before aortic valve closure. Three waveform segments are present on the left atrial pressure tracing: the *a* wave, *c* wave, and *v* wave. The specific waveforms correspond to their position within the cardiac cycle. The *a* wave represents the end of atrial systole just before mitral valve closure. The *c* wave represents ventricular contraction and is produced by bulging of the mitral valve caused by increasing left ventricular pressure. The *v* wave represents increased pressure in the LA caused by blood return from the pulmonary veins before mitral valve opening.

Physiology of Coronary Circulation.

The anatomy of the coronary circulation has already been discussed. A description of the physiologic determinants of coronary blood flow follows.

Coronary Blood Flow.

The rate of blood flow is determined by a change in the pressure within the vessel divided by resistance of the system. Alterations of the radius of a vessel change the flow to the fourth power of the radius. This phenomenon is an extension of Poiseuille's law, which determines the flow of a fluid through a tube.

At rest, approximately 4% to 5% of the CO, or approximately 225 mL/min of blood, passes through the coronary vasculature. Phasic changes have been documented during coronary blood flow. A greater amount of LV coronary blood flow occurs during diastole. During systole, left coronary artery blood flow ceases to the subendocardium due to compression of the subendocardial vessels by the myocardium; flow through the epicardial vessels is not affected during systole to this extent. The flow to the left coronary artery is greatest during diastole as a result of the decreased resistance to flow from decreased myofibril tension that occurs as the intra-cavity pressure decreases ([Fig. 25.18](#)).

FIGURE 25.18 Blood flow in the left and right coronary arteries. The right ventricle is perfused throughout the cardiac cycle. Flow to the left ventricle is largely confined to diastole. (From Hibbert B, et al. Coronary physiology and atherosclerosis. In Kaplan JA, et al., eds. *Kaplan's Cardiac Anesthesia: For Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia: Elsevier; 2017:185.)

Control of Coronary Circulation and Oxygen Supply and Demand.

Coronary artery blood flow is regulated by intrinsic and extrinsic factors that affect coronary artery tone. Intrinsic factors include the anatomic arrangement of the coronary arteries and perfusion pressure within the coronary vessels. Extrinsic factors include compression within the myocardium, as well as metabolic, neural, and humoral factors. Blood flow through the coronary circulation is primarily controlled by the factors that determine oxygen supply and demand. Myocardial oxygen supply is determined by arterial blood content, diastolic blood pressure (DBP), diastolic time as determined by HR, oxygen extraction, and coronary blood flow. Myocardial oxygen demand is determined by preload, afterload, contractility, and HR (Fig. 25.19).

FIGURE 25.19 The heart's oxygen supply and demand must be balanced by the anesthetist, who should increase the former and reduce the latter. *Hgb*, Hemoglobin; *Sao₂*, arterial oxygen saturation.

The factors that increase myocardial oxygen consumption (MVO_2) are listed in [Table 25.3](#). Notice in [Fig. 25.19](#) that HR appears on both the supply (diastolic time) side and demand side of the balance. Increasing HR not only increases demand but also decreases diastolic time, which is when 80% to 90% of coronary filling and myocardial perfusion occurs. Increased HR is the most important factor that negatively affects MVO_2 . Doubling the HR doubles MVO_2 .¹⁶ This phenomenon most dramatically affects patients with coronary artery disease, because the supply of blood is compromised and may not be able to meet the oxygen demands caused by tachycardia. As a result, myocardial dysfunction or infarction can occur. By slowing HR and decreasing contractility, β -blocking medications increase supply and decrease demand, protecting the heart from ischemia.¹⁷

TABLE 25.3
Components and Effects on Myocardial Oxygen Consumption

A 50% Increase in	Resultant Increase in MVO_2
Heart rate	50%
Pressure work	50%
Contractility	45%

Wall stress	25%
Volume work	4%

$M\dot{V}O_2$, Myocardial oxygen consumption.

Due to the high metabolic demand, the myocardium extracts 65% to 70% of the available oxygen from hemoglobin. Therefore, the only way to increase oxygen delivery to the myocardium is by increasing blood flow. During periods of increased myocardial oxygen demands, coronary artery vasodilation occurs and blood flow through the coronary arteries can increase by three to four times. Several vasodilator substances have been identified and are released from the myocardium in response to decreased oxygen delivery or concentration. Among these substances are adenosine, adenosine phosphate compounds, potassium ions, hydrogen ions, carbon dioxide, bradykinin, and prostaglandin. Experts believe that adenosine is the primary substance responsible for coronary vasodilation.

The normal physiologic parameters of the heart are present in [Table 25.4](#). The determinants of $M\dot{V}O_2$ include myocardial contractility, myocardial wall tension (preload), HR, and mean arterial pressure (MAP; afterload). Oxygen extraction is determined by measurement of the difference between the oxygen tension in the pulmonary arterial blood and that in the coronary sinus.

TABLE 25.4
Normal Physiologic Parameters

Heart size	230–280 g (female) 280–340 g (male)
Coronary blood flow	225–250 mL/min or 4%–7% total cardiac output
Myocardial O ₂ consumption	65%–70% extraction 8–10 mL O ₂ /100 g per min
Normal autoregulation	60–140 mm Hg (MAP)
Coronary filling	80%–90% during diastole

MAP, Mean arterial pressure.

Oxygen supply relies on the blood oxygen content (see following equation), which is affected by both the oxygen carried on the hemoglobin (Hgb) molecule (constant = 1.34 mL of oxygen per gram of Hgb, exact value 1.24–1.39) and to a lesser extent the oxygen dissolved in the plasma (0.003 mL of oxygen per milliliter of

plasma).

$$\begin{aligned} \text{Arterial oxygen content equation (CaO}_2\text{)} \\ = (\text{SaO}_2 \times \text{Hgb} \times 1.34) + (0.003 \times \text{PaO}_2) \end{aligned}$$

where SaO₂ is the % of hemoglobin saturated with oxygen (normal range 93–100%); Hgb is hemoglobin, (normal range adult female 12–16 g/dL, adult male 13–18 g/dL); PaO₂ is arterial oxygen partial pressure, (normal range, 80–100 mm Hg); and CaO₂ is arterial oxygen concentration, reflection of total number of oxygen molecules in arterial blood (both bound and unbound to hemoglobin).

Other factors that have an influence on coronary circulation include the direct and indirect effects of the sympathetic nervous system and the effect of certain substrates of cardiac metabolism.

Autoregulation.

Under normal physiologic conditions, the coronary circulation, like other tissue beds in the body, exhibits *autoregulation*, which is the ability to maintain coronary blood flow across a range of MAPs by dilating or constricting. Coronary blood flow is maintained at a constant flow rate through a MAP range of 60 to 140 mm Hg. When arterial blood pressure is less than or exceeds these pressure limits, coronary blood flow becomes pressure dependent. Therefore, during hypotension, when the coronary arteries are maximally dilated, coronary blood flow is determined by the MAP minus the right atrial pressure.

A method for directly estimating coronary perfusion pressure (CPP) can be calculated by subtracting left ventricular end-diastolic pressure (LVEDP) from DBP—that is, $\text{CPP} = \text{DBP} - \text{LVEDP}$. Under normal conditions, LVEDP (10 mm Hg) is significantly less than DBP (80 mm Hg). Therefore the major determinant of CPP is DBP.

Coronary vascular reserve is the difference between the maximal flow and the autoregulated flow. The closer these two values, the lower the coronary reserve of the patient. Factors that increase myocardial oxygen demand and limit supply decrease coronary reserve flow and can result in myocardial dysfunction.

The concept of “coronary steal” can be used in reference to vasodilation associated with the use of medications such as adenosine, nitroglycerin, and isoflurane. When stenosis of a coronary artery exists (e.g., atherosclerotic plaque), this region of the coronary artery is maximally dilated to meet the metabolic demands of the myocardium. If vasodilator treatment is administered to a patient who has both an ischemic area of the heart that is supplied by a stenotic vessel with collateral flow and another area that has an intact autoregulated vessel, only the autoregulated vessel dilates further and has the ability to increase its flow. Therefore, only the areas of the heart with intact autoregulation respond to vasodilators and receive preferential flow over the stenotic area. Lastly, by dilating the coronary arterial system, flow in the region of stenosis can decrease causing myocardial ischemia. The existence of this phenomenon is questionable. As long as adequate CPP is maintained, coronary steal and myocardial ischemia caused by isoflurane do not occur.^{18,19} A second factor that could result in this phenomenon is coronary steal-prone anatomy. This has been defined as complete occlusion of one coronary artery and at least 50% occlusion of a second coronary artery that supplies collateral blood flow to the area in which the complete occlusion exists.¹⁸ In addition, recent evidence suggests that the inhaled anesthetics isoflurane, desflurane, and sevoflurane produce myocardial protection during periods of ischemia in humans by decreasing the formation of free radicals, preserving myocardial ATP stores, and inhibiting intracellular calcium.^{19,20} This phenomena is referred to as *anesthetic preconditioning*.

Cardiac Output.

Cardiac output is the amount of blood ejected from the LV during one minute. Comparing various CO values among humans requires a method for calculating output in relation to the size of the patient. The CO is measured in L/min. Cardiac output is indexed, because a CO of 3.5 L/min may be adequate for a woman who is 5 feet tall and weighs 95 lbs, but it is less than optimal for a man who is 6 feet 5 inches tall and weighs 250 lbs. The average CO is 5 L/min, and the average cardiac index (CI) is 2.5 L/min or more per square meter of

body surface area (BSA). The formula for this relationship is $CI = CO/BSA$.

The primary determinants of CO are HR and SV. CO is derived by using the equation $CO = HR \times SV$. The SV is the amount of blood ejected from the LV with each beat. The average SV is approximately 70 mL. If the average HR is 70 to 80 beats/min, a CO of 5 L/min results.

Several key factors affect SV, including preload, afterload, and myocardial contractility. When increased, all these factors increase myocardial oxygen demand. Preload is the effective tension of the blood on the ventricle or the wall tension at the end of diastole. Preload can either be passive (the flow of blood from the atria to the ventricles during diastole) or active (the volume contributed by the atrial kick). With increased preload, there is an associated increase in contractility. This phenomenon is known as the *Frank-Starling Law* of the heart, which states that the greater the wall tension (preload), the greater the compensatory increase in myocardial contractility. This mechanism allows the heart to immediately compensate for increased preload and avoid over distention of the ventricular chambers by increasing SV, which facilitates chamber emptying. However, there is a point at which progressive increases in preload no longer increase contractility but can contribute to decreased myocardial performance. Increased preload increases myocardial oxygen demand. Clinically, preload can be estimated by using the PCWP and the pulmonary artery diastolic pressure. In patients with a normal mitral valve orifice and ventricular muscle function, either of these measures provides an estimate of the preload or LVEDP and volume.

Cardiac output can be calculated by applying this equation, which is known as the *Fick principle*:

$$CO \text{ (L/min)} = \frac{\text{O}_2 \text{ absorbed per minute by the lungs (mL/min)}}{\text{Arteriovenous O}_2 \text{ difference (mL/L of blood)}}$$

This can also be expressed as:

$$\text{CO (L/min)} = \text{VO}_2 / (\text{C}_a - \text{C}_v)\text{O}_2$$

where CO is cardiac output (Fick) (L/min), VO_2 is oxygen consumption (mL/min), $\text{C}_a - \text{C}_v\text{O}_2$ is arterial venous oxygen content difference (mL/dL) ($\text{C}_a - \text{C}_v\text{O}_2$ is multiplied by 10 to convert to mL/dL to mL/L).

Afterload is the wall tension the myocardium needs to overcome to eject the SV. It is the pressure within the LV during peak systole. Factors affecting LV afterload include the state of the ventricular chamber and the compliance of the arterial vasculature. The shape, size, and wall thickness of the ventricle play an important role in afterload. The vascular component of the afterload includes SVR and MAP because these variables relate to the vascular compliance of the aorta. Thus, increases in blood pressure increase afterload.

Afterload is most often estimated clinically by determining the SVR. The SVR may be calculated once the CO and the difference between the MAP and the central venous pressure (CVP) are known (see the following equation). The normal SVR is 800 to 1500 dynes/sec/cm⁵.

$$\text{SVR} = (\text{MAP} - \text{CVP}) \times 80 / \text{CO}$$

The problem with equating afterload with SVR is that ventricular wall tension, which is an integral part of the afterload, is not considered.

Contractility of the myocardium is the state of inotropy that is independent of either preload or afterload. It may be altered by many cardiovascular disease states. Factors such as rate of pressure changes over time (dP/dt [first derivative of pressure measured over time]), force-velocity or Starling ventricular function curves, pressure-volume loops, ejection fraction (EF), and velocity of circumferential fiber shortening have all been used to estimate contractility.

Left ventricular dP/dt measurements require a high-fidelity recording system, and for this reason these measures are not readily available in the clinical setting. A wide range of normal values exists (800 to 1700 mm Hg/sec), making patient-to-patient

comparisons difficult.

Ventricular function curves²¹ (Fig. 25.20), define the relationship between the left ventricular filling pressure (left ventricular diastolic pressure, left atrial pressure, PCWP) and the left ventricular stroke work index (LVSWI), which is calculated by use of the following equation:

FIGURE 25.20 The ventricular function curve. CO, Cardiac output; LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure; LVSW, left ventricular stroke work; LVSWI, left ventricular stroke work index; PADP, pulmonary artery diastolic pressure; PCWP, pulmonary capillary wedge pressure; SV, stroke volume.

$$\text{LVSWI (in g/m}^2 \text{ per beat)} = 0.0136 \times \text{SVI} \times (\text{MAP} - \text{PCWP})$$

where $\text{SVI} = \text{CI}/\text{HR}$ and SVI is stroke volume index.

Each left ventricular function curve has a steep upstroke that has a plateau at higher filling pressures. To apply the Frank-Starling mechanism to Fig. 25.20, notice in the "normal" and

“hyperdynamic” curves that as pressure (horizontal axis) increases, so does LV output (vertical axis). However, at the top of these curves, there is a plateau where increasing the filling pressures no longer increases performance and can then decrease ventricular output. Symptoms may be elicited by either high or low filling pressures. On the “failure” curve, with compromised cardiac function, increases in filling pressures do not dramatically increase myocardial performance and can lead to cardiogenic shock. The clinical determination of LSWI is an indication of the factors that contribute to CO, and it gives measures of both systolic and diastolic performance.

Left ventricular pressure-volume loops have been mentioned before as conceptual models depicting phases of the cardiac cycle. They may also be used as tools to determine myocardial performance and the presence of cardiac pathology. Left ventricular pressure-volume loops simultaneously measure chamber pressures and the resultant volumes ([Fig. 25.21](#)). Movement from left to right on the horizontal axis represents increased volume. Movement from right to left on the horizontal axis represents decreased volume. Movement up and down on the vertical axis represents increases and decreases in pressure, respectively. The distinct phases of the left ventricular pressure-volume loop are represented in [Fig. 25.22](#).

FIGURE 25.21 Phases of the left ventricular (LV) pressure-volume loop, which is a continuous cycle divided into four phases. Phase I represents diastolic filling. Left ventricular filling begins at point *B* and ends at point *C*. Note the increase in volume of 70 mL from point *A* to point *B* and the upward movement of the curve at point *C*, representing a slightly increased pressure in response to the increased volume. Point *C* or mitral valve closure represents end-diastolic volume (EDV). Phase II represents isovolumetric contraction. Note there is a significant increase in pressure but no change in volume. Cardiac muscle fibers are shortening and increasing the pressure on the LV volume until point *D*, where the LV pressure exceeds aortic pressure. Phase III represents systolic ejection. Note the decrease in LV volume throughout LV systolic ejection. Phase IV represents isovolumetric relaxation. At point *A* the aortic pressure exceeds LV pressure, and the aortic valve closes. Point *A* represents end-systolic volume (ESV). The LV relaxes, and the pressure decreases significantly. At maximal LV relaxation, the mitral valve opens and the process starts again.

Left Ventricular Pressure-Volume Loop

FIGURE 25.22 Phases of the cardiac cycle represented by a left ventricular pressure-volume loop.

The interior of the curve (distance between the two vertical lines of the LV pressure-volume loop) is representative of SV. In this diagram, SV is calculated by subtracting end-systolic volume (ESV) from end-diastolic volume (EDV), or EDV (110 mL) – ESV (40 mL). Thus, in this example, SV is 70 mL. EF can then be estimated using the following equations:

$$EF = (EDV - ESV)/EDV \times 100$$

or

$$EF = (SV/EDV) \times 100$$

The EF is the percentage of the EDV ejected during systole, as seen in [Fig. 25.23](#). The normal EF is 60% to 70%. An EF of less than 40% is associated with significant left ventricular impairment.

FIGURE 25.23 Pressure-volume diagram indicating end-diastolic volume (*EDV*), end-systolic volume (*ESV*), stroke volume (*SV*), and the equation for ejection fraction (*EF*).

(From Johnson B, et al. Cardiac physiology. In Kaplan JA, et al., eds. *Kaplan's Cardiac Anesthesia: The Echo Era*. 5th ed. Philadelphia: Elsevier; 2006:73.)

Deviations from the normal left ventricular pressure-volume loops occur for a variety of reasons. Factors that alter the normal loop include increases and decreases in LV preload, LV afterload, and LV contractility. These factors can be acute and transient, such as during the administration of vasoactive medications, or chronic because of myocardial compensation caused by valvular heart disease (stenosis vs regurgitation). In [Fig. 25.24](#), these changes are consistent with valvular heart disease. As stated, many factors contribute to variations in pressure and volume from beat to beat within the LV, each pressure volume loop is distinct, represents one LV systolic ejection, and is different for each contraction. A discussion of these pathologic curves is presented later in this chapter.

FIGURE 25.24 Pathologic left ventricular pressure-volume loops. *A*, Mitral stenosis; *B*, normal curve; *C*, aortic stenosis; *D*, mitral regurgitation; *E*, aortic regurgitation.

A clinically useful tool to determine a beat by beat assessment of myocardial performance is transesophageal echocardiography (TEE). When this technology is appropriately used, real-time movement of all four chambers of the heart, as well as that of the valves, may be visualized.

TEE can be used to detect valvular function and blood flows in both regurgitant and stenotic lesions. It is also useful in determining areas of hypokinesis, dyskinesis, or akinesis caused by myocardial infarction (MI), ischemia, or injury. It can be useful in determining myocardial contractility, and it is a more direct measure of intraventricular volume status than pulmonary artery catheter pressure measures. TEE has also proven useful in directing fluid and pharmacologic therapy in patients who have undergone coronary bypass and other surgical procedures. Ventricular dysfunction or reperfusion injury, as well as the presence of intraventricular air, can be determined with TEE. This diagnostic tool is the gold standard for assessing intraoperative myocardial performance.²² The practical problems associated with the clinical use of TEE entail acquiring the skills necessary for accurate interpretation of the visual data, the possibility of esophageal rupture, and the cost associated with its use.

Cardiovascular Reflexes

Cardiac Output Regulation.

A direct interplay exists between CO and venous return. As long as either contractility or HR is not compromised, maintenance of a constant return of blood flow to the heart ensures an adequate CO. The body's regulation of CO depends on its ability to regulate HR and contractility of the myocardium, as well as constriction and distention of the vascular tree.

Many of the factors that affect CO also affect the MAP and are addressed later in this chapter on regulation of MAP. Some of the more common reflexes that can alter the CO are described in this section or in the section on regulation of MAP.

Valsalva Maneuver.

The Valsalva maneuver occurs as a result of forced expiration against a closed glottis. The reflex is mediated through the baroreceptors located near the bifurcation of the internal and external carotid arteries (carotid sinus) and the aortic arch. The afferent pathway is directed via Hering's nerve and either the glossopharyngeal nerve (to the carotid sinus) or the vagus nerve (to the aortic arch), as shown in [Fig. 25.25](#). Stimulation of either of these areas inhibits the vasomotor center in the medulla. The response inhibits the sympathetic nervous system and stimulates the parasympathetic nervous system, producing a decrease in HR, myocardial contractility, a rate of cardiac impulse conduction, and induces vasodilation, resulting in a decrease in blood pressure. The Valsalva maneuver also increases intrathoracic pressure, which decreases venous return and thereby decreases CO.

FIGURE 25.25 Afferent and efferent neural pathways from carotid and aortic baroreceptors. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2017:220.)

Baroreceptor Reflex.

The baroreceptors respond to fluctuations in arterial blood pressure. Afferent and efferent impulse transmission travels along the same pathway as previously described for the Valsalva maneuver. Decreases in arterial blood pressure are sensed by the baroreceptor, and increased sympathetic tone results in increased myocardial performance and vasoconstriction. Acute hypertension causes the opposite cardiovascular response to occur. A more in-depth explanation of the baroreceptor response and its role in short- and long-term blood pressure control is presented later in this chapter. The baroreceptor response is inhibited by inhalation anesthetic agents in a dose-dependent manner and results in a

decreased ability of the baroreceptors to respond to blood pressure changes when these agents are used.

Oculocardiac Reflex.

Traction on the extraocular muscles (especially the medial rectus), conjunctiva, or orbital structures can cause hypotension and a reflex bradycardia, as well as dysrhythmias. The *oculocardiac reflex*, also known as *Aschner phenomenon*, may also be elicited during retrobulbar block, ocular trauma, or pressure on the tissue that remains after enucleation. The afferent path of this reflex is mediated by the long and short ciliary nerves to the ciliary ganglion of the oculomotor nerve and then to the ophthalmic division of the trigeminal nerve (cranial nerve V) and finally to the gasserian ganglion. The efferent branch of the reflex is mediated by the vagus nerve (cranial nerve X). Due to the nervous system pathway, it can also be referred to as a *trigeminovagal reflex*. This reflex may be blunted by the use of retrobulbar block or the release of the offending stimulus. The resulting vagal response to the heart can be inhibited by an anticholinergic agent (atropine or glycopyrrolate).

Celiac Reflex.

The *celiac reflex* is elicited by traction on the mesentery or the gallbladder or stimulation of the vagus nerve in other areas of the body, such as the thorax and abdominal cavity. Stimulation of this reflex causes bradycardia, apnea, and hypotension. Clinically, the celiac reflex can be initiated indirectly as a result of a pneumoperitoneum. As with the oculocardiac reflex, the celiac reflex is frequently resolved by stopping the initiating stimulus. This vagal response to the heart can be antagonized by administration of an anticholinergic agent (atropine or glycopyrrolate).

Bainbridge Reflex (Atrial Stretch Reflex).

The *Bainbridge reflex* is elicited as a result of an increased volume of blood in the heart, which causes sympathetic nervous system stimulation. Stretch receptors are located in the right atrium, junction of the vena cava, and pulmonary veins. The SA node is also involved in this process and can increase heart rate by 10% to

15%. This reflex helps to prevent sequestration of blood in veins, atria, and pulmonary circulation. Antidiuretic hormone secretion from the posterior pituitary gland is decreased, resulting in decreased circulating blood volume. Atrial natriuretic peptide is increased, which also promotes diuresis.

Cushing Reflex.

This physiologic response to CNS ischemia caused by increased intracranial pressure is called the *Cushing reflex*. It is triggered as a result of an elevation of intracranial pressure to a value greater than the MAP, thereby decreasing cerebral perfusion and potentially causing cerebral ischemia. An intense sympathetic nervous system response is initiated by the vasomotor center, resulting in intense vasoconstriction. These compensatory physiologic changes attempt to restore adequate cerebral perfusion. However, if cerebral ischemia is not relieved, cerebral infarction results. When the vasomotor area becomes ischemic as a result of hypotension (MAP less than 50 mm Hg), maximal stimulation of the vasomotor center occurs. *Cushing triad* is a late sign of high and sustained intracranial pressure prior to cerebral herniation. The triad signs include hypertension, bradycardia, and respiratory irregularity.

Chemoreceptor Reflex.

The central chemoreceptors are located beneath the ventral surface of the medulla and are directly stimulated primarily by increased hydrogen ion concentrations. The peripheral chemoreceptors are located at the bifurcation of the internal and external carotid arteries (carotid body) and within the aortic arch (aortic body) and are primarily stimulated by decreased arterial oxygen concentration. The response elicited from hypoxia, hypercarbia, and acidosis is increased minute ventilation and increased sympathetic nervous system stimulation, resulting in increased blood pressure. Like the baroreceptor reflex, the chemoreceptor response is inhibited by the inhalation anesthetic agents in a dose-dependent manner. Thus, if residual inhalation agent is present during the emergence from anesthesia, the carbon dioxide threshold will be increased, necessitating a higher partial pressure of carbon dioxide in arterial blood (PaCO_2) prior to the beginning of spontaneous

respirations. [Table 25.5](#) provides a summary of the cardiovascular reflexes.

TABLE 25.5
Cardiac Reflexes

Reflex	Stimulus	Response
Baroreceptor reflex	Hypertension resulting in baroreceptor stimulation; carotid baroreceptors send afferent response via Hering's and glossopharyngeal nerves (CN IX); aortic baroreceptors send afferent response via the vagus nerve (CN X)*	Decreased heart rate, decreased contractility, peripheral vasodilation from efferent response via the vagus nerve (CN X)
Valsalva maneuver	Forced expiration against a closed glottis mediated via baroreceptors; see baroreceptor reflex for neural pathways	Decreased heart rate, decreased contractility, peripheral vasodilation from efferent response via the vagus nerve (CN X)
Cushing reflex	Increased intracranial pressure resulting in cerebral ischemia	Sympathetic nervous stimulation resulting in increased blood pressure
Chemoreceptor reflex	Decreased oxygen saturation, increased carbon dioxide, increased hydrogen ion concentration; peripheral chemoreceptors located in the carotid body and aortic arch; see baroreceptor reflex for neural pathways	Increased respiratory drive, increased blood pressure
Atrial stretch reflex (Bainbridge reflex)	Hypervolemia, increased venous return causes stimulation of atrial stretch receptors	Increased heart rate, decreased blood pressure, decreased systemic vascular resistance, diuresis
Oculocardiac reflex	Traction on the extraocular muscles (especially medial rectus) or pressure on the globe causes an afferent response via the trigeminal nerve (CN V) and results in an efferent vagal response via the vagus nerve (CN X)	Bradycardia, hypotension, and arrhythmias
Celiac reflex	Traction or pressure on structures within abdominal and thoracic cavities causes vagal nerve stimulation	Bradycardia, hypotension, and apnea

* Efferent response increases parasympathetic tone via the vagus and sympathetic nerves.

CN, Cranial nerve.

Vascular System

Anatomy

Vascular Anatomy

The vascular circulation is divided into the pulmonary circulation and the peripheral systemic circulation (Fig. 25.26). This system is composed of several functional parts.

FIGURE 25.26 The vascular circuit. *LA*, Left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *PAoP*, pulmonary artery occlusion pressure; *RA*, right atrium; *RV*, right ventricle; *SVC*, superior vena cava.

Arteries.

Arteries transport blood in a retrograde fashion from the heart to periphery tissues under high pressure. Arteries have an average diameter of 4 mm and a wall thickness of 1 mm. They have a thick layer of elastic tissue, smooth muscle, and fibrous tissue. Arteries are able to maintain the flow of blood because of their large internal diameter. Due to the muscular layer within arterial walls, arterial constriction or dilation has a significant effect on SVR.

Arterioles.

Arterioles are the last small branches of the arterial system, and they act as control valves for the release of blood into the capillary beds. Arterioles have an average diameter of 30 μm and a wall

thickness of 20 μm . Like arteries, arterioles have a thick layer of elastic tissue, smooth muscle, and fibrous tissue. Constriction of the arterioles, compared with that of other structures within the vascular system, causes the greatest increase in SVR. Because of this contribution, arterioles exhibit the greatest pressure drop in the vascular system across the length of their vessels.

Capillaries.

The exchange of fluids, nutrients, electrolytes, hormones, and other substances occurs between the blood and the interstitial fluids in the capillaries. Capillaries have an average diameter of 8 μm and a wall thickness of 1 μm . The walls of capillaries are only one cell thick and have no elastic tissue, smooth muscle, or fibrous tissue. The capillary cell membrane is semipermeable to water and other small molecules.

Venules.

Venules collect blood from capillaries and gradually coalesce into progressively larger veins. Venules have an average diameter of 20 μm and a wall thickness of approximately 0.5 mm. They do not have an elastic or smooth muscle layer but have a thin fibrous layer.

Veins.

Veins act as conduits for the transport of blood back to the heart. They also act as a large reservoir because they are very distensible. They have an average diameter of 30 mm and a wall thickness of 1.5 mm. The venous system contains approximately 60% of the blood volume, as opposed to the 20% contained within the arteries (Fig. 25.27). The elastic tissue and the fibrous tissue layers are similar in size to those of the arterioles, but the smooth muscle layer in the veins is smaller than that in the other large vessels.

FIGURE 25.27 The venous system. v., Vein.

Arterial Circulation

Knowledge of the anatomy of the arterial circulation is an important part of anesthesia practice. Such information is essential for obtaining intra-arterial access, assessing HR and pulse quality, understanding the anatomic relationships for the purpose of regional blocks, and understanding the physiologic implications of

decreased blood flow during shock states.

Microscopic Anatomy of the Arterial Circulation.

Arteries are classically divided into two types: conducting, or elastic, arteries and distributing, or muscular, arteries. Conducting arteries include the major arteries, such as the aorta, and their major branches, such as the brachial, radial, and ulnar arteries. The walls of the arteries are thicker than the walls of veins and consist of three major layers: the tunica intima, the tunica media, and the tunica adventitia.

Thoracic Aorta.

The thoracic aorta is divided into three sections: the ascending aorta is the portion that leaves the LV; the transverse aorta, or arch, is the portion that levels off; and the descending aorta is the portion that descends into the thorax. After the thoracic aorta penetrates the diaphragm, the vessel is then referred to as the *abdominal aorta* (Fig. 25.28).

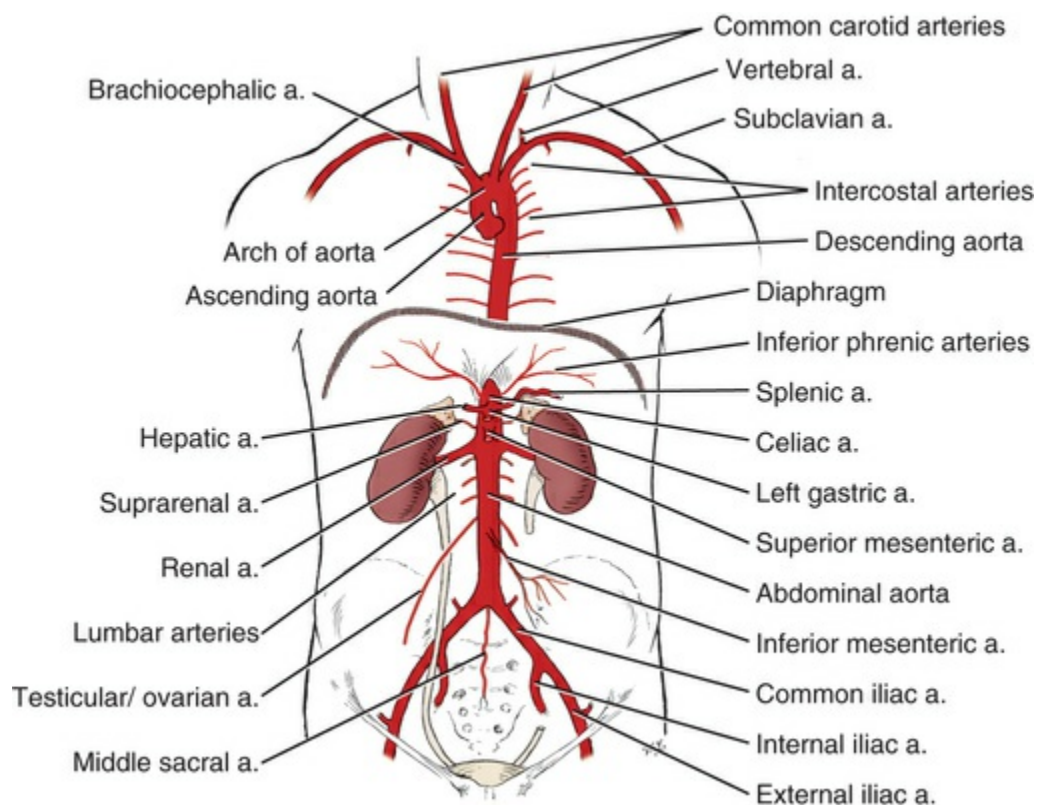

FIGURE 25.28 Thoracic aorta and abdominal aorta and

their branches. *a.*, Artery.

The first branches of the ascending aorta are the right and left coronary arteries which are located immediately superior to the aortic valve. From this point, three major branches of the thoracic aorta exist: the brachiocephalic (innominate) artery, the left common carotid artery, and the left subclavian artery.

The brachiocephalic artery branches and then divides into the right common carotid artery and the right subclavian artery. The left and right common carotid arteries then branch into internal and external carotid arteries. The external carotid arteries supply blood to the face and neck, and the major branches are the superior thyroid artery, the lingual artery, the facial artery, the posterior auricular artery, the maxillary artery, the transverse facial artery, the middle temporal artery, and the superficial temporal artery (Fig. 25.29).

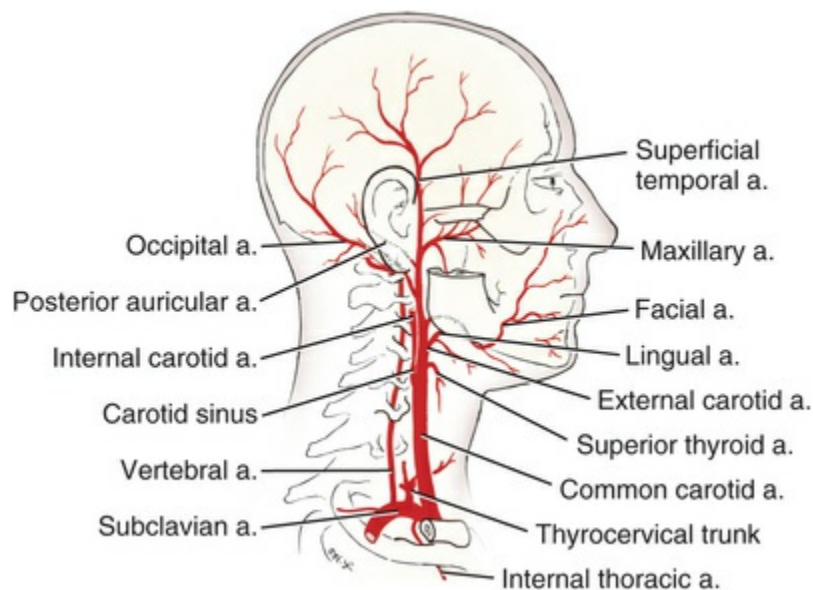

FIGURE 25.29 Arterial supply to the face. *a.*, Artery.

The internal carotid arteries supply 80% of blood to the brain, via the circle of Willis, and to the eyes, via the ophthalmic arteries (Fig. 25.30). The circle of Willis also receives a significant amount of blood supply from the vertebral branches of the subclavian artery.

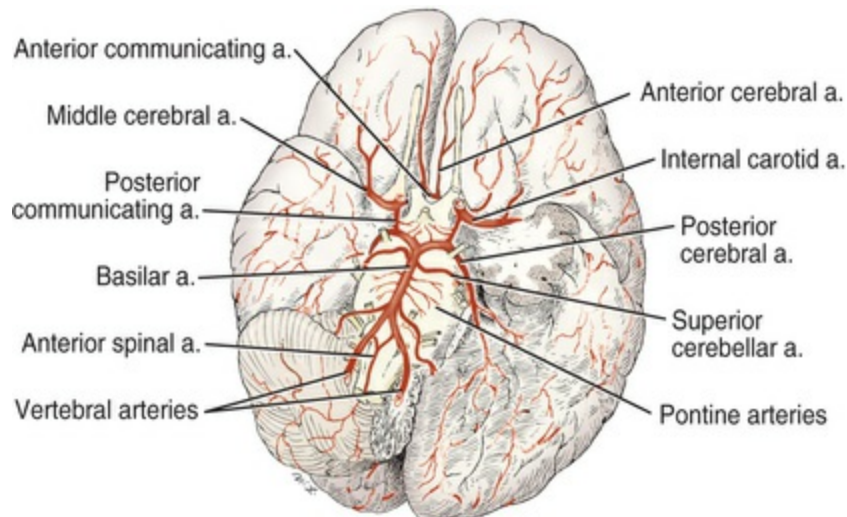

FIGURE 25.30 The circle of Willis. a., Artery.

Upper Extremity Arteries.

The subclavian arteries branch before entering the upper arm. These branches include the vertebral arteries, as noted earlier; the thyrocervical trunk, which supplies blood to the thyroid gland, as well as other structures in the neck; the internal thoracic artery, which supplies blood to the anterior chest; and the costocervical trunk, which supplies blood to the first two intercostal spaces and the muscles of the neck.

The subclavian artery continues at the border of the first rib as the axillary artery (Fig. 25.31). Branches from the axillary artery supply blood to the axillary region and include the highest thoracic artery, the thoracoacromial artery, the lateral thoracic artery, the subscapular artery, and the anterior and posterior circumflex humoral arteries.

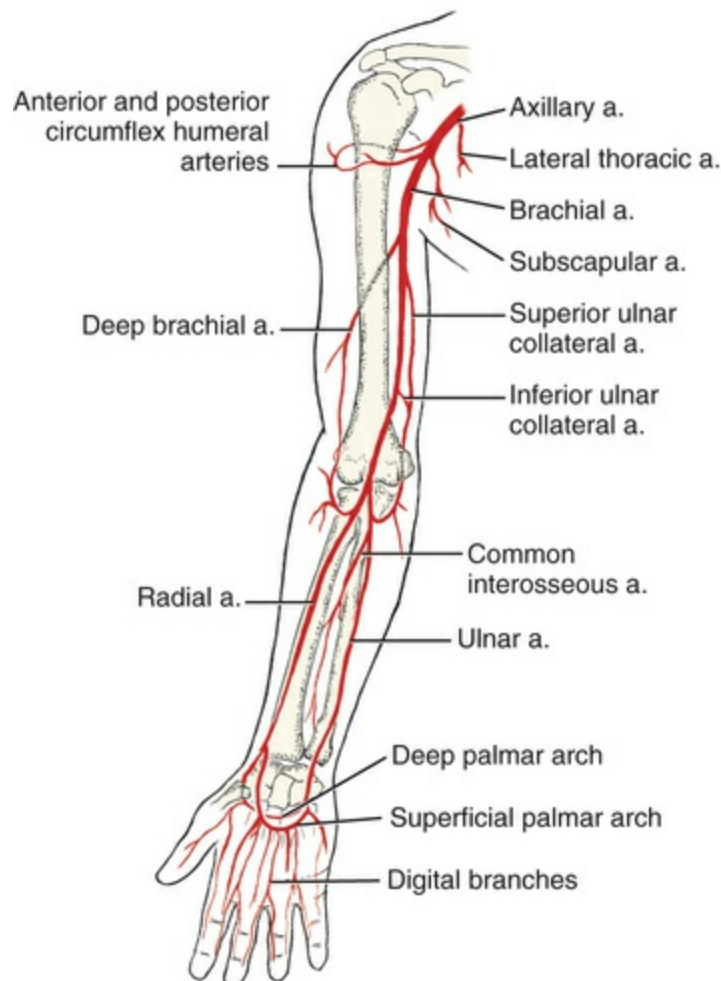

FIGURE 25.31 Arterial supply to the upper extremity. a., Artery.

The brachial artery begins at the terminal end of the axillary artery at the inferior border of the teres major muscle. The artery continues until the neck of the radius, where it ends by dividing into the radial and ulnar arteries. The radial artery forms the deep palmar arch, and the ulnar artery supplies blood to the superficial palmar arch.

Descending Thoracic Aorta.

The descending thoracic aorta courses inferiorly through the posterior mediastinum on the left side of the thorax. At the level of the twelfth thoracic vertebra, the aorta passes through the aortic hiatus and becomes the abdominal aorta. Branches of the descending thoracic aorta include the lower nine posterior intercostal arteries, the subcostal arteries, the pericardial arteries, the esophageal arteries, and the bronchial arteries.

Longitudinal blood flow to the spinal cord includes (1) two posterior and two posterolateral arteries supplying blood to the dorsal or sensory portion of the spinal cord (20% of spinal cord blood flow) and (2) one anterior spinal artery supplying blood to the anterior or motor portion of the spinal cord (80% of spinal cord blood flow). Transverse blood flow originating from the thoracic aorta is via the greater radicular artery (artery of Adamkiewicz). The exact location of this artery is variable and dependent on an individual's specific anatomical characteristics. However, the artery most often originates between spinal segments T8–T12 but it can be as low as L2 in a small segment of the population. Interruption of blood flow to the greater radicular artery in the absence of collateral blood flow has been identified as a factor that can cause paraplegia.

Abdominal Aorta.

As the thoracic aorta passes through the aortic hiatus of the diaphragm, it becomes the abdominal aorta. The first branches of the abdominal aorta are the inferior phrenic arteries, which supply blood to the underside of the diaphragm and the adrenal glands (see [Fig. 25.28](#)).

The next major branch of the abdominal aorta is the celiac trunk, which supplies blood to many of the organs in the upper abdomen. Its branches include the splenic artery, the left gastric artery, the gastroduodenal artery, and the hepatic artery. The cystic artery, which supplies blood to the gallbladder, is a branch of the hepatic artery.

Below the celiac trunk of the aorta lies the superior mesenteric artery, which arises at the level of L1. This artery supplies blood to the jejunum, the ileum, and the transverse colon by means of an anastomosis with the middle colic artery. The jejunum and iliac branches unite to form the arterial arcades of the colon.

Below the superior mesenteric artery are the right and left renal arteries. The right renal artery branches to the right adrenal gland, where it is called the *middle suprarenal artery*. Below the renal arteries are the testicular or ovarian arteries. Inferior to the renal arteries lies the inferior mesenteric artery. This artery has branches to the transverse colon, the descending colon, and the sigmoid colon and rectum.

Iliac Arteries.

The abdominal aorta terminates at the common iliac arteries in the pelvis. These arteries divide into internal and external iliac arteries. The internal iliac arteries supply blood to structures within the pelvis, whereas the external iliac arteries supply blood to the legs. The right and left femoral arteries are branches of the external iliac arteries.

Lower Extremities.

The external iliac artery continues as the femoral artery and the deep femoral artery ([Fig. 25.32](#)). The femoral artery becomes the popliteal artery behind the knee and then divides into the anterior and posterior tibial arteries. The anterior tibial artery continues as the dorsal artery of the foot. The posterior tibial artery continues and supplies blood to the plantar arches. Clinically, the dorsal artery of the foot is not only an important landmark for the assessment of lower extremity circulation but can also be used for arterial cannulation if the radial artery catheter insertion is not possible.

FIGURE 25.32 Arterial supply to the lower extremity. *a.*, Artery.

Venous Circulation

An understanding of the anatomy of the venous system is essential for obtaining vascular access but also for identification of significant landmarks to help locate nerve bundles when performing nerve blocks. Evaluation of venous distention is an important assessment tool to determine the presence of fluid overload and cardiovascular dynamics.

Head and Neck.

In the head and neck, venous drainage returns to the heart via the internal and external jugular veins. The drainage from the brain originates from the sagittal, transverse, and sigmoid sinuses. These sinuses drain into the internal jugular vein, whereas the more superficial structures of the face and head drain into the external jugular vein. Clinically, jugular venous distention can be a sign of

cardiogenic shock and or cardiac compressive shock (cardiac tamponade).

Upper Extremities.

Superficial veins of the upper extremities include those that drain into the axillary vein, the cephalic vein laterally, and the basilica vein medially. The axillary vein drains into the subclavian vein on the right and then into the right brachiocephalic vein. The left subclavian vein drains into the left brachiocephalic vein. The right and left brachiocephalic veins empty into the superior vena cava and account for the venous drainage that occurs from the upper extremities. Pressure and occlusion of the superior vena cava from a mass can result in a decrease in venous drainage, causing superior vena cava syndrome.

Thorax.

Venous drainage of the thorax originates from the branches of the superior and inferior vena cava and the azygos and hemiazygos systems. These venous networks are an important alternative blood return route if a major obstruction of the inferior vena cava occurs. These vessels include intercostal vessels, bronchial veins, and pericardial veins.

Abdomen, Pelvis, and Lower Extremities.

The deep and superficial femoral veins receive venous drainage from the legs and join to form the external iliac veins. The internal iliac veins drain blood from the pelvis. The common iliac vessels receive blood from the internal and external iliac veins and drain into the inferior vena cava. In this region, the common iliac vessels are joined by branches from the abdomen and the hepatic portal system.

Microcirculation

Microcirculation refers to blood flow that occurs through microvessels that are present within the vasculature of tissues. The microcirculation system is comprised of arterioles, capillaries and venules. The function of the microcirculation is to control the

delivery of nutrients to the capillary tissue beds, remove waste products, maintain ionic concentrations, and transport hormones to the tissues.

Anatomy.

In general, a main nutrient artery enters an organ, where it branches six to eight times until the vessels are small enough to be called *arterioles* (less than 20 μm in diameter). Arterioles then branch two to five times and reach diameters of 5 to 9 μm , small enough to supply blood to the capillary bed.

In the capillary bed, the blood enters through an arteriole that has a muscular coat. Arterioles are connected to metarterioles, which have many interconnections to the true capillaries and whose branches are protected by precapillary sphincters. These sphincters can control blood flow through the capillary bed.

The capillary wall is a unicellular layer of endothelium surrounded by a basement membrane. The total wall thickness is 0.5 μm , and the diameter of the capillaries is 4 to 9 μm . In the capillary membrane, intercellular clefts allow the diffusion of water-soluble ions and small solutes. Plasmalemmal vesicles form channels in the cell membrane. The diffusion of substances through the cell membrane is determined by several factors: lipid solubility, water solubility, size of the molecule, and concentration difference from one side of the membrane to the other.¹

Movement of fluid volume from the plasma and the interstitial fluid is determined by four factors: capillary pressure, interstitial fluid pressure, plasma colloid osmotic pressure, and interstitial fluid colloid osmotic pressure. Excess fluid from the interstitial space is transported through the lymphatic system, which plays an important role in the prevention of pulmonary edema formation when pulmonary artery pressures are elevated.

Local Control of Capillary Blood Flow.

Blood flow to the various capillary beds is regulated by local tissue metabolic requirements. Therefore, capillary blood flow may be controlled by the delivery of oxygen and other nutrients, the removal of end products of metabolism, or the maintenance of ionic balance of pH in the tissues.

Two major theories regarding regulation of capillary blood flow include the vasodilator theory and the oxygen-demand theory. According to these theories, the vessels dilate to increase the blood flow as a result of either hypoxemia or release of a vasodilator substance in response to hypoxemia. Some of the vasodilator substances that have been suggested are adenosine, carbon dioxide, nitric oxide, lactic acid, adenosine phosphate compounds, histamine, potassium ions, and hydrogen ions. These theories assume an active microcirculatory process exists that responds to tissue metabolic needs.

Certain tissue capillary beds do not function as explained by the vasodilator and the oxygen-demand theories of microcirculatory blood flow. Blood flow to the skin is dependent on external temperature and dissipation of body heat, whereas blood flow to the kidneys is dependent on the amount of fluid and sodium that needs to be excreted.

Autoregulation is another process demonstrated by certain organ tissues; it keeps blood flow through the capillary bed constant, despite the normal changes in MAP. Autoregulation has been demonstrated in such tissues as the brain, the kidney, and the coronary circulation. Autoregulation keeps the blood flow to an organ constant by way of vasodilation or vasoconstriction in response to fluctuations in MAP. When MAP is above or below autoregulatory pressures for a particular organ system, blood flow becomes pressure dependent.

A substance that causes secondary vasodilation of the large arteries in response to increased flow has been isolated and was once called the *endothelium-derived relaxing factor*.²³ Currently, it is referred to as *nitric oxide*. This factor is synthesized by the endothelial lining of the arterioles and the small arteries. Shear stress on the walls of the vessels accelerates the release of this substance and allows larger vessels to dilate when blood flow to the tissues increases.

Angiogenesis-Growth of Collateral Circulation

Microcirculation is a good example of vascular growth that can occur to provide collateral circulation. The growth of new vessels results in part from angiogenesis and the release of angiogenic

factors. These substances are released from ischemic tissues, rapidly growing tissues, and tissues with high metabolic rates.

Several angiogenic factors have been identified, including endothelial cell growth factor,²⁴ fibroblast growth factor,²⁵ and angiogen.²⁶ These factors act by the dissolution of the basement membrane of the endothelial cells, followed by the rapid dissolution of new endothelial cells that stream out of the vessels into cords. The cells in these cords divide and then gradually fold over into a tube. The tubes then connect with other tubes to form a vascular network.

Vascular flow is dependent on neurologic as well as hormonal regulation. Some vasoconstrictor hormones include epinephrine and norepinephrine from the CNS and the adrenal medulla, angiotensin from the lungs, cortisol from the adrenal cortex, and vasopressin from the posterior pituitary. Some vasodilator substances include bradykinin, serotonin, histamine, and the prostaglandins. Various other ionic and chemical factors can also produce vasoconstriction and vasodilation and have an effect on the flow of blood that is delivered to tissues.

Blood Pressure

Pressure, Flow, and Resistance Interrelationships

Ohm's Law.

Ohm's law correlates the flow of electricity (current), the applied electrical pressure (voltage), and the resistance to this flow (resistance). A modification of this law is used in medicine to describe the flow of a fluid (blood) through a tube (blood vessel), even though the vessels are dynamic rather than static. Ohm's law and fluid flow are described by the following equation:

$$Q = (P_1 - P_2) / R$$

where flow through a cylinder (Q) is equal to the change in pressure from one end of the tube to the other ($P_1 - P_2$) divided by

the resistance (R) of the tube. Therefore, either a decrease in resistance or an increase in pressure change across the tube increases the flow of fluid through the tube.

Blood Flow.

Blood flow is the quantity of blood that passes a given point in a given amount of time. Clinically, CO may be inserted into the equation as blood flow. Two types of flow exist: laminar and turbulent (Fig. 25.33).

FIGURE 25.33 Laminar and turbulent flow.

Laminar flow has a parabolic profile that illustrates the parallel movement of molecules. Conversely, turbulent flow is described as a whirlpool and does not move as easily, thereby increasing resistance to flow. Reynolds number (Re) is a means of determining the type of flow in a tube and uses the diameter of the blood vessel (d) and the velocity (v), density (ρ), and viscosity (η) of the fluid to determine whether turbulence occurs.

The formula for calculating Reynolds number includes the velocity of blood flow in centimeters per second multiplied by the diameter of the tube in centimeters, multiplied by the density of the fluid in grams per cubic centimeter, divided by the viscosity (see the following equation). A Reynolds number below 200 indicates

laminar flow. A Reynolds number of 200 to 400 indicates that turbulence occurs at bends in the tube, and a Reynolds number above 2000 indicates turbulent flow, even in straight, smooth vessels.

$$Re = (v \times d \times \rho) / \eta$$

Reynolds number demonstrates that in large vessels with high velocities, such as the aorta and large arteries, turbulent flow occurs even in the straight portions of these vessels.

Poiseuille's Law.

Poiseuille's law (see the following equation) describes the amount of fluid flowing through a tube (Q) in relation to the pressure drop across the tube ($P_1 - P_2$), the radius of the tube (r), the length of the tube (l), and the viscosity of the fluid (η):

$$Q = ([P_1 - P_2] r^4) / (8 \times \eta \times l)$$

One of the most important factors in determining fluid flow is the radius of the vessel.

Clinical applications of Poiseuille's law include selection of intravenous (IV) catheter size, endotracheal tube size, and determination of vascular dilation and constriction in response to pharmacologic agents.

Resistance.

Resistance is the impediment to blood flow in a blood vessel. Clinically it cannot be measured directly but is calculated from measures of blood flow (CO) and pressure differences in the vessels.

The units of measure most commonly used in the clinical area are centimeter-gram-second units. The normal SVR is 800 to 1500 dyne/sec per cm^{-5} , and the normal pulmonary vascular resistance is approximately one-tenth of that number, or between 50 and 150 dyne/sec per cm^{-5} .

Resistance of Systems.

Resistance is calculated for two major systems (Fig. 25.34). In a series system, such as the systemic vasculature, the total resistance (R_T) is equal to the sum of the collective resistance for the individual tissue beds within the system and can be expressed as:

FIGURE 25.34 Resistance in series and parallel systems. R , Resistance; R_T , total resistance; SVR , systemic vascular resistance.

$$R_T = R_1 + R_2 + R_3 + \dots R_n$$

In a parallel system, such as a capillary bed, the total resistance is less than any of the individual resistances (see the following equation). Therefore, the blood flow through a capillary bed such as the pulmonary capillaries is less than the resistance through any of the individual capillaries of the pulmonary system.

$$1/R_T = 1/R_1 + 1/R_2 + 1/R_3 + \dots 1/R_n$$

Regulation of Mean Arterial Blood Pressure

Regulation of arterial blood pressure is an important function in maintaining homeostasis for patients receiving anesthesia. MAP is an important indicator of perfusion of the tissue beds. Blood pressure regulation can be categorized as either short-term or long-

term. The choice of category depends on the onset of action, the duration of action, and the intensity the physiologic reaction to return the MAP to normal values.

Short-Term Regulation.

The short-term blood pressure regulators are those that respond to rapid changes in MAP and attempt to rapidly (within 30 minutes) return the MAP back to normal range. These reflexes rely on an intact autonomic nervous system, and this interaction is responsible for the rapid onset of action of these blood pressure regulators. The reflexes include baroreceptor response, chemoreceptor response, atrial stretch reflex, and CNS ischemic reflex. All these homeostatic reflexes are initiated rapidly in response to acute changes in MAP.

The cardiovascular (vasomotor) center is located in the medulla and pons. This center regulates four basic actions: vasoconstriction, vasodilation, cardiac excitation, and cardiac inhibition. These areas activate the sympathetic and parasympathetic nervous systems in response to various stimuli. Under normal conditions, the vasomotor center maintains peripheral vascular tone.

Baroreceptors are located in the internal carotid arteries and the aortic arch and are called the *carotid and aortic sinuses*. They are spray-type nerve endings that increase impulse production when they are stretched. Impulses from the baroreceptors affect the inhibitory centers of the vasomotor center. At MAP of less than 60 mm Hg, the baroreceptors do not transmit impulses. However, as the MAP increases to between 60 and 180 mm Hg, impulses sent to the inhibitory area of the vasomotor center incrementally increase. The baroreceptors are most efficient in responding to rapid changes in blood pressure. They are not as efficient in long-term blood pressure regulation, because they adapt to the higher pressures, in effect by being reset. Therefore the baroreceptors act as a buffer system to prevent extreme short-term swings in blood pressure. Two clinically significant examples of stimulation of the baroreceptor reflex during surgery include carotid sinus manipulation during carotid endarterectomy and aortic baroreceptor stimulation from pressure exerted on the aortic arch during mediastinoscopy.

Chemoreceptors are chemosensitive cells located within the carotid

and aortic bodies. These are known as the *peripheral chemoreceptors*. Each area is supplied by a small nutrient artery and thereby maintains constant contact with the internal environment. Chemoreceptors send impulses to excite the vasomotor center, primarily in response to decreases in PaO₂. Chemoreceptors play a greater role in respiratory system regulation than in blood pressure regulation.

Low-pressure receptors, or stretch receptors, are located in many areas of the vasculature, especially within the atria and pulmonary arterial tree. They act in conjunction with the baroreceptors to buffer changes in the blood pressure caused by changes in volume status.

The *atrial stretch reflex* is initiated by input from low-pressure receptors. Stretching of the atria caused by an increase in volume results in a dilation of the peripheral arterioles, which decreases SVR, MAP, and CO. Furthermore, hypervolemia causes the release of the atrial natriuretic factor by the atria as a result of increased stretch.²⁷ This factor causes a reflex dilation of afferent arterioles in the kidney, a phenomenon that increases the glomerular filtration rate and decreases the secretion of antidiuretic hormone via signals to the hypothalamus. The combination of these events causes an increase in urine formation and an attempt to change the MAP by decreasing vascular volume.

The CNS ischemic mechanism exerts a powerful effect on the blood pressure control system. When hypotension exists, this reflex is initiated in an attempt to restore the MAP to adequate levels for CNS perfusion and especially for perfusion to the vasomotor center. The reflex is most intensely initiated when MAP is less than 20 mm Hg, and the result is one of the most powerful sympathetic vasoconstrictor responses within the human body.¹ The stimulation persists for approximately 10 minutes, by which time either the ischemia has been relieved or the vasomotor center becomes severely ischemic and infarcts, and the stimulation ceases.

Several hormones are instrumental in the short-term regulation of MAP. The onset of action is not as rapid as that of neural control mechanisms, but activation occurs within a short time of stimulation. Norepinephrine and epinephrine are released from the CNS and the adrenal medulla during times of sympathetic

stimulation and cause vasoconstriction.

Angiotensin I is converted to angiotensin II in the lungs by angiotensin-converting enzyme. This substance is one of the most potent vasoconstrictors secreted by the body. It takes approximately 20 minutes to become fully activated. Angiotensin II also plays a role in the secretion of aldosterone from the adrenal cortex. Aldosterone has a role in the long-term regulation of MAP.

The antidiuretic hormone vasopressin has both short-term and long-term effects on blood pressure control. The short-term effect of antidiuretic hormone causes potent and direct vasoconstriction. The long-term control effects of antidiuretic hormone decrease urine output from the kidneys.

Two short-term systems for maintenance of blood pressure that could be classified as intermediate mechanisms are the capillary fluid shift and the stress-relaxation mechanism. Both these mechanisms depend on an intact vascular system.

The capillary fluid shift is a simple mechanism. As the hydrostatic pressure (MAP) increases within the capillaries, a larger movement of fluid occurs across the capillary membrane as increased pressure. This phenomenon lowers the fluid volume within the vasculature and results in a decrease in MAP.

The stress-relaxation mechanism is an example of the ability of the vasculature to compensate for hypervolemia and hypovolemia as a result of alterations of smooth muscle tone within the vasculature. As intravascular fluid volume increases, tension on the blood vessels results in dilation of the vasculature to compensate for increased volume. Conversely, as the blood volume decreases, the vessels constrict to compensate for the decreased volume to maintain MAP.

Long-Term Regulation.

Long-term regulation of MAP includes mechanisms that eventually regulate blood volume to within normal range. The renal body fluid system is one of the major long-term regulators of MAP. Renal homeostasis of blood pressure occurs as the kidneys preferentially excrete sodium and water to maintain a normal fluid balance.

Intravascular fluid status has a direct effect on arterial blood pressure. A chronic increase in blood volume leads to increases in

mean filling pressure, venous return, CO, and SVR. The combination of an increased CO and an increased SVR can increase the arterial blood pressure by more than 30%. This causes an increase in myocardial oxygen demand.

Several factors govern the effectiveness of the renal body fluid system, including the renin-angiotensin system, aldosterone secretion, and the nervous system. As fluid intake and blood pressure increase, the secretion of renin by the kidneys decreases. This decreased renin secretion causes a reduced secretion of aldosterone as a result of the decreased production of angiotensin II, which is a potent vasoconstrictor. A decrease in sympathetic nervous system response to the kidney also occurs. The net effect is an increased renal output of sodium and water.

Physiology of the Venous System

In the past, the venous system has been described as simply the return conduit for the arterial system, and it was not thought to play a very active role in the maintenance of circulation and CO. The modern view gives the venous system an integral role in support of the circulation.²⁸

The venous system's ability to accommodate large volume changes helps to buffer the intravascular volume during periods of hypervolemia or hypovolemia and thereby helps to maintain CO. In addition, the venous system is well innervated by the autonomic nervous system, and therefore has the ability to respond to the wide variations in intravascular volume that occur over the course of long surgical procedures and during intensive fluid resuscitation.

Hypertension

Extent, Definition, and Etiology

The pathophysiologic cardiovascular condition that is most commonly encountered in patients who require surgery is hypertension. Hypertension affects 1 out of every 3 or approximately 70 million people in the United States, and the frequency increases with age. It is vital for the anesthesia provider to understand the pathophysiology of the condition and its relation to the cardiovascular system and other body systems. Only then can a comprehensive anesthesia plan be constructed.

Patients frequently do not exhibit signs or symptoms associated with hypertension. Chronic uncontrolled hypertension affects specific target organs, including the heart, brain, and kidney. Hypertension accelerates and exacerbates the onset of atherosclerotic changes in the arterial vessels of the target organs. It is a primary risk factor for the development of coronary artery disease. Hypertension is a significant cause of congestive heart failure and cardiomyopathy because it causes increased afterload from chronic vasoconstriction. Hypertension increases the likelihood of the development of atherosclerosis and thus, chronic untreated hypertension increases the incidence of MI, stroke and chronic kidney injury.²⁹

Hypertension is classified based on its causes. Essential hypertension, also referred to as *primary* and *idiopathic*, has no identifiable cause, accounts for 95% of all cases of the disease, and its diagnosis is determined on the basis of exclusion. The relationship between an individual's genetic predisposition and environmental (modifiable) risk factors most probably influences the potential development and severity of essential hypertension. Theoretical physiologic causes of essential hypertension include sympathetic nervous system hyperactivity and/or increased activity of the renin, angiotensin, and aldosterone system. Remedial (secondary) hypertension has an identifiable and potentially curable cause. Examples of pathophysiologic conditions that cause remedial hypertension include pheochromocytoma, coarctation of

the aorta, renal artery stenosis, primary renal diseases (e.g., pyelonephritis, glomerulonephritis), primary aldosteronism (Conn syndrome), and hyperadrenocorticism (Cushing disease).

Guidelines regarding blood pressure values that constitute hypertension have been published by the National Institutes of Health.³⁰ Evidence based guidelines for the management of hypertension in adults is present in [Box 25.1](#). To determine accurate blood pressure measurements, two readings taken 5 minutes apart with the patient in the sitting position are necessary. It is estimated that the implementation of antihypertensive therapy is associated with a 25% decrease in cardiovascular complications and a 38% decrease in stroke.³¹ If lifestyle modifications are unsuccessful in decreasing blood pressure to acceptable levels, then antihypertensive therapy should be prescribed.³² In many instances, patients may have developed advanced atherosclerotic vascular disease or target-organ dysfunction before the start of treatment for hypertension.^{33,34}

Evidence Based Guidelines for Management of Hypertension in Adults

Grade A (Indicative of Strong Evidence)

- Initiation of drug therapy to lower a systolic BP (SBP) of ≥ 150 mm Hg or diastolic BP (DBP) of ≥ 90 mm Hg for the general population at 60 years of age or older.
- The target DBP to start pharmacologic therapy for subjects 30–59 years of age is ≥ 90 mm Hg.

Grade B (Indicative of Moderate Evidence)

- Initial drug therapy for nonblack patients (including diabetic patients) should include a thiazide-type diuretic, a calcium channel blocker, an angiotensin-converting enzyme (ACE) inhibitor, or an angiotensin receptor blocker.
- Initial drug therapy for black patients should include a thiazide-type diuretic or a calcium channel blocker. This includes patients

with diabetes mellitus.

- For patients 18 years and older with chronic kidney disease, initial or additional therapy should include an ACE inhibitor or angiotensin receptor blocker, regardless of race or diabetic status.

From James PA, et al. 2014 evidence-based guideline for the management of high blood pressure in adults: report from the panel members appointed to the Eighth Joint National Committee (JNC 8). *JAMA*. 2014;311(5):507–20.

Pathophysiology

Systemic blood pressure is regulated by interactive feedback mechanisms involving the sympathoadrenal axis and baroreceptors in the heart and great vessels. It is accepted that some degree of sympathetic hyperactivity is responsible for essential hypertension. Dysfunction of the sympathetic nervous system leads to a state of chronic vasoconstriction. In an attempt to maintain normal intravascular volume, the renal juxtaglomerular apparatus secretes renin. All the vascular and hormonal effects of renin are caused by its conversion of angiotensin I to angiotensin II. Angiotensin II is the major stimulus for the secretion of aldosterone by the adrenal cortex.

Deposition of collagen and metalloproteinases within the intima of arteries leads to vascular stiffness, and this occurs normally as part of the aging process. Narrowing of the vascular lumen and endothelial dysfunction decreases vascular dilation and thus, blood flow is decreased especially within the microvasculature. Furthermore, vascular stiffness increases afterload and myocardial oxygen demand and can cause LV hypertrophy, myocardial ischemia/infarction, and/or congestive heart failure.

Anesthesia Management for the Patient With Hypertension

Preoperative Evaluation

The most important issues to be addressed during the preoperative evaluation of a patient with hypertension is the identification and the adequacy of treatment. The goal of antihypertensive therapy is

to maintain normotension on a consistent basis. Effective antihypertensive therapy that renders the patient normotensive on a routine basis may not necessarily prevent episodes of perioperative hypertension. However, patients whose conditions are optimized before surgery have a more stable perioperative course and a lower incidence of cardiovascular system–related morbidity. Although not ideal, if perioperative DBP is maintained below 110 mm Hg, the risk of perioperative cardiac morbidity does not increase significantly.^{29,35}

It is imperative for anesthesia providers to have an adequate understanding of the pharmacology and side effects of the drugs used for treating hypertension. For a complete discussion of antihypertensive drugs, see [Chapter 13](#). Medications that are used to treat hypertension by blocking or depressing the sympathetic nervous system response decrease the body's compensatory reflexes. These effects may be pronounced during anesthesia. For instance, during acute hemorrhage, tachycardia and vasoconstriction associated with blood loss may be diminished or may not occur if the patient is receiving a β -blocker and antihypertensive drugs that promote vasodilation. Patients treated with antihypertensive medications do not lose their responsiveness to vasoactive drugs but instead may respond to these substances in an exaggerated manner.

The anesthetist should carefully obtain a thorough history of the cardiovascular system to elicit any symptoms of ischemic cardiovascular disease. Hypertension is a major risk factor for coronary artery disease. Any symptoms related to coronary artery disease should be further investigated. In addition to being a risk factor for coronary artery disease, hypertension directly affects myocardial function. The chronic increase in myocardial wall tension caused by prolonged and untreated hypertension can result in left ventricular hypertrophy (LVH) ([Fig. 25.35](#)). Ventricular diastolic dysfunction occurs before the development of hypertrophy. This diastolic dysfunction is not clinically apparent, and the patient may appear to have normal cardiac function except under stressful physiologic conditions. A delayed rate of passive ventricular filling is evidence of ventricular diastolic dysfunction. The rate of ventricular filling from atrial contraction becomes

predominant in hypertensive patients. This represents the inverse of normal ventricular filling patterns. Other information and results from preoperative tests that will help the nurse anesthetist evaluate and create an individualized anesthetic plan for patients with cardiac dysfunction include determining exercise tolerance, ECG, Doppler ultrasound, stress test, and cardiac catheterization results.

FIGURE 25.35 Schematic representation of the relationship between hypertension and heart failure.

(Modified from Matei VA, Haddadin AS. Systemic and pulmonary arterial hypertension. In Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-Existing Disease*. 6th ed. Philadelphia: Elsevier; 2012:106.)

Left ventricular hypertrophy is a consequence of chronic hypertension and increased afterload that results in an enlargement of myocardial mass. This compensatory process increases myocardial oxygen demand. Hypertrophy that occurs in response to chronic increases in intracardiac pressure is termed *concentric hypertrophy*. Ventricular hypertrophy also may produce subendocardial ischemia at perfusion pressures that would normally be adequate in a healthy ventricle. Concomitant development of coronary artery disease coupled with increased myocardial oxygen demand hastens and exacerbates the development of ischemic symptoms. As a rule, all patients with chronic hypertension should be suspected of having some degree of coronary artery disease.

Hypertensive cardiomyopathy and systolic ventricular dysfunction are the direct result of the pathophysiologic changes associated with chronic hypertension. This hypertensive cardiomyopathy manifests as a decrease in both EF and SV.

Increasing diastolic dysfunction results in ventricular dilation in conjunction with systolic dysfunction. The subsequent replacement of myocardial cells with fibrous tissue results in a cardiomyopathy.⁴

Chronic hypertension that has remained either untreated or inadequately controlled has adverse consequences on brain, kidney, and ocular function, and patients with long-standing disease have a higher incidence of strokes than do patients whose blood pressure has been controlled.²⁹ The concurrent preoperative use of a β -blocker, angiotensin-converting enzyme (ACE) inhibitor/angiotensin receptor blocker (ARB), and statin decreases the occurrence of non-fatal MI and mortality in patients with stable coronary heart disease.³⁵ There remains controversy about whether to withhold or administer ACE inhibitor or ARB therapy prior to surgery and anesthesia. ACE inhibitors and ARBs can cause hypotension during anesthesia that is refractory to vasopressor administration. Due to the inadequacy of scientifically based guidelines regarding ACE inhibitors in the perioperative period, there contributes to a lack of consistency in practice. Vasopressin and methylene blue have been found to be effective treatments for ACE inhibitor-associated refractory hypotension.³⁶ In one study, discontinuing ACE inhibitors and ARBs the day of surgery did not result in a significantly increased incidence of preoperative or postoperative hypertension as compared with patients who continued these medications until the day of surgery.³⁷ Reinstitution of ACE inhibitors and ARBs within 2 weeks postoperatively is associated with decreased 30-day mortality.³⁸

Inadequate control of hypertension can lead to alterations in cerebrovascular and coronary artery autoregulation. For example, normal physiologic coronary artery autoregulation occurs at a MAP between 60 and 140 mm Hg. However, a patient with chronic hypertension and coronary artery disease may develop ischemic changes at a MAP of 60 mm Hg or greater. The cerebral and coronary autoregulation curves are shifted to the right in patients with chronic hypertension, necessitating higher perfusion pressures to ensure adequate organ blood flow. Therefore, cerebral and myocardial ischemia may occur with significant decreases in MAP in patients with hypertension and coronary artery disease. This phenomenon makes patients with uncontrolled hypertension more

susceptible to cardiac and cerebral ischemia, compared with normotensive individuals.³⁴ Chronic untreated hypertension can cause nephrosclerosis, which can impair renal function. Nephrosclerosis can produce proteinuria and a gradual decrease in renal function. Early treatment of hypertension results in the preservation of renal function.

Anesthesia Management

An individualized anesthetic plan must be created by taking into account the type and extent of cardiac pathophysiology, other disease states, and the surgical procedure. To maintain a stable intraoperative course, administration of antihypertensive medications should be continued on schedule until the time of surgery. All oral medications can be given with one or two sips of water without increased risk of aspiration.³³ It should be noted that acute hypertensive rebound can occur with abrupt cessation of antihypertensive medications. Tachycardia, hypertension, angina, and MI can result from interruption of therapy with β -blockers and other antihypertensive agents. As a general rule, preoperative antihypertensive medications should be continued up to and including the day of surgery.

Determining whether to proceed with elective surgery in a patient in whom hypertension is untreated and poorly controlled remains controversial. However, evidence suggests that patients with DBPs greater than 110 mm Hg have a significantly increased risk of perioperative cardiac morbidity.³⁹ This caveat may be modified in patients with hypertension in whom DBPs greater than 110 mm Hg occur frequently, despite aggressive antihypertensive drug therapy (e.g., patients with end-stage renal disease).

To attenuate sympathetic responsiveness, preoperative sedation may be indicated for patients with hypertension. Establishing control of the blood pressure before induction should result in a more stable hemodynamic course during the induction, maintenance, and emergence from anesthesia. A fluid bolus and incremental titration of anesthetic induction agents may help decrease the degree and duration of hypotension. β -blockade therapy should be instituted days to weeks before surgery and titrated to a target HR between 50 and 60 beats per minute (bpm).⁴⁰

However, perioperative β -blockade started within 1 day or less before noncardiac surgery prevents nonfatal MIs but increases risks of hypotension, bradycardia, stroke and death. Initiating β -blockade between 2 and 7 days may be preferable but there is a lack of scientific data to support a benefit of beginning therapy greater than a month in advance.⁴¹

Induction of Anesthesia

Patients with hypertension may react in an exaggerated manner to induction agents and the stimulation associated with laryngoscopy and tracheal intubation. This response is highly variable and may result in hypertension or hypotension. It is dependent on the individual's physiology, degree of stimulation, adequacy of preoperative antihypertensive therapy, and amount and type of induction agents administered. Hypertensive patients are hypovolemic, either as a result of renal-compensatory mechanisms, extreme vasoconstriction, or pharmacologic therapy (diuretics). Increased vasoconstriction as a consequence of hypertension results in volume contraction and a greater susceptibility to hypotension from the vasodilating and cardiac-depressant effects of anesthetic agents. Of the anesthetic induction agents, etomidate, propofol, or dexmedetomidine can be used in patients with hypertension. Etomidate offers an advantage in patients with cardiac pathology, as compared to propofol, because it preserves SV and cardiac output.¹⁵ Due to the sympathomimetic response that occurs with the administration of induction doses of ketamine, this drug should be used with caution in patients with cardiovascular disease.

The stimuli of laryngoscopy and tracheal intubation can result in an exaggerated hypertensive response, despite postinduction hypotension. An existing hypertensive state is further compounded by intense stimulation caused by airway manipulation. Suppressing the exaggerated hypertensive response to intubation requires that a greater depth of anesthesia be achieved. However, the depth of anesthesia at induction necessary to suppress this response may produce a more profound hypotensive state. Administration of adjunct medications before induction (e.g., β -blockers or arterial dilators) can reduce the hyperdynamic sympathetic response to tracheal intubation. Hypotensive episodes can be treated with fluid

administration, decreasing anesthetic depth, and administration of vasopressors. Numerous strategies have been suggested for the management of this hyperdynamic response. The sympathetic stimulatory response caused by laryngoscopy and intubation could be significantly reduced by laryngotracheal or IV administration of lidocaine.⁴² Reducing the duration of airway manipulation to 15 seconds or less may be helpful. Use of a β -blocker before induction has been shown to reduce the hyperdynamic sympathetic responses.³³ Administration of fentanyl prior to induction also helps attenuate the sympathetic response.

With regard to suppression of marked hemodynamic responses, a controlled induction followed by a rapid and atraumatic intubation is imperative. Producing an adequate depth of anesthesia at induction that produces extreme hypotension may be more detrimental to both coronary and cerebral perfusion than the hypertensive response it was intended to prevent. Due to vasoconstriction, patients with untreated hypertension are frequently hypovolemic as compared with those who are normotensive. Thus adequate hydration before induction may help prevent postinduction hypotension.^{29,33} A combination of low doses of more than one agent in addition to titration of medications may prove a better choice than a full dose of a single agent. In emergency cases in which rapidly securing the airway is of paramount importance, the choice of agents may be limited, and hyperdynamic response then becomes a secondary issue.

Maintenance of Anesthesia

A general hemodynamic goal during anesthetic management for the hypertensive patient undergoing general anesthesia is to maintain blood pressure stability within 20% of their normal MAP. Intraoperative events that cause wide fluctuations in blood pressure should be anticipated and treated immediately. The most common event that precipitates intraoperative hypertension is surgical stimulation. This induces increased sympathetic stimulation resulting in the release of catecholamines, cortisol, and aldosterone, which is representative of the physiologic stress-induced response. Inhalation and narcotics administered alone and in combination have the ability to attenuate this response.^{2,33,34} Altering the depth of

anesthesia to suppress maximal surgical stimulation may not be adequate for achieving rapid and complete control of hypertensive responses. The adjunct use of drugs such as β -blockers and vasodilators may be necessary to achieve hemodynamic control. These drugs offer the advantage of continued control of hypertensive response in the immediate postanesthesia recovery period. [Table 25.6](#) lists hemodynamic goals for patients with coronary artery disease.

TABLE 25.6

Hemodynamic Goals for Management of Coronary Artery Disease

Parameter	Goal
Preload	Decrease/Maintain
Afterload	Maintain
Contractility	Decrease/Maintain
Heart rate	Slow
Heart rhythm	Normal sinus rhythm

The onset of profound hypotension during anesthesia maintenance should be immediately recognized, diagnosed, and treated. Prolonged severe hypotension has predictive significance in perioperative cardiac morbidity.³⁹ Treatment of hypotension may require reduction of the amount of inhalation agent used and infusion of IV fluid. Should these measures prove inadequate or untimely, a rapid-acting vasopressor such as phenylephrine or ephedrine may be administered as a temporizing measure until the cause of the hypotension can be diagnosed. It is important to realize that hypertensive patients may have exaggerated responses to vasopressor agents. The goal of intraoperative anesthesia management is maintenance of hemodynamic stability, which includes anticipation of intraoperative events that may affect cardiovascular stability and thereby prevent extreme fluctuations in blood pressure.

Postoperative Considerations in the Hypertensive Patient

Termination of anesthesia allows for sympathetic nervous system

predominance and frequently results in hyperdynamic, hypertensive responses, even in patients with well-controlled hypertension. Intraoperative control of blood pressure should continue into the immediate postoperative period. Initiation of adjunct administration of antihypertensive medications should be anticipated at the end of surgery and early in the postoperative period. Adequate control of pain represents a primary antihypertensive consideration. Patients with hypertension are more susceptible to perioperative cardiac morbidity than the normotensive patient during the postoperative period. Adequate control of blood pressure in the postoperative period reduces the incidence of cardiovascular complications.²⁹ Maintenance of normothermia is imperative because postoperative shivering significantly increases myocardial oxygen consumption.

Pericardial Disease

In reviewing the anesthetic management of patients with pericardial disease, this section focuses on the pathophysiology, clinical presentation, and anesthetic implications of three primary disease processes: acute pericarditis, constrictive pericarditis, and cardiac tamponade.

The pericardium surrounds the heart and anchors it to its anatomic position, concomitantly reducing contact between it and surrounding structures. It consists of an inner visceral layer, which envelops the surface of the heart, and an outer parietal layer. The pericardial space between these layers usually contains 20 to 25 mL of clear fluid that under normal circumstances can accommodate gradual volume fluctuations. Rapid accumulation of pericardial fluid in the pericardial space can result in cardiac tamponade and cardiovascular collapse.⁴³

Acute Pericarditis

Acute inflammation of the pericardium is caused by a number of disorders. The most common cause of acute pericarditis is viral infection. Post-MI syndrome (Dressler syndrome), cardiac injury (trauma, surgery), metastatic disease, irradiation, uremia, tuberculosis, and autoimmune (rheumatoid arthritis) represent the

remaining primary predisposing conditions that contribute to the development of this process.⁴⁴

Pathophysiology.

It is common for a serofibrinous inflammatory reaction associated with a small intrapericardial exudative effusion to evolve. This may result in adherence of the two layers of the pericardium. The sequelae are largely dependent on the severity of the reaction, as well as on the specific cause. Most often when the condition is left untreated or undiagnosed, complete resolution is the end result. Infrequently, however, extended organization of fibrinous exudate within the pericardial sac may lead to encasement of the heart by dense fibrous connective tissue (chronic constrictive pericarditis) or to the accumulation of a large amount of pericardial fluid and consequent cardiac tamponade, usually when fluid levels exceed 1 L. Constrictive pericarditis and cardiac tamponade result in impaired diastolic filling, which results in decreased CO.⁴⁴

Clinical Presentation.

The principal symptom associated with acute pericarditis is sudden onset chest pain. Although similar in nature to that experienced during MI, this pain is differentiated by the inclusion of a pleural component, which includes increased discomfort associated with postural changes and relief on sitting or leaning forward. Other signs that are characteristic of acute pericarditis include fever with a pericardial friction rub, absence of elevation of cardiac enzymes levels, and diffuse ST-segment elevation in two or three limb leads and in most of the precordial leads. Echocardiography is another reliable method for diagnosing pericarditis and pericardial effusion.

Anesthetic Management.

Acute pericarditis in the absence of an associated pericardial effusion or scarring does not alter cardiac function. Specific considerations for anesthetic management are directed toward the underlying illness.

Chronic Constrictive Pericarditis

Chronic constrictive pericarditis results from pericardial thickening and fibrosis. In the past, tuberculosis was the most common cause of pericardial constriction. Currently the most common cause is idiopathic in nature and can occur following cardiac surgery, neoplasia, uremia, radiation therapy, and rheumatoid arthritis.^{44,45}

Pathophysiology.

Stiff, fibrous tissue encircles the heart and limits its ability to expand during diastole. The fundamental hemodynamic abnormality in chronic constrictive pericarditis is abnormal diastolic filling. Reduced myocardial compliance impairs filling of both ventricles. Consequently, filling pressures increase, and as a result, pulmonary and peripheral congestion occurs. SV and CO can also be decreased. Equilibration of pulmonary artery diastolic pressure, PCWP, and right atrial pressure commonly occurs. Initially, ventricular systolic function is normal. However, over time the underlying myocardial tissue may atrophy, and systolic function may decrease.

Clinical Presentation.

Clinical features representative of chronic constrictive pericarditis include gradually increasing fatigue and dyspnea. Typical signs of increasing venous pressure and congestion are engorgement of neck veins, hepatomegaly, ascites, and peripheral edema. In approximately 50% of patients, the fibrous enclosure becomes calcified and is visible on a chest radiograph.³³ The ECG may reveal diffuse low-voltage QRS complexes, T-wave inversion, and notched P waves. As many as 25% of patients have atrial dysrhythmias because of the involvement of atrial conduction pathways. Diagnosis is confirmed by demonstration of pericardial thickening with echocardiography or computed tomography.

The treatment used for patients with hemodynamically significant constrictive pericarditis is pericardiectomy. Unfortunately, the surgical removal of adherent pericardium may precipitate malignant cardiac dysrhythmias and massive bleeding. Consequently, pericardiectomy is associated with relatively high perioperative morbidity and mortality rates, ranging from 6% to 19%.^{46,47}

Anesthetic Management.

Large-bore IV lines must be established preoperatively because of the potential for sudden, rapid hemorrhage. A cardiopulmonary bypass circuit should be readily available. Invasive hemodynamic monitoring is essential. Arterial catheterization allows beat-to-beat blood pressure monitoring and assists in the evaluation of significant cardiac dysrhythmias or acute hemorrhage.

The anesthetic agents chosen for management of patients with constrictive pericarditis should preserve myocardial contractility, HR, preload, and afterload. Among these parameters, HR is of greatest concern. Cardiac output is dependent on HR in patients with constrictive pericarditis. As a consequence of limited ventricular diastolic filling, bradycardia is poorly tolerated and reflects a decrease in SV that can lead to hypotension. Using anesthetic medications that preserve HR and myocardial contractility, such as ketamine, is hemodynamically advantageous. Inhalation agents cause myocardial depression and vasodilation in a dose dependent fashion and therefore, the concentration should be carefully titrated to avoid excessive myocardial depression and hypotension. The anesthetist should be aware that vigorous positive-pressure ventilation may cause a decrease in venous return to the heart and result in a further decrease in CO.⁴⁸

Immediate hemodynamic improvement may not occur after removal of the constricting tissue. Consistently low CO after pericardiectomy may be secondary to diffuse atrophy of myocardial muscle fibers or myocardial damage from the underlying disease. Intensive postoperative care with inotropic support and awareness for the potential of dysrhythmias and or hemorrhage are essential components for creating a comprehensive anesthetic plan.

Cardiac Tamponade

Cardiac tamponade is a syndrome caused by the impairment of diastolic filling of the heart because of continual increases in intrapericardial pressure.⁴⁹ Slow accumulation of fluid in the pericardial space initially causes minute increases in intrapericardial pressure. This occurs as a result of the pericardium's ability to stretch to accommodate an increased

volume. If the pericardial fluid accumulates rapidly, the presence of a few hundred milliliters may cause a significant increase in intrapericardial pressure that may result in cardiovascular collapse. Cardiac tamponade that results in shock is also known as *cardiac compressive shock* and can result in inadequate peripheral perfusion, acidosis, and death (Fig. 25.36).

FIGURE 25.36 Pathophysiology associated with cardiac tamponade. AO, Aorta; LA, left atrium; LV, left ventricle.

Classification of the causes of cardiac tamponade includes: (1) trauma, including sharp or blunt trauma to the chest and dissecting aortic aneurysms; (2) causes associated with cardiac surgery; (3) malignancy within the mediastinum; and (4) expansion of pericardial effusions after any form of pericarditis.⁵⁰

Pathophysiology.

Normal intrapericardial pressure is subatmospheric. Accumulation of pericardial fluid leads to an increase in intrapericardial pressure. As a result, diastolic expansion of the ventricles decreases. As in constrictive pericarditis, poor ventricular filling develops and leads to peripheral congestion and a decrease in SV and CO. The decrease in SV decreases peripheral perfusion causing catecholamine release manifested as tachycardia, vasoconstriction, and increased venous pressure, which helps maintain CO. If these mechanisms fail, cardiac collapse can occur.⁵¹ The left ventricular pressure-volume loop associated with cardiac tamponade represents decreased LV

volume and decreased SV due to compression (Fig. 25.37).

FIGURE 25.37 Left ventricular pressure-volume loop associated with cardiac tamponade.

Clinical Presentation.

In addition to obvious indications of cardiac distress, specific signs of cardiac tamponade include Beck's triad: hypotension, jugular venous distention, and muffled heart sounds.⁵² Another specific finding associated with cardiac tamponade is pulsus paradoxus, an exaggerated (i.e., greater than 10 mm Hg) decrease in systolic blood pressure that normally occurs with inspiration. Other conditions that may result in pulsus paradoxus are chronic obstructive pulmonary disease, obesity, and congestive heart failure. Jugular venous distention that occurs because of decreased forward blood flow through the heart may also be present.

In cardiac tamponade, chest radiography may show an enlarged cardiac silhouette. The ECG usually demonstrates a decrease in voltage across all leads or electrical alterations of either the P wave or the QRS complex.⁵³ Echocardiography is the most sensitive, noninvasive method for detection of pericardial effusion and exclusion of tamponade. Use of a pulmonary artery catheter may reveal equilibration of right and left atrial pressures and right

ventricular end-diastolic filling pressures at approximately 20 mm Hg.⁵⁴

The definitive treatment for cardiac tamponade is pericardiocentesis, performed either percutaneously by needle decompression, through a subxiphoid incision, or via thoracotomy or video-assisted thorascopic surgery to create a pericardial window. In contrast to patients with constrictive pericarditis, in patients with cardiac tamponade, immediate hemodynamic improvement occurs once the pericardium is opened and the direct pressure exerted on the heart is relieved. However, despite this fact, pulmonary edema, acute right and left ventricular dysfunction, and circulatory collapse can occur.⁵⁵

Anesthetic Management.

Preoperatively the patient's clinical status should be optimized. This includes expansion of intravascular fluid volume, use of positive inotropic agents, and correction of acidosis. Volume expansion can augment preload and improve SV during cardiac tamponade.^{56,57} The degree to which these measures are instituted depends on the hemodynamic state of the patient. Severely compromised patients require immediate medical therapy, and therefore emergency pericardiocentesis is indicated. Invasive hemodynamic monitoring should be established before the procedure. Intraarterial and CVP catheters are required for frequent sampling of blood, continuous blood pressure monitoring, and assessment of intravascular fluid status.

Local infiltration anesthesia can be accomplished for emergency operative correction of cardiac tamponade.⁵⁷ Severe hypotension and cardiac arrest after induction of general anesthesia in patients with tamponade can occur.^{58,59} The potential for decompensation associated with the use of general anesthetics is attributed to direct myocardial depression and vasodilation in patients with established impairment of cardiac filling. The use of positive-pressure ventilation in such patients may result in a decrease of venous return to the heart and can further decrease CO.⁶⁰ After percutaneous pericardiocentesis and the improvement of hemodynamic status, induction of general anesthesia and initiation of positive-pressure ventilation are sufficient for further surgical

exploration.

When it is not possible to relieve intrapericardial pressure that causes cardiac tamponade before the induction of anesthesia, the same anesthetic principles that are applied to the anesthetic management of patients with constrictive pericarditis should be used, including the use of anesthetic agents that preserve myocardial contractility, HR, preload, and afterload. Due to the sympathomimetic effects of ketamine, this drug has been advocated for the induction and maintenance of anesthesia.^{4,57} However, many combinations of anesthetic agents that preserve the previously mentioned determinants of CO have been used safely.^{48,57,59}

Continuous postoperative monitoring of blood pressure, CVP, and chest-tube drainage is necessary. Possible complications after pericardiocentesis include reaccumulation of pericardial fluid, coronary laceration, cardiac puncture, and pneumothorax. [Table 25.7](#) lists hemodynamic goals for patients with cardiac tamponade.

TABLE 25.7

Hemodynamic Goals for Management of Cardiac Tamponade

Parameter	Goal
Preload	Maintain or increase
Afterload	Maintain
Contractility	Maintain or increase
Heart rate	Maintain
Heart rhythm	Normal sinus rhythm
Treatment	Pericardiocentesis, pericardial window

Acquired Valvular Heart Disease

The cardiac valves are membranous leaflets that separate the chambers of the heart. When open, they allow blood flow between the chambers and great vessels, and when closed, they prevent regurgitant blood flow between the chambers or backflow from the great vessels. A valve orifice of normal size presents a small degree of flow obstruction and thereby creates a hemodynamically insignificant gradient. Primary dysfunction of the mitral and aortic valves represents the most common and most severe hemodynamic derangement. Acquired primary dysfunction of the tricuspid or pulmonic valves is rare and therefore is not addressed in this

chapter.

Valvular disease is classified according to the type of lesion that exists, stenosis, insufficiency, or mixed lesions. Valvular stenosis is a narrowing of the valvular orifice, which restricts flow through the orifice when the valve is open. This situation creates an increase in flow resistance and increases turbulent blood flow. Valvular insufficiency results in regurgitation secondary to incomplete or partial valve closure, which allows blood to flow back through the valve into the previous chamber. In patients with mixed lesions (stenosis with insufficiency or insufficiency with stenosis), one type of dysfunction is considered dominant over the other based on the severity of clinical symptoms.

Valvular dysfunction is classified as either primary or secondary. In primary valvular dysfunction, the valve leaflets or the anchoring and supporting structures are damaged or do not function properly. In secondary valvular dysfunction, the valve is not directly damaged. However, normal valve function is altered secondary to another pathophysiologic entity. Causes of secondary valvular dysfunction include ventricular dilation, which produces mitral insufficiency; retrograde aortic dissection, which creates aortic insufficiency (AI); and papillary muscle infarction, which causes mitral insufficiency.⁶¹

Cardiac Output.

The primary components of CO are preload, afterload, contractility, LV compliance, and HR.⁶¹⁻⁶³ Blood flow may increase due to an increase in HR or an increase in SV. Because blood viscosity decreases with decreasing hematocrit and increasing flow rate, normovolemic anemia reduces cardiac afterload, thereby facilitating the augmentation of CO. This sequence of events occurs so long as intravascular volume is maintained and cardiac reserve is ample. The amount of afterload present determines the degree of tension cardiac fibers must develop before systolic ejection can occur.⁶⁴

Evaluation of the Patient.

Evaluation of the patient with valvular heart disease should focus on the pathophysiologic derangements and their effects on cardiac

function and hemodynamic status. The systematic evaluation of primary valvular dysfunction should include the following:

1. *Category of valvular dysfunction*

- Stenosis (progressive narrowing of the valve orifice)
- Insufficiency (incomplete valve closure that causes backflow through the valve)
- Mixed (regurgitant and stenotic dysfunction)

2. *Status of left ventricular loading*

- LV overload from mitral or aortic regurgitation
- Pressure overload from aortic stenosis
- Volume under load from mitral stenosis

3. *Acute versus chronic evolution of the dysfunction*

- Acute valvular pathology have severe and precipitous hemodynamic consequences (e.g., regurgitant valvular disease).
- Chronic valvular pathology occurs over time and the heart compensates for stenotic and regurgitant valvular dysfunction (discussed later)

4. *Cardiac rhythm and its effects on ventricular diastolic filling time*

5. *Left ventricular function*

- Poor left ventricular function places the patient at higher risk for perioperative cardiac morbidity.

6. *Secondary effects on the pulmonary vasculature and right ventricular function*

- Secondary pulmonary hypertension from valvular lesions can significantly affect right ventricular function.

7. *Heart rate*

- Changes in HR (either bradycardia or tachycardia) can significantly alter the hemodynamic manifestations of a specific valvular lesion.
- Bradycardia occurring with regurgitant lesions can result in a significant increase in the regurgitant fraction and decreased SV.
- Tachycardia is detrimental in patients with stenotic lesions because it shortens the time period for ejection which decreases SV and increases myocardial oxygen demand.^{27-30,33,34}

8. *Perioperative anticoagulation (as discussed in [Chapter 38](#)).*

Clinical Symptoms.

The most frequent clinical signs and symptoms associated with valvular dysfunction are congestive heart failure, dysrhythmias, syncope, and angina pectoris. Symptoms commonly associated with congestive heart failure include dyspnea, orthopnea, and

fatigue. The severity of valvular and left ventricular dysfunction can be related to the patient's activity level before the onset of cardiac symptoms.³⁹

Patient Evaluation: Compensatory Mechanisms.

To maintain cardiac function despite progressive valvular dysfunction, increased sympathetic activity increases to compensate for decreased peripheral perfusion. A decrease in sympathetic tone that occurs during anesthesia can cause severe hemodynamic compromise. Evaluation of the patient should include recognition of sympathetic compensatory mechanisms and strategies that can be used to maintain hemodynamic stability. Despite maximum medical therapy, patients with severe valvular dysfunction may remain in congestive heart failure.

The evaluation should also focus on associated organ dysfunction. Cardiac output that is decreased by chronic myocardial failure can cause significant major organ dysfunction, including renal and hepatic insufficiency, as well as poor cerebral perfusion, which can produce an altered level of consciousness, restlessness, agitation, lethargy, and stroke.

Diagnostic Modalities.

The most valuable diagnostic modalities used to evaluate valvular heart disease include electrocardiography, chest radiography, color flow Doppler imaging, echocardiography, and cardiac catheterization of both the right and left chambers of the heart. Electrocardiography can be used for evaluation of ventricular hypertrophy, atrial enlargement, axis deviation and—most important—determining cardiac rhythm. Chest radiography demonstrates the size of the cardiac silhouette and signs of pulmonary vascular congestion. Color flow Doppler imaging can be used to determine the valvular area, transvalvular gradients, degree of regurgitation, and flow velocity and direction, and can measure cardiac function. Cardiac catheterization can be used directly to measure transvalvular gradients, estimate the degree of regurgitation, visualize the coronary arteries, and determine intracardiac pressures.⁶⁵⁻⁶⁹

Mitral Stenosis

Pathophysiology

In mitral stenosis, the mitral valve orifice becomes progressively narrowed. The normal mitral valve area is 4 to 6 cm². This narrowing reduces flow from the LA into the LV during diastole. The narrowing of the mitral valve orifice has two significant hemodynamic consequences. First, a gradient develops across the valve orifice. This change represents a compensatory response directed at maintaining adequate flow. Second, as the cross-sectional area of the orifice decreases and the gradient increases, flow is restricted and left ventricular volume is decreased. The clinical symptomatology associated with severe mitral stenosis results in pulmonary congestion, decreased CO, and potential RV overload/failure. Pulmonary congestion occurs as a result of increases in left atrial pressure. Decreased SV is caused by decreased left ventricular volume. Left ventricular filling is dependent on the length of diastole, the gradient between the LA and LV, and the surface area of the mitral valve. As the valve area narrows to 1.5 to 2.5 cm², patients frequently develop increased HR and CO.⁷⁰ When the mitral valve area becomes less than 1 cm², the prolonged diastolic filling time and elevated mean left atrial pressure are incapable of maintaining normal LVEDV, and decreases in left ventricular preload occur, resulting in symptoms that occur at rest.⁶¹ Atrial systole accounts for 20% to 30% of LVEDV. Because mitral stenosis presents a fixed resistance to ventricular inflow, most of the pressure generated during atrial systole is used to overcome the resistance caused by the stenotic valve rather than used for producing forward flow. As the HR increases to greater than 90 bpm and diastolic time intervals are shortened, LVEDV is decreased. Blood flow through the mitral valve can be calculated by using the Gorlin formula, which has been described earlier.

Any subsequent increase in flow rate or decrease in diastolic filling time reflects an increase in the pressure gradient between the LA and the LV. As the diastolic time interval shortens, the pressure

gradient increases by the square of the increase in flow rate. Therefore, any marked increase in HR can result in an increase in left atrial pressure, which can precipitate a rise in pulmonary artery pressures and ultimately leads to pulmonary edema.⁷¹

Left atrial hypertrophy and distention are consequences of elevated left atrial pressures. As a result of the increased left atrial pressure caused by mitral stenosis, the PCWP is artificially high. That is, PCWP overestimates the actual LVEDP and LVEDV. This distention of the LA can lead to atrial dysrhythmias, most commonly atrial fibrillation. The atrial systolic “kick” is lost during atrial fibrillation; this implies that diastolic filling can be maintained only by a further increase in left atrial pressure. Mean left atrial pressure is limited by the development of pulmonary congestion at pressures greater than 25 mm Hg. Elevation of left atrial pressures to greater than 25 mm Hg leads to pulmonary congestion and eventually pulmonary edema. In patients with chronic mitral stenosis, pulmonary hypertension develops because of continuous elevations in left atrial pressure (Fig. 25.38).

FIGURE 25.38 Pathophysiology associated with mitral stenosis.

Pulmonary Vascular Changes in Right Ventricular Function

The pulmonary vasculature and eventually the RV are adversely affected by the chronic elevation of left atrial pressure that occurs with mitral stenosis. As mitral stenosis progresses, chronic elevation of left atrial pressure causes increased blood volume in the pulmonary vascular circuit. This can cause perivascular edema, and changes in pulmonary vascular resistance may ensue. These changes in pulmonary vascular resistance result in an increase in RV afterload. As a compensatory response, right ventricular hypertrophy occurs; however, because the RV is not capable of generating high pressures, it eventually begins to fail.⁶¹⁻⁶³ As the disease progresses, overt signs of biventricular failure such as low CO with poor systemic perfusion become evident. Peripheral edema, hepatic congestion, and marked venous distention are signs of right ventricular failure. The deterioration of right ventricular function decreases adequate left ventricular filling and therefore causes further deterioration in CO (Fig. 25.39).

FIGURE 25.39 Left ventricular pressure-volume loop associated with mitral stenosis. *LV*, Left ventricle.

Anesthetic Considerations

Any anesthetic technique should be based on a thorough

understanding of the pathophysiology of mitral stenosis, as well as the cardiovascular effects of the anesthetic agents administered. The following goals should be achieved in the anesthetic management of the patient with mitral stenosis:

- Maintenance of sinus rhythm at low normal heart
- Administering IV fluid to maintain LVEDV (LV preload) and thus SV without causing pulmonary congestion
- Avoid significant degree of myocardial depression
- Avoid significant increases in afterload which can decrease SV
- Cardioversion as treatment for atrial tachyarrhythmia's that cause hemodynamic instability
- Hypotension treated with phenylephrine (50–100 mcg)

The LVEDV is normal in approximately 85% of patients with mitral stenosis. An increased LVEDV in patients with mitral stenosis should alert the anesthetist to the presence of mitral or aortic insufficiency or primary coronary artery disease. Most patients with moderate mitral stenosis also have low to normal SV and therefore may have a normal EF. Approximately 33% of patients with mitral stenosis have an EF below normal (normal, 0.67 ± 0.08).⁶² When the mitral valve is narrowed to less than 1 cm^2 (severe mitral stenosis), a mean left atrial pressure of 25 mm Hg is necessary for maintaining even an adequate resting CO. Owing to the abnormal transvalvular gradient, the PCWP overestimates LVEDP. On the PCWP, a prominent *a wave* and a decreased *y descent* is associated with mitral stenosis.

Mitral Regurgitation and Insufficiency

Pathophysiology

During ventricular systole, the mitral valve is closed, preventing blood flow from the LV back into the LA. However, if for any reason the two leaflets of the mitral valve are not in opposition to each other, a portion of systolic ventricular flow regurgitates back through this incompetent (insufficient) valve. Therefore, the LV has a double outlet (aorta and LA) during systolic ejection. Ejection into the aorta is a high-impedance outlet, and regurgitation through the mitral valve back into the LA is a low-impedance outlet. This condition is termed *mitral regurgitation* (MR) or *mitral insufficiency*. The degree of regurgitation (quantitatively), called the *regurgitant fraction*, is determined by four factors:

1. Size of the regurgitant valve orifice (surface area measured in cm^2)
2. The pressure gradient between the LA and the LV
 - Inotropic state of the LV (peak systolic pressure)
 - Compliance of the LA and pulmonary veins
3. Time available for regurgitation (systole); systolic interval determines length of time during which regurgitation can occur; length of systolic time interval is inversely proportional to HR.
4. Aortic outflow impedance SVR; regurgitant fraction can be significantly influenced by changes in impedance to aortic blood flow. Increased afterload will decrease SV.

The major pathophysiologic derangement associated with MR is volume overload of the LA and LV. This occurs because the regurgitant fraction (retrograde blood flow ejected into the LA during ventricular systole) delivers an increased diastolic volume to

the LV. This increase in LVEDV results in ventricular dilation.^{49,61,71} Acute MR and chronic MR have substantially different pathophysiologic manifestations. The primary determinant of these pathophysiologic adaptations is left atrial compliance. If acute MR is caused by papillary muscle rupture which can occur after an acute MI, the mortality rate approaches 75% within 24 hours and 95% within 48 hours.⁷² Chronic MR produces longstanding and gradual elevation of left atrial pressure results in remodeling of LA architecture causing LA dilation. This consequently facilitates containment of relatively large EDV while reflecting relatively low increases in LA pressures (Fig. 25.40). With chronic MR, compensatory hypertrophic changes occur in response to a continual increased left ventricular volume by increasing the left ventricular chamber size. This type of hypertrophic change is called *eccentric hypertrophy*.

FIGURE 25.40 Pathophysiology associated with mitral regurgitation. LA, left atrium; LV, left ventricle; PCWP, pulmonary capillary wedge pressure.

In contrast, with acute MR the LA is small and noncompliant, but over time eccentric hypertrophic changes occur to compensate for progressive increases in volume (Fig. 25.41). In this situation, a small regurgitant volume bolus can generate deflections or *v* waves that appear in the PCWP tracing. This *v* wave appears as a result of a systolic jet (ejection) back through the incompetent mitral valve. The pressure wave produced by this jet is transmitted upstream into the pulmonary artery and designated as a *pathologic v wave*.

The time delay for this pressure wave to be transmitted results in its appearance at the time interval in which the normal *v* wave (passive atrial filling) occurs.⁶¹ The height of the *v* wave in MR does not represent a measurement of regurgitant volume but rather of left atrial compliance in relationship to the regurgitated volume. The hypertrophic LA accommodates a larger regurgitant volume, which results in small increases in pressure. The dilated and compliant LA allows the pulmonary vascular circuit to be buffered from the excessive left atrial volume. However, chronic MR causes pulmonary venous congestion, which creates pulmonary vascular reactive changes that eventually result in pulmonary artery hypertension. Distention of the LA may lead to atrial fibrillation, a common arrhythmia associated with MR. A non-hemodynamic symptom associated with MR is hoarseness. Compression of the left branch of the recurrent laryngeal nerve which circumscribes the aortic arch can be compressed by the enlarged LA in chronic MR. Because the recurrent laryngeal nerve provides the majority of the motor function to the vocal cords, partial paralysis of the left vocal cord could also result in respiratory distress in those patients with respiratory disease.

FIGURE 25.41 Left ventricular (LV) pressure-volume loop

associated with mitral regurgitation. The large volume and stroke volume associated with chronic mitral regurgitation occur because of LV hypertrophy. Notice that during the isovolumetric contraction phase, LV volume decreases as a result of the incompetent mitral valve.

Pulmonary Vasculature and Right Ventricular Function

In acute MR, the pulmonary vasculature is exposed to immediate and marked elevation of left atrial pressure because of a small and noncompliant LA. Pulmonary vascular congestion is precipitous and results in almost immediate development of pulmonary edema. An acute rise in left atrial pressure and congestion of the pulmonary circuit creates an increased right ventricular workload. This immediate increase in right ventricular afterload results in ventricular dilation and consequently may lead to right ventricular failure. In chronic MR, elevation of baseline pulmonary pressures is much more gradual, occurring over a prolonged period. This allows secondary pulmonary artery hypertension via intimal fibroelastosis generated by chronic perivascular edema. If the patient has coexisting mitral stenosis, pulmonary vascular resistance and right ventricular pressures may be excessively elevated.^{49,61,71}

Effects of Afterload Reductions

The path of least resistance for blood flow during left ventricular systole is retrograde into the LA. Reduction of SVR via arterial vasodilation reduces impedance to systolic outflow into the aorta and increases forward flow. Conversely, increases in SVR have marked effects on the reduction in forward flow and the increase in the regurgitant fraction. A 20% increase in MAP raises LA pressure by 50% and reflects a 120% increase in regurgitant flow concurrent with a 16% decrease in forward flow.⁶¹

Anesthetic Considerations

An otherwise healthy patient with stable and controlled MR undergoing an ambulatory or uncomplicated surgical procedure

has a minimal increase in risk of adverse hemodynamic fluctuations. Patients with cardiovascular disease who undergo major vascular, intrathoracic, intraabdominal, neurosurgical, orthopedic, or emergency procedures may have a 25% to 50% higher mortality risk than patients without the disease process. Controversy exists regarding whether the duration of surgery correlates with perioperative cardiac morbidity.^{39,61}

Preoperative assessment is essential for evaluating the degree of cardiac compensation (Table 20.7 and 20.8). Anesthetic management of the patient with MR should focus on these hemodynamic goals: decreasing regurgitant blood flow to enhance CO by decreasing afterload, maintaining or increasing preload, and maintaining cardiac contractility. Bradycardia or dysrhythmias that cause a loss of atrial kick can result in pulmonary congestion, left atrial and left ventricular overload, and a significant decrease in CO.^{61,62}

Another anesthetic consideration for MR includes decreasing SVR or afterload. Cautiously lowering SVR via an arterial vasodilator such as sodium nitroprusside improves forward flow. However, extreme reductions in blood pressure, and especially diastolic pressure, can lead to decreased coronary artery blood flow and decreased CO.

Selection of the anesthetic technique should take into consideration the adverse effects associated with changes in HR and SVR. General anesthesia is the technique of choice in patients with MR. Regional anesthesia (spinal or epidural) is not contraindicated; however, the potential for profound and precipitous decreases in blood pressure via sympathetic blockade should be considered. Induction of general anesthesia can be safely achieved with any of the presently available agents. Hemodynamic goals include avoiding bradycardia and significant increases in afterload. The use of muscle relaxants does not present a significant risk as long as the resulting changes in HR do not cause severe bradycardia. The vagolytic properties of pancuronium may help to maintain HR. Maintenance of anesthesia can be accomplished with narcotics and an inhalation agent. There is no definitive evidence to support that a particular inhalation agent yields superior outcomes for patients with MR. Isoflurane may be an ideal choice because of

its significant vasodilatory effects, causing an increased HR. However, because all inhalation agents cause a dose-dependent decrease in myocardial contractility, their use may be detrimental in patients with severe ventricular dysfunction. In this instance, the use of a high-dose opioid technique may provide for a more effective hemodynamic profile. Anesthetic management should focus on avoiding bradycardia or increases in SVR.⁶¹ See [Table 25.8](#) for anesthetic goals for management of mitral lesions.

TABLE 25.8

Hemodynamic Goals for Management of Mitral Valve Lesions

Parameter	Mitral Regurgitation (Insufficiency) Goal	Mitral Stenosis Goal
Heart rate	Increase, avoid bradycardia	Low normal
Rhythm	Maintain normal sinus rhythm	Maintain normal sinus rhythm
Afterload	Decrease	Maintain normal
Pulmonary vascular resistance	Avoid increases	Avoid increases
Preload	Normal to increased	Normal to increased

Aortic Stenosis

Etiology and Pathophysiology

The most common causes of aortic stenosis include a congenital defect resulting in a bicuspid aortic valve (especially in males) and as a sequelae of rheumatic valvular heart disease. Isolated aortic valvular dysfunction in patients with rheumatic heart disease is rare. Commonly, rheumatic valvular disease is associated with mitral valve involvement. Whatever the cause, the pathophysiology remains the same and results in the need for increased left ventricular systolic pressure to overcome the left ventricular outflow tract obstruction caused by a narrowed aortic valve orifice (Fig. 25.42). During auscultation, a low-frequency, systolic ejection murmur is characteristic of aortic stenosis.⁴²

FIGURE 25.42 Pathophysiology associated with aortic stenosis. LA, Left atrium; LV, left ventricle; AO, aorta.

A normal aortic valve area of 2.5 to 3.5 cm² and SV of approximately 80 mL result in a flow rate of 250 mL/min during the interval of ventricular systole (80 mL/sec × 0.32 sec – systolic time interval). The flow rate through a normal orifice results in a minimal gradient (2 to 4 mm Hg). The normal left ventricular systolic pressure of 100 to 130 mm Hg is sufficient to generate flow

rates of 250 to 300 mL/sec. To ensure normal flow rates and CO through the narrowed orifice, the velocity of systolic ejection must increase. For systolic ejection to increase, ventricular systolic pressure increases dramatically, depending on the degree of valvular pathology. The LV must compensate for gradually increasing mechanical impedance to ejection. This results in LVH, which allows the heart to generate high ventricular systolic pressure and overcome impedance to ejection. The elevation of systolic ejection pressure produces a gradient between the left ventricular cavity and the aorta. The valve area must be constricted by at least 50% before the gradient becomes significant to the point that symptoms occur at rest. An aortic valve area of less than 1 cm² produces a clinical triad of symptoms that includes angina (even in the absence of significant coronary artery disease), syncope, and congestive heart failure.⁷³ An aortic valve area of less than 1 cm² represents severe aortic stenosis and should be a cause of concern during anesthetic management because of the associated increase in perioperative cardiac morbidity. The prognosis is poor if the flow velocity is greater than 4.0 m/sec which corresponds to a mean aortic valve gradient greater than 40 mm Hg.⁷⁴ An aortic valve area less than 0.7 cm² is associated with sudden death.⁷⁵ For adequate assessment of the degree of valvular stenosis, both the flow rate across the valve and the pressure gradient should be evaluated, either by cardiac catheterization or echocardiography.^{68,69}

Left Ventricular Function

Left ventricular concentric hypertrophy is the compensatory change associated with aortic stenosis. It results in several hemodynamic adaptations that are unique to aortic stenosis and present a challenge and a dilemma with regard to anesthesia management. The consequence of LVH in aortic stenosis is a decrease in ventricular compliance, hypertrophic remodeling, and an eventual decrease in the intrinsic contractility of the myocardium.⁷⁶ The reduction in ventricular compliance affects normal hemodynamics as follows:

- I. Higher filling pressures are needed to produce the same amount of ventricular work.

II. To achieve adequate left ventricular filling, normal sinus rhythm must be maintained to ensure adequate LVEDV from the atrial kick.

III. Concentric ventricular hypertrophy increases myocardial oxygen demand.

A. Myocardial oxygen consumption is increased.

1. Myocardial mass is increased.
2. Pressure generation (isovolumetric contraction) uses more energy than left ventricular ejection; a high intracavitary pressure must be generated to maintain CO.
3. The ejection phase is prolonged.

B. Myocardial oxygen supply is decreased.

1. CPP is decreased as a result of an increase in LVEDP.
2. Systolic coronary flow is absent because left ventricular systolic pressure exceeds aortic systolic pressure.
3. Prolonged systolic ejection reduces the coronary perfusion interval.
4. Subendocardial capillaries are compressed by hypertrophic myocardium.^{49,61}

Pulmonary Circuit and Right Ventricular Responses

To maintain CO in the presence of a noncompliant and hypertrophic LV, left atrial pressures increase to accommodate left ventricular filling (Fig. 25.43). Left atrial pressures of greater than 18 mm Hg can cause an increase in pulmonary artery pressure, resulting in passive pulmonary venous congestion. Eventually, pulmonary fibroelastosis occurs, causing pulmonary artery hypertension. If left ventricular EF is decreased to less than 40% in association with aortic stenosis, CO can be maintained only with increases in left atrial pressures. These pressures increase to 25 to 30 mm Hg, which results in increased mean pulmonary artery pressure. Elevated mean pulmonary artery pressure increases pulmonary vascular resistance, which can cause right ventricular failure. Decreasing left ventricular preload in association with significant aortic stenosis can result in decreases in CO.

FIGURE 25.43 Left ventricular pressure-volume loop associated with aortic stenosis.

Anesthetic Considerations

The goals of anesthesia management include maintaining

hemodynamic stability without causing significant alterations in compensatory mechanisms. Anesthetic management of patients with aortic stenosis should focus on the following hemodynamic factors:

- Maintain normal sinus rhythm and HR 70 to 80 bpm
- Ensure sufficient preload (LVEDV) to maintain CO
- Ensure adequate coronary perfusion by maintaining DBP values
- Avoid myocardial depression, especially with poor LV function
- Maintain or allow slight increase in afterload

General anesthesia is the preferred technique for major surgical procedures involving patients with aortic stenosis because of the ability to manipulate hemodynamic parameters, especially DBP. Neuraxial blockade (spinal or epidural) must be used with extreme caution, because precipitous reductions in blood pressure associated with a sympathectomy decrease SVR.⁴² Epidural anesthesia offers the advantage of a slower onset of vasodilation. Depending on the degree of compromise, the heart may not be able to compensate for moderate to severe systemic vasodilation. Therefore, lower dermatome level blocks decrease the degree of systemic vasodilation and maintain afterload. Successful cardiopulmonary resuscitation is virtually impossible because of the mechanical left ventricular outflow obstruction associated with aortic stenosis. The pressure necessary to overcome outflow obstruction and produce adequate coronary artery perfusion and CO cannot be generated with closed-chest compressions. Furthermore, short periods of hypotension may lead to a decrease in coronary perfusion and should be treated with IV fluid and phenylephrine.⁷⁷ Due to the increased oxygen demands of the LV, irreversible myocardial ischemia and cardiovascular collapse can occur if hypotension is not promptly and aggressively treated.

Intraoperative control of HR and rhythm is a major goal of the anesthetic management of patients with aortic stenosis. Tachycardia can be detrimental because it decreases diastolic filling time, resulting in a reduction of left ventricular preload. The reduced time interval for coronary artery perfusion reduces oxygen supply to the myocardium. In patients with HRs of greater than 110 bpm, systolic ejection time and CO are decreased.^{61,62} Bradycardia (fewer

than 60 bpm) is detrimental in aortic stenosis. Prolonged diastolic filling time, which occurs as a result of bradycardia, causes ventricular distention, which can further decrease CPP, especially to the subendocardium.^{49,61}

Monitoring and Premedication

It is prudent to titrate preoperative sedatives while vital signs can be continuously monitored. In addition to standard intraoperative monitoring, complete invasive monitoring may be required for patients with aortic stenosis, even for routine procedures. Any significant change in basic hemodynamic variables (i.e., HR, heart rhythm, LVEDV, CPP) can rapidly cause irreversible myocardial deterioration. It is imperative that these variables be monitored closely and appropriate interventions be performed to prevent adverse hemodynamic consequences. The complexity of hemodynamic monitoring modalities is dependent on the physical status of the patient, the severity of aortic stenosis, the extent of the surgical procedure, and the ability of the anesthesia provider to use and interpret hemodynamic values.

The use of intra-arterial monitoring for direct beat-to-beat blood pressure assessment allows the anesthesia provider to rapidly treat undesirable hemodynamic changes. The use of intraoperative TEE provides real time quantitative and qualitative information regarding valvular function and changes in anesthetic management can be accomplished to maximize hemodynamic status.⁷⁸ Absolute criteria for intraoperative invasive monitoring for patients with aortic stenosis remain controversial. However, clinical judgment, experience, and the ability to appropriately use the pulmonary artery catheter should be considered before implementation.^{76,79}

Maintenance of Anesthesia

Commonly used induction agents can be administered but caution to avoid profound hypotension is a primary goal. Tracheal intubation can be performed with any of the available muscle relaxants, but caution must be exercised to avoid histamine release, which can dramatically increase HR and decrease blood pressure. Anesthetic maintenance can be accomplished with the use of an

inhalation agent in conjunction with opiates. The adverse cardiovascular effects of the inhalation agents must be considered before these drugs are used. Higher concentrations of inhaled agent result in greater degrees of myocardial depression and vasodilation. Inhalation agents must be used with caution, because the myocardial depressant effect can be deleterious in patients with impaired ventricular function. The use of higher-dose opioid-based technique is an alternative anesthetic approach that may help achieve cardiovascular stability without causing a significant amount of myocardial depression. Finally, a combination of inhalation agents and narcotics has been used safely to provide anesthesia for patients with aortic stenosis. Whatever the anesthetic technique chosen for patients with aortic stenosis, immediate and aggressive treatment of adverse changes that occur in HR and rhythm, SVR, blood pressure, and LVEDV is paramount if successful anesthetic outcomes are to be achieved.^{75,79}

Aortic Insufficiency

Aortic insufficiency, also known as *aortic regurgitation*, can be classified as acute or chronic and as primary or secondary, depending on the cause. Primary *chronic* AI is caused by rheumatic valvular disease and almost always involves the mitral valve to some degree. Primary *acute* AI is most commonly caused by infective endocarditis, which results in direct damage to the aortic valve cusps. Acute secondary (functional) AI results from aortic root dissection caused either by trauma or aneurysm and results in a mechanical and functional impairment of functional aortic valve closure.

Pathophysiology

The major hemodynamic aberration related to AI occurs during diastole. A portion of the blood volume ejected from the LV into the aorta regurgitates back into the ventricle because of incomplete closure of the aortic valve. AI causes volume overload of the LV. Chronic ventricular overload causes eccentric ventricular hypertrophy and chamber dilation (Fig. 25.44). The degree of regurgitation depends on three factors: the diastolic time available for regurgitation to occur, the diastolic pressure gradient between the aorta and the LV, and the degree of incompetence of the aortic valve.^{71,75}

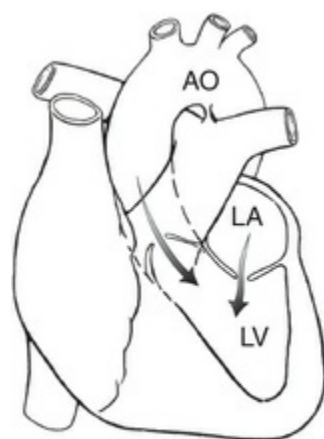

FIGURE 25.44 Pathophysiology associated with aortic regurgitation. AO, Aorta; LA, left atrium; LV, left ventricle.

Diastolic time and diastolic pressure can be manipulated during the course of anesthesia so that the amount of regurgitant flow is decreased and the amount of forward flow is increased. An HR of 90 to 100 bpm decreases the diastolic time period and thereby reduces the time available for regurgitation. Reducing SVR reduces aortic diastolic pressure and decreases the gradient between the aorta and the LV. Unique pathophysiologic adaptations differentiate chronic AI from the acute form. In chronic AI, the LV has had time to compensate for the increased volume. In time, LV hypertrophy allows the LV to tolerate significant increases in volume without dramatic decreases in EF.^{49,61} In situations in which the onset of AI is acute, the LV has inadequate time to adapt to volume overload, which renders compensatory mechanisms ineffective (Fig. 25.45). Frequently, left ventricular failure, pulmonary edema, and cardiovascular collapse occur. LVEDP rises precipitously in acute AI because of the inability of the LV to alter its compliance.

FIGURE 25.45 Left ventricular (LV) pressure-volume loop associated with aortic insufficiency. Increased LV pressure, volume, and stroke volume are associated with chronic aortic insufficiency and are reflective of LV hypertrophy. Notice that during the relaxation phase, as isovolumetric

relaxation occurs, LV volume increases as a result of the incompetent aortic valve.

Patients with chronic AI can remain asymptomatic for long periods. Except during times of stress, the clinical symptoms associated with chronic AI are usually not incapacitating. End-stage AI is characterized by myocardial failure with decreased CO and precipitous elevation of LVEDV with evidence of pulmonary congestion. As long as ventricular hypertrophy and dilation do not affect the mitral valve, the pulmonary circulation is not affected by the pathophysiologic changes associated with AI. Increased myocardial oxygen consumption occurs partly because of the development of eccentric hypertrophy. The decrease in aortic diastolic pressure that results from AI reduces coronary flow and can cause subendocardial ischemia. In acute AI, a precipitous increase in LVEDP with a decrease in aortic diastolic pressure can severely compromise coronary blood flow and result in acute myocardial ischemia. The RV and pulmonary vascular circuit are usually spared in chronic AI until secondary (functional) MR occurs. This results in dilation of the mitral valve annulus. A gradual increase in LA pressure and pulmonary artery pressure caused by functional MR eventually causes pulmonary hypertension; right ventricular failure can occur if pulmonary hypertension becomes severe. In acute AI, functional MR is poorly tolerated, owing to a noncompliant LA. This situation leads to immediate pulmonary vascular congestion and pulmonary edema. Patients with asymptomatic AI have a 0.2% annual mortality rate as compared with symptomatic patients, who have a greater than 10% mortality rate per year.⁷⁴ Therefore, when evidence suggests that increases in left ventricular volume result in left ventricular dysfunction, aortic valve replacement is recommended.

Anesthesia Management

The goals for anesthesia management are to increase forward flow and decrease the degree of regurgitation and therefore should focus on the following hemodynamic factors:

- Heart rate should be maintained between 80 to 100 bpm
- Afterload (especially diastolic pressure) should be decreased

- Avoid myocardial depression
- Maintain normal sinus rhythm
- Maintain/increase preload

Neuraxial blockade is an appropriate anesthetic choice, depending on the invasiveness of the surgical procedure. Reduction in SVR resulting from sympathetic blockade may reduce the degree of regurgitation. The potential for immediate and uncontrolled hypotension during spinal anesthesia is a concern. However, spinal and epidural anesthesia has been used successfully for patients with AI. Induction of general anesthesia can be accomplished with any of the available IV agents. Tracheal intubation can be achieved with the use of available nondepolarizing muscle relaxants. As mentioned in the anesthetic management for patients with MR, the vagolytic properties associated with pancuronium are desirable and may offset the vagotonic effects of narcotics. Succinylcholine may be used, but its potential to cause bradycardia (although rarely) must be considered. Maintenance of anesthesia can be achieved with an inhalation agent. Isoflurane, with its ability to increase HR and decrease SVR, produces little myocardial depression in lower doses, and therefore its use is preferred over use of other inhalation agents. If significant ventricular dysfunction exists, an opioid-based anesthetic technique may be preferable.^{59,61,62}

Monitoring and Premedication

Unless end-stage AR or significant preoperative ventricular dysfunction exists, aggressive invasive monitoring is not warranted. However, if the surgical procedure is extensive or if vasodilators or inotropes are being used, then an arterial line and a pulmonary artery catheter should be used for assessing the results and efficacy of these therapeutic agents. Premedication should be tailored to the patient's clinical condition. In elderly or debilitated patients, a conservative amount of premedication in a monitored environment should be titrated until effective.

Appropriate anesthetic management of the patient with valvular heart disease requires a basic knowledge of cardiac physiology and the pathophysiologic changes that occur with valvular dysfunction. The cardiovascular effects of all the agents, techniques, and adjunct

pharmacologic agents used during anesthesia must be integrated into the anesthetic plan. A thorough understanding of the use of invasive monitoring along with other sophisticated diagnostic modalities enables the clinician to continuously monitor hemodynamic parameters. Contemporary anesthesia practice has allowed patients with severe valvular dysfunction to undergo surgical procedures that would not have been performed a decade ago.⁷⁵ Table 25.9 lists anesthetic goals for management of aortic lesions.

TABLE 25.9

Hemodynamic Goals for Management of Aortic Valve Lesions

Parameter	Aortic Regurgitation (Insufficiency) Goal	Aortic Stenosis Goal
Heart rate	Moderate increase	Low normal
Heart rhythm	Normal sinus rhythm	Normal sinus rhythm
Afterload	Decrease	Maintain to slight increase
Pulmonary vascular resistance	Maintain	Maintain
Preload	Normal to increased	Increased

Mitral Valve Prolapse

Description and Etiology

The incidence of mitral valve prolapse (MVP), which was thought to be present in 5% to 15% of the US population, is presently estimated at 1.6% to 2.4% of adults.⁷⁴ A familial predisposition exists, and women are three times more likely than men to develop MVP. Other conditions frequently associated with MVP include pectus excavatum and kyphoscoliosis. Symptoms are general and include weakness, dizziness, syncope, atypical chest pain, and palpitations. Atrial and ventricular dysrhythmias are common findings in asymptomatic patients. A diagnosis of MVP is confirmed through echocardiography. Most patients with this condition remain undiagnosed. Despite infrequent signs and symptoms, MVP can produce potentially life-threatening complications. Premature ventricular contractions are the most common dysrhythmia associated with MVP. Prolonged periods of ventricular tachycardia occur in approximately 21% of patients with MVP. It is also the most common cause of isolated MR.

Supraventricular tachyarrhythmias and bradycardia associated with AV block may occur. Medical therapy for MVP consists primarily of the use of β -blocking drugs, which are thought to inhibit an autonomic imbalance that exists in women who have it. Additionally, β -blocking drugs may increase end-diastolic volume and thereby decrease the degree of prolapse. Most patients with MVP do not require medical or pharmacologic management, which reflects the asymptomatic nature of this relatively common valvular abnormality (Table 25.10).^{33,79}

TABLE 25.10

Hemodynamic Goals for Management of Mitral Valve Prolapse

Parameter	Goal
Preload	Maintain or increase
Afterload	Maintain
Contractility	Maintain
Heart rate	Maintain
Heart rhythm	Normal sinus rhythm

Pathophysiology and Unique Problems

The pathophysiologic changes that occur in MVP primarily affect the cusps and the chordae tendineae. Involved is a myxomatous degeneration of the valve cusps that replaces normal fibrous tissue. In addition, this myxomatous degeneration affects the chordae tendineae and causes them to become pliable and elongated. The valve leaflets become supple and redundant, as the valve can evert into the LA during systole.⁸⁰

Mitral valve prolapse is undiagnosed in the majority of patients. A manifestation that commonly occurs in healthy patients who are receiving anesthesia is an unexpected dysrhythmia (e.g., premature ventricular contractions), many of which resolve spontaneously. β -Blockers are the best choice for control of dysrhythmias in patients with MVP. Hemodynamic events and certain positions tend to exacerbate the degree of MVP and dysrhythmias. Hemodynamic changes that cause a decrease in ventricular preload and increase the incidence of eversion of the mitral valve are caused by increased myocardial contractility, decreased SVR, head-up or sitting positions, use of drugs that decrease ventricular preload (e.g., nitroglycerin and sodium nitroprusside), and hypovolemia.

Pharmacology

Preoperative anxiety stimulates the sympathetic nervous system and can increase the degree of MVP and concomitant dysrhythmias. Decreasing anxiety can reduce the sympathetically mediated responses and improve the hemodynamic profile characteristic of MVP. Anticholinergics can cause tachycardia and should therefore be omitted from the preoperative regimen.

Anesthetic Management

Regional anesthesia is acceptable for patients with MVP. SVR should be maintained slightly above normal, even in the presence of sympathetic blockade. General anesthesia is an appropriate choice and may be preferred in many instances. Whichever technique is chosen, it is important that preload be maintained.

Induction of anesthesia can be accomplished with any of the available IV agents. Ketamine, with its ability to stimulate the sympathetic nervous system, should not be used in patients with MVP. Use of an inhalation agent alone or in combination with opioids is appropriate for maintenance of anesthesia. Muscle relaxants that have a stable cardiovascular profile can be used. Antibiotic prophylaxis is recommended for patients with MVP because of the potential for endocarditis. Currently, only patients with prosthetic valves, patients with prior endocarditis, heart transplant patients with a valvulopathy, and certain congenital heart disease patients now require endocarditis prophylaxis.⁸¹

Cardiomyopathy

Cardiomyopathy is defined as heart muscle disease involving the myocardium that is chronic and frequently progressive in nature. The term is used to describe distinct cardiac pathological conditions that can ultimately result in fatal dysrhythmias, progressive cardiac disability, and sudden cardiac death. All forms of cardiomyopathy can result in congestive heart failure and death. Cardiomyopathies can be categorically differentiated by a general pathologic cause as either extrinsic or intrinsic. *Intrinsic cardiomyopathy* is described as decreased contractile state of the heart muscle that cannot be attributed to a specific external causative factor. In contrast, the cause of *extrinsic cardiomyopathy* can be directly attributed to a disease process or toxin that adversely damages cardiac muscle. Factors that can cause extrinsic cardiomyopathy include but are not limited to ischemia, chronic inflammation, congenital heart disease, metabolic diseases (e.g., hemochromatosis), and toxins (e.g., chronic alcohol intake, chemotherapeutic agents). Frequently, histologic findings consistent with cardiomyopathies include myocyte hypertrophy, degradation of the cardiac cytoskeleton, and cellular fibrosis. The four major types of progressive cardiomyopathies include dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy (RCM), and arrhythmogenic right ventricular cardiomyopathy (ARVC). Takotsubo cardiomyopathy (TCM) most often resolves within 4–8 weeks after diagnosis but the long-term prognosis has not definitively been determined.

Frequently the discovery of significant cardiomyopathy is accomplished post mortem because sudden cardiac death commonly occurs in those with this disease. A discussion of various types of cardiomyopathies, signs and symptoms, and anesthetic implications are included in the following sections.

Patients with severe cardiomyopathy frequently have surgery for cardiac procedures such as pacemaker implantation or heart transplantation. A thorough preoperative evaluation is essential to create a comprehensive anesthetic plan that is individualized. In addition to physical examination, a determination of the patient's

preoperative medication regimen and assessing the degree of compliance with his or her medications is a component part of medical optimization. A detailed analysis of the invasive and noninvasive cardiac studies including TEE and the cardiologist's impression of the patient's cardiac status is vital.

Hypertrophic Cardiomyopathy (HCM)

Hypertrophic cardiomyopathy, a genetically transmitted disorder, is a form of myocardial dysfunction that can cause coronary artery disease, valvular dysfunction, ventricular remodeling, and hypertension. The incidence in the adult population is approximately 1 in 500 persons.⁸² Obstructive HCM has previously been referred to as *idiopathic hypertrophic subaortic stenosis*. Currently, the preferred term used to describe this pathologic state is *HCM with or without left ventricular outflow obstruction*.⁸³

A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in [Table 25.11](#).

TABLE 25.11

Pathology and Anesthetic Considerations for Various Cardiomyopathies

Cardiomyopathy	Distinctive Features	Signs and Symptoms	Anesthetic Considerations
Dilated	Eccentric left and right ventricular hypertrophy causing systolic and diastolic dysfunction	Chest pain	Promote afterload reduction Avoid large fluid bolus Choose anesthetic techniques, agents that minimize myocardial depression
		Jugular venous distention	
		Weakness	
		Exercise intolerance	
		Rales	
Restrictive	Stiff and noncompliant ventricles decrease ventricular end-diastolic volume despite near-normal systolic function	Tachycardia	TEE and invasive hemodynamic monitoring IV inotropic support may be necessary
		Pulsus alternans	
		Atrial fibrillation	
		Atrial and ventricular dysrhythmias	
		Atrioventricular valve regurgitation	
		X-ray—pulmonary venous congestion/spherical appearance of LV/cardiomegaly	
		Dyspnea	
		Fatigue	
		Cardiomegaly	
		Atrioventricular	

		valve regurgitation	Choose anesthetic techniques, agents that minimize myocardial depression
		JVD Pulmonary hypertension Rales	
Hypertrophic	Left ventricular hypertrophy resulting in decreased LV chamber size and LV outflow tract obstruction	Chest pain Shortness of breath Palpitations Rales	Ensure adequate preload Myocardial depression is desirable Maintenance of normal sinus rhythm Avoid tachycardia
		Systolic murmur (S ₃ and S ₄)	Ensure adequate depth of anesthesia
		Ventricular dysrhythmias Syncope	
Arrhythmogenic right ventricular	Fatty tissue infiltrates; dilation and outflow tract obstruction of the right ventricle	Tachycardia Ventricular dysrhythmias (ventricular tachycardia, ventricular fibrillation)	Treat events that cause moderate to severe sympathetic nervous system predominance Monitor and treat hemodynamically compromising ventricular dysrhythmias with amiodarone
		T wave inversion (leads V ₁ and V ₃) Bundle branch block Hypokinetic right ventricle	
		Decreased right ventricular ejection	
		Jugular venous distention	
		Syncope	
		Peripheral edema	

JVD, Jugular venous distention; LV, left ventricle; TEE, transesophageal echocardiography.

Pathophysiology

Hypertrophic cardiomyopathy is the most common cause of sudden death in the pediatric and young adult populations.⁸⁴ The major cardiac changes associated with HCM include: (1) ventricular hypertrophy, (2) decreased ventricular chamber size, (3) increased ventricular wall thickness, and (4) impaired ventricular relaxation. The myocardial defect associated with HCM is related to the contractile mechanism. An increase in the density of calcium channels is one abnormality that appears to lead to myocardial hypertrophy. Asymmetric hypertrophy of the interventricular

septum of the LV occurs. It has been determined that there is a genetic predisposition to developing HCM.⁸⁵ Patients with HCM and sarcomere myofilament mutations have a greater degree of microvascular impairment, an increased incidence of myocardial fibrosis, and impaired myocardial remodeling.⁸⁶ The asymmetric hypertrophy of the intraventricular septum causes a left outflow tract obstruction, and the hemodynamic consequences are similar to those that are characteristic of aortic stenosis. The coronary arterial walls become narrowed because of the presence of collagen. If the entire myocardium is involved, a disproportionate hypertrophy of the intraventricular septum exists. The contraction of the hypertrophic septum bulging into the subaortic area of the left ventricular outflow tract creates a dynamic gradient. The left ventricular outflow tract is bounded anteriorly by the intraventricular septum and posteriorly by the anterior leaflet of the mitral valve. The rapid acceleration of blood traveling through the narrowed outflow tract creates a Venturi effect, which pulls the anterior mitral valve leaflet into the outflow tract. A LV outflow tract obstruction is present in approximately two thirds of patients with HCM.⁸⁷ The systolic anterior motion of the anterior mitral valve leaflet further obstructs left ventricular outflow. The valve leaflet may even contact the septum and further compromise left ventricular outflow.

The pathophysiologic abnormalities related to HCM include the presence of systolic and diastolic dysfunction. A loss of diastolic compliance results in an abnormally elevated LVEDP in the presence of low-normal end-diastolic volume. Loss of left ventricular diastolic compliance requires a greater contribution of volume from atrial contraction. As a result, congestive heart failure may ensue as left atrial pressures continue to increase.⁷⁵ Because as much as 75% of LV preload comes from the LA, maintenance of normal sinus rhythm is critical for adequate SV. The increase in LVEDP, which results from a noncompliant LV, decreases CPP to the hypertrophic LV. Altered coronary perfusion decreases myocardial blood supply, and the presence of left ventricular hypertrophy increases myocardial oxygen demand. Thickening of the internal lumen of the coronary arteries decreases myocardial perfusion, leading to ischemia.⁸⁷

Hypertrophic cardiomyopathy with obstruction is characterized by its dynamic nature. Three basic hemodynamic parameters can affect the degree of left ventricular outflow tract obstruction. Manipulation of these parameters can exacerbate or ameliorate the hemodynamic consequences of outflow obstruction. These three parameters include preload, afterload, and contractility.³³ Increasing myocardial contractility in patients with HCM exacerbates the obstruction by increasing septal wall contraction and decreasing CO. Increased blood flow velocity causes a greater degree of systolic anterior motion of the mitral valve's anterior leaflet, creating further obstruction. Decreased preload changes left ventricular geometry and thereby brings the anterior leaflet of the mitral valve into closer proximity to the hypertrophic septum. Increases in left ventricular contractility cause the LV to empty more completely and increase the degree of septal contractility, which results in a greater degree of obstruction.⁸³ A summary of the signs and symptoms are included in [Table 25.11](#).

In HCM with RV and or LV outflow tract obstruction, conditions that impair ventricular function under normal physiologic conditions improve cardiac function. This implies that factors that normally impair contractility (e.g., myocardial depression, increased end-diastolic volume, and increased SVR) improve forward flow and diminish the degree of obstruction. [Fig. 25.46](#) illustrates the pathology related to HCM.

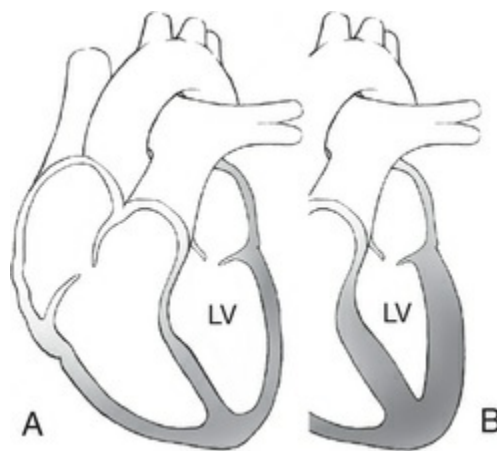

FIGURE 25.46 **A** Normal left ventricular outflow tract. **B** Hypertrophic cardiomyopathy with an enlarged interventricular septum and left ventricular wall, a

decreased left ventricular chamber size. A further decrease of left ventricular outflow is caused by migration of the anterior mitral leaflet toward the septum. LV, Left ventricle.

Anesthetic Considerations

Anesthetic management should focus on strategies that alleviate and do not increase LV outflow obstruction. It is imperative that adequate or slightly elevated LV volume be maintained. Measures that decrease venous return and interfere with adequate ventricular preload should be avoided. Factors that increase myocardial contractility should be avoided. Inadequate depth of anesthesia that causes sympathetic nervous system stimulation may be detrimental. If hypotension occurs, adequate perfusion pressure should be maintained by increasing preload with fluid administration and increasing SVR with phenylephrine.

Pharmacologic therapy used to treat HCM (including β -blockers and calcium channel blockers) should be continued until the time of surgery.¹⁵ β -Blockers may be administered intraoperatively to reduce HR and contractility. Dysrhythmias must be avoided and immediately treated if they occur; the atrial contribution to left ventricular volume is necessary to maintain CO.^{79,83} Table 25.12 lists hemodynamic goals for patients with HCM.

TABLE 25.12

Hemodynamic Goals for Management of Hypertrophic Cardiomyopathy

Parameter	Goal
Preload	Increase
Afterload	Increase
Contractility	Decrease
Heart rate	Maintain
Heart rhythm	Normal sinus rhythm

Anesthetic management must focus on increasing left ventricular preload, decreasing myocardial contractility, controlling HR, and maintaining or increasing afterload. Regional anesthesia is not contraindicated in patients with HCM. Decreases in blood pressure must be treated immediately. Hypovolemia must be avoided and

expeditiously treated if it occurs. Deep general anesthesia with an inhalation agent is preferred in patients with HCM.

The potential for hemodynamic deterioration because of increasing subaortic obstruction along with secondary MR necessitates aggressive hemodynamic monitoring. Invasive monitoring via a pulmonary artery catheter allows for maintenance of adequate LVEDV. HCM is associated with reduced diastolic compliance, and therefore PCWP does not accurately correlate directly with LVEDV. The PCWP should be maintained at approximately 18 to 25 mm Hg. If the hemodynamic status deteriorates and exacerbation of outflow obstruction is suspected, β -blocking drugs (propranolol, metoprolol or esmolol) should be administered. In addition, vasoconstrictors such as phenylephrine should be used to increase SVR.³³

Dilated Cardiomyopathy (DCM)

Dilated cardiomyopathy is the most common form of cardiomyopathy, and it most often occurs in adults. As with HCM, there is believed to be a genetic link for those people who develop this cardiac pathology. Between 20% and 30% of DCM cases are caused by an autosomal dominant mutation resulting in abnormal cardiac cytoskeleton protein generation.⁸⁸ DCM can also occur in patients as a result of autosomal recessive traits, such as in patients with Duchenne muscular dystrophy. When genetic predisposition is not the cause, the specific etiology has not been definitively determined but is not limited to a viral illness, increased inflammation from metabolic abnormalities, autoimmune mechanism, or toxins. It occurs more often in men than in women and is attributed to being a significant risk factor for developing congestive heart failure. A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in [Table 25.11](#).

Pathophysiology

In DCM, eccentric hypertrophy affects both left and right ventricles. As cardiac cytoskeleton uncoupling occurs, caused by interstitial fibrosis and myocardial cell death, the ventricular chambers

increase in size without an associated increase in the diameter of the ventricular walls or interventricular septum. The law of Laplace, as shown in the following equation, helps us describe why the heart becomes an inefficient pump for patients with DCM. Tension on the ventricular walls is increased due to the decreased size and increased diameter of the ventricular walls. After a period when increased ventricular volumes induce compensatory eccentric hypertrophic changes, impaired systolic function (decreased SV) occurs because of the loss of myocardium causing decreased contractility. Myocardial oxygen consumption is increased as ventricular end-diastolic volume and pressure are increased.

$$T = (P \times R) / M$$

T = tension, P = pressure, R = radius, M = wall thickness

This pathologic process does not cause direct damage to the atrioventricular valves. However, as ventricular dilation occurs, changes in ventricular dimensions can cause mitral valve and/or tricuspid valve regurgitation potentially intensifying volume overload, decreased SV, and increased pulmonary congestion.

As the EF decreases, decreased peripheral perfusion causes increased circulating catecholamines, cortisol excretion, and activation of the renin-angiotensin-aldosterone system, which causes vasoconstriction and increased renal absorption of fluid. Left-sided heart failure resulting in pulmonary venous congestion or biventricular failure leads to fulminant congestive heart failure. These patients are at increased risk of thromboembolism as a result of stasis of blood from inadequate ventricular emptying.⁸⁹

Anesthetic Considerations

Pharmacologic medical treatment for patients with DCM include diuretics, ACE inhibitors, and digoxin. Other interventions for moderate to severe DCM include dual chamber pacing, cardiomyoplasty, or use of a left ventricular assist device. Because of the potential for severely compromised ventricular performance,

minimizing myocardial depression is essential. Afterload reduction is important to promote forward blood flow through the heart. As a result, neuraxial anesthesia is an acceptable anesthetic technique for patients with DCM.⁹⁰ Narcotics are a common choice for patients with cardiomyopathy because they do not have a direct effect on myocardial contractility. However, patients with DCM who have a severely compromised EF depend on sympathetic nervous system innervation to augment their cardiac output. Therefore, incremental titration of narcotics is warranted. Etomidate is an appropriate choice of induction agent because of the lesser amount of myocardial depression as compared to propofol. All inhalation agents cause myocardial depression in a dose-dependent fashion, thus titration of inhalation agents based on blood pressure, CVP, and PCWP is indicated.⁸⁶ Sevoflurane has been safely used in infants with DCM.⁹¹

Restrictive Cardiomyopathy (RCM)

The term *restrictive cardiomyopathy* represents several types of pathologic conditions depending on whether the myocardium or endomyocardial muscle layer is affected. Causes of myocardial RCM include genetic predisposition (e.g., familial cardiomyopathy), infiltrative disease (e.g., sarcoidosis), storage diseases (e.g., hemochromatosis), and endomyocardial dysfunction (e.g., endomyocardial fibrosis). RCM can occur in the pediatric population; however, it is one of the rarest forms of cardiomyopathy that occurs in children. It is associated with a high mortality rate once symptoms begin to develop.⁹² A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in [Table 25.11](#).

Pathophysiology

Infiltration of fibrous tissue and deposition into the myocardium and or endomyocardium is the pathologic mechanism by which RCM develops. As a result, one or both ventricles become stiff and noncompliant, which inhibits normal diastolic filling. Because of reduced end-diastolic volume (reduce ventricular preload) caused by restricted ventricular filling, SV is decreased. An increase in the

sensitivity of the troponin and tropomyosin complex of calcium-mediated myofilament is thought to be the cause of genetically derived RCM.⁹³ Systolic ejection remains relatively normal. The atria become dilated as a compensatory response to volume overload, and left- and/or right-sided heart failure can occur. Significantly elevated RA pressures (15 to 20 mm Hg) and pulmonary artery systolic pressure (as high as 50 mm Hg) can occur as the disease progresses.⁹⁴

Anesthetic Considerations

Medical management for RCM is similar to DCM and includes use of diuretics, sodium and water restriction, anticoagulation agents, and treatment of dysrhythmias. Maintenance of normal sinus rhythm, adequate preload, and minimal myocardial depression is essential to anesthetic management. As with DCM, an anesthetic technique that minimizes myocardial depression, which is accomplished using higher doses of narcotic as compared to inhalation agents, may be prudent. Results from studies are often conflicting regarding the degree of myocardial depressant effects of modern inhalation agents (isoflurane, sevoflurane, desflurane) in relation to cardiomyopathy and impaired systolic ejection and diastolic relaxation.^{94,95} Patients with moderate to severe cardiomyopathy depend on sympathetic nervous system activity to augment myocardial performance. Despite the minimal direct myocardial depressant effects of narcotics, their inhibition of the sympathetic nervous system has an indirect depressant effect on the heart. Thus, titration of narcotics and assessment of the patient's hemodynamic status is important.

Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)

Arrhythmogenic right ventricular cardiomyopathy, also known as *arrhythmogenic right ventricular dysplasia*, is an autosomal dominant genetically inherited disorder. Diagnosis is often made post mortem in patients with ARVC because sudden cardiac death is a common occurrence with this cardiomyopathy. Signs and symptoms can occur during childhood, but more often manifest during

adolescence. During sports-related exercise, severe intolerance caused by increasing myocardial oxygen demand can result in lightheadedness, syncope, and or sudden death. A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in [Table 25.11](#).

Pathophysiology

Fibrous fatty infiltrates invade the right ventricular myocardium and cause myocyte dysfunction and death. As a result, right ventricular cardiac output is decreased. The left ventricle undergoes this type of pathologic change in approximately half of patients with ARVC, and congestive heart failure is a sign of disease progression. Ventricular dysrhythmias are common and range from premature ventricular contractions to ventricular fibrillation. Patients with ARVC may be exquisitely sensitive to increased catecholamine levels, which may further provoke these dysrhythmias.⁹⁶

Anesthetic Considerations

Anesthetic management for patients with ARVC should focus on identification and treatment of fatal dysrhythmias. Many events increase sympathetic nervous system predominance, examples include hypoxia, hypotension, hypercarbia, and surgical stimulation. Excessive catecholamine release can induce fatal dysrhythmias. Amiodarone has been used successfully to treat dysrhythmias in these patients. Prophylactic preoperative administration of antiarrhythmic agents has not been shown to be effective at suppressing ventricular dysrhythmias intraoperatively.⁸⁰

Takotsubo Cardiomyopathy (TCM)

Takotsubo cardiomyopathy has been described as a transient cardiac syndrome that involves left ventricular apical akinesis. The signs and symptoms mimic acute coronary syndrome. This cardiac phenomenon has also been referred to as *stress cardiomyopathy*, *transient-left-ventricular ballooning syndrome*, *apical ballooning*

syndrome, and *broken heart syndrome*. It is most likely to occur in postmenopausal women (approximately 90%, mean age 66 years).⁹⁷ A patient with TCM often complains of chest pain, develops ST segment elevation on ECG, and has elevated cardiac troponin levels consistent with an acute MI. However, a cardiac angiogram will reveal an absence of significant coronary artery disease and severe left ventricular apical enlargement or ballooning. The Mayo Clinic criteria are the most widely adopted diagnostic guidelines for TCM and include (1) akinesis or dyskinesis of LV wall motion abnormalities (ballooning), (2) chest pain, (3) electrocardiographic changes (ST segment elevation or T wave inversion), (4) absence of obstructive epicardial coronary artery disease, and (5) absence of pheochromocytoma or myocarditis.

The exact mechanism by which TCM occurs has not been determined. Coronary artery vasospasm, altered myocardial fatty acid metabolism, and LV outflow tract obstruction have all been postulated. There has also been discussion of a possible genetic link. However, the leading theory is that elevated endogenous catecholamine concentrations cause myocardial toxicity leading to myocardial inflammation and dysfunction. Myocardial stunning, increased LV afterload and decreased SV occur. Physiologic or psychological stress appears to be the trigger for the development of TCM.⁹⁸ The onset of TCM has occurred during general anesthesia. The causes are multifactorial and all elicit physiologic stress and catecholamine release such as anaphylaxis, local administration of cocaine and spine surgery.⁹⁹⁻¹⁰¹ Signs can include rapidly occurring LV failure with or without pulmonary edema, MR, ventricular dysrhythmias, thromboembolism, cardiogenic shock, LV wall rupture and cardiovascular collapse. Echocardiographic characteristics show LV wall motion abnormalities including hypokinesia, akinesia and dyskinesia. Systolic function is significantly reduced, with the reported EF ranging from 20% to 49%.¹⁰²

Currently, the treatment for TCM is supportive. The majority of patients who develop TCM regain normal cardiac function within 4-8 weeks after onset of symptoms. However, mortality rates for TCM are higher than previously estimated expected, and long-term mortality exceeded that of patients with ST-elevation MI.¹⁰³

Summary

As the population continues to age and the incidence of obesity rises, the prevalence of cardiovascular disease will increase to reflect the progressive nature of its pathology. Anesthesia providers are nonetheless able to safely manage these extremely critical patients with respect to the full spectrum of surgical needs. A thorough knowledge of cardiac physiology and function is imperative to maintaining administration of high-quality anesthesia care. Improved patient outcomes are consistently being achieved as better assessment, monitoring, and anesthesia management techniques are developed.

Anesthesia for Cardiac Surgery

Margaret A. Contrera, Melissa Patterson, Mary Ruth Cushing

Despite advances in prevention and treatment, cardiovascular disease (CVD) remains the leading cause of death globally, accounting for 31% of mortality. The World Health Organization estimates that CVD will remain the predominant cause of mortality, resulting in 23.6 million deaths by 2030, mostly from coronary artery disease (CAD).¹ In the United States, CVD causes 1 of every 2.9 deaths, half of them due to CAD.² Because of the aging population, degenerative valvular heart disease (VHD) is on the rise. There are currently more than 290,000 heart valve operations performed annually worldwide. That number is expected to triple by 2050, reaching 850,000 annually.³ Both CAD and VHD lead to heart failure, which impacts more than 5 million Americans. The mortality rate for symptomatic patients is a staggering 45%, worse than that of most cancers.⁴ The Centers for Disease Control and Prevention estimates that \$316.6 billion, or \$1 out of every \$6 in health care costs, is spent on CVD treatment.²

Clearly CVD presents an enormous public health burden. Scientific and medical communities, together with governmental agencies, have worked tirelessly to improve this situation. Consequently, new knowledge about these diseases is accumulating exponentially, and technologic advancements have led to the development of cardiac procedures that were once inconceivable. Percutaneous techniques, hybrid operating rooms (ORs), mechanical assist devices, robotics, and minimally invasive technology now play significant roles in the practice of cardiothoracic anesthesia. The field has become more diverse, exciting, challenging, and rewarding than ever before.

Care of these high-risk patients with regard to the complex, ever-evolving surgical procedures may seem intimidating at first. But as Richard Morris, a pioneer in the field of cardiothoracic nurse

anesthesia advised, “It's simple really; just manage the pump, pipes and volume.” Accordingly, the first half of this chapter is about general cardiac surgery. It begins with a brief overview of the key physiologic principles that form the foundation of the evidence-based anesthetic management strategies for cardiac surgery. Next, cardiopulmonary bypass (CPB) is discussed, including a description of the circuit components and the physiologic implications of bypass. Then, each phase of the perioperative period is examined, and the anesthetic implications are detailed. The second half of the chapter covers anesthetic considerations for specific CVDs and procedures. The pathophysiology of CAD and VHD is briefly reviewed, and anesthetic management of traditional myocardial revascularization and valvular surgery is detailed. New technologic advancements have changed the landscape of cardiac anesthesia. Consequently, the next section is devoted to management of the innovative, minimally invasive approaches that are now used for both valvular surgery and myocardial revascularization. This is followed by a discussion of the devices and procedures that are bringing new hope to the management of end-stage heart failure. The chapter concludes with the anesthetic management of procedures on the ascending aorta and arch that require CPB, including the considerations for deep hypothermic circulatory arrest (DHCA).

Anesthetic Management of General Cardiac Surgery

Key Physiologic Principles

Appropriate management of the cardiac surgical patient begins with a comprehensive understanding of normal cardiac anatomy, physiology, pharmacology, and monitoring, as well as the pathophysiologic response to disease. The reader is advised to review the excellent discussions of these topics found in [Chapters 13, 17, 20 and 25](#) as background for the information presented in this chapter. There are certain key principles that apply to most cardiac surgical patients. An imbalance in myocardial oxygen (O_2) supply and demand, often as a result of CAD, leads to ischemia or infarction. The abnormal pressure and volume loads caused by stenotic and regurgitant valves likewise cause the ventricle to compensate by altering its structure, function, and neurohormonal balance. As a result of these imbalances, the left ventricle (LV) hypertrophies by thickening or dilating. Although each disease starts with a different etiology and pathophysiologic process, with progression of the disease, the limits of compensation are reached, and severe decompensated heart failure then ensues.

Myocardial Oxygen Supply and Demand

Myocardial injury, or infarction, is the most frequent complication following cardiac and major vascular surgery, as well as the primary cause of hospital morbidity and mortality.⁵ Clearly, optimizing the balance between myocardial O_2 supply and demand is of paramount importance ([Fig. 26.1](#)). Coronary perfusion pressure (CPP) is equal to the aortic diastolic blood pressure (BP) minus the left ventricular end-diastolic pressure (LVEDP) divided by the coronary vascular resistance. Normally, CPP is autoregulated between a mean arterial pressure (MAP) of 60 to 140 mm Hg. The heart alters the coronary vascular resistance based on the local metabolic need of the myocardium. MAP is therefore the most useful measure of coronary perfusion in the clinical setting.⁶

However, in patients with CAD, flow is no longer autoregulated after it passes the partial obstruction. Instead, coronary perfusion becomes pressure dependent, especially when the MAP drops below 70 mm Hg^{7,8} (Fig. 26.2). Total coronary blood flow is determined by the perfusion pressure gradient, the time allotted for flow, coronary anatomy, and the coronary vascular resistance. Eighty percent of blood flow to the LV occurs during diastole when the LVEDP is low (Fig. 26.3). Diastolic time progressively shortens as the heart rate increases, resulting in decreased time for coronary perfusion at higher heart rates. The subendocardium or inner third of the heart muscle is at greatest risk for ischemia because it is exposed to the highest LVEDP, especially at the peak of systole.^{9,10} Note that elevations in heart rate and LVEDP not only decrease myocardial blood supply, but also increase myocardial O₂ demand. An increase in heart rate proportionally increases myocardial O₂ demand and decreases diastolic time.⁶ Large epidemiologic studies show that a high heart rate is an independent predictor for cardiac and all-cause morbidity and mortality in men and women with and without CVD.⁷ Increased heart rate is also the most significant cause of perioperative ischemia.⁸ Therefore maintaining an adequate MAP and a low heart rate is critical, particularly in patients who have CAD or an elevated LVEDP. The ideal heart rate must be determined on an individual basis, but less than 70 beats per minute (bpm) is a reasonable guide.¹⁰ Patients with a thick LV, known as *concentric left ventricular hypertrophy* (LVH), have an elevated LVEDP and are best managed with a higher MAP and lower heart rate. Table 26.1 outlines some of the causes of and treatments for alterations in myocardial O₂ supply and demand.

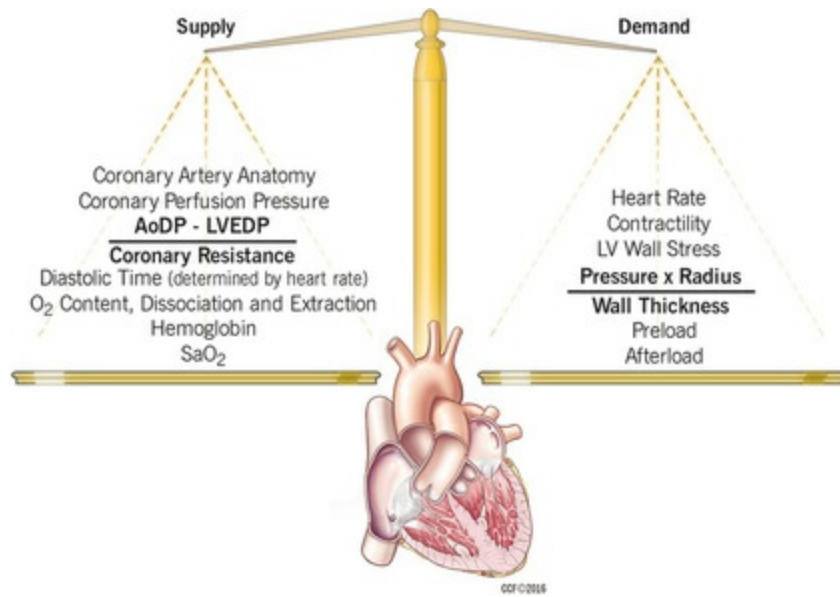

FIGURE 26.1 Myocardial oxygen supply and demand balance. Note, heart rate and left ventricular pressure affect both supply and demand. *AoDP*, Arterial diastolic pressure; *LV*, left ventricular; *LVEDP*, left ventricular end-diastolic pressure; O_2 , oxygen; SaO_2 , arterial oxygen saturation. FIGURE 26.2 Pressure-flow relations of the subepicardial and subendocardial thirds of the left ventricle in anesthetized dogs. In the subendocardium, autoregulation is exhausted and flow becomes pressure-dependent when pressure distal to a stenosis declines to less than 70 mm

Hg. In the subepicardium, autoregulation persists until perfusion pressure declines to less than 40 mm Hg.

Autoregulatory coronary reserve is less in the subendocardium. (Redrawn from Guyton RA, et al. Significance of subendocardial ST segment elevation caused by coronary stenosis in the dog. *Am J Cardiol.* 1977;40:373.)

FIGURE 26.3 Blood flow in the left and right coronary arteries. The right ventricle is perfused throughout the cardiac cycle. Flow to the left ventricle is largely confined to diastole. (From Pappano AJ. Properties of the vasculature. In Koeppen BM, Stanton BA, eds. *Berne & Levy Physiology*. 7th ed. Philadelphia: Elsevier 2018:369.)

TABLE 26.1
Perioperative Management of Alterations in Myocardial O₂ Balance

Causes of Decreased O ₂ Supply	Perioperative Management Strategy
Tachycardia (↓ diastolic time)	Keep heart rate relatively low (less than 70 bpm) Deepen anesthesia during stimulating periods
Hypotension	Maintain high normal MAP; consider phenylephrine ↓ anesthetic depth during less stimulating periods and surgical manipulation that causes ↓ MAP
↑ PaEDP	Consider nitroglycerin Evaluate LV volume with TEE (PaEDP ↑'d in patients with concentric LVH and > LVEDV)
↓ O ₂ Content	Maintain SaO ₂ at greater than 95%
Anemia	Maintain adequate hemoglobin
Causes of Increased O ₂ Demand	Perioperative Management Strategy
SNS stimulation	Maintain adequate depth of anesthesia Anticipate stimulating events and treat preemptively
Tachycardia	Keep heart rate relatively low (less than 70 bpm) Consider β-blockers
↑ Preload	Consider nitroglycerin or diuretic
↑ Contractility	Consider agents that depress contractility (β-blockers/volatile anesthetics)
↑ Afterload	Avoid hypertension Consider vasodilator

↓, Decrease; ↑, increase; bpm, beats per minute; LV, left ventricular; LVEDV, left ventricular end diastolic volume; LVH, left ventricular hypertrophy; MAP, mean arterial pressure; PaEDP, pulmonary artery end-diastolic pressure; SaO₂, saturation of arterial oxygen; TEE, transesophageal echocardiography.

Ischemia Cascade

Myocardial ischemia leads to a cascade of events, as shown in [Fig. 26.4](#).^{11,12} It is important to emphasize that diastolic dysfunction precedes systolic dysfunction, and that regional wall motion abnormalities occur on echocardiography before changes on the electrocardiogram (ECG). An imbalance between myocardial O₂ supply and demand will initially induce diastolic dysfunction, making the ventricle stiff and less compliant. These abnormalities will manifest as an increase in the pulmonary artery end-diastolic pressure (PAEDP). However, multiple studies show that the PAEDP is not specific for ischemia.¹³ Systolic dysfunction causes regional wall motion abnormalities that can be readily detected on transesophageal echocardiography (TEE). TEE is the most sensitive intraoperative monitor for detecting myocardial ischemia.¹² Traditionally, V₅ has been considered to be the single best ECG lead for detecting myocardial ischemia.¹¹ More recently in 2002, Landesberg showed that V₄ and V₃ were more sensitive than V₅ in

detecting perioperative ischemia (87%, 79%, and 66%, respectively).¹⁴ Therefore it is important to ensure that the V lead (brown) of the ECG is correctly placed at the fourth intercostal space midclavicular line. Automated ST segment analysis is also recommended because it has a high sensitivity and specificity for detection of intraoperative ischemia. Three-lead ECG systems are not recommended for monitoring perioperative ischemia.¹⁵

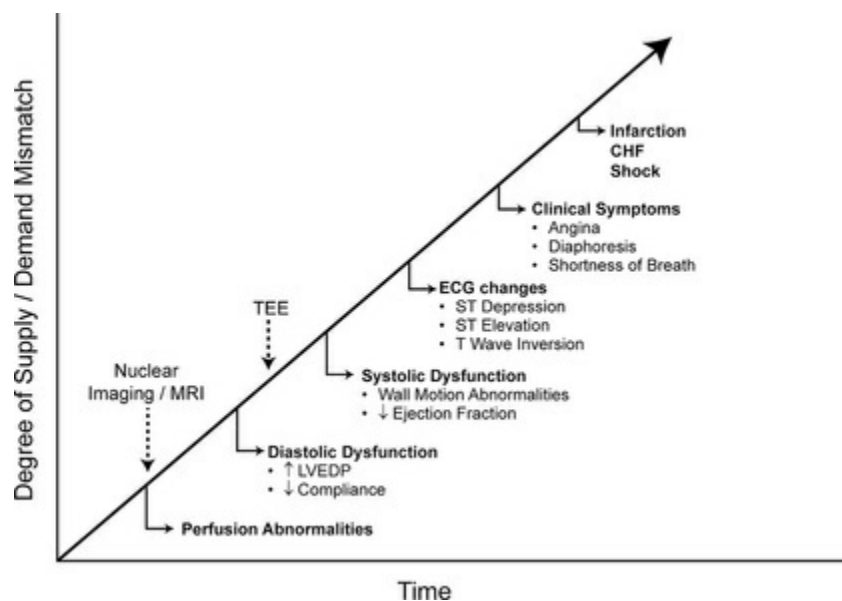

FIGURE 26.4 The ischemic cascade. Pathophysiologic sequence of developing myocardial ischemia correlated with timing of detection using various cardiovascular examinations. *CHF*, Congestive heart failure; *ECG*, electrocardiogram; *LVEDP*, left ventricular end-diastolic pressure; *MRI*, magnetic resonance imaging; *TEE*, transesophageal echocardiography. Preconditioning, Stunning, and Hibernation

When the heart muscle experiences brief periods of ischemia lasting less than 20 minutes, necrosis (or cell death) does not occur, but reversible contractile dysfunction, known as *stunning*, can develop and last for several hours.^{16–18} Many cardiac surgical patients require 12 to 24 hours of inotropic support after CPB, often as a

result of stunning.

Ischemic preconditioning refers to the phenomenon whereby a short period of ischemia improves the heart's ability to tolerate subsequently longer periods of ischemic insult.^{16,19} Multiple animal and clinical studies have demonstrated that volatile agents all produce this preconditioning effect, thereby protecting the myocardium from ischemic and reperfusion injury and reducing infarct size.²⁰⁻²³ Internationally, there is expert consensus support for the use of volatile agents in hemodynamically stable cardiac surgery patients as a means of reducing myocardial damage and death.²¹ Consequently, there has been a resurgence of inhalation anesthesia as a primary technique for cardiac surgery, especially in patients with near-normal ventricular function. The role of volatile agents in unstable patients and those with significant LV dysfunction is less clear, and large randomized controlled trials in cardiac surgery patients are still needed.

When stable coronary plaques cause chronic reductions in coronary perfusion, steady-state ischemia occurs, which results in left ventricular perfusion-contraction matching, or *hibernation*. This phenomenon is considered a self-preservation mechanism whereby left ventricular contractile function is reduced to match the amount of O₂ available.^{24,25} Unlike patients with stunned myocardium, patients with hibernating LVs often have significantly improved function after coronary artery bypass grafting (CABG). Differentiation of ischemic myocardium that is considered “viable” (versus necrosed) is important because approximately 20% to 40% of patients with chronically ischemic LV dysfunction will have significant improvement after revascularization.^{24,26} Nuclear imaging tests and dobutamine stress echocardiography are used to help determine the presence of ischemia and viability. The common cardiovascular tests are outlined in [Table 26.2](#).

TABLE 26.2

Significant Findings on Cardiac Preoperative Testing

Diagnostic Tool	Significant Findings
ECG and/or AECG	ST-T wave changes and presence of significant Q-waves If recent ACS: STEMI vs. NSTEMI vs. unstable angina Presence of significant arrhythmia

	BBB (concern if placing PAC) and LVH Presence of pacemaker
Chest X-ray	Cardiomegaly Pulmonary vascular congestion/pulmonary edema Pleural effusion Presence of pacemaker or implantable cardioverter defibrillator
Echocardiogram	Valve stenosis (grade, cross-sectional area, and gradient) Valve regurgitation (grade and mechanism) LV ejection fraction (systolic dysfunction) Presence and grade of diastolic dysfunction Amount and type (concentric or eccentric) of LVH RV function Pericardial effusion/tamponade Presence of PFO (extra concern for air R to L) Presence of plaque on the ascending aorta (problem cannulating and/or clamping)
Exercise Stress Test	Level and severity of ischemic changes, leads involved. Patient characterization of symptoms Maximum heart rate (target \geq 85% of predicted)
Pharmacologic Stress Test	Adenosine and dipyridamole cause vasodilation in normal coronaries leading to steal or supply ischemia in areas with CAD; used to identify viable myocardium Dobutamine (β -1 agonist) \uparrow HR and contractility inducing demand ischemia; also used for stress echocardiogram
Nuclear Imaging	Radionuclides with varying tracer actions and kinetics are used to evaluate myocardial perfusion and function.
SPECT	Two sets of images are obtained: after stress and after rest. Defects that are initially seen (ischemic area) and fill later indicate viable myocardium, whereas fixed defects indicate scar.
PET	Ischemia shifts metabolism from fatty acids to glucose. An isotope is given that attaches to glucose. The scan can show flow as well as identify areas of uptake; uptake indicates ischemic areas and viable myocardium.
Stress Echo (Exercise or Dobutamine)	Segments with new wall motion abnormalities during stress are considered ischemic and therefore viable myocardium.
Coronary Computed Tomography Angiogram (CTA)	Advanced CT technology and angiography are used to obtain high-resolution, 3D images of the moving heart and great vessels. Able to identify extent and location of plaque in coronaries and aorta.
Cardiac Catheterization	LVEDP Cardiac index Presence of L main, triple vessel disease, or equivalent Quality of targets Type and timing of PCI Type, location, and timing of coronary stents Presence of pulmonary hypertension

\uparrow , Increase; *ACS*, acute coronary syndrome; *AECG*, ambulatory electrocardiogram; *BBB*, bundle branch block; *CAD*, coronary artery disease; *CT*, computed tomography; *ECG*, electrocardiogram; *HR*, heart rate; *L*, left; *LV*, left ventricle; *LVEDP*, left ventricular end-diastolic pressure; *LVH*, left ventricular hypertrophy; *NSTEMI*, non-ST elevation myocardial infarction; *PAC*, pulmonary artery catheter; *PCI*, percutaneous coronary intervention; *PET*, positron emission tomography; *PFO*, patent foramen ovale; *R*, right; *RV*, right ventricle; *SPECT*, single-photon emission computed tomography; *STEMI*, ST elevation myocardial infarction.

The need to balance myocardial O₂ supply and demand is not

limited to patients with CAD. Angina and myocardial infarction (MI) in patients with normal coronary arteries were demonstrated as far back as 1959.²⁷ Many other patients, such as those with chronic hypertension, aortic stenosis (AS), or obstructive cardiomyopathy, will also benefit from a relatively high perfusion pressure and low heart rate because of the structural, functional, and neurohumoral changes that occur in the ventricle in response to abnormal pressure or volume loads.

Heart Failure

Heart failure is a complex pathophysiologic process that causes a clinical syndrome characterized by pulmonary congestion resulting from the heart's inability to fill with or eject blood in a sufficient quantity to meet tissue requirements.²⁵ The heart was once thought of as simply the pump of the circulatory system, but it is now known that it evolves into an “endocrine organ” under stress, actively secreting neurohormonal factors in an attempt to meet the needs of the body. For example, atrial natriuretic peptide (ANP) is released from the atria in response to volume overload, and B-type natriuretic peptide (BNP) is released primarily from the ventricles in response to increased wall stress. These peptides help protect the myocardium by inducing physiologic effects such as diuresis, natriuresis, and vasodilation.²⁸ In fact, BNP has been recognized as a powerful biomarker for diagnosis, determination of severity, and prognostication of heart failure.²⁹ Heart failure is caused by an insult that alters perfusion and leads to a state of neurohumoral imbalance. Activation of the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system induces a host of pathologic responses. Many patients with heart failure will receive multimodal drug therapy aimed at interrupting the response and slowing disease progression⁴ (Fig. 26.5). β -Blockers, angiotensin-converting enzyme inhibitors (ACEIs), and aldosterone antagonists can have a synergistic effect when combined with anesthetics that leads to intraoperative hypotension. Nevertheless, it is recommended that medications used to control the patient's heart failure should be continued in the perioperative period, as their benefits are well-documented.^{25,28–30} If ACE inhibitors are withheld to prevent intraoperative hypotension, then they should be

restarted early in the postoperative period, as soon as the patient is hemodynamically stable.³⁰ Based on the results of multiple large-scale randomized controlled clinical trials, it is estimated that 465 lives are saved for every thousand patients treated with a combination of β -blockers, ACE inhibitors, and aldosterone antagonists.³¹

FIGURE 26.5 Sites of action of drugs used for acute left ventricular (LV) failure. Note opposing effects of (1) vasoconstriction resulting from α -adrenergic effects (norepinephrine, high doses of epinephrine or dopamine), and (2) vasodilation resulting from vascular cyclic adenosine monophosphate (cAMP) elevation from β_2 -effects or phosphodiesterase (PDE) inhibition. *alpha*, α -adrenergic; *BP*, blood pressure; *pr*, pressure; *V-1a*, vasopressin agonist action on receptor subtype 1a (Figure © L.H. Opie, 2012. In Opie LH, Gersh BJ. *Drugs for the Heart*. 8th ed. Philadelphia: Elsevier; 2013:172.)

Left Ventricular Failure and Remodeling.

In the face of sympathetic activation coupled with alterations in

perfusion, pressure, and volume, the heart changes its size, shape, and function; that is, it *remodels* itself in an attempt to maintain cardiac output (CO). *Supply ischemia* causes an increase in ventricular compliance (dilation) and a decrease in contractility, whereas *demand ischemia* reduces compliance (stiffening) without initially impacting contractility.^{24,25} The primary characteristics of remodeling are: hypertrophy or dilation, myocyte death, and increased interstitial fibrosis. The clinical impact manifests as a change in systolic and diastolic function. [Figs. 26.6](#) and [26.7](#) help summarize and visualize the process.

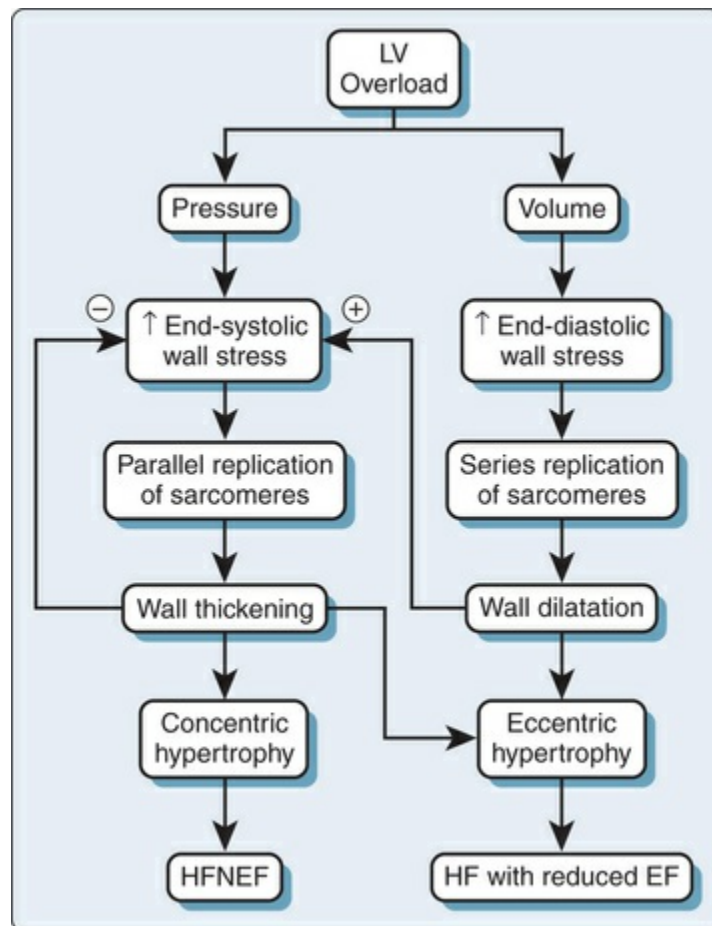

FIGURE 26.6 Left ventricular (LV) pressure and volume overload produce compensatory responses based on the nature of the inciting stress. Wall thickening reduces (–) and chamber dilation increases (+) end-systolic wall stress, as predicted by Laplace’s law. LV pressure-overload hypertrophy has been linked to heart failure with normal ejection fraction (HFNEF), but LV volume overload most often causes heart failure (HF) with reduced ejection

fraction (EF). (From Pagel PS, Freed JK. Cardiac physiology. In Kaplan JA, et al. eds. *Kaplan's Cardiac Anesthesia: For Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia: Elsevier; 2017:160.)

FIGURE 26.7 Ventricular remodeling is a compensatory mechanism in response to abnormal pressure and volume loads. **A**, Normal heart. **B**, Concentric LVH in response to a pressure overload leads to diastolic failure. **C**, Eccentric LVH in response to a volume overload or myocardial infarction leads to systolic failure. *LVH*, Left ventricular hypertrophy.

Systolic Dysfunction.

As demonstrated in [Fig. 26.7A](#), supply ischemia resulting from MI or chronic volume overload of the LV causes *eccentric* hypertrophy or dilation. The chamber size increases in an attempt to preserve stroke volume (SV). In the dilated state, the heart loses its normal elliptical football shape and becomes more spherical, resembling a basketball.²⁶ In this shape, the heart is unable to contract effectively (systolic dysfunction), and the mitral apparatus is stretched, potentially to a point that results in mitral regurgitation (MR). Of patients with heart failure, 35% to 50% will experience MR.³² The degree of systolic dysfunction is commonly expressed as an ejection fraction (EF). The EF is calculated as SV divided by end-diastolic volume (EDV). According to the American Society of Echocardiography's guidelines, a normal EF is 55% or greater.

Dysfunction is graded as mild (45% to 54%), moderate (30% to 44%), and severe (less than 30%). When the SV is reduced, the body compensates by activating the SNS to raise the resting heart rate in an effort to maintain CO. Systolic heart failure (SHF) is caused by CAD, dilated cardiomyopathy, chronic volume overload (regurgitant valves, high output failure), and the later stages of chronic pressure overload (AS and chronic hypertension). MI causes regional defects that can eventually encompass the entire myocardium, whereas other causes of heart failure typically reduce global function from the onset.²⁸ As shown in Fig. 26.6, SHF is associated with a volume overload of the LV that is managed using multiple drug therapies, as shown in Fig. 26.5.

Diastolic Dysfunction.

Diastolic dysfunction is a more difficult concept to explain, but one that is equally important. Pulmonary congestion and all the symptoms of heart failure can indeed develop with a normal EF. In fact, diastolic heart failure (DHF) is often called *heart failure with preserved EF* (greater than 40%) (see Fig. 26.6). *Demand ischemia*, resulting from chronic pressure overloading secondary to stenotic heart valves, obstructive cardiomyopathy, chronic hypertension, or obesity, causes the myocardium to thicken (*concentric hypertrophy*) and compliance to decrease (see Fig. 26.7).⁴ Pulmonary congestion develops because the fibrosed, nondistensible LV, with an increased LVEDP, is unable to fill adequately, despite near-normal systolic function. Diastolic failure is graded from class I to IV based on echocardiographic examination findings.³³ The LV with concentric hypertrophy is prone to ischemia; therefore maintenance of a high MAP and slow normal heart rate is crucial.³⁴ Hypotension should be treated promptly, usually with phenylephrine to avoid rapid decompensation, which can potentially lead to cardiac arrest. If the patient arrests, chest compressions rarely generate enough pressure to perfuse the hypertrophied, noncompliant LV. The mortality and hospitalization rates are similar in both systolic and diastolic failure.^{28,34} Table 26.3 compares the characteristics of patients with systolic and diastolic failure, and Table 26.4 outlines the anesthetic management strategies for systolic and diastolic dysfunction. Oftentimes, as DHF progresses, SHF will develop, and the two will

TABLE 26.3

Characteristics of Patients With Diastolic and Systolic Heart Failure

Characteristic	Diastolic HF	Systolic HF
Age	Often in the elderly	Usually 50–70 years
Gender	Often in females	Often in males
LV EF	Preserved, ≥ 40%	Depressed, ≤ 40%
LV cavity size	Normal with concentric LVH	Dilated with eccentric LVH
Chest x-ray	Congestion ± cardiomegaly	Congestion + cardiomegaly
HTN	+++	++
DM	+++	++
Previous MI	+	+++
Obesity	+++	+
COPD	++	0
Sleep apnea	++	++
Dialysis	++	0
Atrial fibrillation	+ Usually paroxysmal	+ Usually persistent
Gallop rhythm	4th heart sound	3rd heart sound

+, Occasionally associated with; ++, often associated with; +++, usually associated with; 0, no association; *COPD*, chronic obstructive pulmonary disease; *DM*, diabetes mellitus; *EF*, ejection fraction; *HF*, heart failure; *HTN*, hypertension; *LV*, left ventricle; *LVH*, left ventricular hypertrophy; *MI*, myocardial infarction.

TABLE 26.4

Anesthetic Considerations for Systolic and Diastolic Dysfunction

	Systolic Dysfunction	Diastolic Dysfunction
Preload	Already ↑, avoid overload, especially coming off pump NTG helps reduce preload and ↑ subendocardial perfusion	Volume will be needed to stretch noncompliant LV Evaluate with TEE as PaEDP ↑ and > LVEDV
Contractility	Reduced, avoid agents that cause further reductions May need inotropic support	Usually good, but caution with agents that depress function
Afterload	Reductions will enhance forward flow as long as coronary perfusion pressure maintained SNP works well if volume is adequate	Already ↑ Higher MAP needed to perfuse thick myocardium Treat hypotension aggressively with phenylephrine
Heart rate	Usually high normal due to sympathetic	Slow normal to maximize diastolic time

	activation	for coronary perfusion and ↓ MVO ₂ Prone to ischemia Maintain SR; dependent on atrial kick (cardiovert early)
CPB	Expect large pump volumes Consider ultrafiltration, diuretic	Pump volume normal

↓, Decreased; ↑, increased; CPB, cardiopulmonary bypass; LV, left ventricle; LVEDV, left ventricular end-diastolic volume; MAP, mean arterial pressure; MVO₂, myocardial oxygen consumption; NTG, nitroglycerin; PaEDP, pulmonary artery end-diastolic pressure; SNP, sodium nitroprusside; SR, sinus rhythm, TEE, transesophageal echocardiography.

Right Ventricular Failure.

Right heart failure (RHF) is most often secondary to left heart failure, but can also be caused by pulmonary hypertension (PHTN) or a right-sided MI. RHF causes systemic venous congestion, hepatomegaly, and peripheral edema.^{25,28} Management of RHF can be more difficult than that of left-sided failure because fewer options exist for unloading and supporting the right ventricle. The goal in managing RHF is to improve contractility while reducing right heart afterload. Therefore conditions or medications that increase right heart afterload, including those used to treat hypercarbia, hypoxemia, acidosis, and similar conditions, which can potentially increase pulmonary pressure and exacerbate PHTN, should be avoided. Nitrous oxide and desflurane can also increase pulmonary pressures, so they too should be avoided.²⁸ Normally, the right heart is perfused throughout the cardiac cycle (see Fig. 26.3); however, when the right ventricle is distended, coronary perfusion occurs primarily during diastole, as it does in the LV.²⁴

Cardiopulmonary Bypass

Principles

Most cardiac surgeries must be accomplished with the aid of CPB. The machine is operated by a perfusionist, but it is imperative that the anesthetist have a clear understanding of the components and physiologic impact of CPB. The purpose of CPB is to provide a motionless, bloodless heart for the surgical procedure. This goal is achieved by temporarily diverting venous blood away from the heart to an extracorporeal circulation apparatus that adds O₂

removes carbon dioxide (CO₂) and then filters the blood before returning it to the body, most often via the ascending aorta. The CPB circuit is continuous with the systemic circulation and provides artificial ventilation, perfusion, and temperature regulation while diverting the blood from the surgical field. The technique results in stopping nearly all blood flow to the heart and lungs. To stop the heart's electrical activity and to protect it during the procedure, the heart is intermittently perfused and cooled with a chemical solution called *cardioplegia*. Although the goal is to provide near-physiologic hemodynamics and acid/base balance, the technique is nonphysiologic. A near-normal cardiac index (CI) is usually maintained with an arterial flow of 2.0 to 2.4 L/min per m², but it is nonpulsatile. There is controversy over what is the most appropriate MAP on bypass, but most advocate no less than 50 to 60 mm Hg. Older patients, or those with known carotid disease, should have a higher MAP, closer to 60 to 70 mm Hg, to assure that there is adequate cerebral perfusion pressure.⁸ The patient's blood and blood components are exposed to the nonendothelial surfaces, which increase the incidence of platelet dysfunction and coagulopathy. CPB incites a host of inflammatory responses; these are outlined after the discussion of the circuit components.

Basic Circuit

The CPB machine consists of five basic components: a venous reservoir, a main pump, an oxygenator, a heat exchanger, and an arterial filter (Fig. 26.8). The following is a simple explanation of full CPB: venous (deoxygenated) blood is drained from the right side of the heart via a cannula in the atrium and vena cava and carried by tubing to a reservoir; the main pump (centrifugal or roller) then propels the blood to an oxygenator and a heat exchanger; and the oxygenated blood passes through an arterial line filter before returning to the arterial circulation via a cannula in the ascending aorta to perfuse the rest of the body. The modern bypass machine also performs several other functions, including delivering cardioplegia by means of accessory pumps. The heart is vented, and blood is salvaged from the field, by means of suction devices.

FIGURE 26.8 A typical cardiopulmonary bypass circuit interfaced with a patient. *ALF*, Arterial line filter; *K*, potassium; *LV*, left ventricular. (From Miller RD. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015:2032.)

Cannulae.

The CPB circuit includes cannulae and tubing made of medical grade polyvinyl chloride with a biocompatible coating to decrease the inflammatory response associated with CPB and to preserve blood components. *One-, two-, or multi-stage* (meaning more than one hole to drain the blood) venous cannulae are used to remove the deoxygenated blood from the heart. A large-bore two-stage or multistage venous cannula that drains blood from both the right atrium and the inferior vena cava (IVC) is used for CABG and aortic valve (AV) procedures in which the heart remains closed and small amounts of retained blood will not interfere with the surgery (Fig. 26.9). Open-cavity procedures, such as mitral, pulmonic, and tricuspid valve surgery, or procedures that repair defects such as atrial septal defects, patent foramen ovale (PFO) defects, or ventricular septal defects, all require a bloodless field. For such procedures, two separate single-stage venous cannulae are individually inserted into the superior and inferior vena cava, and

the vessels are snared with elastic loops to prevent systemic venous blood from entering the heart (Fig. 24.10). This technique is also known as *bicaaval* or two-vessel cannulation.

Prime.

Prime is the fluid used to fill the CPB circuit and components. It is composed of an isotonic balanced electrolyte solution, such as lactated Ringer's, Plasmalyte-A, or Normosol-R, that closely matches the principal ionic composition of blood. During setup, the perfusionist must take great care to de-air the circuit. Traditionally, the priming volume for the CPB is 1 to 2 L. However, the

development of minimally invasive cardiac procedures necessitated the use of smaller cannulae and tubing to enable the surgeon to visualize the field. Medications and other solutions are often added to the prime for a variety of purposes: colloid to decrease postoperative edema, blood to treat anemia, mannitol to promote diuresis, heparin to ensure adequate anticoagulation, and bicarbonate to treat acidosis. Upon instituting CPB, the prime added to the circulating blood volume causes dilutional anemia, which will often result in a decrease in hematocrit (22% to 25%). The dilution offsets some of the increase in blood viscosity that occurs when the blood cools during CPB.

Venous Reservoir.

CPB is initiated when the perfusionist removes a clamp that occludes the tubing connecting the venous cannulae to the venous reservoir (see [Fig. 26.8](#)). The venous reservoir is typically hard-shelled and divided into two compartments, one for the venous drainage from the heart and the other for the blood suctioned or vented directly from the surgical field. This portion of the reservoir is known as the *cardiotomy*, and is discussed in detail later.

Traditionally, blood drains from the patient to the reservoir by gravity. The rate of venous drainage is determined by the size and placement of the cannulae, the height of the bed, and the patient's intravascular volume status. With the introduction of minimally invasive techniques, gravity drainage proved to be inadequate due to the small size of the cannulae and tubing. Subsequently, the practice of vacuum-assisted venous drainage (VAVD) was established. A vacuum regulator is added to the venous reservoir with a piece of Y tubing, and a pressure of -40 mm Hg is applied. This Y tubing is used to turn on the suction or open the system to atmospheric pressure. Improved drainage can facilitate surgical exposure and decrease the necessity of adding more crystalloid and/or blood to the CPB circuit. The inherent risks include hemolysis of blood cells and air embolism. VAVD at a suction of -40 mm Hg causes less hemolysis than when the suction is increased to -80 mm Hg.³⁵ It is critical that the fluid level in the venous reservoir be kept sufficiently high to prevent air entrainment from the main pump, which can result in an air

embolism. An alarm is incorporated into the venous reservoir to alert the perfusionist if the fluid level drops below a specified level. The perfusionist may add fluid and medications to the venous reservoir.

Main Pump.

Blood is propelled through the CPB machine by an electrical pump (see Fig. 26.8). Two types of pumps are available. A *roller pump* produces flow by subtotally compressing large bore tubing against a tract and propelling the blood forward. Constant nonpulsatile flow is produced that is directly proportional to the number of revolutions per minute of the roller heads, regardless of arterial resistance in the circuit. A *centrifugal pump* uses a magnetically controlled impeller that rotates rapidly, creating a pressure drop that causes blood to be sucked into the housing and ejected. A major difference between the two pumps is that the flow from the centrifugal pump will vary with changes in preload and afterload. For this reason, a flowmeter must be attached to the arterial side of the pump. The roller pump is economical and simple to use. However, unlike the centrifugal pump, it has the disadvantage of increased destruction of blood elements. As a result, centrifugal pumps are replacing roller head pumps in contemporary practice. In the event of a power failure, a hand crank can be used to manually operate either pump.

Oxygenator.

The oxygenator performs the functions of oxygenating venous blood and removing CO₂ (see Fig. 26.8). Historically, bubble oxygenators were used, but today only membrane oxygenators are in use. The membrane oxygenator is a coated bundle of hollow microporous polypropylene fibers that are tightly wound to create a large surface area. Blood flows around the tightly packed fibers, and gas flows through the fibers. The gas, consisting of O₂ or a mixture of O₂ and medical-grade air, diffuses passively across the membrane and into the blood. The O₂ level in the blood can be controlled by changing the fraction of inspired O₂ (FiO₂), or O₂ concentration. The amount of CO₂ removed from the blood is

controlled by changing the liter gas flow rate or “sweep” of gas through the oxygenator. Volatile anesthetic can also be added to the fresh gas inlet that enters the oxygenator to maintain appropriate blood concentration and depth of anesthesia while on CPB.

Heat Exchanger.

The blood enters a heat exchanger either separately or in combination with the oxygenator (see [Fig. 26.8](#)). The heat exchanger is usually made of stainless steel tubes with heated or cooled water flowing through them. Blood flows around the tubes, and the temperature is adjusted to the desired level. Traditionally, patients were cooled in an effort to protect the heart and other vital organs during CPB. Today, active cooling is less common, and the patient's temperature is allowed to naturally drop or *drift* while the surgery is performed. The patient is then actively rewarmed in preparation for the termination of CPB.

For some procedures, the patient is actively cooled to decrease the metabolic rate. This process is discussed later in the chapter (see [Surgery on the Ascending Aorta and Aortic Arch](#)). As the patient is rewarmed, gas solubility decreases, and it is possible for air bubbles to form in the CPB circuit. Consequently, the oxygenated blood passes through a filter before it is returned to the patient.

Arterial Filter.

The final phase of the CPB circuit requires the blood to pass through an arterial filter before returning to the arterial cannula and the rest of the body (see [Fig. 26.8](#)). The arterial filter has a pore size of 21 to 40 μm , and acts as an air bubble trap and particulate filter, ideally preventing thrombi, fat globules, calcium, and tissue debris from entering the circulation. The arterial cannula is most often placed in the ascending aorta, but alternate sites include the femoral or the subclavian artery.

Accessory Pumps and Devices

Cardiotomy and Basket Suction.

As illustrated in [Fig. 26.8](#), the perfusionist also operates several accessory roller pumps (generally located to the right of the main

pump), used to control suction devices and deliver cardioplegia. A surgical assistant helps improve the surgeon's view by aspirating blood from the surgical field using a Yankauer or other suction tip. A "basket" type suction device can be placed in an open cardiac cavity to help drain the blood (see [Fig. 26.8](#)). This *shed* blood can then be returned to the patient in one of two ways. First, the blood can be returned to a portion of the venous reservoir known as the *cardiotomy*. The cardiotomy portion of the venous reservoir has a separate integrated filter that defoams the blood and removes air and debris that is picked up by the suction tip (*pump sucker*) used in the surgical field or the vents used to drain the heart. Blood returned via the cardiotomy may contain fat, bone, and other debris. For that reason, some surgeons prefer an alternate method to return this blood, which is using a separate cell-saver reservoir. Cell-saver blood is later centrifuged, washed, and returned to the patient. Research shows that systemic inflammatory markers decrease when shed blood is not returned to the patient undergoing CABG on CPB.³⁶⁻³⁸ The disadvantage of this approach is that the volume of blood in the pump is reduced, especially if there is significant bleeding. If bleeding is a problem, the cell-saver blood can be washed and returned to the venous reservoir, but this requires time for processing.

Left Ventricular Vent.

The LV vent is a catheter placed in the LV through the right superior pulmonary vein for the purpose of draining blood that has accumulated in the cavity (see [Fig. 26.8](#)). Although the majority of blood is diverted from the heart during CPB, small amounts of blood may enter the LV from the bronchial arteries (which arise directly from the aorta or the intercostal arteries) or the Thebesian vessels (coronary veins that drain directly into the heart). Blood and cardioplegia can also fill the LV if the patient has aortic insufficiency (AI). This volume can cause the LV to distend, raise LVEDP, and compromise preservation by opposing the cardioplegia flow into the coronary arteries. Prior to inserting the vent, it is placed in a bowl of water to confirm that it is suctioning rather than blowing, because accidental blowing of the vent could lead to an air embolism. The vented blood returns to the

cardiotomy portion of the venous reservoir.

Cardioplegia Pump.

The perfusionist controls the infusion of cardioplegia by means of an accessory roller pump (see [Fig. 26.8](#)). A separate heat exchanger is utilized to regulate temperature, rate, and pressure of cardioplegia administration. Cardioplegia is discussed later (see [Myocardial Preservation](#)).

Anticoagulation

Systemic anticoagulation is always essential prior to cannulation and initiation of CPB. The absence of proper anticoagulation can cause clots to form in the pump, which can lead to serious neurologic injury or death. Heparin, derived from porcine intestinal mucosa or bovine lung, is the preferred anticoagulant for cardiac surgery. It is a mucopolysaccharide that potentiates circulating antithrombin (AT III) by binding to AT III and thrombin. Heparin increases the inhibitory effect of AT III on the procoagulant effect of thrombin by binding to it by one thousand–fold. Heparin increases the speed of the reaction between AT III and multiple clotting factors, including factors II, IX, X, XI, XII, and XIII. The standard cardiac dosage is 300 to 400 units/kg, preferably administered through a central venous line. Adequate anticoagulation is most commonly measured with point-of-care testing that includes activated clotting times (ACT) or heparin concentration assays (Hepcon). A baseline ACT is obtained sometime prior to heparin administration. The normal value is approximately 80 to 120 seconds. The ACT is measured 3 to 5 minutes after heparin administration. An ACT of more than 400 seconds (or more than 480 seconds, in some centers) is necessary before CPB is initiated. The lower ACT limit of 400 seconds was determined in 1978 using monkeys on CPB. This level prevented the appearance of fibrin monomers in the CPB circuit.³⁹ A heparin concentration monitor such as Hepcon HMS Plus (Medtronic, Inc., Minneapolis, MN) can be used in place of, or in addition to, the ACT measure. The Hepcon generates a heparin dose response (HDR) curve that can then be used to calculate the most appropriate dose of heparin to initiate

CPB and maintain an adequate level of anticoagulation during bypass. The amount of protamine needed to reverse the heparin after bypass is also calculated. The level of anticoagulation should be checked every 20 to 30 minutes during bypass so that more heparin can be administered as needed to maintain a safe level of anticoagulation.

Patients who have been recently exposed to heparin may become “heparin resistant” and require higher doses of heparin to obtain therapeutic anticoagulation. Heparin resistance is defined as an ACT of less than 480 seconds despite administration of 400 to 500 units/kg of intravenous (IV) heparin. AT III deficiency should be suspected if the patient does not become anticoagulated with additional heparin administration. AT III deficiency can be treated empirically with 2 units of fresh frozen plasma (FFP), AT III concentrate, or recombinant AT III (rh AT III). rh AT III has been shown to be effective in reducing heparin resistance by increasing circulating AT III, without exposing patients to FFP.⁴⁰

Heparin-induced thrombocytopenia (HIT) is an immune reaction that occurs as a direct consequence of exposure to heparin. A comprehensive review of this disorder is found in [Chapter 38](#). The ¹⁴C-serotonin release assay and an enzyme-linked immunosorbent assay that detects antibodies to the platelet factor 4 are used to definitively diagnose the disorder. For patients with a history of HIT, but a negative HIT antibody screen at the time of cardiac surgery, the American College of Chest Surgeons' guidelines recommend the use of heparin only during CPB. There is a decreased risk of a patient being rediagnosed with HIT if the prior diagnosis of HIT occurred more than 3 months before the scheduled cardiac surgery. Use of an anticoagulant other than heparin is recommended in the preoperative and postoperative period. In all cases, there should be no heparin added to the flush solution or heparin lock IV ports, and heparin-bonded catheters are avoided. Surgery should be postponed, if feasible, in patients with acute HIT and those who are antibody-positive (subacute HIT). If urgent surgery is required, bivalirudin is suggested over other nonheparin anticoagulants and over heparin plus antiplatelet agents.⁴¹

Myocardial Preservation

Mild to moderate systemic hypothermia and cold cardioplegia are used for myocardial preservation. The patient can be actively cooled by the CPB circuit, or his or her temperature can be allowed to drift toward the ambient room temperature. Some surgeons cool the heart topically by packing icy slush around it. The goal is to achieve hypothermic diastolic circulatory arrest to decrease the metabolic rate, O₂ consumption, and excitatory neurotransmitter release, and to preserve high-energy phosphate substrates.⁸ The brain also benefits from the hypothermia, and may be at least partially shielded from neurologic injury as a result. The cerebral metabolic rate decreases 6% to 7% for every degree Celsius decrease in brain temperature.

A hyperkalemic crystalloid solution mixed with blood is the most commonly used cardioplegia solution today. The ratio of the mix varies, but is most often a 4 : 1 blood to crystalloid solution (i.e., Buckberg solution). The exact composition of cardioplegia solution is institution-driven, but the first dose (*induction dose*) is cold (2°C to 5°C), and contains 20 to 30 mEq/L of potassium. Maintenance doses are also cold, and contain 12 to 16 mEq/L of potassium. The goal is to maintain a myocardial temperature between 8°C and 10°C.⁴² An alternative, del Nido cardioplegia solution, which was historically used in pediatric heart surgery, is gaining popularity in the adult cardiac surgical arena. It consists of a 1 : 4 blood to a non-glucose-based crystalloid solution that is delivered as a single dose that lasts up to 180 minutes. It has been shown to be used effectively and safely in adult isolated valve surgery, and is associated with lower insulin requirements and potential time and cost savings.⁴³

The amount of cardioplegia given in any single dose can be based on time, volume, or myocardial temperature, according to the surgeon's preference. It is generally readministered every 15 to 20 minutes while the aorta is clamped. ECG activity and/or an increase in myocardial temperature indicate that cardioplegia may need to be redosed at shorter intervals.

There are two possible approaches to delivering cardioplegia: *antegrade*, delivered down the coronary arteries; or *retrograde*, via the coronary sinus and cardiac veins. The first dose of cardioplegia is usually antegrade, and it is given just after placement of the

aortic clamp. A catheter is inserted into the aortic root, just proximal to the aortic clamp, and cardioplegia is administered into the root and flows antegrade down the coronary arteries. Hypothermic diastolic circulatory arrest usually follows in 1 to 2 minutes, depending on how well the heart is perfused. Antegrade cardioplegia can also be given directly down the coronary ostia with a direct catheter when the aorta is opened for surgeries that involve the aorta or AV, especially with aortic regurgitation (AR). In CABG surgery, it is also infused directly into the new vein or arterial bypass grafts once the distal anastomosis is completed. Maintenance cardioplegia is administered every 15 to 20 minutes to maintain asystole. Myocardial preservation is occasionally incomplete if the cardioplegia does not reach the entire myocardium, either because the coronary arteries are blocked by atherosclerotic disease, or because the solution has leaked into the LV due to an incompetent AV. When myocardial preservation is inadequate, there may be difficulty achieving diastolic arrest, and electrical activity may reappear on the ECG between doses of cardioplegia. Additionally, the fluid that leaks into the LV when the patient has AR can cause the ventricle to distend. The increased pressure caused by the distension opposes the antegrade flow of the cardioplegia in the coronary arteries, thereby increasing the risk of myocardial ischemia. The purpose of the LV vent is to suction out this fluid and prevent distension. In these cases, retrograde cardioplegia can significantly improve myocardial preservation. In fact, many surgeons choose to maximize myocardial protection by routinely giving both antegrade and retrograde cardioplegia.

In the retrograde approach, a catheter is blindly inserted into the right atrium or directly inserted after CPB and advanced into the coronary sinus, the largest venous drainage vessel of the heart. To place the catheter, the surgeon often lifts the heart to help locate the sinus and advance the catheter. If this catheter is placed before CPB, lifting and manipulation of the heart frequently results in dysrhythmias and hypotension. It is not unusual for this maneuver to cause atrial fibrillation (AF). Synchronized cardioversion of the AF may be required if the patient becomes hemodynamically unstable. Once the catheter is in place, cardioplegia is administered to the myocardium in a retrograde fashion through the cardiac

veins. Retrograde perfusion protects the myocardium that is distal to the coronary obstructions.

Just before releasing the aortic cross-clamp, many surgeons administer a single terminal dose of warm blood (37° C) cardioplegia. This so-called “hotshot” contains metabolic substrates (i.e., glucose, glutamine, and aspartate), which have been found to accelerate myocardial recovery from global ischemia.⁴⁴

Blood Conservation

A review of over four million cardiac surgery patients between 1999 and 2010 showed that blood product utilization was increasing and peaked at 34% in 2010, despite publication of blood conservation guidelines by the Society of Thoracic Surgeons (STS) in 2007.⁴⁵ Currently, 10% to 15% of the nation's blood supply is used for patients having cardiac surgery. The risks of transfusion are well-documented (see [Chapter 22](#)), and blood transfusions during cardiac surgery are associated with worse short-term and long-term survival,^{46,47} including a dose-related increase in the number of postoperative infections with the number of red blood cell (RBC) transfusion units.⁴⁸ Additionally, the donor blood supply is either stable or decreasing.^{49,50} Blood is considered a finite, scarce, and expensive resource, and there is a national effort to limit its use. Three preoperative risk factors have been linked to bleeding and blood transfusion: (1) advanced age (70 years or older); (2) low red cell volume either from preoperative anemia and/or small body size; and (3) urgent or complex surgery involving prolonged CPB times.⁵¹

In 2011, the STS and the Society of Cardiovascular Anesthesiologists (SCA) published instructions for blood conservation in clinical practice guidelines.⁵¹ Practitioners of cardiac anesthesia are encouraged to review this important document; this chapter discusses only the highlights. The recommended techniques that promote the conservation of blood and blood products include the administration of antifibrinolytics, blood salvage, limiting the quantity of pump prime, ultrafiltration when appropriate, and the development of multidisciplinary blood management teams.

Antifibrinolytics.

Antifibrinolytics are commonly administered to cardiac surgical patients requiring CPB. Use of antifibrinolytics reduces surgical bleeding and decreases the incidence of blood transfusion.⁵¹

Aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron) are both lysine analogs that inhibit plasmin, the key enzyme in the fibrinolytic cascade. Both drugs form a reversible complex with plasmin that then inhibits fibrinolysis, or the natural breakdown of clots. Dosing regimens vary, but a common recommendation for aminocaproic acid is a 50 mg/kg bolus over 20 to 30 minutes, followed by an infusion of 25 mg/kg per hr into the immediate postoperative period. A standard dosing regimen of tranexamic acid is 10 mg/kg over 20 minutes, followed by 1 to 2 mg/kg per hr maintenance infusion into the immediate postoperative period. Dosing regimens vary among institutions. Tranexamic acid is known to be five to ten times more potent than aminocaproic acid, but also more expensive.

Blood Salvage.

Blood that is suctioned from the surgical field while the patient is not on CPB, as well as the residual blood that remains in the CPB circuit at the end of bypass, should be directed into a centrifugal red cell salvage device. As previously discussed, the blood aspirated from the field during CPB can return to the pump cardiectomy or to the cell-salvage reservoir, depending on the surgeon's preference. The shed blood is stored in a reservoir until it reaches a quantity or weight specified by the device manufacturer. The blood is then "washed", a process that removes the serum, coagulation factors, and platelets. The red cells are preserved and placed in a bag that can then be infused into the patient. Cell-salvaged blood has a hematocrit of approximately 55% to 70%. Infusing large quantities of salvaged blood can contribute to a dilutional coagulopathy, because this blood is devoid of coagulation factors and platelets. Contraindications to the use of salvaged blood include infection and the use of topical hemostasis agents. Malignancy was previously considered a contraindication to salvage administration. However, the new guidelines state: "In high-risk patients with known malignancy who require CPB, blood

salvage using centrifugation of salvaged blood from the operative field may be considered because substantial data supports benefit in patients without malignancy and new evidence suggests worsened outcome when allogeneic transfusion is required in patients with malignancy.” Blood shed from mediastinal chest tubes can also be salvaged, washed, and reinfused.⁵¹

Limiting Pump Prime.

Traditionally, the addition of pump prime to the patient's blood volume at the initiation of CPB resulted in significant hemodilution. Several mechanisms have been devised that help limit the volume of pump prime. Minicircuits that require a smaller volume of pump prime are available, and should be considered for patients at high risk for anemia. VAVD in conjunction with these minicircuits has also proved helpful. Retrograde autologous priming (RAP) is a perfusion technique in which the CPB prime is displaced by passive exsanguination (back-bleeding) through the arterial and venous lines back into an empty bag that is out of the main circuit, prior to initiating CPB. This means that once the primed CPB circuit is attached to the arterial and venous cannulae, the blood is allowed to back up, filling the circuit, and the crystalloid prime fluid is discarded. A recent meta-analysis found that RAP significantly reduces allogenic blood transfusion for adult cardiac surgery patients who require CPB.⁵²

Ultrafiltration.

Ultrafiltration is a process in which the perfusionist diverts the patient's blood to an ultrafilter made of hollow capillary fibers that act as a membrane to separate the aqueous portion of blood from the cellular and proteinaceous elements. The aqueous portion is then discarded, while the red cells and coagulation factors are *hemoconcentrated*. Ultrafiltration raises the hematocrit, so the technique is most often performed in an effort to prevent transfusing a patient who has a low hemoglobin (Hgb) level. An adequate pump volume is needed for ultrafiltration. When a patient is volume-overloaded preoperatively, there is excess volume in the pump, and ultrafiltration can be used to remove the excess volume.⁸

Of course, the most critical questions are what to transfuse, and

when. Even the 2011 STS/SCA Blood Conservation Guidelines do not provide clear answers to these complicated questions. Oxygen-carrying capacity is extremely important in cardiac surgical patients, but research has not been able to elucidate what Hgb level correlates with organ failure or long-term adverse outcomes. The guidelines suggest transfusion for patients on CPB with a Hgb level of 6 g/dL or less, but a higher Hgb level may be justified in patients at risk of decreased cerebral O₂ delivery. If the patient's Hgb level is greater than 6 g/dL and the patient's clinical situation (including comorbidities, clinical setting, and laboratory or clinical data) warrants transfusion, it is reasonable to transfuse earlier.⁵¹ Based on the increased age and comorbidities of the typical cardiac surgical population, it is generally accepted to keep a patient's hematocrit in the 22% to 25% range. Another recommendation is that a multidisciplinary team be created to manage blood resources.⁵¹

Physiologic Effects of Cardiopulmonary Bypass

Despite improvements in perfusion, anesthesia, and cardiac surgery, patients are still at risk for developing organ dysfunction after CPB. CPB causes a systemic inflammatory response syndrome (SIRS) that potentially can impact every organ system of the body. The inflammatory response to CPB can be mild and asymptomatic, or result in multiple organ dysfunction syndrome. SIRS and ischemia related to emboli or hypoperfusion within an organ seem to be the common pathophysiologic mechanisms for organ dysfunction after CPB. The heart, brain, lungs, kidneys, and gastrointestinal system are all at risk for negative impact or trauma. Finally, hemostasis is impaired as related to CPB.

Systemic Inflammatory Response.

SIRS is thought to be activated as a result of CPB when the blood is exposed to the foreign surfaces of the CPB machine. Ischemia-reperfusion injury or embolization may occur and cause the release of endotoxins, primarily from splanchnic hypoperfusion. Endothelial damage occurs, and the cellular immune response is activated, as are the complement and coagulation cascades. When bypass is initiated, the body exhibits a marked stress response:

cortisol, catecholamines, arginine vasopressin, and angiotensin levels are elevated. Large amounts of O₂-free radicals are also produced. More research is needed into protective strategies. A 2014 critical review of the literature regarding attenuating the systemic inflammatory response to CPB in adults showed that no single intervention limited the adverse outcomes related to SIRS and CPB. The most promising interventions were those that targeted multiple inflammatory pathways. These interventions included surgical/perioperative measures, perfusion-related measures, and pharmacologic measures. The most widely-studied intervention (use of steroids) showed no improvement in clinical outcomes for mortality, cardiac or pulmonary complications.^{53,54}

Heart.

Myocardial injury can occur even when protection strategies seem adequate. The injury can vary from being asymptomatic, with only an elevation of cardiac enzymes postoperatively, to severe, with a marked decrease in cardiac function that results in failure to separate from bypass. Substantial increases in cardiac enzymes resulting from the activation of SIRS and/or ischemic injury can occur from embolization and hypoperfusion during CPB. Due to the very nature of the surgery, cardiac insult and ischemia after CPB may occur even with use of myocardial protection techniques. Myocardial injury manifesting as increased cardiac enzymes after CABG has been shown to increase the risk of both early and late death.⁵⁵ Management strategies and devices that may become necessary after myocardial injury during cardiac surgery and bypass are discussed later in the chapter.

Brain.

Injury to the brain or the central nervous system (CNS) after cardiac surgery is a devastating outcome for both the patient and family. Neurologic deficits have been categorized into type 1 outcomes, which include death due to stroke/encephalopathy, stroke, coma, or transient ischemic attack (TIA), and type 2 outcomes, which include new deterioration in intellectual function such as confusion, agitation, disorientation, memory deficit, or seizure. A classic prospective study of 2108 CABG patients found that the incidence

of type 1 injury was 3.1%, and the incidence of type 2 injury was 3.0%. The patients who experienced the type 1 outcomes had a substantial increase in mortality, length of hospital stay, and need for long-term care.⁵⁶ Atherosclerotic disease of the ascending aorta is the biggest predictor for type 1 injury, but increased age is also predictive. Most of the type 2 outcomes have been shown to improve in the first 3 months after surgery.⁵⁷ Late cognitive decline in CABG patients, which was originally attributed by many to CPB, has been shown to occur to the same degree in patients of similar age with CAD who have not undergone CPB.⁵⁸ A current review of recent literature regarding neurocognitive outcomes and cardiac surgery revealed there is no evidence to suggest that cardiac surgery, and CPB in particular, has a causal role in progression to dementia or long-term neurologic deficit.⁵⁹ TEE and epiaortic echocardiography may diagnose atheroma in the aorta, and minimizing manipulation of the aorta may decrease the risk of this neurologic insult. Filters on the CPB circuit decrease embolic debris, and flooding the operative field with CO₂ is thought to decrease gaseous emboli. A wide array of neuroprotective and CNS monitoring strategies has been introduced into practice to combat the causes of post-CPB neurologic dysfunction; however, only the efficacy of hypothermia has been proven.

Lungs.

Pulmonary complications after CPB can range from mild atelectasis that develops because the lungs are not ventilated on bypass to severe pulmonary dysfunction that was at one time known as *pump lung*, but is now known as *acute lung injury* (ALI) or acute respiratory distress syndrome (ARDS), depending on the severity. Atelectasis and pleural effusions, which occur in 60% of cardiac surgery patients, are the most common injuries, but hemothorax, pneumothorax, and pulmonary edema may also occur.⁴² Patients with chronic obstructive pulmonary disease or any other preexisting respiratory disease are at increased risk for exacerbation of their existing pulmonary illness after CPB. Embolic insults, prolonged CPB, and the CPB-induced systemic inflammatory response, which causes an increase in pulmonary endothelial permeability, pose the biggest risk to the development of ALI and

ARDS.⁶⁰

Kidneys.

Renal dysfunction manifesting as acute kidney injury is one of the major complications of cardiac surgery, and serves as a major predictor of morbidity and mortality for postoperative cardiac surgical patients. Bove et al.⁶¹ found 3.4% of 5,068 patients who underwent cardiac surgery with CPB developed acute renal failure (ARF; 100% creatinine increase), and 1.9% required renal replacement therapy. Hospital mortality was over 40% for patients with ARF, and increased to over 63% in patients who required renal replacement therapy. Optimizing cardiovascular volume status and CO, as well as limiting CPB time, are suggested to decrease the incidence of ARF.

Gastrointestinal.

Gastrointestinal system dysfunction is a relatively rare occurrence, but significantly increases the incidence of perioperative MI, renal failure, stroke, and even death.⁶² Gastrointestinal dysfunction seems to also be affected by hypoperfusion and/or embolic events related to CPB. Splanchnic hypoperfusion causes the release of endotoxins that can initiate SIRS.

Coagulation.

Even with adequate heparinization, CPB activates the extrinsic and intrinsic hemostatic pathways, as well as fibrinolysis. Contact of the blood with the internal surface of the CPB circuit results in the activation of: complement, the coagulation cascade, platelets, plasminogen, and kallikrein. During CPB, platelets and clotting factors are first diluted and then denatured by the mechanical trauma from the bypass circuit and suction devices. Platelets and leukocytes are also activated by mechanical trauma. The end result is the development of coagulopathies that manifest as increased perioperative bleeding.

Anesthetic Considerations in the Perioperative Period

Preoperative Evaluation

Because of the serious nature of the primary disease and the high prevalence of comorbidities, all patients undergoing cardiac surgery should have a thorough preoperative evaluation, including a history of the patient's medical condition and a complete physical examination. The preoperative assessment should focus on the cardiovascular system, but information must also be gathered and recorded about the airway, as well as pulmonary, neurologic, endocrine, renal, hepatic, and hematologic functions.

Cardiovascular System.

The medical record should be examined, and the results of all cardiovascular tests noted. [Table 24.2](#) summarizes many of the common tests and findings that are used to identify cardiac pathology. Ventricular function and a history of heart failure are important considerations that affect anesthetic choice, hemodynamic management, and requirements for intraoperative pharmacologic support. The New York Heart Association (NYHA) functional class of heart failure has prognostic significance and predicts postoperative quality of life. The American Heart Association (AHA) and American College of Cardiology (ACC) stages of heart failure emphasize disease progression ([Table 26.5](#)).

TABLE 26.5
Comparison of the Primary Heart Failure Classifications

ACC/AHA HF Stage	NYHA Functional Class
A—At high risk for HF but without structural heart disease or symptoms	None
B—Structural heart disease without symptoms	I—Asymptomatic
C—Structural heart disease with prior or current symptoms	II—Symptoms with moderate exertion III—Symptoms with minimal exertion
D—Refractory heart failure requiring specialized interventions	IV—Symptoms at rest

ACC, American College of Cardiology; AHA, American Heart Association; HF, heart failure; NYHA, New York Heart Association.

Adapted from Popescue WM. Heart failure and cardiomyopathies. In Hines RL, Marschall KE, eds. *Anesthesia and Co-Existing Diseases*. 6th ed. Philadelphia: Elsevier; 2012.

Patients with a history of severe heart failure are likely to have a cardiac electronic implantable device (CEID), including a pacemaker alone or in combination with an implantable cardioverter defibrillator (ICD). Many patients will have a biventricular pacemaker for cardiac resynchronization therapy (CRT). CRT improves CO, hemodynamics, heart failure symptoms, and quality of life.⁶³ All implantable devices should be evaluated prior to cardiac surgery, and the results of the device interrogation should be readily available.

CEIDs may need to be reprogrammed in the surgical suite just prior to surgery in order to prevent electrocautery-induced discharge. Usually, the antitachyarrhythmia functions on an automatic ICD and the rate response (if present) on a pacemaker are suspended.⁶⁴ Patients with an ICD should have defibrillation pads placed prior to induction so that a means for pacing and defibrillation is immediately available. The pads are positioned away from the generator to prevent damage to the device should defibrillation be necessary. A magnet must be available, and the magnet response identified. In emergency situations, the magnet will usually deactivate ICD devices and place most modern pacemakers in an asynchronous mode. If the programmed backup asynchronous pacing rate is less than 70, it is often advisable to have the pacemaker reprogrammed to a higher rate.⁶³

Patients with CAD or AS often have carotid artery disease and/or peripheral vascular disease (PVD) as well. The BP is kept within a relatively higher range in patients with carotid disease to ensure adequate cerebral perfusion pressure.⁶⁵ The presence of PVD may limit the locations available for invasive monitoring. The presence of aortic disease can impact the surgeon's ability to cannulate or clamp the aorta. If alternate cannulation sites are selected, this too can impact invasive line placement.

Comorbidities.

For elective surgery, patient comorbidities should be optimized prior to the time of the operation. Multiple studies have correlated the following conditions with increased risk in the cardiac surgical population: diabetes mellitus, compromised renal function, depressed ventricular function, and heart failure.^{66,67}

Diabetes mellitus and perioperative hyperglycemia are associated with increases in sternal wound infections, extended length of stay, recurrence of angina, postoperative mortality, and decreased long-term survival.⁶⁸⁻⁷¹ In 2009, the STS developed evidence-based practice guidelines for blood glucose management in the perioperative period.⁷² Highlights of the STS recommendations are **Box 26.1**.

Highlights of STS Perioperative Glucose Management Recommendations

Preoperative

- Hold oral hypoglycemic for 24 hours prior to surgery.
- Hold nutritional insulin after dinner the night before surgery.
- Continue basal insulin dose (NPH dose may be cut by 1/3 to 1/2).
- Check glucose level frequently day of surgery.
- Maintaining glucose at 180 mg/dL or less is reasonable.

Intraoperative

- Intermittent bolus acceptable if nondiabetic and glucose less than 180 mg/dL.
- Continuous infusion preferred if glucose 180 mg/dL or greater.
- Continuous infusion preferred for diabetics, maintain postoperatively.
- Adjust infusion per institutional protocol with a goal of maintaining glucose at 180 mg/dL or less.
- Check glucose level every $\frac{1}{2}$ to 1 hour or more frequently.

Postoperative in ICU

- Consult endocrinology for diabetic patients.
- If glucose persistently greater than 180 mg/dL, continue infusion.
- If patient in ICU more than 3 days, target should be 150 mg/dL or less.
- Before stopping infusion, transition to subcutaneous insulin.

In Step-Down or Floor

- Endocrinology to adjust basal and nutritional insulin doses
- General goal is 180 mg/dL or less after meals and 110 mg/dL or less fasting.
- Restart oral hypoglycemic if target achieved and no contraindications.

Data from The Society of Thoracic Surgeons (STS) Guidelines on Blood Glucose Management During Adult Cardiac Surgery. *Ann Thorac Surg.* 2009;87:663-669.

Preoperative renal impairment is correlated with increases in morbidity and mortality. Despite research into reducing postoperative risk, thus far, only maintenance of normovolemia has proven effective in preventing further decline in renal function.^{73,74}

Laboratory Studies.

Laboratory studies that will assist in the perioperative period include a room-air arterial blood gas (ABG), electrolytes, serum blood urea nitrogen (BUN) and creatinine, fasting lipid profile, complete blood count, coagulation profile, Hgb A1c, and fasting blood glucose. Any serum biomarkers drawn to evaluate ischemia, infarction, or failure should be noted. Methicillin-resistant *Staphylococcus aureus* (MRSA) infection has a low prevalence but high mortality associated with cardiac surgery. Preoperatively, nasal swab cultures are taken, and those patients colonized with

MRSA ($\approx 3.9\%$) have vancomycin added to their antibiotic routine.⁷⁵

Airway Assessment and Pulmonary Function.

Airway assessment and pulmonary function deserve special attention. A plan must be developed to safely secure the airway and ventilate the patient while maintaining hemodynamic stability. In this situation, the art of anesthesia care becomes evident. It can be especially challenging for the anesthetist to maintain hemodynamic stability in the face of a difficult airway, severe PHTN, lung disease, or compromised ventricular function. A double-lumen tube and a pediatric fiberoptic scope are required for procedures performed through a thoracotomy incision. If prolonged postoperative ventilation is anticipated, a slightly larger endotracheal tube (ETT) aids mechanical ventilation and pulmonary toileting.

Surgical Risk.

After collecting the aforementioned information, the preoperative team can estimate surgical risk. Risk-scoring schemes for cardiac surgery were first published in 1983. Today, several validated scoring systems are available. Each system uses different demographic data, laboratory markers, and type of surgery to calculate risk. One of the most widely cited systems is the STS score. The STS maintains a robust national database that estimates the risk of operative mortality and morbidity after adult cardiac surgery on the basis of patient demographics and preoperative clinical variables. The risk calculator is accessible on the internet.⁷⁶ Risk can be calculated for primary procedures, as well as combined CABG and single valve surgeries. The risk calculation includes overall morbidity and mortality, length of stay, risk of reoperation, and several other quality measures.

A simpler online risk analysis tool is the EuroSCORE II, or European System for Cardiac Operative Risk Evaluation.⁷⁷ The validity and utility of one tool over the other is a subject of academic debate, but both are reliable; therefore use is institutionally specific. Seven variables—age, female gender, left ventricular function, body habitus, reoperation, type of surgery, and urgency of surgery—correlate with major risk across very diverse study settings. In addition, the cardiac surgeon must also

consider the extent of his or her training and clinical experience, and the breadth of professional support offered by his or her institution because these factors also have been correlated to risk.^{78,79} The AHA and the ACC recommend that patients who are considered high-risk, because of complex pathology or significant comorbidities, be cared for by a heart team at a center of excellence.^{80,81} In tertiary care centers specializing in cardiac care, there are likely to be many patients and procedures that exceed any risk model's ability to accurately calculate risk. Procedures such as reoperations for multiple valve replacements in a patient with endocarditis or placement of an assist device are not included in these models.

Management of Preoperative Medications.

Cardiac surgical patients are likely to be on multiple medications to manage their primary disease and comorbidities. As a general rule, the patient should receive medicines that are used to manage his or her medical conditions on the morning of surgery with a sip of water.⁸² However, a few medications merit further discussion.

Clinical research has demonstrated the benefit of perioperative β -blocker therapy to improve hemodynamic stability, decrease dysrhythmias, and reduce morbidity and mortality.⁸³⁻⁸⁵ Unless there is a contraindication, patients having coronary surgery should receive β -blockers preoperatively, and patients who are on β -blockers for any reason preoperatively should have them continued in the perioperative period.^{30,80,81,86}

Medical management of heart failure includes the use of several drugs (see Fig. 26.5). Controversy has arisen regarding administering ACEIs and angiotensin receptor blockers (ARBs) within 10 hours prior to induction. Some studies report moderate to profound intraoperative hypotension in patients who have received these drugs,⁸⁷⁻⁸⁹ whereas other studies claim that these medications actually improve hemodynamic stability.^{30,90,91} It is generally agreed that ACEIs and ARBs in patients on chronic therapy should be reinstated in the postoperative period if the patient is stable, but the safety of preoperative administration remains uncertain.^{80,80,81}

ACEIs and ARBs have also been implicated as a cause of postoperative vasoplegic syndrome. Patients who are resistant to

phenylephrine may exhibit increased responsiveness to small doses of norepinephrine (16 mcg) or vasopressin (1 unit).⁹² (See [Chapter 13](#) for a further discussion of vasoplegic syndrome.)

With regard to medications that affect coagulation, most institutions follow the STS recommendations, which include consideration for each individual patient by a multidisciplinary team.^{51,93} A complete review of these recommendations is beyond the scope of this chapter, but a few important points will be addressed. Warfarin (Coumadin) is usually discontinued and surgery delayed until the prothrombin time and International Normalized Ratio (INR) normalize. In high-risk situations, the patient is bridged, most often with heparin. Aspirin (acetylsalicylic acid [ASA]) and heparin are vital in the treatment of CAD, especially in patients with acute coronary syndrome (ACS). Heparin and ASA are administered to patients requiring emergency surgery for ACS, and heparin is continued until shortly before skin incision. ASA is also recommended postoperatively for patients having CABG because it increases graft patency and reduces mortality.⁸¹ ASA administered preoperatively is associated with increased bleeding and the need for transfusions. The most recent consensus statement by the STS recommends that ASA be discontinued in purely elective cases without CAD.⁹³ The ACC/AHA guidelines recommend that patients receive dual antiplatelet therapy (DAPT) for 1 year or more following placement of a drug-eluting stent (DES) and 3 months after placement of a bare-metal stent (BMS) to prevent stent thrombosis. Patients most often receive ASA (a COX-1 inhibitor) and a thienopyridine (ticlopidine, clopidogrel, prasugrel), which blocks adenosine diphosphate (ADP)-mediated platelet activation by binding with the P2Y12 receptor.⁹⁴ The administration of ASA and P2Y12 inhibitors is associated with an increased risk of bleeding, so it is recommended that patients referred for elective cardiovascular surgery discontinue thienopyridines for at least a few days. The interval between discontinuation of antiplatelet drugs and surgery is uncertain and depends on multiple factors, mostly related to patient drug responsiveness and risk of thrombotic complications. For this reason, the guidelines recommend multidisciplinary care.⁹³ Patients who are considered to be a high thrombotic risk and who

require urgent surgery while on DAPT may benefit from bridging strategies using short-acting antiplatelet agents. DAPT improves graft patency and reduces mortality, so DAPT should be resumed as soon as the risk of bleeding has decreased in the postoperative period.⁹³ ASA should most likely be continued in patients on DAPT. IV glycoprotein IIb/IIIa (GPIIb/IIIa) inhibitors vary in their pharmacodynamics. Patients receiving abciximab (ReoPro) are at increased risk of bleeding, especially if the last dose was within 12 hours of surgery. Shorter acting GPIIb/IIIa inhibitors like eptifibatid (Integrilin) do not seem to increase bleeding, and may improve myocardial outcomes.⁹⁵

Preparation for Possible Blood Loss.

Because cardiac surgical procedures are associated with significant blood loss, the anesthesia provider must confirm with all patients their willingness to accept blood products. In patients with specific religious beliefs or personal preferences, the permissibility of specific products and/or cell-saver devices should be discussed and documented.⁵¹ Prior to induction, the anesthetist should confirm the validity of the patient's type and cross-match, as well as the anticipated blood product availability. This is particularly important in patients who have a positive antibody screen, because it can sometimes take multiple hours to secure cross-matched units. Patients having "re-do" operations should have blood immediately available prior to sternotomy.

Psychological Preparation and Preoperative Sedation.

Because the cardiac OR is a fast-paced, high-intensity environment, it is easy for the team to become task-oriented, inadvertently overlooking the emotional needs of the patient. Patients facing major surgery are acutely aware of their mortality, and are often apprehensive about the procedure and pain. Concerns about the future of loved ones, especially those who are dependent upon them for support, are common. The preoperative interview provides a unique opportunity to gather needed data and share information about what to expect. Ideally, the provider caring for the patient during the surgery should conduct the preoperative interview so that he/she can establish rapport and address the

patient's and family's concerns. Patients who are mentally prepared will be more calm, confident, and cooperative in the OR and in the intensive care unit (ICU).

Preoperative sedation is selected on an individual basis taking into consideration the patient's functional status and anxiety level. Generally, patients with normal LV function and few comorbidities can tolerate heavier sedation, whereas the frail only require minimal sedation. Sedation should not be so heavy as to prevent coherent patients from participating in the identification and interview process. When in doubt, sedation is withheld preoperatively and then administered in the OR while the patient is monitored during line placement.

Preparation for Surgery

Operating Room Preparation.

The surgical suite should be readied in preparation for the planned surgical procedure prior to the patient's arrival. Communication with the surgical, nursing, and perfusion teams is essential to ensure that all parties are ready to act appropriately if the patient should rapidly deteriorate requiring emergent surgical intervention and/or institution of CPB. The basic set-up and monitoring is similar to most major cases, with a few additions, as outlined in [Table 26.6](#).

TABLE 26.6

Typical Anesthesia Preparation of the Cardiac Operating Room

Anesthesia Machine	Routine Check
Airway	Nasal cannula or mask as needed Facemask, laryngoscope handle and blades Oral airways and appropriate endotracheal tubes Suction (Yankauer and endotracheal) Ambu bag and any anticipated difficult airway equipment
Vascular Access	Large-bore PIV catheter (14 or 16 gauge preferred) 2nd PIV catheter on a warmer for complex cases or expected blood loss Arterial line (radial or brachial based on institutional preference) R may be preferred for LITA conduit L may be preferred for "redo's" requiring R subclavian cannulation Avoid side of radial artery conduit and sites distal to prior brachial cut-down for cardiac catheterization Central venous access

	CVP for normal LVF and primary, simple cases PAC with cardiac output for poor LVF and complex surgery	
Monitors	Standard Monitors	Extended Monitors
	BP (noninvasive + invasive) ECG (II, V ₅ + automated ST analysis) Pulse oximetry Capnography Temperature (core ± peripheral) CVP Urine output Intermittent arterial blood gases (ABGs) Neuromuscular blockade monitor Machine with cassettes for monitoring anticoagulation (ACT or Hepcon) Paper or electronic medical record	PAC Specialized PACs (pacing, etc.) Cardiac output measurement Mixed venous saturation TEE Left atrial pressure Infrared absorption spectrophotometry BIS Cerebral oximetry Retrograde coronary sinus cardioplegia perfusion pressure Spinal drain (intrathecal) pressure
Medications	Anesthetic sedation Line placement (midazolam) Transport to ICU (propofol or dexmedetomidine) Induction (propofol or etomidate) Muscle relaxant (succinylcholine for difficult airway + nondepolarizing) Narcotic (fentanyl, sufentanil, or remifentanyl) Inhalation anesthetic Heparin (300–400 units/kg in a syringe) Vasoactive bolus: nitroglycerine, phenylephrine, ephedrine, epinephrine, ± atropine, ± calcium Infusions as needed on pumps: Aminocaproic acid or tranexamic acid Nitroglycerin (NTG) for patients with CAD or volume overload Sodium nitroprusside (SNP) for patients with HTN, regurgitant valve lesions, or systolic HF Inotrope (epinephrine or dobutamine) for patients with poor left or right ventricular function Vasopressor for septic or vasoplegic individuals Insulin	
Miscellaneous	Pacemaker with battery Warm water mattress or forced-air warming device with appropriate blanket	

ACT, Activated clotting time; BIS, bispectral index; BP, blood pressure; CAD, coronary artery disease; CVP, central venous pressure; ECG, electrocardiogram; Hepcon, machine for determining circulating heparin concentration; HF, heart failure; HTN, hypertension; ICU, intensive care unit; L, left; LITA, left internal thoracic artery; LVF, left ventricular function; PAC, pulmonary artery catheter; PIV, peripheral intravenous; R, right; TEE, transesophageal echocardiography.

Monitoring.

Standard and extended monitors for cardiac surgery are listed in [Table 26.6](#). ECG monitoring should include lead II for detection of dysrhythmias and lead V₄ or V₅ with automated ST analysis for detection of ischemia. Classically, data from London et al.¹¹ identify V₅ as the most sensitive single lead for detecting perioperative ischemia, but newer evidence from Landesberg et al.^{14,15}

demonstrates that V_4 has greater sensitivity. In practice, the V lead may need to be placed posteriorly at the 5th intercostal space, posterior to the axillary line to avoid the surgical field. The usefulness of the five ECG electrodes used during cardiac surgery is limited because much anterior and posterior wall ischemia cannot be detected. The TEE is more sensitive than the ECG for detection of ischemia.⁹⁶ The 2015 STS guidelines recommend that core temperature be measured using a nasopharyngeal probe, or the pulmonary artery catheter (PAC). To avoid excessive nasopharyngeal bleeding, the probe should be placed at the beginning of the surgical procedure, before heparinization. It is recommended that the oxygenator arterial outlet blood temperature is used as a surrogate for cerebral temperature measurement during CPB.⁹⁷ Many centers find a peripheral temperature monitor (bladder or rectal) is useful to compare core and shell temperatures during cooling and rewarming.

Arterial Line (A-Line).

It is generally safest to place the arterial line (A-line) before induction, using sedation as tolerated and local anesthesia for patient comfort. A noninvasive BP cuff should be placed as a backup monitor in case of A-line malfunction. The A-line can be used to obtain an ABG with the patient spontaneously breathing room air or supplemental O_2 . The baseline ABG will provide an estimate of lung function, and can assist providers when weaning the patient from mechanical ventilation in the postoperative period.

Most importantly, the A-line will provide instantaneous and continuous monitoring of hemodynamics during induction of anesthesia. This is crucial when the patient has life-threatening cardiac pathology, including severe AS, left main CAD, severe PHTN, or moderate to severely decreased left or right ventricular function. In stable patients with less severe disease, the A-line can be placed shortly after induction. The A-line can be placed in almost any location, but the radial or brachial arteries are most frequently cannulated, based on personal or institutional preference. Radial artery cannulation is safer than brachial artery cannulation secondary to redundant blood flow to the hand via the ulnar artery.⁹⁸ However, the radial pressure waveform may

dampen during chest wall retraction as a consequence of subclavian artery compression between the clavicle and first rib, especially during dissection of the internal thoracic artery (ITA). Additionally, radial A-lines should not be placed below the site of a previous brachial or radial cut-down (for prior cardiac catheterization), because they are prone to thrombosis and waveform distortion. Some providers prefer the brachial artery because it is a more reliable measure of central aortic pressure before and after CPB.^{99,100} Although concerns for thrombosis persist, the safety of brachial A-line use in heparinized patients has been well documented.^{100,101} The surgeon may wish to avoid aortic cannulation if the patient has aortic atheroma. As an alternative to aortic cannulation, the right subclavian artery or either femoral artery may be cannulated. The right subclavian or femoral arteries may be exposed and/or cannulated prior to repeat sternotomy if the surgeon is concerned about the risk of injuring cardiac structures while opening. In cases of right subclavian cannulation, the A-line is usually placed in the left upper extremity. Sometimes the radial artery (most often from the nondominant arm) is harvested as a conduit for CABG. In this situation, the A-line must be placed in the opposite arm or in the ipsilateral brachial artery proximal to the antecubital fossa.

Central Venous Access.

Central venous access is mandatory in adult cardiac surgery for volume resuscitation and administration of vasoactive medications. In most cases, central access is obtained after the induction of anesthesia. However, it may be prudent to place the central line prior to induction if the patient is hemodynamically unstable prior to induction or likely to decompensate on induction. Occasionally, preinduction central access is obtained because of inadequate peripheral access. The right internal jugular vein is the preferred cannulation site because it is relatively easy to access and provides a straight, short course to the right atrium. If the left internal jugular vein is used, the anesthetist must be careful to avoid the thoracic duct and the left brachiocephalic vein, which crosses the internal jugular vein at a right angle. Some providers prefer to use a short introducer on the left for this reason. Catheters placed in the external jugular or subclavian vein, especially on the left, are prone

to kinking during chest wall retraction. The use of ultrasound to guide placement is becoming increasingly common, especially if the patient has had prior neck surgery, has carotid atherosclerosis, or has been anticoagulated prior to surgery. Studies suggest decreased rates of infection and complications when ultrasound is used.¹⁰¹

A PAC is frequently placed instead of a central venous pressure (CVP) monitor when more hemodynamic information is desired. Although considered an extended monitor, the PAC may be placed in order to measure intracardiac pressures (Table 26.7) and CO using thermodilution. The information obtained can then be used to derive several other hemodynamic parameters to assist patient management (Table 26.8). Generally, a PAC is preferred in patients undergoing complex surgery in which large volume shifts are anticipated. Other indications include: frailty with multiple comorbidities, left or right ventricular dysfunction, and PHTN. In these situations, the PAC may be most valuable postoperatively in the ICU when TEE is no longer available. During CPB, the PAC can advance and become wedged; therefore it is recommended that the catheter be retracted 2 to 3 cm during this time, and the balloon inflated slowly (if used to wedge) after weaning from bypass. Many providers avoid wedging completely to decrease the risk of pulmonary artery (PA) damage or rupture. Special precautions must be taken when a PAC is placed in a patient with a left bundle branch block (LBBB). As the catheter enters the right ventricular outflow tract, approximately 3% of patients will develop a right bundle branch block that can lead to complete heart block (CHB) in patients with preexisting LBBB.¹⁰² If a PAC is placed in a patient with an LBBB, defibrillation/pacing pads should be prophylactically applied prior to insertion. Alternatively, the PAC can be left in the superior vena cava (SVC) until the chest is open, and then advanced. If CHB does develop, rapid CPB is an option.¹⁰³ PACs should generally be avoided in patients who have had pacemaker leads placed in the past 6 weeks because of the possibility of lead displacement.⁶³

TABLE 26.7**Normal Intracardiac Pressures**

Location	Mean (mm Hg)	Range (mm Hg)
Right atrium	5	1–10
Right ventricle	25/5	15–30/0–8
Pulmonary arterial systolic/diastolic	23/9	15–30/5–15
Mean pulmonary arterial	15	10–20
Pulmonary capillary wedge pressure	10	5–15
Left atrial pressure	8	4–12
Left ventricular end-diastolic pressure	8	4–12
Left ventricular systolic pressure	130	90–140

BSA, Body surface area; CI, cardiac index; CO, cardiac output; CVP, central venous pressure; HR, heart rate; LVSWI, left ventricular stroke work index; MAP, mean arterial pressure; MPAP, mean pulmonary arterial pressure; PCWP, pulmonary capillary wedge pressure; PVR, pulmonary vascular resistance; PVRI, pulmonary vascular resistance index; RVSWI, right ventricular stroke work index; SI, stroke index; SV, stroke volume; SVR, systemic vascular resistance; SVRI, systemic vascular resistance index.

From Mittnacht AJC, et al. Monitoring the heart and vascular system. In Kaplan JA, et al. eds. *Kaplan's Cardiac Anesthesia: For Cardiac And Noncardiac Surgery*. 7th ed. Philadelphia: Elsevier; 2017:407.

If a PAC is deemed necessary, pads for external pacing are placed prior to insertion. Occasionally in cardiac surgery, specialized PACs

are useful, including those that can pace or continuously measure mixed venous saturation and CO. In surgical procedures where large blood loss is anticipated, or when peripheral access is limited, a 9-French two-lumen introducer or a large bore double-lumen CVP is useful.

Transesophageal Echocardiography.

TEE has become an invaluable source of information about cardiovascular anatomy and function during cardiac surgery. It is the most sensitive clinical monitor for detecting wall motion abnormalities caused by myocardial ischemia. Additional uses include evaluation of: right and left systolic and diastolic ventricular function; valvular area, function, and pathology; intravascular volume status; intracardiac air or pulmonary embolism; aortic atheroma and dissection; pericardial effusions or tamponade; and cannula or catheter placement. Unless there is a contraindication, TEE is recommended for all open chamber procedures and catheter-based valve procedures. TEE should be considered for CABG procedures. Absolute contraindications to TEE include pathologic conditions of the esophagus, including strictures, diverticula, tumors, traumatic interruption, or recent suture lines.¹⁰⁴ A comprehensive exam encompasses at least 20 views, but a targeted perioperative exam can be completed using 11 selected views.^{104,105} The TEE exam is completed before CPB by a credentialed provider to identify baseline pathology and function. This information is communicated to the surgeon and used for comparison after bypass to immediately evaluate the surgical repair(s) and identify new pathology or dysfunction after CPB. Although even an introductory discussion of TEE is beyond the scope of this chapter, a basic understanding of TEE is valuable for nurse anesthetists to help them monitor ventricular function and intravascular volume status. More advanced diagnoses should be made by credentialed providers.

The use of other extended monitors is related to personal preference (e.g., bispectral index [BIS] monitor) or case requirement (e.g., spinal fluid pressure in descending thoracic aneurysms [TAs]). The BIS monitor has not been shown to reliably prevent recall,¹⁰⁶ but the trend is useful in detecting changes in anesthetic depth. The

BIS can serve as a reminder to the practitioner to administer a medication to prevent recall when the inhalation agent is titrated down during periods of hemodynamic instability.

Cerebral oximetry uses near-infrared regional spectroscopy (NIRS) technology, which is similar to that used in pulse oximetry. It has proven beneficial in both cardiac and major vascular surgery, especially when the procedure requires DHCA. A relative decrease in regional saturation to less than 70% of baseline or to an absolute level of less than 50% is associated with an increase in adverse outcomes such as stroke, postoperative cognitive dysfunction, organ dysfunction, and mortality. NIRS has been used to extend the “safe time” of DHCA and to identify SVC cannula malposition. NIRS helps the practitioner assess the adequacy of cerebral oxygenation and the effectiveness of interventions such as increasing the BP, administering volume, or adjusting ventilation to improve oxygenation.¹⁰⁷

Selection of Medications.

An enormous body of information has accumulated regarding the cardiovascular effects of various anesthetic agents. The most significant considerations are highlighted. Traditionally, the choice of anesthetic has been based primarily on preexisting ventricular function and comorbidities, coupled with the desired length of action. However, the same anesthetic combination may cause different responses in patients with similar histories and hemodynamic profiles. Therefore the combination of medications selected for the anesthetic is far less important than the skill and judgment with which they are administered.

Volatile Anesthetics.

Volatile anesthetics can potentially cause myocardial depression, vasodilation, and hypotension. They lower the arrhythmogenic threshold to catecholamines, and do not provide pain relief in the postoperative period.¹⁰⁸ In cardiac anesthesia, they are often combined with a narcotic in a balanced technique. Inhalation agents are now considered beneficial because of their preconditioning effect. A meta-analysis demonstrated that including halogenated anesthetics in the anesthetic regimen is associated with a better

outcome after cardiac surgery than using a total IV technique.¹⁰⁹ Most cardiac surgical patients will benefit from the myocardial protection of volatile agents; the exception may be those with severe LV dysfunction who cannot tolerate any further cardiac depression. Desflurane is a potential concern because sudden increases in inspired concentration can lead to tachycardia and hypertension, which can be detrimental in patients who have CAD, hypertrophic cardiomyopathy (HCM), or stenotic valvular lesions. Desflurane and nitrous oxide raise pulmonary vascular resistance, PA pressure, and wedge pressure.^{108,110} Nitrous oxide should be avoided just before, during, and after CPB because of the potential for expansion of air introduced into the circulation during bypass. Nitrous oxide also may cause catecholamine release and LV dysfunction.

The trend today favors fast-track or early extubation in cardiac surgery because decreased length of stay translates into reduced cost without increasing adverse outcomes.^{111,112} Thus the goal of early extubation, generally within 6 hours, is now a major consideration in the selection of medications. Early extubation can be achieved using a variety of techniques, including low to moderate dose narcotics (fentanyl 5–20 mcg/kg or sufentanil 2–10 mcg/kg) combined with a volatile agent, or total IV anesthesia with short- to moderate-acting drugs such as remifentanyl, propofol, or dexmedetomidine.

Opioids do not cause myocardial depression, and maintain stable hemodynamics. Therefore a high-dose narcotic technique (fentanyl 100–200 mcg/kg) was popularized in past decades. Problems with the technique included significant bradycardia, recall, chest wall rigidity, and prolonged intubation. Today, a primary narcotic technique is reserved for hemodynamically unstable patients. Moderate doses of the fentanyl derivatives are most popular, but morphine, hydromorphone, and other narcotics also can be used effectively.

Sedation.

Sedation prior to induction can be accomplished with low doses (1–4 mg) of midazolam. Caution is advised because the combination of a benzodiazepine and fentanyl-type drugs reduces systemic

vascular resistance (SVR) and causes myocardial depression, leading to hypotension. Sedation for transport to the ICU is often facilitated with infusions of propofol or dexmedetomidine.

Induction Agents.

Induction of anesthesia can be accomplished with any of the agents alone or in combination with narcotics, volatile agents, or benzodiazepines. Etomidate causes less myocardial depression than propofol; therefore it may be preferable for use in patients who have reduced left ventricular function. The significance of the adrenal suppression caused by etomidate has been the subject of much debate. A large review of studies involving single-dose etomidate induction versus other standard induction agents showed an increase in adrenal insufficiency in critically ill patients.¹¹³ However, a 2015 study of patients having cardiac surgery concluded that the adrenal suppression caused by etomidate lasted less than 24 hours and had no significant impact on outcome. Furthermore, etomidate provided more stable hemodynamic parameters when used for induction of anesthesia as compared to propofol in patients with poor LV function.¹¹⁴ If adrenal insufficiency is suspected, a dose of a steroid such as hydrocortisone (100 mg) may be administered. Etomidate and propofol may cause pain with injection, but this can be blunted by diluting the drug and giving it slowly and/or by administering IV lidocaine or narcotic prophylactically.

Muscle Relaxants.

Muscle relaxants are needed to facilitate tracheal intubation, to prevent movement during cannulation, and to attenuate shivering and skeletal muscle contraction from defibrillation. Most nondepolarizing muscle relaxants used today lack significant cardiac effects. The choice of relaxant is based on the airway examination, patient history, and procedure length. Succinylcholine is often preferred for difficult airways.

Antibiotic Prophylaxis.

The STS has published guidelines for antibiotic prophylaxis in cardiac surgery.¹¹⁵ A β -lactam antibiotic (cephalosporin) is the

prophylactic antibiotic of choice (class 1A) for cardiac surgical patients who are not at increased risk for MRSA. Cefazolin 1 g (or 2 g for patients weighing more than 60 kg) IV is recommended every 3 to 4 hours while the surgical incision is open. Cefuroxime 1.5 g IV is another alternative. Patients at increased risk for MRSA (known or presumed), including those undergoing an operation using prosthetic valvular or vascular material, should have vancomycin 1 to 1.5 g (or 15 mg/kg weight adjusted) added. Patients with a known β -lactam allergy should be dosed with vancomycin as discussed earlier, and an aminoglycoside such as gentamicin 4 mg/kg should be added for gram-negative coverage. Redosing of vancomycin and the aminoglycoside is not recommended. The Surgical Care Improvement Project (SCIP) guidelines recommend that the antibiotic be administered within 1 hour of incision, or 2 hours for vancomycin.¹¹⁵

Intraoperative Management

This section focuses on management of general cardiac surgery from the time the patient enters the OR until his or her care is safely transitioned to the ICU team. What follows is a sequential description of events that occur during most cases, so that the anesthetist can gain an understanding of important perioperative milestones. The rationale for pharmacologic and hemodynamic management, as well as patient monitoring, was previously discussed. A discussion of management of specific cases and specialized equipment follows.

The cardiothoracic OR is a fast-paced, high-intensity environment where up to a dozen practitioners must focus for extended periods. The patient population is high-risk because of the prevalence of multiple comorbidities in addition to the primary cardiac pathology. The surgical procedures can be quite complex, and manipulation of the heart and vasculature can profoundly impact hemodynamic function. The anesthetist is required to intently focus on both the surgical procedure and the patient's response to widely varying levels of stimulation. Problems must be anticipated, and interventions must be prompt. Throughout the process, communication between the anesthesia, surgical, nursing, and perfusion teams is critical. Failure to communicate can have

devastating consequences. Closed-loop communication, the practice of clearly repeating back information when one team member makes a request of another, is imperative for safety.¹¹⁶

Precardiopulmonary Bypass Period.

The precardiopulmonary bypass period begins when the patient arrives at the operating suite and ends when the patient is on CPB. A review of the patient's preoperative vital signs and cardiac function will help the anesthetist determine the "normal" range for that particular individual. The general goal is to maintain hemodynamic stability. Individual hemodynamic perturbations must be considered within the context of the patient's baseline status. For example, a patient with an acceptable heart rate, MAP, O₂ saturation, and arterial pH does not need an inotropic agent if the CI is below the normal range. In this particular instance, general anesthesia reduces O₂ demand, and the decreased CO is probably adequate to meet demand. Starting an inotrope to increase the CI within the normal range (higher than 2.2 L/min per m²) might paradoxically lead to ischemia by increasing myocardial O₂ demand.

The prebypass period is marked by periods of marked variable stimulation. The most intense stimulation occurs at intubation, incision, sternal split and spread, sympathetic nerve dissection, pericardial incision, and aortic cannulation. Hypertension and tachycardia that occur as a result of inadequate analgesia or sympathetic activation can lead to ischemia, dysrhythmias, or heart failure. The anesthetist must anticipate these events and consider a preemptive dose of narcotic and/or an increase in the concentration of the volatile agent. Hyperdynamic individuals may also need the addition of a short-acting β -antagonist such as esmolol (0.1–0.5 mg/kg) or an IV infusion of a titratable vasodilator such as nitroglycerin or sodium nitroprusside to treat the adrenergic response to these events. During the remainder of the prebypass period, including preincision and the harvesting of conduit, there is little stimulation, and the BP and heart rate tend to decrease. Hypotension and significant bradycardia may decrease the CPP and lead to ischemia. Oftentimes, intermittent boluses of phenylephrine or ephedrine may be required to support coronary

perfusion.

Preinduction Period.

During the preinduction period, the patient is identified and interviewed before entering the OR. The information from the preoperative assessment is reviewed, and the anesthetist confirms that there have been no significant changes in the patient's medical condition, with a particular focus on worsening symptoms and recent infectious illness. The airway is re-examined, and the lungs and heart are auscultated. Medications taken within the last 24 hours are recorded. The patient's willingness to accept blood products is confirmed. The interview also gives the anesthesia provider an opportunity to assess patient anxiety, communicate expectations, and provide emotional support.

Once in the OR, areas prone to pressure ischemia like the sacrum and heels may be protected by the application of foam pads. The perioperative management of ICDs and pacemakers, if present, was discussed earlier. External adhesive defibrillator pads are usually placed for patients with deactivated ICDs or a history of recent serious ventricular ectopy, as well as those having minimally invasive surgery or a repeat sternotomy. A time out is performed where the surgeon and patient, together with the nursing, anesthesia, and perfusion teams review the operative plan, needed equipment, and safety checklists. Next, the patient is moved to the OR table, and standard monitors are applied (see [Table 26.7](#)). Pulse oximetry volume is adjusted to a level that is loud enough to provide an audible warning to the clinician in case of decreasing O₂ saturation while attention is focused on another task. Some centers routinely administer supplemental O₂ during the preinduction phase, whereas others use O₂ as needed. A large-bore peripheral IV catheter (14 or 16 gauge) is placed, using local anesthesia for patient comfort. Patients with normal left ventricular function will often benefit from supplemental sedation, especially if invasive monitors need to be placed. The decision as to the location and timing of invasive monitoring was discussed in the monitoring section of the chapter. Once the A-line is placed, the baseline ABG and ACT are measured. Central venous access is most often deferred until after induction, but regardless of the timing, baseline measurements

(including the CO) are recorded after placement. When the patient and all teams (nursing, perfusion, surgery, and anesthesia) are prepared, induction can begin.

Induction and Intubation.

The plan for induction is based on the length and complexity of the proposed procedure, as well as multiple patient-specific considerations, including cardiac pathology, comorbidities, ventricular function, and the airway examination. No combination of induction medications has proven superior in cardiac anesthesia. Rather, the artful skill each practitioner uses to administer preferred drugs to achieve hemodynamic stability and block the stimulating effects of laryngoscopy based on the individual patient's history is most important. Generally, a combination of a sedative, hypnotic, opioid, volatile agent, and muscle relaxant, with or without lidocaine and/or a β -blocker, is used. Achieving hemodynamic stability can be especially challenging when a difficult airway must be secured. After intubation and confirmation of correct ETT placement, the fresh gas flows are adjusted. One hundred percent O₂ has been advocated for cardiac surgery to maximize O₂ tensions, but a lower inspired concentration may prevent absorption atelectasis and reduce the risk of O₂ toxicity.¹¹⁷ Inhalation anesthetics have been correlated with improved outcomes in cardiac anesthesia (most likely because of the preconditioning effect), and they are usually included in the maintenance plan. Patients with severe LV dysfunction may require a primary narcotic technique because all inhalational agents cause some degree of myocardial depression and afterload reduction.

Preincision Period.

The preincision period is generally not very stimulating, so the anesthetic level can often be reduced. Occasional boluses of phenylephrine may be required for hemodynamic support. A second peripheral intravenous (PIV) line is inserted if necessary, and central access obtained. The stomach is decompressed with an oral gastric (OG) tube before placement of the TEE probe. A generous amount of water-soluble jelly is placed in the oropharynx to facilitate placement of the probe, and the probe is unlocked prior

to insertion. Many institutions use a mouth guard to protect the patient and the probe. Probe placement is facilitated by lifting the tongue and jaw manually or displacing them with the aid of a laryngoscope. Once the probe is in the posterior pharynx, turning the head slightly to the right helps it to advance smoothly to the 30-cm marking. To prevent damage to the mouth, pharynx, or esophagus, force is never applied when placing the TEE probe. The TEE examination is completed by a credentialed provider. If the TEE cannot be placed, the surgeon can perform a transthoracic echocardiogram using a sterile glove filled with sterile saline between the probe and the cardiac structures to improve visualization. The urinary catheter (which often incorporates a temperature monitor) is inserted, and a nasopharyngeal temperature probe is placed, if necessary.

Next, the patient is carefully positioned, and pressure points are padded. All routine positioning precautions apply, along with some areas of special concern. Brachial plexus injury can occur if the arms are hyperextended or if the chest wall retraction is excessive. Brachial and radial artery or nerve compression can occur if the upper arm is compressed by the ether screen or the post that is sometimes used to support the chest wall retractor during dissection of the internal mammary artery (IMA), also referred to as the ITA. Occipital alopecia is a common problem that develops in the weeks after surgery. The head should be placed on a well-padded surface and repositioned frequently during the operation. Nothing that can cause pressure, such as the ECG cable, should be placed under the patient's head.

After final positioning, the anesthetist reconfirms ETT position. The antibiotic infusion is completed (vancomycin may take longer), and the antifibrinolytic agent, if used, is initiated. Proper placement of monitors and lines is verified. Transducers are placed at heart level and zeroed to atmospheric pressure. All lines and access ports are labeled and neatly secured for easy access. Hemodynamic parameters, blood gases, and blood chemistry are all rechecked, and any abnormalities treated. Mild hypokalemia is not typically treated during the pre-CPB period because cardioplegia solution contains significant amounts of potassium. Insulin infusions may be required to lower the serum glucose level, especially in those with

diabetes mellitus. The STS guidelines recommend that blood glucose levels greater than 180 mg/dL be treated with an insulin infusion in both diabetic and nondiabetic patients (see [Box 24.1](#)).⁷² Insulin is titrated cautiously to avoid dramatic changes in serum glucose levels.

Incision to Bypass.

The incision-to-bypass period begins with intensely stimulating events: incision, sternotomy, and sternal spread. The anesthetist should prepare for these events by deepening the anesthetic and administering additional muscle relaxant, if needed. The highest rate of recall in cardiac surgery has been recorded during this period; therefore an amnestic can be given if not previously administered.¹¹⁸ The lungs are deflated during sternotomy to decrease the risk of cardiac or pulmonary laceration.

Repeat or redo sternotomy requires greater preparation and vigilance. Patients who have had a prior CABG may have an arterial or venous bypass graft lying directly beneath the sternum. Patients who have had prior chest radiation (often for breast cancer or lymphoma) can also have adherent scar tissue that is difficult to dissect. In these situations, the surgical team will examine the patient's lateral radiograph and possibly a magnetic resonance image (MRI) or computed tomography (CT) scan to determine the proximity of the cardiac structures to the sternum. If the heart appears to be adherent to the sternum, there are several management options for sternotomy and dissection. Some surgeons may expose the femoral vessels so they can quickly cannulate and institute CPB if arterial or cardiac trauma occurs at sternotomy. Other surgeons will cannulate the femoral vessels before sternotomy and institute CPB during dissection (the heart is not arrested and continues beating). An oscillating saw is often selected for slow, cautious sternotomy. Communication between the surgeon and anesthetist is crucial because the lungs may need to be deflated several times for short periods. In the rare event that a cardiac structure or great vessel is damaged and bleeding becomes uncontrollable, IV heparin (300–400 units/kg) is administered centrally emergently. If the patient is not already cannulated, the surgeon will emergently place the arterial cannula in the femoral

artery or aorta, and the cardiotomy suckers will be used for venous return in what is sometimes called “sucker bypass.” BP is kept high enough to maintain adequate coronary perfusion, yet hypertension must be avoided to minimize excess bleeding. Crystalloid or colloid can be administered if necessary, but hemodilution will exacerbate preexisting anemia. Packed RBCs should be readily available in all redo sternotomies because the potential for inadvertent vascular injury is significantly increased, as previously discussed.

After sternotomy, the conduit will be harvested if the procedure involves a CABG. The anesthetic considerations related to conduit harvesting are reviewed later in the chapter during the discussion of CABG. If no conduit is required, the heart and vascular structures are dissected as individual exposure requirements of the surgical procedure dictate. The period of harvesting and dissection is generally less stimulating, so anesthetic levels may be reduced. Often dissection requires considerable manipulation of the heart and vasculature that can result in hypotension and dysrhythmias. Vigilance is required on the part of the anesthetist so the surgeon can be alerted when excessive manipulation results in hypotension and/or dysrhythmias. Hypotension usually responds to placing the patient in the Trendelenburg position (head down) and administering small doses of phenylephrine. The surgeon may ask for ventilation to be withheld and the lungs deflated to improve the surgical view. When the lungs are down, it is recommended that the anesthetist either leave the ventilator alarm sounding or keep his or her hand on the anesthesia bag as a reminder to resume ventilation. Inadvertent failure to ventilate is a hazard in cardiac anesthesia that can have devastating consequences. Both sympathetic nerve dissection and opening of the pericardium are additional stimulating events that may require increased levels of anesthesia. After the anterior pericardium is opened, it may be lifted (especially in the ministernotomy approach) and sutured to improve the surgical view. This surgical maneuver is likely to cause bradycardia and hypotension because the position of the heart in the pericardium is changed, decreasing venous return with activation of the parasympathetic nervous system. Most patients respond to small doses of phenylephrine or ephedrine, but occasionally the anesthetist must ask the surgeon to decrease

tension on the pericardial sutures. After the pericardium is opened, surgical preparation for cannulation begins.

Cannulation.

Cannulation is the next major event in the prebypass period. Full heparinization is essential before cannulation. Heparin (300–400 units/kg) is administered through a central line after aspiration of blood confirms line patency, to ensure intravascular administration. The ACT or heparin concentration assay is checked 3 to 5 minutes after the heparin is administered. Muscle relaxants are given if needed because movement during cannulation could prove disastrous. The aortic cannula is placed first, followed by the single venous cannula or double venous cannulae (see [Figs. 26.9](#) and [26.10](#)). Then, the antegrade and retrograde cardioplegia cannulae may be inserted, or the surgeon may wait until after CPB is initiated.

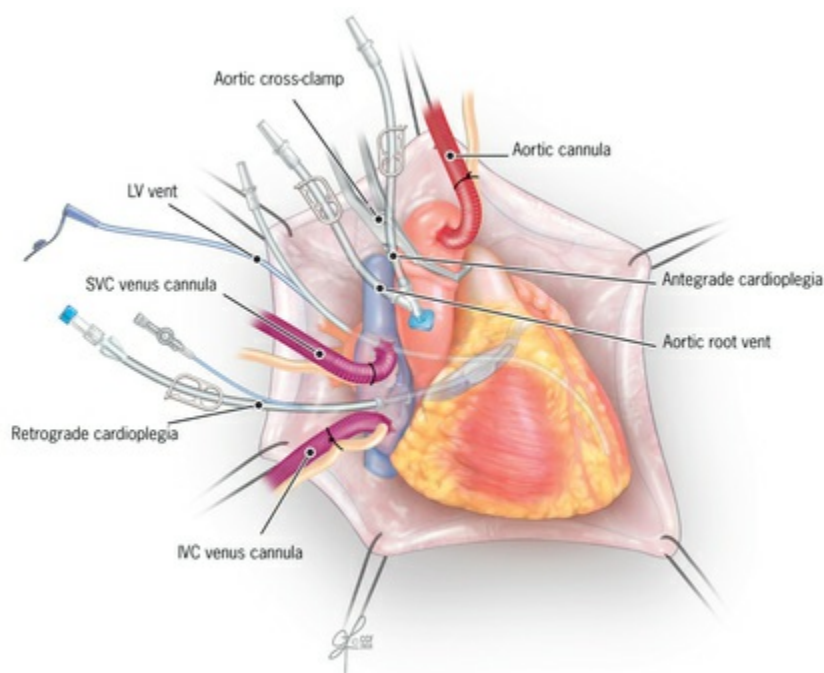

FIGURE 26.10 Full cannulation for cardiopulmonary bypass (CPB). Deoxygenated venous blood is drained from the patient to the CPB machine via two separate venous cannulae (bicaval cannulation). One cannula is in the superior vena cava (SVC) and the other is in the inferior vena cava (IVC). Oxygenated and filtered blood from the CPB machine returns to the patient via the aortic

cannula that is located distal to the aortic cross-clamp and proximal to the innominate. Cardioplegia may be administered antegrade down the coronary arteries via a cannula placed in the aorta just proximal to the cross-clamp. Cardioplegia is sometimes administered retrograde into the venous system via a balloon-tipped cannula placed in the coronary sinus. Vents are used to decompress the left ventricle (LV vent) and to remove air from the ascending aorta (root vent). Note that the aortic vent is the same cannula that is used for antegrade cardioplegia. A Y connector and clamps are used to control flow. *IVC*, Inferior vena cava; *LV*, left ventricle; *SVC*, superior vena cava. (Reprinted with permission from Cleveland Clinic Center for Medical Art and Photography © 2006-2012. All rights reserved.)

Surgical manipulation of the heart and great vessels during cannulation often leads to hypotension and dysrhythmias; therefore careful attention and clear communication between the anesthetist, surgeon, and perfusionist are critical. Before the aortic cannula is placed, BP is decreased to a systolic blood pressure (SBP) of 90 to 100 mm Hg or a MAP less than 70 mm Hg to decrease the risk of aortic dissection. To achieve this goal, the anesthetic level can be deepened, or vasodilators can be carefully titrated. The aortic cannula and aortic line from the CPB machine are connected and inspected, and all air bubbles are purged. Complications of aortic cannulation include arterial dissection, hemorrhage, plaque or air embolization, and inadvertent placement of the distal tip of the cannula in an aortic arch vessel. Once aortic cannulation is completed, the perfusionist will confirm intraarterial placement of the arterial cannula by verifying pressure variation in the manometer connected to the aortic line (called *checking the swing*). Then, a test transfusion is administered to confirm normal flow and pressure into the aortic cannula. The anesthetist may then allow the BP to increase by either decreasing the anesthetic level or discontinuing vasodilators. The perfusionist can give volume through the aortic line to augment MAP.

Next, the venous cannulae are placed. Again, the anesthetist should watch for hypotension, dysrhythmias, or hemorrhage. Once placement is completed, the perfusionist may initiate the RAP process. As described earlier, this process requires an increased BP. Finally, the surgeon may choose to place the retrograde

cardioplegia cannula. Because this is done by palpation of the coronary sinus, a posterior structure, it almost inevitably leads to hypotension and dysrhythmias. For this reason, some surgeons place this cannula after bypass has been initiated. The retrograde cannula is sometimes connected to a pressure transducer to monitor the mean pressure. The baseline retrograde pressure is generally reflective of venous pressure, and should increase approximately 20 mm Hg when retrograde cardioplegia is infused. If the retrograde pressure is low, it could indicate that the cannula has fallen into the atria; if it is too high (greater than 40 mm Hg), the catheter could be positioned too distally, increasing the risk of coronary sinus rupture. **Box 26.2** contains a preparation-for-bypass checklist.

Preparation for Bypass: Prebypass Checklist

1. Anticoagulation
 - a. Heparin administered
 - b. Desired level of anticoagulation achieved
2. Arterial cannulation
 - a. Absence of bubbles in arterial line
 - b. Evidence of dissection or malposition?
3. Venous cannulation
 - a. Evidence of superior vena cava obstruction?
 - b. Evidence of inferior vena cava obstruction?
4. Pulmonary artery catheter (if used) pulled back

5. Are all monitoring/access catheters functional?
6. Transesophageal echocardiograph (if used)
 - a. In “freeze” mode
 - b. Scope in neutral/unlocked position
7. Supplemental medications
 - a. Neuromuscular blockers
 - b. Anesthetics, analgesics, amnestics
8. Inspection of head and neck
 - a. Color
 - b. Symmetry
 - c. Venous drainage
 - d. Pupils

Cardiopulmonary Bypass Period

Initiation.

Initiation of CPB can begin after the ACT is greater than 400 seconds. The venous clamp is first released, allowing blood to fill the venous reservoir; then the arterial clamp is removed, initiating CPB. Adequate venous drainage is necessary for the pump flow to be gradually increased to reach a calculated CI of 2.0 to 2.5 L/min

per m². Acceptable venous drainage usually correlates with a CVP of less than 5 mm Hg (and possibly a negative pressure, if VAVD is used). The heart should appear empty and not distended.

Hypotension is common at the initiation of bypass, and is most likely related to the instantaneous hemodilution and reduced blood viscosity that occur, which can then result in a reduction of SVR. Phenylephrine boluses administered by the perfusionist are routinely necessary to augment the MAP during the initial phase of CPB. The most ominous reason for significant persistent hypotension (MAP less than 30 mm Hg) is an aortic dissection. The diagnosis can be confirmed by TEE, and the surgeon may note a hematoma on the wall of the aorta. If a dissection is suspected, CPB must be discontinued until the aorta can be recannulated distal to the dissection. Other causes of persistent hypotension while on CPB include vasoplegia and sepsis.

When the CPB machine reaches full flow, there will no longer be a pulsatile trace visible on the PA-line, or A-line, indicating that blood is now bypassing the lungs. Consequently, mechanical ventilation is discontinued. During CPB, the anesthetist must ensure that adequate levels of anesthetic and muscle relaxant are maintained. Equipment integrity should be verified throughout the duration of CPB. If a volatile agent is to be used, the vaporizer must be properly seated on the oxygenator gas inlet of the CPB machine and turned on. An improperly seated vaporizer can obstruct gas flow to the oxygenator, resulting in hypoxemia. The infusion of all IV fluids and most medications is stopped. Antifibrinolytics, if used, are continued, and insulin is often necessary because hyperglycemia usually manifests during CPB. The PA catheter, if present, should be pulled back 2 to 3 cm to prevent pulmonary rupture. Sometimes, the surgeon will complete the dissection of the heart while it is still beating on CPB before aortic cross-clamp. The vent for the LV is most often inserted through the left superior pulmonary vein.

Next, the surgeon will ask the perfusionist to temporarily decrease the CPB flow while the aortic cross-clamp is applied. The clamp time is noted. Cardiac arrest will follow soon after aortic cross-clamp. After the cross-clamp is applied, full CPB flow will be resumed, and antegrade cardioplegia infused through a catheter

placed in the aorta between the cross-clamp and the AV (see Fig. 26.10). As the infusion of the high-potassium solution reaches the myocardium via the coronary arteries, the heart arrests in diastole, and electrical and mechanical asystole should ensue quickly. As explained earlier, achieving diastolic arrest can be difficult in patients with significant AR because some of the cardioplegia leaks into the ventricle rather than perfusing the coronaries. Any heart rhythm besides asystole indicates incomplete myocardial protection and the need for additional cardioplegia. Retrograde cardioplegia through the coronary sinus may also be administered, or cardioplegia may be given directly into the coronary ostia if the aorta is opened. To further enhance myocardial and cerebral protection, the surgeon may allow the patient's temperature to "drift" toward the ambient room temperature, or may begin active cooling centrally through the CPB circuit. Some surgeons cool topically by packing ice around the heart. Box 26.3 contains a checklist of items the anesthetist should check after bypass is

Box 26.3

Anesthesia Checklist at the Initiation of Bypass

Face	Examine for color, temperature, plethora, edema, and symmetry
Eyes	Examine pupils for size and symmetry and conjunctiva for edema
CPB lines	Arteriovenous color difference should be visible.
PAC	If present, pull back 3 to 4 cm. Mean pressure should be less than 15 mm Hg mean
CVP	Less than 5 mm Hg, possibly negative with VAVD
Heart	Avoid distension
Ventilation	Stop when PA ejection and/or aortic ejection ceases

CPB, Cardiopulmonary bypass; CVP, central venous pressure; PA, pulmonary artery; PAC, pulmonary artery catheter; VAVD, vacuum-assisted venous drainage.

Maintenance.

The flow rate on CPB is maintained at 50 to 60 mL/kg per min to reach a calculated CI of 2.0 to 2.5 L/min per m². The ideal systemic pressure on CPB is 50 to 70 mm Hg, depending on the patient's age and comorbidities. The mixed venous O₂ saturation should be monitored and maintained at 70%. Hypertension may indicate a light anesthetic level. This can be treated by increasing the

inhalational agent or by administering a supplemental dose of narcotic or benzodiazepine. If hypertension persists, a vasodilator may be added. Hypotension is usually treated with bolus doses of phenylephrine by the perfusionist, but occasionally an infusion of a vasopressor may be needed. The train-of-four should be completely suppressed to prevent movement or shivering during CPB. Shivering may not be obvious, but it greatly increases O₂ consumption, which may be manifested as low O₂ on the venous gas sensor.

ABGs and ACTs are monitored every 30 minutes. Acid/base imbalances are corrected as needed. Blood may be needed, depending on the patient's hematocrit and comorbidities, as well as on the complexity of the surgical procedure. Blood glucose usually increases to a level that requires treatment with an insulin infusion. Patients often develop some level of hyperkalemia related to the potassium in the cardioplegia solution. The insulin infusion counters this problem by driving potassium into the cell. Urine output is monitored: 1 mL/kg per hr is considered satisfactory. If urine output is low and the pump volume is adequate, the addition of a diuretic should be considered, especially if the patient was taking a diuretic preoperatively. If the hematocrit is low, hemoconcentration (ultrafiltration) through the CPB circuit can be considered as a blood conservation technique.

Preparation for Separation From CPB.

[Box 26.4](#) outlines many of the factors that must be considered in preparation for separation from CPB. The need for possible inotropic or vasopressor support is anticipated, and infusions prepared. Rewarming begins as the surgeon is completing the repair. The process is begun early enough to facilitate slow, gradual warming to an nasopharyngeal or esophageal temperature of 36°C to 37°C.¹¹⁹ During rewarming, the bladder temperature may lag 2°C behind the nasopharyngeal or esophageal temperatures.¹²⁰

Preparation for Separation-From-Bypass Checklist

1. Air clearance maneuvers completed

2. Rewarming completed
 - a. Nasopharyngeal temperature 36°C to 37°C
 - b. Rectal/bladder temperature $\geq 35^{\circ}\text{C}$, but $\leq 37^{\circ}\text{C}$
3. Address issue of adequacy of anesthesia and muscle relaxation
4. Obtain stable cardiac rate and rhythm (use pacing if necessary)
5. Pump flow and systemic arterial pressure
 - a. Pump flow to maintain mixed venous saturation $\geq 70\%$
 - b. Systemic pressure restored to normothermic levels
6. Metabolic parameters
 - a. Arterial pH, PO_2 , PCO_2 within normal limits
 - b. Hct: 20% to 25%
 - c. K^+ : 4–5 mEq/L
 - d. Ionized calcium
7. Ensuring all monitoring/access catheters functional?
 - a. Transducers re-zeroed
 - b. TEE (if used) out of freeze mode

8. Respiratory management

- a. Atelectasis cleared/lungs re-expanded
- b. Evidence of pneumothorax?
- c. Residual fluid in thoracic cavities drained
- d. Ventilation reinstated

9. Intravenous fluids restarted

. Inotropes/vasopressors/vasodilators prepared

Hct, Hematocrit; K^+ , potassium; PCO_2 , partial pressure of carbon dioxide; PO_2 , partial pressure of oxygen; *TEE*, transesophageal echocardiography.

From Grocott HP, et al. Cardiopulmonary bypass management and organ protection In Kaplan JA, et al. eds. *Kaplan's Cardiac Anesthesia: For Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia: Elsevier; 2017:1141.

Arterial and venous blood gases are normalized before termination of CPB. Potassium levels are addressed if greater than 5.5 mEq/L or less than 4.0 mEq/L, to decrease the incidence of dysrhythmias. If the patient is hyperkalemic, calcium may also be given to counteract the potassium and stabilize the membrane to prevent dysrhythmias. The administration of calcium is controversial. Some clinicians have a low threshold for treating low ionized calcium, given its beneficial positive inotropic effects and its essential role in the coagulation cascade. Other clinicians avoid calcium because it contributes to coronary vasospasm and may exacerbate reperfusion injury. Magnesium (2–4 g IV) is frequently administered prophylactically to minimize dysrhythmias. In a recent meta-analysis, CABG patients who received IV magnesium intraoperatively experienced a significant reduction in postoperative AF.¹²¹ Treatment for high glucose levels should

continue, but the rate of insulin infusion often can be lowered significantly, especially in a nondiabetic patient after separation from CPB.

An adequate circulating blood volume is necessary for separation from CPB. The amount needed varies with the patient's weight, prebypass volume status, ventricular function, and comorbidities. As previously indicated, the ideal hematocrit is a matter of debate, but most cardiac surgical patients require a hematocrit of 22% to 25% to ensure adequate tissue perfusion.⁵¹

As the cardiac chambers are surgically closed, the lungs are inflated to remove air from the heart and pulmonary veins and to assist in filling the heart. Terminal warm reperfusion cardioplegia solution (a hotshot) is administered, and the perfusionist lowers the pump flow temporarily as the surgeon removes the aortic cross-clamp. The time of clamp removal is noted. It is not uncommon for the heart to fibrillate, especially if the myocardial preservation is insufficient or there are electrolyte imbalances during CPB. Intracardiac air can migrate into the coronary arteries, most commonly the right coronary artery (RCA), because it is anatomically superior and air rises. Ischemic changes may manifest on the ECG and echocardiogram. The surgeon may shake the heart or insert a needle through the muscle into the ventricle in an attempt to displace residual air. Echocardiography and the ECG can aid the surgeon in determining when all air pockets have been removed.

If fibrillation occurs, the heart is defibrillated with internal cardiac paddles placed directly on the myocardium, using 10 to 20 joules. Antidysrhythmics such as lidocaine or amiodarone may also be administered. The MAP can be increased using phenylephrine boluses, if necessary, to improve coronary blood flow and ensure optimal ventricular function. In some centers, magnesium (1–2 g IV) and lidocaine (100 mg IV) are administered prophylactically with discontinuation of CPB. Sinus is the optimal heart rhythm. A rate between 80 and 90 bpm represents a balance between adequate cardiac performance and myocardial O₂ demand. Temporary ventricular pacing wires are routinely placed because the intrinsic conduction system of the heart may be temporarily or permanently altered.

Atrioventricular pacing is preferred for bradycardia because the atrial contribution to the CO can be preserved. Unfortunately, atrial tissue is more prone to disruption or damage when the pacing wires are removed in the postoperative period, so they are placed less commonly. Patients with chronic AF are generally unable to conduct with atrial pacing. After separation from CPB when electrocautery is used, a pacemaker in a synchronous mode may sense discharge from the electrocautery as intrinsic cardiac activity and not discharge. Therefore an asynchronous pacing mode (VOO [ventricular asynchronous] or DOO [atrial ventricular sequential asynchronous]), is frequently employed to prevent electrocautery-induced pacemaker inhibition. However, asynchronous pacing modes place the patient at risk for developing ventricular fibrillation as a result of the R-on-T phenomenon. The pacer should therefore be converted to a synchronous mode as soon as electrocautery use becomes limited.

Once the heart begins ejecting, the lungs are gently reinflated manually, limiting the positive pressure to 30 cm H₂O, and mechanical ventilation is resumed. The anesthetist will visually inspect the lungs as they reinflate, in order to detect atelectasis and adequacy of reinflation. Positive end-expiratory pressure (PEEP) and/or recruitment maneuvers, such as manual sighs, can be used to treat significant atelectasis. However, overinflation of the lungs must be avoided, especially in CABG patients, because an in situ ITA bypass graft may be stretched, or even disrupted, during hyperinflation of the lungs. Delivery of an inhalation or IV anesthetic is continued by the anesthetist. Monitors and transducers are zeroed to atmospheric pressure and recalibrated. Ventricular function is assessed using TEE and direct visual inspection of the heart in the surgical field. The surgeon is notified of any echocardiographic findings that are of concern. Valvular integrity and ventricular wall motion are carefully examined. If ventricular function is marginal, an inotrope (most commonly epinephrine, dopamine, or dobutamine) is initiated. If hypotension persists, a vasoconstrictor such as norepinephrine may be started. Once the volume, hemodynamic function, and ventilation are satisfactory, weaning from CPB can begin.

Separation From CPB.

The perfusionist uses a clamp to gradually occlude the venous return to facilitate filling of the right ventricle. The right ventricle moves volume through the pulmonary system and into the LV. As the beating heart continues to fill, ejection resumes, and arterial pressure rises. Then the perfusionist gradually decreases CPB flow. Volume (preload) can be added through the arterial pump line until loading conditions are optimized. Once adequate volume has been supplied through the in situ arterial cannula, the line is clamped, and the time of separation from CPB is recorded. The immediate postbypass period demands close attention because hemodynamic instability and cardiovascular collapse may occur. If a radial A-line is present, the practitioner must be aware of the potential discrepancy between the radial and aortic pressures.⁹⁹ If a PAC was pulled back during the procedure and is now in the right ventricle, it can be repositioned into the PA.

If pulmonary pressures rise precipitously with concurrently falling arterial pressures, this may indicate severely decreased ventricular function and an inability to separate from CPB. If the patient fails separation despite significant efforts at support, CPB can be reinstated and the situation reevaluated, focusing on potentially reversible causes of failure. TEE is an invaluable tool to assist in diagnosis and guide management. Visual inspection of the operative field may reveal a surgically correctable problem, such as a kinked bypass graft. If, however, no obvious anatomic problem is identified, a period of resting perfusion on CPB will help resolve the cardiac stunning that commonly occurs after cardiac surgery. Pharmacologic inotropic or vasopressor support is initiated or increased. If pharmacologic support is insufficient for separation from CPB, an intraaortic balloon pump (IABP) may be placed. As a last resort, extracorporeal membrane oxygenation (ECMO) or a ventricular assist device (VAD) may be used for ventricular support. The indications for and use of these devices are discussed in the section on mechanical circulatory support of heart failure.

Postbypass Period

Decannulation.

Blood from the pump is transfused to the patient either at a slow but continuous rate or in 100-mL increments. Caution is taken to prevent overdilatation and volume overload of either ventricle. Once major surgical bleeding is controlled and hemodynamic stability is satisfactory, preparation for decannulation can begin. The BP is usually lowered to 90 mm Hg systolic or a MAP of 70 mm Hg or less to reduce bleeding. The atrial (venous) cannula(e) are removed first, then the aortic cannula is removed, and the time is recorded. Blood that remains in the CPB reservoir and pump tubing is sent to the cell-saver device so that it can be washed and reinfused.

Protamine Administration.

Protamine is used to reverse the anticoagulation caused by heparin. Protamine neutralizes heparin through electrostatic interaction, forming a heparin-protamine complex that renders heparin inactive. A test dose of 10 mg of protamine is routinely given to check for anaphylaxis because allergies or intolerance to protamine are relatively common. Protamine reactions can range from mild hypotension to anaphylaxis. Some surgeons prefer to give the test dose of protamine while the aortic cannula is in the aorta, in case anaphylaxis develops. Otherwise, the protamine is not administered until the patient is decannulated because clot formation in the CPB pump will have devastating consequences. Slow drug administration is the most effective strategy for avoiding hypotension, which is common when protamine is delivered rapidly. Giving protamine over a period of 10 to 15 minutes will decrease the probability of both type I (systemic vasodilation-histamine release) and type III (pulmonary vasoconstriction-delayed anaphylactoid) protamine reactions. However, an anaphylactic reaction (type II) can occur at any rate of administration.¹²² The normal dose of protamine is 1 mg of protamine to reverse every 100 units of heparin that was given. Therefore a normal heparin dose of 30,000 units would require 300 mg of protamine for reversal. An ACT is obtained at least 3 to 5 minutes after the entire protamine dose is given, to confirm that ACT has returned to baseline. Alternatively, an HDR assay can be used to determine the optimal protamine dose and check for

residual heparin after protamine administration. Additional protamine doses of 50 to 100 mg are routinely administered to cover residual anticoagulation, if inadequate hemostasis is visualized in the surgical field.

Hemodynamic Management.

After CPB, most patients fall into one of four groups.¹²³ The first group includes patients with good LV function preoperatively and few comorbidities; they usually separate from CPB easily and require little support. Patients with good ventricular function usually have a BP, heart rate and rhythm, and CO within the normal range. This group of patients may need some occasional adjustments of their volume or BP, but they are generally stable during the postbypass period.

The second group consists of patients with significant concentric LVH and diastolic dysfunction. This group tends to be volume-dependent. The intravascular volume status should be continually reassessed using TEE, because the LVEDP may be elevated despite low ventricular volume due to decreased ventricular compliance. As volume is added from the pump, these patients may become hypertensive, even though their CO is still low, due to hypovolemia. In other words, this group of patients is prone to DHF. Judicious boluses of nitroglycerin will help the LV to relax and accept volume, as well as aid in controlling hypertension. As discussed at the beginning of the chapter, patients with concentric LVH require a high MAP and adequate diastolic time to fill the noncompliant ventricle (see [Table 26.4](#)). If the MAP decreases, they are prone to ischemia; therefore they may benefit from a low-dose vasoconstrictor such as norepinephrine if the BP is low after volume has been optimized. These patients are also very reliant on their atrial kick, which can contribute up to 40% of left ventricular EDV.⁸² If the patient's heart rate is slow or nodal, atrial or atrioventricular pacing can significantly improve hemodynamic function. Left ventricular outflow tract (LVOT) obstruction with possible systolic anterior motion (SAM) of the mitral valve can also occur, particularly in patients with septal hypertrophy. This problem is best assessed using TEE and treated by keeping the heart full, heart rate in the slow-normal range, and SVR up (see the

section on hypertrophic obstructive cardiomyopathy [HOCM]). Once the diastolic filling volume, heart rate, and BP are optimized, the patients usually separate from bypass easily.

The third group of patients comprises those who develop systolic failure after CPB. This group can be further subdivided into left, right, or biventricular failure.¹²³ As volume is added from the pump, the heart chamber(s) begin to dilate, and contractility is poor. Patients with poor preoperative left or right ventricular function, long CPB runs, complex procedures, uncorrected structural defects, or inadequate myocardial protection on CPB are at high risk for failure.⁸ The pathophysiology of failure was discussed early in the chapter (see [Tables 26.3](#) and [26.4](#)). Many times, CPB must be reinitiated while the beating heart is given a chance to rest, or a medication infusion is added. LV systolic failure is managed with an inotrope such as epinephrine or dobutamine, combined with gentle afterload reduction using a vasodilator such as nitroprusside if the SVR is high. An inodilator such as milrinone will provide inotropic support and reduce afterload. Milrinone has the added benefit of significantly increasing the flow in anastomosed saphenous vein grafts after CPB.¹²⁴ It may be used alone or in conjunction with other inotropes and vasopressors. RHF can be initially managed with a combination of epinephrine to support contractility and nitroglycerin titrated to reduce afterload while maintaining BP to support coronary perfusion. If this is ineffective, a bolus and/or infusion of milrinone can be helpful because it is particularly effective in reducing pulmonary vascular resistance, thereby lowering right ventricular afterload. Unfortunately, milrinone may cause an excessive decrease in the SVR that leads to hypotension. A norepinephrine infusion may be initiated to augment the BP to a level sufficient for coronary perfusion. Rarely (due partly to cost), inhaled nitric oxide or epoprostenol sodium (Flolan) is used to selectively dilate the pulmonary vasculature and decrease right heart afterload.⁸² If maximal pharmacologic support fails, then mechanical support of the ventricle is considered, including the use of an IABP, ECMO, or VAD. Because management of these devices is complex and rather specialized, the anesthetic considerations are discussed separately (see the section on the treatment of heart failure).

The fourth and final group of patients present with persistent hypotension in the post-CPB period, despite a normal to high CO. Patients in this group may be septic because of preexisting endocarditis, or may develop vasoplegic syndrome. Vasoplegic syndrome is a well-described type of vasodilatory shock that occurs after CPB. The reported incidence (9% to 44%) varies widely, as do the purported causes. Preoperative administration of (ACEIs and calcium channel blockers, amiodarone, and IV heparin have been implicated as potential causative agents. Diabetes and moderate-to-poor LV dysfunction are also correlated with this syndrome.^{125,126} Unfortunately, no particular medical history consistently predicts manifestation of this syndrome; however, hypotension early in the pump run is predictive of its development after CPB.¹²⁷ Patients with the syndrome often require large doses of phenylephrine, or even norepinephrine, while on CPB. Post-CPB, they develop resistance to phenylephrine and respond much better to boluses of norepinephrine (16–32 mcg) or vasopressin (1–2 units.) A norepinephrine and/or vasopressin infusion is often needed to support the BP. Vasopressin has been demonstrated to be more effective in the management of vasoplegic syndrome than norepinephrine.^{128,129} Although a patient's CO may fall into the normal or even the hyperdynamic range, the heart may still benefit from low to moderate doses of inotropic support to sustain contractility in this state of vasodilatory shock.¹³⁰ Maintaining a relatively high hematocrit level augments preload and also improves BP.¹²³

Additional Considerations.

After the patient is decannulated, the surgeon may pack the chest to encourage hemostasis. Electrocautery is used routinely. During this period, the surgeon may need to lift the heart to inspect for bleeding on the posterior surface. Lifting and manipulating the heart and vasculature can cause significant dysrhythmias and hypotension. The surgeon should be informed if hypotension is severe or excessive in duration. As previously mentioned, electrocautery-induced suppression of the pacemaker can occur, so the pacemaker is often placed in an asynchronous mode. Synchronous pacing should be resumed as soon as the surgeon

finishes using the electrocautery. Most patients require volume supplementation post-bypass. Often, a combination of crystalloid, colloid, and cell-saver blood is used. This combination usually results in a hematocrit of 25% to 30%.

Persistent bleeding occasionally develops after CPB, especially if the surgery was complex and required a long pump run. The causes are multifactorial, but readily treatable problems should be addressed. Adequate reversal of heparin is confirmed via ACT or a heparin concentration assay, and additional doses of protamine are given, if needed. Hypothermia accentuates hemostatic defects, so the patient and the room are warmed to promote normothermia. Surgical causes of persistent bleeding are identified, as inadequate surgical hemostasis may develop and progress insidiously. If oozing persists, laboratory coagulation studies may reveal a deficiency in the coagulation cascade. Platelets, plasma, cryoprecipitate, and red cell transfusions may be required, depending on the underlying deficiency. If the patient has platelet dysfunction due to pre-existing pathology (e.g., uremia, liver disease), medications (e.g., ASA, thienopyridines), or even CPB, then desmopressin (DDAVP) should be considered. Recombinant activated factor VII can be administered in severe, uncontrolled bleeding situations when no surgical source of bleeding can be identified and replacement with red cells, plasma, platelets, and cryoprecipitate has been ineffective.^{82,131}

As discussed in the section on the physiologic effects of CPB, a host of other complications can arise, including ARDS, renal failure, and neurologic injury. Although these are most evident in the postoperative period, problems with adequate ventilation may occur in the OR as well. Most patients will respond to the addition of PEEP and other recruitment measures. Occasionally, ALI is so severe that an ICU ventilator with advanced ventilating modes is required.

Chest Closure.

When hemostasis has been achieved and the patient is hemodynamically stable, preparations are made for chest closure and transport to the ICU. The lungs are deflated temporarily when the sternum is pulled together to facilitate chest closure and prevent

the kinking of bypass grafts, if present. The CO and echocardiogram (if available) are reviewed before and after chest closure because the preload decreases and the afterload increases with chest closure. If the patient becomes unstable, the wires are released, and the situation reevaluated. Patients who have received massive transfusions or require high-dose pharmacologic and/or mechanical support may not tolerate the hemodynamic consequences of chest closure. In this situation, the patient may have the chest left open with a negative pressure wound dressing (V.A.C., KCI, San Antonio, TX, USA) applied. The patient is maintained in the ICU for the next 24 to 48 hours until hemostasis and hemodynamic stability are achieved. Then, the patient is returned to the OR for chest closure.

Once the chest is closed, preparations for safe transport to the ICU are initiated. Emergency medications and airway equipment are gathered for transport because transfer to the ICU represents a particularly vulnerable time outside of the OR. The echocardiogram probe is removed at the end of the procedure, and an OG tube is inserted to decompress the stomach. Although some stable patients may be extubated at the end of the procedure, most surgeons prefer that fast-tracking occur in the ICU.

Transport.

With the numerous monitors, invasive lines, chest tubes, pharmacologic infusions, and requisite airway equipment, moving a patient safely to the ICU can be complicated and hazardous. Most patients are sedated with propofol or dexmedetomidine infusions during transport and initially in the ICU. A thorough patient-handoff to ICU personnel is vital for patient safety. A hand-off checklist helps to ensure that all critical information is communicated to the ICU team.¹¹⁶ Once the patient is hemodynamically stable and chest tube output is adequate, then the weaning and extubation process begins.

Postoperative Bleeding and Cardiac Tamponade

Bleeding is not uncommon after cardiac surgery, and in approximately 4% to 5% of cases, patients must return to surgery to

have the chest re-explored for persistent bleeding, tamponade, or unexplained hemodynamic instability that is presumed to be tamponade.⁸ Cardiac tamponade is reported to occur in up to 8.8% of patients after cardiac surgery, depending on the complexity of the surgical procedure and the presence of comorbidities.^{132,133} Cardiac tamponade occurs when fluid trapped in the pericardial sac increases in volume enough to cause myocardial compression.⁸ The compression then limits diastolic filling of the heart, thus reducing SV and CO.⁸ Severe hypotension, myocardial ischemia, and eventually cardiac arrest can ensue once venous pressures fall below pericardial pressures, causing ventricular collapse.⁸ Pericardiocentesis, subxiphoid drainage, or mediastinal exploration must occur without delay once decompensated cardiac tamponade occurs, to prevent complete cardiac collapse.^{134,135}

Cardiac tamponade can occur due to nonloculated pericardial effusions, which can be caused by many medical conditions such as malignancies, viral pericarditis, uremia, and bacterial infections.¹³⁵ Coagulopathy, postoperative bleeding, and/or localized compression from blood that is in contact with the heart may all contribute to tamponade that occurs in the period immediately following cardiac surgery.^{8,82,133} Cardiac tamponade should be suspected after cardiac surgery if there is a sudden dramatic decrease in chest tube drainage with concomitant hypotension, tachycardia, increased and equalizing filling pressures, and decreased cardiac indices, despite increased inotropic and vasopressor support.^{8,133} Pulsus paradoxus, electrical alternans, and the Beck triad are all considered classic clinical indicators of cardiac tamponade.¹³⁶ Pulsus paradoxus is defined as a decrease in SBP by more than 10 to 12 mm Hg on inspiration or on exhalation with positive pressure ventilation.^{82,133} The drop in BP on inspiration occurs because fluid accumulates around the pericardium and prevents ventricular filling.⁸² This causes ventricular interdependence, a phenomenon in which any change in volume of one side of the heart causes an opposing change in volume on the other side of the heart.⁸² During inspiration, there is increased venous return to the right ventricle, causing the ventricular septum to bulge into the LV and decrease CO and left ventricular SV.¹³⁴ With positive pressure ventilation, venous return is greatest on

exhalation, so the BP drop occurs then. Electrical alternans is the cyclic alteration in the magnitude of P waves, QRS complexes, and T waves that occurs as a result of the tamponade.^{134,136} The Beck triad is characterized by low BP, jugular venous distension, and distant heart sounds.¹³⁶ A chest x-ray will often reveal an enlarged cardiac silhouette, and the TEE examination will find diastolic collapse of the right atrium or right ventricle.^{82,133}

Crystalloid, colloid, and/or blood should be administered to optimize preload until pericardiocentesis or mediastinal exploration can be undertaken in the ICU or operating suite.^{82,134} If the postoperative cardiac surgical patient is brought to the operative room for re-exploration because of tamponade, drugs such as anesthetics, sedatives, and narcotics should be either carefully titrated or avoided to prevent further myocardial depression until the tamponade is relieved.⁸² Ketamine, because of its sympathomimetic effects, may be selected for induction of anesthesia in order to preserve heart rate, preserve the BP, and support myocardial function.^{8,82,134} Bradycardia should be avoided, and tachycardia must be recognized as an important compensatory mechanism that serves to maintain CO during cardiac tamponade.^{82,133} If cardiac arrest seems likely to occur with induction, a temporary improvement in cardiac function can be achieved by performing a pericardiocentesis under local anesthesia before induction, to create enough drainage to provide some relief.^{82,134} Postoperative cardiac surgical patients returning to the OR because of bleeding and tamponade who no longer have invasive monitoring in place will require insertion of an A-line and CVP.^{82,134} However, surgical drainage should not be delayed for placement of central access. TEE is useful for monitoring ventricular function and as an aid in guiding the surgeon in removing trapped fluid. The patient is sometimes kept spontaneously breathing until the pericardial sac is opened to prevent further decreases in ventricular filling caused by positive pressure ventilation.^{82,134} If positive pressure ventilation is used, tidal volumes should be reduced in order to prevent further decrease in preload and CO. Once the tamponade is surgically relieved, an immediate improvement in hemodynamics is usually noted. At this time, hypertension and tachycardia from endogenous

catecholamine release should be anticipated by the anesthetist and treated accordingly.⁸²

Anesthetic Considerations for Specific Cardiac Diseases and Surgical Procedures

Coronary Artery Disease and Myocardial Revascularization

Pathophysiology

On-pump CABG surgery is the most frequently performed cardiac surgical procedure. Anesthetic management for these patients requires an understanding of coronary anatomy and physiology, as discussed in [Chapter 25](#), as well as an understanding of the key physiologic principles covered at the beginning of this chapter. This section focuses on the considerations that pertain to CABG surgery.

CAD is a complex disease state that involves narrowing of the coronary arteries. The pathogenesis of CAD is not definitively clear, but several theories have been proposed. Scientists believe the endothelium or innermost layer of the artery becomes injured. Over time, cholesterol components (such as low-density lipoproteins) and macrophages adhere to the endothelium and form plaques. The plaques continue to build and decrease the vessels' ability to distend. Because coronary O₂ extraction is maximal at rest, the only way to increase O₂ delivery to the tissues is to increase coronary flow. In normal coronaries, flow can increase 3 to 5 times over baseline when demand increases. However, this increase in flow, known as *coronary reserve*, is limited in patients with CAD. Thus, when patients with CAD increase demand by exercise or stress, they develop *demand ischemia*, which is symptomatically experienced as predictable, stable angina. General anesthetics protect against demand ischemia.

ACSs and perioperative ischemia are usually caused by *supply ischemia*.^{15,137,138} Ischemia occurs when a piece of the plaque ruptures, causing a thrombus to form that significantly or totally occludes a segment of a coronary artery, leading to ischemia, dysrhythmias, and/or MI. The problem can be exacerbated by spasm, which can

develop even in normal adjacent vessels.⁸ Great strides have been made in the nonsurgical treatment of CAD and ACS in the past two decades. The development and evolution of coronary stents have revolutionized care. Most patients presenting for CABG surgery with CAD and/or ACS will have been referred for some type of percutaneous coronary intervention (PCI). Surgeons and anesthesia providers must take this into consideration when planning care. Much research has been done comparing the risk-benefit ratio of surgical intervention to optimal medical management. The Coronary Revascularization Writing Group states that surgical intervention (CABG) remains appropriate for patients with a high burden of CAD, although PCI may also have a role in these patients. Additionally, patients who have failed PCI or who have coronary lesions not amenable to PCI will benefit from surgery.¹³⁹ In these situations, CABG has been found to have a lower mortality risk, as well as a lower risk of major cardiovascular complications or cerebral events than optimal medical management.¹⁴⁰⁻¹⁴²

Anesthetic Considerations and Surgical Options for On-Pump CABG

The anesthetist should carefully review preoperative cardiac tests to determine the location and extent of the lesions, to assess ventricular function, and to detect the possible presence of concurrent cardiac abnormalities such as AS. [Table 26.2](#) reviews significant findings on cardiovascular preoperative testing. Preoperative ventricular function correlates with the risk of developing postoperative low cardiac output syndrome (LCOS). Patients with ACS or NYHA class IV heart failure (see [Table 26.5](#)) are at high risk of LCOS. If the patient develops cardiogenic shock, often requiring an IABP to maintain stable hemodynamics, the patient is in the highest risk category. Patients who have had BMSs implanted within 3 months of surgery and/or DESs within 1 year of surgery will have special considerations because of their antiplatelet therapy. The general management of drugs affecting coagulation has already been discussed. However, in patients with recent coronary stents, the cardiologist and surgeon collaborate to determine the best management for the individual patient. For

emergency procedures, both aspirin and GPIIb/IIIa inhibitors may be continued, despite the increased risk of bleeding.¹⁴³

Optimizing myocardial O₂ supply and minimizing myocardial O₂ demand are clearly key anesthetic considerations in CABG surgery (see Fig. 26.1). The patient must be monitored carefully for ischemia throughout the procedure. Using a combination of ECG and TEE findings, together with direct inspection of the heart, is advised.¹⁴⁴ Table 26.1 outlines causes of and treatments for myocardial ischemia. Anesthetic considerations are summarized in Table 26.9. It is most important to keep a relatively high MAP to maintain coronary perfusion, while keeping the heart rate and LVEDP low. Patients with left-main and triple-vessel disease should have an A-line and a large-bore IV in place before induction so that hypotension can be treated promptly. β-Blockers are used to control heart rate, and the preferred vasodilator for CABG is nitroglycerin.¹⁴³ Preoperative β-blockade is a quality metric for both the National Quality Forum and the STS database, which is used for quality report cards in conjunction with Consumer Reports.^{145,146} In low doses, nitroglycerin acts immediately to reduce preload by decreasing vascular tone; in higher doses, it also decreases coronary artery resistance. Kaplan et al. showed that nitroglycerin is superior to nitroprusside in CABG patients.¹⁴⁷

TABLE 26.9

Anesthetic Considerations in the Management of CABG

Factor	Hemodynamic Goals	Anesthetic Considerations
Preload	↓	↓ LVEDP will ↑ myocardial O ₂ supply and ↓ demand Nitroglycerin selectively dilates coronary vessels
Heart rate	Slow normal	Too fast → ischemia; consider β-blockade Too slow → not enough CO for coronary perfusion
Rhythm	Maintain sinus	Maintains atrial contribution to cardiac output
Compliance	Improve	Concentric LVH (common with history of HTN) → ↓ compliance
Contractility	Depress if normal LVF Support if ↓ LVF	↓ Contractility → ↓ MVO ₂ If poor LVF, may not tolerate depression
SVR	Maintain	Hypertension better tolerated than hypotension Treat hypotension promptly with phenylephrine
PVR	Maintain	Usually not a problem

↓, Decreased; ↑, increased; →, leads to; CABG, coronary artery bypass graft; CO, cardiac output; HTN, hypertension; LVEDP, left ventricular end-diastolic pressure; LVF, left ventricular function; LVH, left ventricular hypertrophy; MVO₂, myocardial oxygen consumption; O₂, oxygen; PVR, pulmonary vascular

resistance; *SVR*, systemic vascular resistance.

Volatile anesthetics should also comprise part of the anesthetic plan because of their preconditioning effect.¹⁰⁹ Nitrous oxide should be avoided because of the possibility of expanding gaseous spaces. Patients considered for fast-track protocols, generally those with EFs above 35%, should receive a limited dose of narcotics. The highest risk patients may still require a primary narcotic technique to maintain hemodynamic stability.

Conventional CABG surgery is performed through a median sternotomy with CPB. Different types of conduit can be used to bypass occluded areas of the patient's native coronary arteries to revascularize the myocardium distal to the occlusions (Fig. 26.11). The surgeon must take into consideration the viability of the myocardium, the quality of the target vessel, and the type and length of conduit needed to reach a point distal to the occlusions. The most commonly used conduits are the ITAs (formerly known as *IMAs*) and greater saphenous veins. The free radial artery graft is popular with some surgeons, whereas others question its long-term patency.¹⁴⁸ Arterial grafts are generally reserved for high-grade lesions because flow in the native coronary can compete with flow in the arterial bypass graft. If there is not enough flow in the muscular artery, it will spasm and shut down. Topical (papaverine) and IV antispasmodic drugs such as calcium channel blockers or low-dose nitroglycerin infused intraoperatively are used to treat spasm.

FIGURE 26.11 Coronary artery bypass graft (CABG) surgery. The in situ left internal thoracic artery is most often grafted to the left anterior descending native coronary. Free grafts (saphenous vein grafts, free radial artery, or right internal thoracic artery) are anastomosed proximally to the aorta (or branched from another bypass—not shown) and distally to a target area of the native coronary vessel that is beyond the obstruction. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006–2012. All rights reserved.)

The left internal thoracic artery (LITA) is usually left in situ at its proximal origin from the left subclavian artery, dissected from the chest wall, and anastomosed to the left anterior descending (LAD) artery. A LITA graft to the LAD artery has a 10-year patency rate of 85% to 99.1%.^{149,150} The right internal thoracic artery is usually transected from its proximal origin to become a free graft with a proximal anastomosis originating from the aorta or another conduit. The surgical table is elevated and turned while the ITA is

dissected. Lung volumes are reduced to improve the surgical view. The patient's arm should be well-padded because the axillary artery can be compressed by the chest wall retractor, lowering radial A-line pressures. A noninvasive cuff on the contralateral arm helps confirm the diagnosis. Heparin is usually administered before the LITA pedicle is clamped.

The saphenous vein graft (SVG) and radial artery conduit can be harvested by open surgery or endoscopically. As with any endoscopic procedure, the respiratory rate may have to be increased to compensate for the addition of carbon dioxide. Most vein grafts are now removed endoscopically, but there are concerns that endovascular vein harvest (EVH) might decrease long-term graft patency.^{151,152} Some surgeons request that low-dose heparin (2500 units) be given intravenously during EVH to decrease these issues. The surgeon reverses the vein to avoid the valves. The distal anastomosis to the native coronary artery is usually completed first, and then the proximal portion is sewn to the aorta or bridged off another graft.

Several surgical and technical complications can result in ischemia. In addition to the previously mentioned concerns about reoperations, patients who have undergone prior CABG surgery may have a patent LITA or other grafts lying directly under the sternum. Sternotomy can lead to marked ischemia if flow in the vessel is accidentally disrupted. The surgeon must take care to make bypass grafts the perfect length. LITA grafts that are too short can be overstretched with vigorous lung inflation, and SVGs can be overstretched when the heart is filled. On the other hand, grafts that are too long can kink when the chest is closed. Other causes of ischemia include coronary embolization of air or debris (discussed earlier) and coronary spasm.

Anesthetic Considerations and Surgical Options for Off-Pump CABG

The first off-pump coronary artery bypass (OPCAB) procedures were attempted in the 1950s, but there has been a resurgence in their popularity since retractors and epicardial stabilizing devices such as the Octopus (Medtronic Inc., Minneapolis, MN, USA) were

developed in the 1990s. Off-pump surgery is also called *beating heart bypass surgery*. Although the procedure is typically performed through a full median sternotomy without the aid of CPB, a perfusionist and a primed or dry pump (based on surgical preference) should be in the OR on standby throughout the case. Occasionally, a limited anterior thoracotomy (minimally invasive coronary artery bypass [MIDCAB]) approach is used. The implications of the MIDCAB incision are detailed in the section on minimally invasive surgery. It is estimated that OPCAB accounts for 20% to 30% of all CABG procedures.¹⁴³ OPCAB is performed to avoid the risks and complications associated with conventional CABG and CPB, but further research is needed to determine its relative safety. Aortic cross-clamping is avoided, theoretically decreasing the risk of debris embolization. Studies comparing the techniques showed that patients from both groups had equivalent rises in inflammatory biomarkers¹⁵³ and similar neuropsychologic outcomes.¹⁵⁴ Additionally, incomplete revascularization was slightly more common in the OPCAB patients, and 1-year patency significantly worse.¹⁵⁴ The STS recommends OPCAB as a blood conservation technique.⁵¹

Anesthetic implications and monitoring are similar to those of on-pump CABG, with a few additional concerns. The procedure is usually limited to patients with relatively good LV function, and bleeding is less of a concern, so patients are even more likely to be candidates for a fast-track anesthetic plan. Volume depletion is not uncommon in patients admitted to the OR. In contrast to on-pump cases, in which patients' blood volumes are diluted by priming volume, OPCAB patients require crystalloid and/or colloid solutions to correct fluid deficit and the hemodynamic changes inherent to the procedure. Patient temperature cannot be corrected on-pump; therefore hypothermia becomes a concern. Normothermia is maintained by warming the room and using fluid warmers, warm water mattresses, or forced-air warming devices. Anticoagulation is necessary, but the decision to partially heparinize (100–200 units/kg with an intended ACT of more than 300 seconds) or fully heparinize (300–400 units/kg with an intended ACT of more than 400 or 480 seconds) depends on the surgeon's preference. ACTs should be monitored at least every 30 minutes,

and heparin administered as needed to maintain adequate anticoagulation. Aminocaproic acid is not routinely used because the blood is not exposed to CPB. ABGs, electrolytes, and blood glucose should be monitored every half-hour to 1 hour and should be treated.

To perform a bypass on a beating heart, the surgeon employs specialized compressive footplate stabilizers (Fig. 26.12) and retractors that use suction to lift and suspend the heart, *verticalizing* the apex (Fig. 26.13). These maneuvers compress cardiac chambers and distort valvular apparatuses, resulting in well-documented hemodynamic compromise and acute ischemia.^{155,156} Every team member needs to be prepared for the possibility of converting to an on-pump procedure in the event of hemodynamic deterioration. Less myocardial manipulation is needed to bypass the LAD or diagonal coronary artery lesions (see Fig. 26.12), but as shown in Fig. 24.13, near verticalization of the apex is necessary to expose the posterior lateral wall for posterior descending artery (PDA) and circumflex lesions to be grafted. Some surgeons routinely shunt the coronary lesion being grafted, whereas others only shunt the lesion if regional ischemia develops. Close communication between the anesthesia providers and the surgical team is critical. Monitoring must be vigilant, and interventions timely. The CPP is maintained by keeping a relatively high MAP (90–100 mm Hg) during distal anastomosis. Hypotension is initially treated with volume and vasopressors (by bolus or infusion) as needed to maintain the BP. The steep Trendelenburg position will facilitate surgical exposure and help restore MAP and CO.^{157,158} Occasionally, patients will also require an inotrope to maintain hemodynamic stability. Dramatic hemodynamic changes can occur when the heart returns to a physiologic position, necessitating the abrupt withdrawal of pharmacologic support. Later, when the surgeon uses a side clamp to perform the proximal graft-aortic anastomoses, the MAP is routinely lowered to approximately 60 to 70 mm Hg. Surgical drying and closure are often more rapid in off-pump than in on-pump procedures because bleeding is minimized.

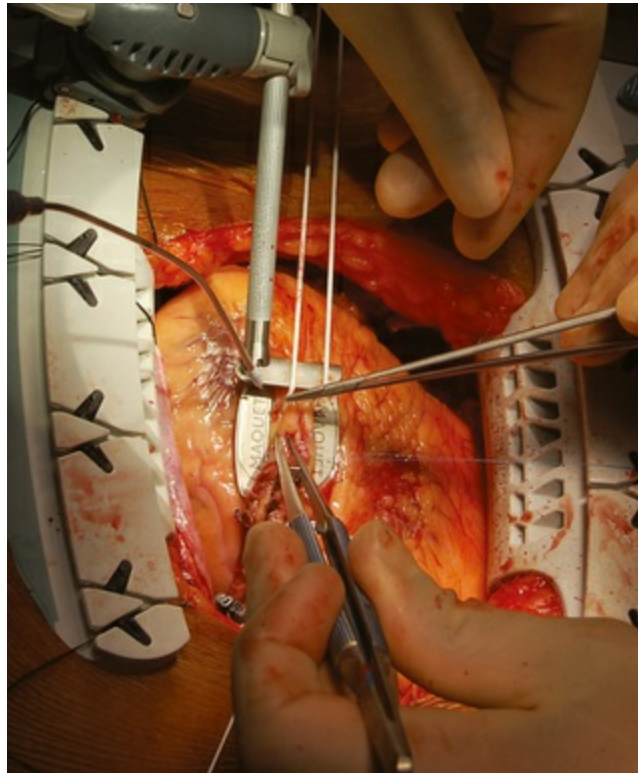

FIGURE 26.12 Left anterior descending (LAD) artery anastomosis during off-pump coronary artery bypass grafting using a left internal mammary artery (LIMA) graft. The view is from the head of the patient. The Maquet mechanical stabilizer (MAQUET, Wayne, NJ) is in place together with vascular snare sutures used to transiently occlude the artery. The LIMA is being anastomosed to the LAD, assisted by use of pressurized and heavily humidified carbon dioxide (“mister blower” metal cannula) to facilitate visualization of the vessel lumen. (Courtesy Alexander Mitnacht, MD, Mount Sinai School of Medicine, New York, NY.)

Valvular Heart Disease and Valve Surgery

Rheumatic heart disease (RHD) is still the primary cause of valvular disease worldwide. However, in industrialized countries like the United States, its prevalence has decreased, and degenerative heart disease, which correlates closely with advanced age, predominates. It is estimated that 2.5% of the overall US population has VHD, but prevalence rises dramatically with increasing age, reaching 13.2% after the age of 75.¹⁵⁹⁻¹⁶¹ Infective endocarditis is also an important cause of valvular disease, and a condition that can be exceptionally challenging for both the surgeon and the anesthetist. The proportion of cardiac surgeries that include valvular procedures has doubled over the past two decades. Currently, 20% of cardiac surgeries involve valve repair or replacement, and a significant proportion of these cases will include multiple lesions or concurrent myocardial revascularization. AS is the most common valvular defect requiring surgical intervention, followed by MR, AR, and finally, mitral stenosis (MS). Right-sided valvular disease occurs much less frequently.^{160,162,163} Often, multiple lesions are present, and a valve may exhibit both stenosis and regurgitation. In this condition, usually one problem predominates, and management is dictated by the pathology causing the majority of the patient's symptoms.

VHD causes abnormalities in the pressure and volume-loading conditions of the heart that result in structural and functional changes. Management requires a clear understanding of the anatomy, pathophysiology, and natural history of each lesion, as discussed in [Chapter 25](#). Echocardiography is an invaluable tool in the diagnosis and management of VHD. Three factors determine valvular flow: valve area, the pressure gradient across the valve, and the duration of flow in systole or diastole. Hemodynamic management of VHD requires manipulation of heart rate and rhythm, preload, afterload, and contractility to enhance forward flow in stenotic lesions and to minimize backward flow in

regurgitant lesions. Although HCM is not technically a valvular defect, its hemodynamic management is similar to that required for AS, so it is addressed in this section of the chapter.

Aortic Stenosis

AS is the most common valvular lesion among patients in industrialized countries. Approximately 1% to 2% of the population has a congenitally bicuspid valve.^{160,163} A bicuspid valve has a smaller orifice and tends to open and close abnormally, which subjects the valve apparatus to increased shear stress and degeneration. Hence, the majority of younger patients (30–50 years of age) undergoing valve replacement have bicuspid valves.¹⁶⁴ Risk factors for the development of acquired AS are the same as those for atherosclerosis: increased age, male gender, smoking, hypertension, and hyperlipidemia. The prevalence of degenerative AS increases markedly with age, and there is often concomitant AR.^{163–165} Many times, aortic valve replacements (AVRs) are combined with CABG. Some patients will be referred for AVR in preparation for subsequent noncardiac surgery because symptomatic AS is one of the cardiac conditions for which the AHA and ACC recommend intensive management before noncardiac surgery.³⁰

Pathophysiology.

The normal AV area measures $3 \text{ cm}^2 \pm 1 \text{ cm}^2$. Stenosis is considered severe when the valve area decreases to 1 cm^2 or less.⁸⁰ The stenotic orifice obstructs the LV outflow, and the ventricle compensates by becoming thicker (concentric hypertrophy), attempting to generate enough pressure to push the blood forward past the stenosis. This forward motion causes accelerated, turbulent blood flow as it crosses the valve, somewhat like the water flow when a garden hose is partially occluded. Secondary to the Venturi effect, this increased flow results in a pressure drop as it crosses the valve so that pressure in the aorta is significantly less than the pressure in the LV. A jet velocity of 4 m/sec or more and a mean pressure gradient drop of 40 mm Hg or more suggests severe AS, and a jet velocity of 6 m/sec with a mean pressure gradient of 60 mm Hg or

more is considered very severe or critical AS.⁸⁰ The pressure drop results in a characteristic slow upstroke and high diastolic notch on the A-line, with a classic narrow pulse pressure (systolic–diastolic) associated with AS. The patient with AS is very prone to ischemia for three reasons: thick, hypertrophied muscle mass has a high O₂ requirement, increased ventricular pressure inhibits coronary perfusion, and there is a high prevalence (more than 50%) of coexisting CAD. The fibrosed ventricle is noncompliant; consequently, diastolic filling becomes compromised, despite normal LV systolic function. LVEDP is elevated and often does not correlate to left ventricular end diastolic volume (LVEDV). Patients with AS are dependent on atrial augmentation of their CO. Atrial kick can contribute up to 40% of LVEDV. The classic triad of AS symptoms, angina, syncope, and congestion causing dyspnea, correlate closely with 5-, 3-, and 2-year survival, respectively. Ventricular systolic function remains normal until late in the course of the disease, when the LV dilates and systolic function deteriorates.^{8,82}

Anesthetic Considerations and Surgical Options.

Valve replacement is a class I recommendation for symptomatic patients with severe AS, as well as for asymptomatic patients with a LV EF less than 50%, or those having cardiac surgery for another indication.^{80,82} Preoperatively, great caution is required in treating angina with nitrates because hypotension may cause a downward spiral of decreasing coronary perfusion and ischemia to develop, which may ultimately end in cardiac arrest and sudden death. Cardiac compressions can rarely generate enough pressure to provide adequate coronary perfusion to permit resuscitation. In patients with AS, hypotension should therefore be treated promptly with a vasoconstrictor like phenylephrine to prevent this hemodynamic decompensation.⁸

Anesthetic management follows directly from an understanding of cardiovascular pathophysiology. [Table 26.10](#) outlines the anesthetic considerations. The anesthesia provider must be prepared for hemodynamic instability on induction and should choose the medications and speed of their administration accordingly. Patients often present with a significant degree of

hypertension preoperatively. The BP may rise or fall abruptly during the procedure, depending on the level of stimulation. Hypertension is better tolerated than hypotension, but it must be kept in mind that hypertension can also be a source of increased myocardial O₂ demand. Patients with severe AS have at least a 40 mm Hg mean (80 mm Hg systolic) pressure gradient between the LV and the aorta. Consequently, a systolic pressure of 180 mm Hg in the aorta correlates with a systolic pressure in the LV of at least 260 mm Hg.^{80,166} Tachycardia decreases the diastolic time needed for adequate coronary perfusion and ventricular filling, while increasing myocardial O₂ demand at the same time. Hypotension or tachycardia must be treated promptly to avoid increased myocardial O₂ consumption, which can provoke the cycle of ischemia that can be disastrous. All vasodilators should be titrated cautiously. AF, with loss of atrial augmentation of CO, can also lead to rapid hemodynamic deterioration, so prompt cardioversion is indicated.

TABLE 26.10

Anesthetic Considerations in the Management of Aortic Stenosis

Factor	Hemodynamic Goals	Anesthetic Considerations
Preload	Full	Need volume to stretch noncompliant LV ↑ preload reduces the gradient across LVOT LVEDP > LVEDV (use TEE to evaluate)
Heart rate	Slow normal	Too fast → ischemia Too slow → not enough CO for coronary perfusion
Rhythm	Maintain sinus	Atrial kick can contribute up to 40% of LVEDV Cardiovert early
Compliance	Improve	Thick, sclerotic LV prone to diastolic failure ↑ LVEDP reduces coronary perfusion Cautiously treat with NTG maintaining LVEDV and MAP
Contractility	Maintain	Concentric hypertrophy with normal chamber size Normal or ↑ EF initially Late dilation and falling EF
SVR	Maintain coronary perfusion gradient	Hypertension better tolerated than hypotension Treat hypotension promptly with phenylephrine Vasodilate cautiously for significant hypertension
PVR	Maintain	Diastolic failure can lead to dyspnea

↑, Increased; → leads to; CO, cardiac output; EF, ejection fraction; LV, left ventricle; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume; LVOT, left ventricular outflow tract; MAP, mean arterial pressure; NTG, nitroglycerin; PVR, pulmonary vascular resistance; SVR,

systemic vascular resistance; *TEE*, transesophageal echocardiography.

Stenotic AVs rarely lend themselves to repair.¹⁶⁷ The choice of valve depends on patient preference, age, and comorbidities, but approximately 60% to 80% are currently replaced with a bioprosthetic (tissue) valve, and that number is increasing.¹⁶³ Other options include a mechanical valve, aortic homograft (cadaver valve), or a Ross procedure, which uses the native pulmonic valve. [Table 26.11](#) shows various surgical options and key points about each alternative. Mechanical valves can theoretically last a lifetime, but they are highly thrombogenic, so the patient is required to take an anticoagulant (like warfarin), and occasionally prophylaxis against endocarditis.¹⁶⁸ It should be noted that the recommendations for antibiotic prophylaxis in patients with VHD have undergone important revisions and are now easier to follow, which should improve compliance.¹⁶⁹ Although tissue valves do not require anticoagulants, they nevertheless degenerate over time. In a 50-year-old patient, there is a 50% chance that the valve will have to be replaced in 15 years. A tissue heart valve tends to last longer as the recipient's age increases.¹⁷⁰ The STS mortality risk benchmark for an isolated AVR is 2.4% in an otherwise healthy patient, but can increase to over 15% if the patient has multiple comorbidities and the surgery is combined with other procedures.¹⁷¹ In these high-risk populations, percutaneous transcatheter aortic valve replacement (TAVR) has revolutionized treatment. TAVR is discussed in the section on minimally invasive approaches to cardiac surgery. According to the STS database, in 2014 there were 29,738 isolated AVRs and 18,322 combined AVR and CABG procedures.¹⁷²

TABLE 26.11
Surgical Options for the Aortic Valve

Surgical Option	Surgical Considerations
Repair	<ul style="list-style-type: none"> Used for aortic regurgitation, usually due to bicuspid valve Technically more difficult than mitral repair Can last a lifetime, but 20% to 25% need replaced in 10 years Preserves heart muscle strength and natural heart anatomy Decreased risk of infection Decreased requirement for life long

(Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

anticoagulation

Replacement With a Mechanical Valve

(Courtesy Medtronic Inc., Minneapolis, MN.)

Designed to last a lifetime
 Requires the use of lifetime anticoagulation so lifestyle, childbearing, and compliance must be considered
 Some antibiotic prophylaxis
 Some make a clicking noise

Replacement With a Bioprosthetic (Tissue) Valve

(Courtesy Medtronic Inc., Minneapolis, MN.)

Made of cow (bovine) or pig (porcine) pericardium sewn on a frame
 Coumadin not required unless patient is in atrial fibrillation
 At age 40, 50% chance of lasting 15 years, but generally less durable if younger and more durable if older at age of implantation
 Straightforward, relatively low risk

Replacement With a Homograft (Also Called Allograft)

Human aortic or pulmonic valve
 Ideal for endocarditis because valve is least prone to infection
 May be good choice for athletes because of excellent flow characteristics and no need to take Coumadin
 Technically challenging and limited availability
 Last only approximately 15 years; durability varies with age

(From Otto CM, Bonow RO. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 4th ed. Philadelphia: Elsevier; 2014.)

Ross Procedure (Also Called Switch Procedure)

(Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

Patient's own pulmonary valve is removed and used to replace the aortic valve; coronaries are reimplemented.
 Pulmonary valve is replaced with a pulmonary homograft.
 Main advantage is that the valves can grow, so a good choice in teens.
 Lifetime anticoagulation is not required.
 Pulmonary autograft (in aortic position) has approximately a 50% chance of lasting a lifetime.
 Pulmonary homograft has a 10% chance of needing replacement in 10 years.
 Technically difficult and reoperation is challenging.

Hypertrophic Cardiomyopathy

HCM is the preferred contemporary nomenclature for this disease, but it was formerly known as *idiopathic hypertrophic subaortic stenosis* (IHSS) or HOCM. HCM is a common inherited disease that affects approximately 1 in 500 persons of all ages globally. It is a heterogeneous disease with diverse clinical presentations ranging from asymptomatic to life-threatening. When complications of HCM develop, they fall into three categories, which are not mutually exclusive: ventricular tachydysrhythmias, which can lead to sudden cardiac death (SCD), especially in young athletes; progressive DHF, despite normal LV systolic function; and AF, with a predisposition to stroke.¹⁷³ HCM is the leading cause of sudden death in young people, but it can cause morbidity and death at any age.⁸² The American College of Cardiology Foundation (ACCF) and AHA recommend that diagnosis and treatment of HCM take place in a clinical center that specializes in management

of this disease.¹⁷³

Pathophysiology.

Concentric LVH is the primary pathology in HCM, as opposed to AS, in which the LVH is secondary to stenosis. The pathophysiology of HCM is complex, and can include LVOT obstruction, MR, diastolic dysfunction, ischemia, and dysrhythmias. HCM can be either obstructive or nonobstructive, based on the degree of outflow tract obstruction and the presence or absence of mitral valve SAM (discussed later). Clinical management is guided by this finding. Echocardiography is used to determine the presence of obstruction and to document the gradient across the obstruction. A gradient of more than 30 mm Hg is considered significant, and a gradient of more than 50 mm Hg is the conventional threshold for surgical or percutaneous intervention if symptoms persist despite optimal medical management. Approximately one-third of patients manifest nonobstructive HCM, one-third manifest obstruction even at rest, and one-third have variable obstruction based on volume-loading conditions. Approximately 25% of patients exhibit autonomic dysfunction that causes their BP to decrease or increase only slightly in response to exercise, which increases the degree of obstruction.¹⁷³

Because of LVH, patients can have angina and ischemia even without significant CAD.⁸ Some patients will present with dyspnea, angina, and syncope; but in more than half of cases, sudden death or cardiac arrest is the presenting finding. It is imperative that patients with HCM be evaluated for the risk of SCD.⁸² In the subset of patients in whom basal septal hypertrophy has become so extensive that it obstructs the LVOT, ventricular contraction becomes hyperdynamic, forcing the blood to eject at high velocity to pass the obstruction. This rapid blood flow can lead to a Venturi effect that causes the anterior leaflet of the mitral valve or the chordal structures to be pulled into contact with the basal septal wall during systole, a phenomenon called *SAM of the mitral valve*. SAM increases LVOT obstruction and causes MR. Any reduction in ventricular volume, directly or reflexively, will increase the degree of SAM-septal wall contact and exacerbate LVOT obstruction and

MR. Therefore increases in heart rate and contractility and/or decreases in preload and afterload must be avoided.¹⁷⁴

Medical management of HCM includes treatment of comorbidities, administration of β -blockers to prevent sympathetically-induced tachycardia and to treat AF, administration of calcium channel blockers to improve diastolic relaxation, and administration of disopyramide or other antidysrhythmics to reduce contractility and treat dysrhythmias. It is also important to maintain sinus rhythm, because, as with AS, the atrial contribution to CO can be considerable. Patients with a history of cardiac arrest or symptomatic ventricular dysrhythmias will likely have an internal cardiac defibrillator (ICD). ICDs should have their antitachyarrhythmia function suspended in the OR before surgery to prevent electrocautery-induced discharge. Means for external defibrillation must be available while the ICD is deactivated, and reactivation should occur as early as possible postoperatively. Alcohol septal ablation is the primary nonsurgical invasive therapy for HOCM. Biventricular pacing may be considered for patients who are inappropriate candidates for surgical correction or alcohol ablation, or who have a biventricular pacer implanted for another reason. The goal is slight pre-excitation of the RV apex, which results in paradoxical septal motion that decreases the ejection velocity and reduces SAM.¹⁷³

Anesthetic Considerations and Surgical Options.

Patients who remain symptomatic with gradients of 50 mm Hg despite optimal medical management are candidates for septal reduction therapy. Surgical septal myotomy via the aortic approach at an experienced surgery center is preferred over alcohol septal ablation.¹⁷³ Approximately two-thirds of patients will also have structural malformations of the mitral valve. It is not uncommon to find that the mitral valve will need repair or replacement at the time of myectomy.⁸² Anesthetic management (Table 26.12) is directed at optimizing preload, avoiding increases in septal wall–anterior leaflet contact caused by increases in heart rate or contractility, and preventing sudden reductions in afterload. Excision of the hypertrophied basal septum may result in disruption of the conduction system of the heart, with new-onset

heart block requiring pacing. After CPB is terminated, the outflow tract and mitral valve are examined using TEE. To determine the adequacy of surgical repair, the patient's heart rate and contractility are deliberately increased while the BP is simultaneously decreased, to mimic a physiologic hyperdynamic state such as exercise. An infusion of isoproterenol is ideal for achieving this goal, but at the time of this writing the use of isoproterenol is limited due to high cost and/or availability. Instead, dobutamine or rapid ventricular pacing (at a rate of 120 bpm), combined with an infusion of nitroglycerin, can be used. The echocardiographic examination will reveal whether obstruction, SAM, or MR develops with the tachycardia and hypotension. If more muscle needs to be excised, or the valve needs repair or replacement to prevent SAM, CPB will be resumed so the surgeon can make the necessary adjustments.

TABLE 26.12

Anesthetic Considerations in the Management of HOCM

Factor	Hemodynamic Goals	Anesthetic Considerations
Preload	Full	Volume is key; first treatment for hypotension Optimize preload to stretch noncompliant LV Reduces the gradient across LVOT Prevents SAM and MR PaEDP > LVEDV (evaluate with TEE)
Heart rate	Low-normal	Too fast → ischemia and not enough time for ventricular filling
Rhythm	Maintain sinus	Atrial kick contributes LVEDV Cardiovert early
Compliance	Improve	↓ due to concentric hypertrophy
Contractility	↓	Usually hyperdynamic Inhalation agents and/or β-blockers are used to depress
SVR	Avoid reductions	Hypertension better tolerated than hypotension Treat hypotension with volume and phenylephrine
PVR	Maintain	Not usually a problem

↑, Increase; ↓, decrease; →, leads to; *EF*, ejection fraction; *HOCM*, hypertrophic obstructive cardiomyopathy; *LV*, left ventricle; *LVEDV*, left ventricular end-diastolic volume; *LVOT*, left ventricular outflow tract; *MR*, mitral regurgitation; *PaEDP*, pulmonary artery end-diastolic pressure; *PVR*, pulmonary vascular resistance; *SAM*, systolic anterior motion of the mitral valve; *SVR*, systemic vascular resistance; *TEE*, transesophageal echocardiography.

Aortic Insufficiency or Regurgitation

AI, or AR, occurs when malcoaptation of the AV leaflet or annular dilation allows a portion of the ejected SV to be regurgitated, or

flow backward, during diastole from the aorta into the LV. The regurgitant blood flow causes the LV to be volume-overloaded. AI can develop acutely or chronically, and can be caused by a primary disease affecting the valve itself or can be secondary to aortic root dilation. Acute AI results in rapid deterioration, and is most frequently caused by trauma, endocarditis, or aortic dissection. Chronic AI can be tolerated for decades, and has multiple etiologies that include: long-standing calcific degeneration, a congenitally bicuspid AV, rheumatic fever, inflammatory or connective tissue disease, idiopathic aortic root or valve dilation, hypertension-induced aortoannular ectasia, syphilis, Marfan syndrome, or Ehlers-Danlos syndrome.¹⁷⁵

Pathophysiology.

The increased LVEDV causes increased diastolic wall tension that leads to a pattern of LV enlargement known as *eccentric hypertrophy*, whereby the sarcomeres replicate in series. By virtue of the Frank-Starling mechanism, the increased preload results in a large SV that in turn rapidly raises aortic systolic pressure. Diastolic run-off is rapid as well because blood can progress forward down the aorta or retrograde through an incompetent AV back into the LV. The rapid systolic ejection and diastolic run-off causes a bounding pulse, a wide pulse pressure (systolic–diastolic pressure), and an arterial waveform with a rapid rise in systolic pressure and a low diastolic notch. Sometimes a double systolic peak called *pulsus bisferiens* can be seen on the A-line. The magnitude of the regurgitant volume is directly proportional to regurgitant orifice size, diastolic time, and SVR. Ventricular compliance is increased, and the LVEDV can be three to four times greater than normal. The regurgitation is graded as mild (1+ [$< 30\%$]) to severe (4+ [$\geq 50\%$]), based on echocardiographic findings.⁸⁰ As volume overload progresses, wall tension also increases, resulting in LV pressure overload and some degree of concentric hypertrophy.^{82,175} The hypertrophy increases O_2 demand, and angina can develop in patients with normal coronaries. However, the O_2 debt incurred for muscle shortening is relatively low, so ischemia is much less of a problem than with AS.⁸ The natural history of chronic AI is such that dilation occurs slowly over years, so the ventricle compensates,

allowing the patient to remain asymptomatic until the AI is severe, causing permanent LV dysfunction. Surgery is recommended for all symptomatic patients and asymptomatic patients when ventricular function falls below 50%, or if they are undergoing cardiac surgery for other indications.⁸⁰

Acute AI can cause rapid deterioration, because the normal ventricle is unable to compensate for the sudden increase in volume. Ventricular distension leads to increased LVEDV and LVEDP. As the LVEDP approaches the aortic diastolic pressure, coronary perfusion decreases, and this, in turn, causes ischemia and systolic dysfunction. Pulmonary congestion is likely because the forward blood flow from the LA is reduced due to higher LV diastolic volume and pressure. MR can develop as the LV dilates further.¹⁷⁶ TEE is invaluable in the etiologic diagnosis and treatment of acute AI, and can help determine the need for urgent or emergent surgery.

Anesthetic Considerations and Surgical Options.

Hemodynamic management of AI (Table 26.13) is focused on enhancing forward flow and minimizing the regurgitant volume. Regurgitation occurs during diastole, so a relatively high heart rate is used to minimize diastolic time. The patient's volume should be kept in the “high normal” range because the heart is dilated and compliance is increased. Judicious vasodilation lowers the SVR to enhance forward flow and reduce the regurgitant volume, while still maintaining adequate pressure to support coronary perfusion. The frequently quoted mnemonic that reflects this hemodynamic management strategy for regurgitant valvular lesions is “fast, full, and forward.”

TABLE 26.13

Anesthetic Considerations in the Management of Aortic Insufficiency

Factor	Hemodynamic Goals	Anesthetic Considerations
Preload	↑	Need increased volume to maintain forward flow
Heart rate	High-normal	Decreased diastolic time minimizes regurgitation Avoid bradycardia
Rhythm	Usually sinus	Not usually a concern

Compliance	Maintain	Eccentric hypertrophy can lead to a LVEDV 3–4 times normal Return large pump volume judiciously after bypass to prevent failure
Contractility	maintain	Normal LVF till late Surgery indicated when EF < 55% May need inotropes after pump
SVR	↓	Judicious vasodilation enhances forward flow
PVR	Maintain	PVR ↑s rapidly with acute AI → acute failure
CPB	↓ LV distention	Can develop due to slow HR or nonbeating heart Consider LV vent; retrograde or ostial cardioplegia

↑, Increase; ↓, decrease, *AI*, aortic insufficiency; *CPB*, cardiopulmonary bypass; *EF*, ejection fraction; *HR*, heart rate; *LV*, left ventricle; *LVEDV*, left ventricular end-diastolic volume; *LVF*, left ventricular function; *PVR*, pulmonary vascular resistance; *SVR*, systemic vascular resistance.

During CPB, AI can lead to ventricular distention and pressure overload that directly opposes coronary perfusion and myocardial preservation. When CPB is initiated, a slow heart rate or ventricular fibrillation can lead to distension. After the aortic cross-clamp is applied, cardioplegia that is usually infused into the aortic root, intended to flow antegrade down the coronaries, can instead run into the LV secondary to the AV's incompetence. Even mild to moderate AI can cause LV distention; consequently, the presence of AI increases the risk of other cardiac surgical procedures. Achieving diastolic standstill in these situations often requires that cardioplegia be delivered directly into the coronary ostia and/or retrograde through the coronary sinus. An LV vent is placed to suction away fluid, thereby alleviating or preventing distension. A positive inotrope is often useful after CPB, especially if there was LV dysfunction prebypass or questionable preservation during bypass.^{82,175}

Valve repair is sometimes possible, but is technically more challenging than mitral repair. Traditional replacement options are the same as for AS (see [Table 26.11](#)). Percutaneous replacement is discussed later in the chapter, but this procedure is limited to severe inoperable stenotic lesions at this time.

Mitral Stenosis

MS is the least common left-sided valvular defect because it is caused primarily by RHD, which is now rare in developed countries.^{177,178} Although RHD affects men and women equally, MS is two to three times more prevalent in women. Occasionally, MS

also develops as the result of severe mitral annular calcification caused by the atherosclerotic process. There are a host of other less common etiologies, including: carcinoid syndrome, left atrial myxoma, endocarditis, and collagen diseases.¹⁷⁵ Clinically, significant stenosis takes decades to develop, and symptoms do not usually appear until the valve area, which is normally 4 to 5 cm², is reduced to 2.5 cm² and many patients remain asymptomatic until the valve area is 1 cm².^{80,178}

Pathophysiology.

As the valve orifice narrows, diastolic filling of the LV is limited, and a pressure gradient develops across the mitral valve. Left atrial pressure (LAP) and volume increases, leading to atrial dilation and elevation in pulmonary pressures. Right ventricular failure can eventually develop if the PHTN is left uncorrected. Stenosis is considered severe when the valve area is less than 1.5 cm², the mean gradient generally exceeds 5 to 10 mm Hg, and PA systolic pressures are greater than 30 mm Hg.⁸⁰ The risk of surgery is 3% to 8% in most studies, but the presence of PHTN increases the risk to 12%.¹⁷⁸ Flow across the valve will decrease in response to an increase in CO or a decrease in diastolic time. Hence, symptoms are usually first experienced during exercise or stress. Conditions such as pregnancy and sepsis may provoke AF in a previously asymptomatic patient, leading to decompensation. Approximately 33% of patients develop AF. The rapid heart rate is the primary cause of hemodynamic instability, rather than the loss of atrial kick.¹⁷⁵ Patients with MS and AF have an embolic stroke rate of 7% to 15% per year. Long-term anticoagulation and heart rate control are important in the management of MS.¹⁷⁸

Anesthetic Considerations and Surgical Options.

Although avoiding tachycardia and treating AF help control the symptoms, MS mechanically obstructs ventricular filling. The three procedures used to relieve this obstruction are mitral balloon valvotomy, open commissurotomy of the mitral valve, and replacement with a mechanical or biologic valve. Closed commissurotomy is no longer recommended. Valvotomy or repair is generally preferred to replacement, but a left atrial thrombus,

concurrent MR, or annular calcification may make replacement the treatment of choice.⁸⁰ If the patient has a history of AF and the valve is approached through a full sternotomy, the surgeon will often elect to add a Maze procedure (see later) or pulmonary vein isolation to treat AF. The choice of radiofrequency (heat) or cryotherapy (cold) ablation is based primarily on surgeon preference. Anesthetic considerations for the Maze procedure and other options for atrial ablation are discussed after the valve section of this chapter. The left atrial appendage may also be excised to decrease the risk of emboli.

Anesthetic considerations for MS are outlined in [Table 26.14](#). Maintaining a low-normal heart rate is a priority so there is adequate time in diastole to fill the LV. If AF is present or develops, the ventricular rate must be controlled. Conditions or medications that can exacerbate PHTN should be avoided. These include hypercarbia, hypoxemia, nitrous oxide, desflurane and the Trendelenburg position. MS is the only valve defect that causes the LV to be chronically underloaded. Volume management can be challenging because an adequate preload is needed to maintain flow across the stenotic valve, but too much volume can lead to pulmonary congestion. The majority of patients have normal left ventricular function; however, the increase in ventricular volume that occurs after valve replacement can cause the chronically underloaded LV to dilate. If failure occurs, it is generally responsive to inotropic support.^{175,178} PHTN with resultant RV failure can be more problematic. Patients may benefit from mild hypocapnea, judicious vasodilator therapy, and inotropic support with epinephrine or milrinone. In extreme cases, inhaled nitric oxide or prostaglandin may be used to dilate the pulmonary vasculature and reduce RV afterload. Routine use of nitric oxide is limited by cost.^{8,82}

TABLE 26.14

Anesthetic Considerations in the Management of Mitral Stenosis

Factor	Hemodynamic Goals	Anesthetic Considerations
Preload	↑	LV chronically underloaded Adequate preload needed to maintain flow across valve Avoid hypovolemia

Heart rate	Low-normal	Need adequate diastolic time to fill LV Too fast → ↑ gradient across valve
Rhythm	If AF, control ventricular rate	AF in 40% May decompensate if rapid ventricular response, otherwise reasonably well-tolerated
Compliance	Maintain	Usually normal
Contractility	Maintain LV RV often needs support	LV may need inotropic support after pump Administer volume cautiously after pump, watching for RV dysfunction and volume overload RV may need support with epinephrine or milrinone Judicious RV unloading with NTG, Flolan or nitric oxide
SVR	Maintain	May need vasoconstrictor to offset vasodilation from milrinone, but watch for pulmonary vasoconstriction
PVR	↓	PHTN can be mild to severe Avoid hypercarbia, hypoxia, acidosis, Trendelenburg position, and nitrous oxide Severe cases may benefit from nitric oxide

↑, Increase; ↓, decrease; →, leads to; *AF*, atrial fibrillation; *LV*, left ventricle; *NTG*, nitroglycerin; *PHTN*, pulmonary hypertension; *PVR*, pulmonary vascular resistance; *RV*, right ventricle; *SVR*, systemic vascular resistance.

Mitral Regurgitation or Insufficiency

MR, or mitral insufficiency, occurs during systole when blood is ejected back into the left atrium because of an incompetent mitral valve. The causes of MR are considered organic or structural, when the regurgitation is due to a problem with the valve leaflets or chordae; or functional, when insufficiency results from a dilated LV stretching a structurally normal valve. In developed countries, MR is usually caused by degenerative processes, but it can also arise secondary to infective endocarditis, mitral annular calcification, RHD, collagen diseases, and connective tissue disorders such as Marfan syndrome. Functional MR is most often caused by ischemic heart disease, but it can also develop in patients who have idiopathic cardiomyopathy. The presentation of the patient with MR varies depending on the etiology or acuity of the condition.¹⁷⁵

Pathophysiology.

In patients with MR, there is no isovolumetric contraction phase of systole, because the left atrium (LA) acts as a low-resistance vent for ventricular ejection. Both the LA and the LV are volume-overloaded because the total SV is equivalent to the volume of blood that goes antegrade down the aorta plus the amount of blood that is ejected retrograde into the LA. Consequently, the EF that is calculated by

TEE overestimates the actual forward flow. Pressure and volume overload lead to LA dilation. AF develops in approximately 50% of patients who undergo surgery.⁸² The amount of regurgitation is dynamic, and is based on the size of the mitral orifice, the pressure gradient between the LA and LV, the time available for regurgitant flow, and the compliance of the receiving chamber. The LA and LV compensate for the chronic volume overload by dilating eccentrically (series replication of sarcomeres) and increasing compliance to accommodate the volume load. Patients with chronic MR may be asymptomatic for years. Large increases in volume can occur with minimal increases in LAP or PAEDP. Increases in heart rate and decreases in preload and/or afterload help minimize the regurgitation and enhance forward flow.⁸ Often, TEE is used to evaluate the extent of regurgitation while the BP is pharmacologically manipulated at various systolic driving pressures. Eventually, volume overload induces pressure overload, and LV dysfunction develops. Because CO is an afterload-dependent measurement, it can be normal or only mildly reduced even in the face of significantly compromised ventricular function. An EF of less than 60% in a patient with severe MR represents significant LV dysfunction and is predictive of a worse outcome. The problem is often first unmasked during the attempt to separate from CPB after valve repair or replacement. Pharmacologic support with epinephrine or dobutamine should be considered if LV dysfunction occurs.^{8,179}

Patients with acute MR often deteriorate rapidly. The LA cannot compensate for the abrupt increase in volume, so the fluid backs up into the pulmonary system, resulting in acute pulmonary edema and RHF. The pulmonary capillary wedge pressure (PCWP) will classically show an enlarged V wave, but the size does not reliably correlate with the degree of MR.¹⁷⁹ Acute MR must often be treated on an urgent or emergent basis with mitral repair or replacement. Oftentimes, an IABP will be used to increase coronary perfusion, decrease afterload, and support the patient during the perioperative period.⁸⁰

Anesthetic Considerations and Surgical Options.

The preload is elevated and must be judiciously maintained or

gently reduced to enhance forward flow and minimize regurgitation. Inhalation agents and vasodilators are generally effective in reducing afterload and maintaining heart rate in the high-normal range (Table 26.15). Valve repair or replacement increases afterload and may unmask previously compensated LV dysfunction. An inotrope or inodilator may be needed after bypass. Occasionally, SAM develops after repair, especially if the anterior leaflet is long or has redundant tissue. TEE is used to diagnose this problem.⁸

TABLE 26.15

Anesthetic Considerations in the Management of Mitral Regurgitation

Factor	Hemodynamic Goals	Anesthetic Considerations
Preload	↑ or ↓	Cautiously ↑ or ↓ to enhance forward flow
Heart rate	High-normal	Decreased diastolic time minimizes regurgitation Avoid bradycardia
Rhythm	Sinus or if AF, control ventricular rate	Not usually a concern as long as rate adequate
Compliance	Maintain	Eccentric hypertrophy of LA and LV
Contractility	Maintain	Surgery indicated when symptomatic or EF ↓ May have LV dysfunction even with mildly ↓ EF May need inotropes after pump
SVR	↓	Cautious vasodilation enhances forward flow
PVR	↓	Acute pulmonary edema and/or RV failure can develop with acute MR or longstanding chronic MR May need to treat urgently with MV repair or replacement and/or an IABP
CPB		LV dysfunction can be unmasked after surgery

↑, Increase; ↓, decrease; *AF*, atrial fibrillation; *CPB*, cardiopulmonary bypass; *EF*, ejection fraction; *IABP*, intraaortic balloon pump; *LA*, left atrium; *LV*, left ventricle; *MR*, mitral regurgitation; *MV*, mitral valve; *PVR*, pulmonary vascular resistance; *RV*, right ventricle; *SVR*, systemic vascular resistance.

Mitral valve repair is almost always recommended over replacement whenever possible, depending on the native valve pathology and on surgical expertise. The advantages of repair include improved postoperative LV function, increased long-term and short-term survival, improved quality of life, lower risk of complications, and less need for long-term anticoagulation.⁸⁰ Over the past decade, as surgeons have gained experience with valve repair techniques, the number of mitral valve repairs performed and variety of approaches taken have risen dramatically. The mitral

valve can be accessed through traditional sternotomy, partial upper sternotomy, right minithoracotomy, and robotically-assisted endoscopy. Another advancement involves endovascular placement of a clip (MitraClip, Abbott Vascular, Santa Clara, CA, USA) that grasps and coapts the mitral valve leaflets, resulting in fixed coaptation (approximation) of the mitral leaflets throughout the cardiac cycle. Transcatheter transapical mitral valve replacement is currently in development. These alternative approaches are discussed later in the chapter. Posterior leaflet problems are often repaired using a triangular or quadrangular resection with a complete or partial annuloplasty ring (Fig. 26.14). Involvement of the anterior leaflet increases the complexity of the repair and requires greater surgical expertise because the chords must often be shortened, transferred, or replaced. If the patient has AF, a Maze procedure or ablation may be performed. Severe mitral annular calcification or rheumatic disease may make repair impossible, in which case the valve can be replaced with a tissue or mechanical device.⁸⁰

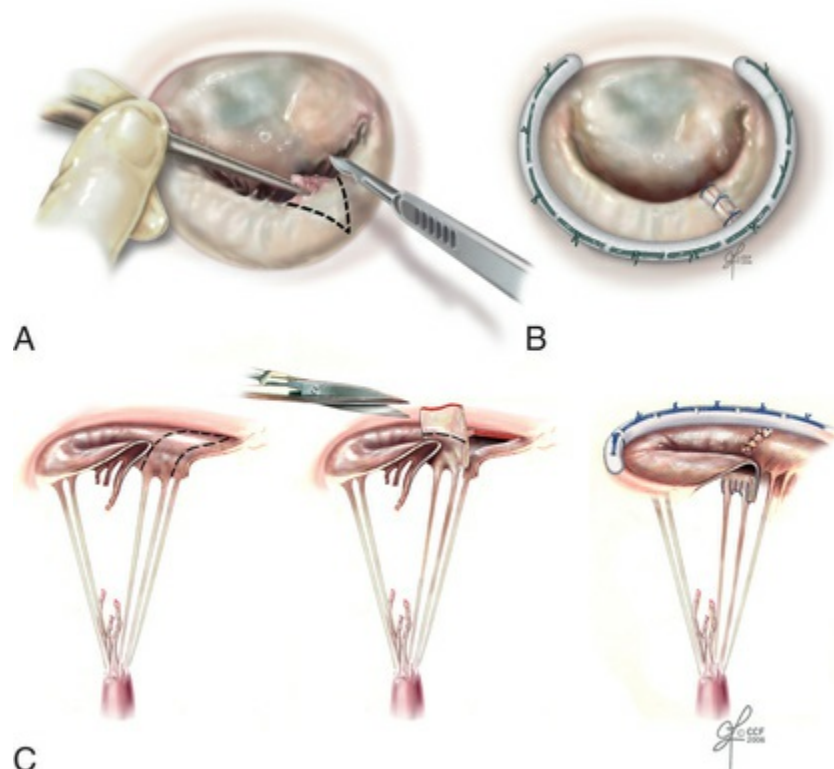

FIGURE 26.14 Mitral valve repair. **A**, Triangular resection is the technique used most often for posterior leaflet

prolapse. Region to be resected is indicated. **B**, Abnormal segment has been removed. Leaflet edges are sewn together. An annuloplasty ring completes the repair. **C**, Chordal transfer to correct anterior leaflet prolapse. Posterior leaflet chordae are transferred to the unsupported free edge of the anterior leaflet. The posterior leaflet is repaired with a quadrangular resection. An annuloplasty ring completes the repair. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

Surgical Therapy for Atrial Fibrillation

Early in 1990, Cox et al. developed the Maze procedure, in which several incisions are made in a specified pattern around the atria to create a maze of scar tissue that blocks the reentry circuits that cause AF while still allowing conduction of an impulse from the sinus to the atrioventricular node.^{180,181} The original procedure has been improved, so that the Cox-Maze IV procedure is currently in use, replacing the original surgical incisions with a combination of bipolar radiofrequency ablation and cryoablation. This approach has achieved 90% freedom from AF at twelve months.¹⁸² The number of surgical and catheter-based techniques used to treat AF has expanded greatly as the understanding of causation has grown. Today, many catheter-based ablative procedures are available in the electrophysiology laboratory, but this discussion will be limited to procedures performed in the operating suite.

Surgical procedures used to ablate AF are often carried out in conjunction with, and usually just prior to, other cardiac procedures, but they can also be performed independently. Traditionally, the Maze procedure requires CPB and includes the ligation or stapling of the left atrial appendage because it is considered a major source for emboli. The right atrial appendage is a significant source of ANP, so it is not removed. The procedure can be carried out through a traditional sternotomy or through a minimally invasive right anterior thoracotomy with femoral cannulation. Newer technology now allows surgeons to use a variety of alternate energy sources to quickly and simply make lesions that interrupt the reentry pathways.⁸² The pulmonary veins

have been found to be a site of reentry, so they are now frequently isolated using ablative energy.¹⁸³ Options for energy sources include radiofrequency and microwave energy, ultrasound, cryotherapy (freezing), and laser. The development of epicardial probes has enabled surgeons to now perform ablative procedures on beating hearts through keyhole incisions off-pump.^{184,185}

Minimally Invasive Surgical Approaches

Overview

Minimally invasive cardiac surgical techniques have evolved considerably in the past two decades. Much of the technology was first developed for other surgical specialties and then adapted to cardiac surgery. The driving force behind the growth has been twofold: first, to reduce the use of CPB, and second, to make the procedures less invasive. As the population ages, the prevalence of comorbidities and aortic atherosclerosis increases. Avoidance of CPB, aortic manipulation, and cross-clamping ideally would prevent some of the known complications. Indeed, TAVR was recently approved for patients with AS who are deemed too high-risk for traditional surgery. Additionally, the public assumes that less is more, so they seek out minimally invasive surgeons on the internet.

What actually constitutes a minimally invasive approach is quite variable. In some cases, only the skin incision is smaller, and the sternotomy is full. In other cases, the approach is robotic and/or endoscopic. [Fig. 26.15](#) shows some of the common incisions that are used in minimally invasive surgery. The field is rapidly evolving, but this chapter focuses on the most innovative approaches at the time of its writing.

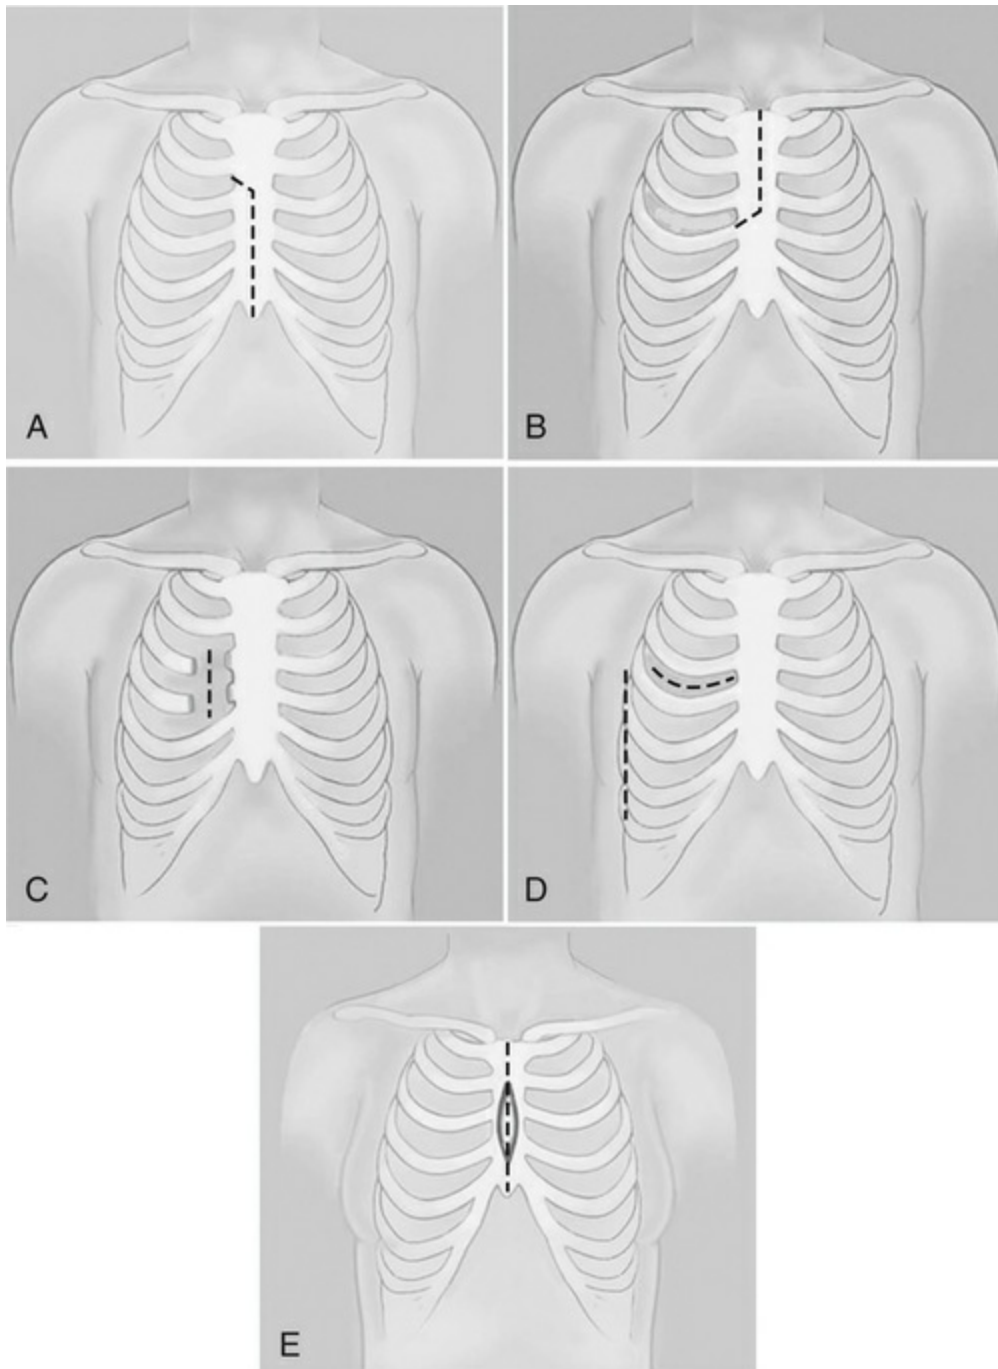

FIGURE 26.15 Minimally invasive incisions. **A**, Lower hemisternotomy. **B**, Upper hemisternotomy. **C**, Parasternal incision. **D**, Anterolateral minithoracotomy. **E**, Full sternotomy with small skin incision. (From Kaplan J. *Essentials of Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier; 2008.)

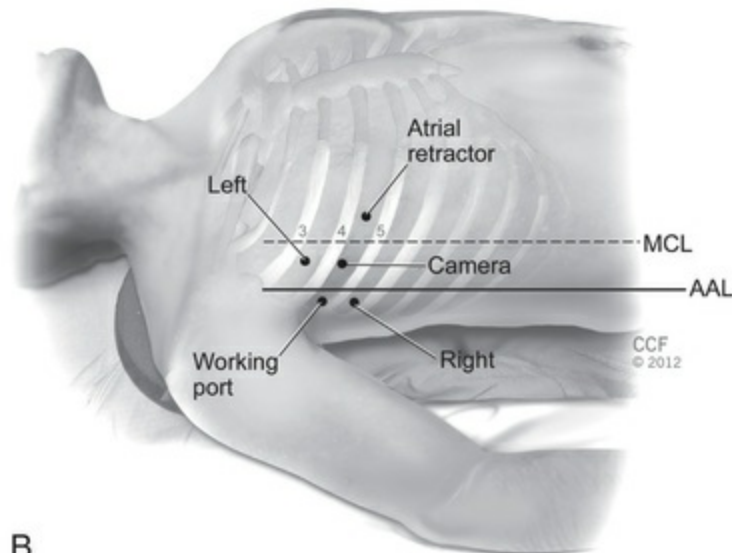

Minimally Invasive Mitral Valve Procedures

Surgical Approaches.

Minimally invasive mitral valve surgery involves repair or replacement of the mitral valve by a variety of less invasive surgical incisions and approaches than the traditional full median sternotomy. Minimally invasive mitral valve surgery has evolved extensively over the last 20 years; that is, since 1996, when Carpentier performed the first video-assisted mitral valve repair through a right minithoracotomy, and 1997, when Mohr performed the first robotic-assisted mitral valve repair.^{179,186} Minimally invasive surgical approaches for repair of the mitral valve today may include a lower hemisternotomy, right minithoracotomy, or total endoscopic approach through port chest incisions, with or without the use of video assistance or robotics (see [Figs. 26.15](#) and [26.16](#)).^{82,187} The minimally invasive mitral valve approach has shown successful surgical results and positive outcomes with regard to mortality and morbidity.^{82,187-189} Advantages of the minimally invasive approaches to the mitral valve include decreased hospital length of stay, faster patient recovery, decreased blood loss, decreased hospital cost, and improved cosmetic appearance compared to the traditional median sternotomy.¹⁸⁷⁻¹⁸⁹ Successful surgical outcomes are dependent on proper patient selection. Contraindications to a minimally invasive approach to mitral valve repair include inability to obtain TEE, severe AR, aortic and/or thoracic disease, Marfan syndrome, and previous aortic and/or thoracic surgery.¹⁹⁰ Atherosclerosis of the descending aorta or femoral vessels precludes surgeries that require retrograde aortic cannulation through the femoral artery.

Anesthetic Considerations.

Regardless of the surgical approach adopted, all minimally invasive mitral valve procedures require a general anesthetic. Principles applied to the anesthetic management of patients with mitral valve disease (discussed earlier in the chapter) are also applicable to the

patient undergoing a minimally invasive mitral valve procedure, but with some additional considerations. A fast-track approach to the selection of induction and maintenance of medications is usually appropriate. Judicious use of narcotics and muscle relaxants will facilitate achieving the goal of early extubation. It is imperative that the level of muscle relaxation be closely monitored because unwanted patient movement during a robotic procedure could cause significant harm. Measures to maintain normothermia, such as fluid warming devices, circuit humidifiers, forced air warming devices, and raising the room temperature, must also be considered, especially if early extubation is a goal.

For robotic surgery, patients are positioned supine with a roll placed under the right scapula to elevate the hemithorax 25 to 30 degrees.^{191,192} The right arm is carefully positioned (slightly deviated from body to allow port access) and padded along the right side of the patient's body to prevent it from interfering with the robotic device. External defibrillator pads should be placed on all patients because the use of internal defibrillation paddles is not possible with limited incisions.¹⁹³

If a minithoracotomy approach is selected, the surgeon makes a 3- to 4-cm right submammary, minithoracotomy incision at the fourth to fifth intercostal space, along with separate smaller chest incisions for port access or for robotic instrumentation access.^{179,186} If a total endoscopic approach is selected, only several small chest incisions are usually made in the right hemithorax for port access (Figs. 26.17 and 26.18).¹⁹¹ Lung isolation is not necessarily required, but is usually preferred (especially for robotic procedures), to allow more working room in the surgical field. Lung isolation can be accomplished with either a double-lumen ETT or a bronchial blocker. If a bronchial blocker or double-lumen ETT is required, then placement and lung isolation confirmation are necessary after final patient positioning because access to the patient's chest and airway is extremely limited once the robotic arms are placed inside the chest. The anesthetist must not only consider management strategies for one-lung ventilation (OLV; if required), but must also be prepared to treat and manage the untoward hemodynamic effects of carbon dioxide insufflation that may be used to create a capnothorax.

CPB Cannulation and Cardioplegia.

Minimally invasive mitral valve surgery employs CPB. CPB cannulation is usually obtained from the femoral artery and vein under TEE guidance to confirm placement.⁸² Complications of femoral CPB cannulation include retrograde aortic dissection, limb ischemia, and chest wall hemorrhage.¹⁹⁰ If additional venous drainage is needed, the surgeon can perform SVC cannulation by passing a wire through a 16-gauge right internal jugular catheter using the Seldinger technique. The 16-gauge catheter is often placed by the anesthetist after induction and then later prepped into the surgical field. An alternative is cannulating the SVC directly from the surgical field. The anesthetist may also access the right internal jugular vein for placement of a specialized catheter that allows delivery of percutaneous retrograde cardioplegia into the coronary sinus (**Fig. 26.19**). Before placement of the percutaneous coronary sinus catheter, 70 to 100 units/kg of heparin is usually administered to avoid coronary sinus thrombus. Placement of the coronary sinus catheter by the anesthetist is performed under fluoroscopy and/or TEE guidance, or it may be placed directly by the surgeon through the surgical incision.⁸² Proper positioning of the retrograde cannula

in the coronary sinus can occasionally be quite challenging. If right internal jugular access is obtained for surgical CPB purposes, the left internal jugular vein will have to be accessed by the anesthetist for the administration of central IV medication.

FIGURE 26.19 Overview of cannulation showing femoral venous and arterial cannulae, retrograde coronary sinus catheter, and endo-balloon. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006–2012. All rights reserved.)

Antegrade cardioplegia may be delivered to the aortic root by an aortic cannula inserted into the ascending aorta by the surgeon through a stab or thoracotomy incision.¹⁸⁶ Administration of antegrade cardioplegia also can be delivered by an endoaortic occlusion cannula that is advanced through a second opening (side arm) of a larger arterial femoral cannula (see Fig. 24.19). The endoaortic catheter is advanced into the aorta and positioned at the sinotubular junction using TEE guidance.¹⁹² The balloon on the

catheter not only allows for endoaortic occlusion, but also for administration of antegrade cardioplegia via an orifice on the end of the endoaortic balloon. Aortic occlusion also can be achieved by direct transthoracic cross-clamping with a Chitwood or Mohr clamp to avoid potential complications associated with the endoaortic balloon system, such as endoaortic balloon rupture or migration.^{82,194} If the endoaortic balloon system is used for aortic occlusion, correct positioning is confirmed with either TEE or fluoroscopy, and continuous monitoring for endoaortic balloon migration during CPB is necessary. Bilateral radial arterial catheters are often placed to detect balloon migration. Migration of the balloon is suspected if a significant discrepancy in pressure readings occurs between bilateral arterial radial catheters.^{186,195} Obstruction of the coronary arteries can occur if the balloon migrates toward the AV because of overventing, high systemic flow, or high CPB flow.^{186,192} Distal migration of the endoaortic balloon can cause neurologic injury due to obstruction of the innominate artery, and may result in cerebral hypoperfusion. Distal migration of the endoaortic balloon and obstruction of the innominate artery should be suspected if there is a loss of the right arterial radial pulse. For percutaneous CPB, some centers place a PA ventilation catheter for venting of the PA.⁸²

As mentioned earlier, there are several minimally invasive surgical methods and techniques that are used to repair the mitral valve. Long-shafted instruments and a thorascopic-televised view of the surgical field may be used to repair the mitral valve when the video-assisted approach is selected. If the robotic system is used to repair the mitral valve, the surgeon will sit at a remote console away from the patient and surgical field. From the remote console, the surgeon directs the extensors of the robot to perform the desired surgical maneuvers to repair the mitral valve (see [Fig. 26.18](#)). A surgical assistant is usually present at the surgical field, and he or she guides the robotic arms and moves the robot whenever necessary. Higher cost, increased complexity, and, according to some reports, longer cross-clamp times (due to a learning curve) are reported as disadvantages of robotic use.^{186,191,192} Reported advantages of the robotic system over the thorascopic video-assisted approach to mitral valve repair include reduction in

surgeon tremor, increased mobility with instrumentation, and three-dimensional vision.^{82,179,186,192,196,197}

Minimally Invasive Aortic Valve Replacement

The surgical approach for AV surgery has traditionally been through a full median sternotomy incision extending from the sternal notch to the xiphoid process, allowing complete exposure of the heart and ascending aorta. Minimally invasive aortic surgical approaches that are in use today include the hemisternotomy (ministernotomy), right parasternal approach, and right minithoracotomy approach.^{82,82,196,197} These approaches may be utilized for isolated AVR or in combination with other cardiac surgical procedures.¹⁹⁶ Minimally invasive AV surgery has several demonstrated advantages over traditional sternotomy. These include not only improved cosmesis, but also decreases in length of ICU and hospital stay, fewer blood transfusions, less postoperative narcotic use, and less need for postoperative ventilatory support.¹⁹⁶⁻²⁰¹ The mini AV approaches are also selected for reoperations to avoid a sternotomy that could potentially disrupt patent bypass grafts. Reported disadvantages of the minimally invasive aortic approach include limited surgical exposure, greater difficulty with ventricular de-airing, potential difficulty in placing a coronary sinus catheter for retrograde cardioplegia, and the potential for postoperative femoral wound infection.¹⁹⁶⁻²⁰¹

Mini-AVR approaches employ CPB. An arterial cannula may be placed directly into the aorta, or arterial access may be obtained from the femoral artery or subclavian artery.⁸² Venous cannulation may be accessed directly from the right atrium.⁸² If direct venous cannulation limits surgical exposure, then venous access to the right atrium may be obtained from either the internal jugular or femoral vein. Femoral access obtained for venous or arterial cannulation requires TEE guidance to place the cannula and confirm proper positioning.⁸² TEE is also required to guide and confirm placement of the retrograde cardioplegia catheter into the coronary sinus.⁸² Anesthetic management for minimally invasive aortic surgery is comparable to anesthetic management for AV surgery with a traditional sternotomy incision, but with some additional considerations. A fast-track approach may be incorporated into the

anesthetic plan, including modalities that maintain normothermia to facilitate early extubation. Internal defibrillation paddles may be difficult to use in a mini-AVR approach; therefore it is necessary to ensure that external defibrillator/pacing pads are placed on the patient before incision.⁸² The anesthetist should anticipate a brief period of hypotension and bradycardia when the surgeon lifts the pericardium to facilitate maximal surgical exposure prior to cannulation. A preemptive bolus of phenylephrine may be administered prior to lifting the pericardium to maintain vascular tone and successful return to baseline MAP. Direct observation of the myocardium is limited with various mini-AVR surgical incisions. The anesthetist will have to rely on TEE and hemodynamic monitoring to assess adequacy of myocardial contractility and ventricular filling. The anesthetist should always be prepared to convert to a full sternotomy incision if surgical complications arise, such as difficulty in removal of intracardiac air, mediastinal bleeding, and cardiac tamponade.

Minimally Invasive Myocardial Revascularization

The quest to develop surgical techniques that are less invasive than the traditional median sternotomy for coronary revascularization has been in progress since the first minimally invasive coronary bypass revascularization was reported in 1967.¹⁴³ In addition to improved cosmetic appearance, the goals driving development include the desire to lower sternal wound infection rates, decrease the risk of brachial plexus injury, decrease cost, promote early patient mobilization, and facilitate earlier hospital discharge.^{143,192,202–204} Several different minimally invasive techniques for single LAD bypass grafting have emerged over the last 40 years. These employ surgical methods already mentioned in this chapter.

Minimally invasive direct coronary artery bypass (MIDCAB), total endoscopic coronary artery bypass (TECAB), and port-access coronary artery bypass (PA-CABG) are the most common approaches for minimally invasive coronary revascularization.²⁰⁵ The most popular alternative approach to sternotomy for single vessel coronary revascularization is the MIDCAB approach.⁸² Out of the three most common minimally invasive coronary revascularization approaches, MIDCAB has been found to be the

most reliable surgical technique for isolated LAD grafting, and the most cost effective.²⁰⁵ As shown in Fig. 26.20, the MIDCAB is performed through a small (6–8 cm) left anterolateral thoracotomy incision that allows direct access for harvesting the IMA and grafting to the LAD artery.^{82,204} A MIDCAB may be performed with CPB and femoral cannulation, but is usually conducted off-pump, and anastomoses are hand-sewn.^{8,82,143} A right anterior thoracotomy may be performed for access to the RCA or PDA. Some institutions are beginning to utilize a hybrid approach combining the MIDCAB approach with PCI in order to perform revascularization in older, suboptimal surgical patients with multi-vessel disease and significant comorbidities.^{205–210} The catheter-based intervention on the circumflex or RCA may either be performed several days prior to the MIDCAB, after the MIDCAB, or on the same day as a hybrid approach.²⁰⁹ The surgical candidates however, must have non-LAD lesions that qualify for DESs.²⁰⁷ TECAB is a minimally invasive coronary revascularization approach that uses thoroscopic instruments and/or robotic instrumentation for assistance with anastomosis, via small chest wall incisions, with or without employment of CPB.¹⁴³ PA-CABG uses video assistance for left LITA harvesting; CPB is employed, and anastomoses are often hand-sewn.

FIGURE 26.20 Left anterior thoracotomy for minimally invasive direct coronary artery bypass. (From Miller RD, et al. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2009.)

Regardless of which minimally invasive technique is selected, the

anesthetist should have a detailed discussion with the surgical team beforehand. Topics that should be discussed include the surgical approach, incision, need for OLV, use of CPB, and method of cannulation. Principles governing anesthetic management for CPB and off-pump coronary revascularization (mentioned earlier in the chapter), along with a fast-track approach, are all applicable to the patient selected for minimally invasive coronary revascularization. Additional considerations regarding surgical use of robotics, video assistance, and use of the endoaortic catheter system may also need to be incorporated into the anesthetic plan.

Transcatheter Aortic Valve Replacement

TAVR or transcatheter aortic valve implantation (TAVI) is an innovative, minimally invasive percutaneous procedure for the correction of severe AS. It does not require sternotomy or CPB. A retrograde (transfemoral) approach via the femoral artery or an antegrade (transapical) approach via the left ventricular apex is most commonly used to implant a bioprosthetic valve into the native calcified valve. Approximately 30% of patients with critical AS are not considered candidates for traditional sternotomy and CPB because of advanced age and the presence of comorbidities making the risk prohibitively high.²¹¹⁻²¹⁴ Trials in both Europe and the United States have shown the superiority of this technology over standard medical therapy in reducing the 1-year death rate by 20%, as well as improving quality of life.²¹⁵⁻²¹⁸ Over the last decade, TAVR has become a reasonable and standard alternative to surgery for many patients with AS who are considered high-risk surgical candidates.²¹⁹⁻²²¹ Several randomized trials such as the Placement of AoRTic TraNscathetER Valves (PARTNER) II Cohort A, the Surgical Replacement and Transcatheter Aortic Valve Implantation trial (SURTAVI), and the United Kingdom TAVI trials are now assessing the effectiveness of TAVI in intermediate risk patients.²²⁰

Surgical Approach.

The two most common valves in use in the United States today are the Edwards Sapien XT, which is a balloon-expandable bovine pericardial tissue valve (SAPIEN Transcatheter Heart Valve,

Edwards Lifesciences, Irvine, CA, USA), and the Medtronic CoreValve (CoreValve, Medtronic Inc., Minneapolis, MN, USA), a self-expanding porcine pericardial valve.^{220,222} The Edwards Sapien valve may be used for several approaches, including the transfemoral, transapical, transaortic, and transsubclavian approaches.^{220,222} The CoreValve is used with the transfemoral approach, but may also be delivered in a retrograde fashion from the subclavian/axillary artery, the carotid artery, and (for direct aortic access) through either a ministernotomy or right anterior thoracotomy.^{220,222} The CoreValve and the Sapien XT valve have CE mark approval for valve-in-valve use in patients with severe AS, who are deemed to be a high surgical risk.

Although not currently available in the United States, the JenaValve transapical TAVR system (JenaValve, Munich, Germany) received worldwide CE approval for treatment of AS in September of 2011 and for treatment for AI in September of 2013.^{223,224} The JenaValve is a porcine root valve that is sewn onto a Nitinol self-expanding stent.^{223,224} Before being sewn onto the stent, the root valve is fitted with an outer porcine pericardial patch.^{223,224} The JenaValve is fully repositionable and retrievable.^{223,224} Six other TAVR device systems (not including the valves described previously) have obtained CE mark approval in Europe for patients with severe AS who are considered high risk surgical candidates.

The bioprosthetic valve is delivered over a catheter system into the diseased stenotic valve, most commonly via a transfemoral or transapical approach. Access is reached by an interventional cardiologist through the right and left femoral arteries and veins for deployment of the device and delivery of rapid ventricular pacing.^{211,214} The femoral arterial and venous access also may be used for rapid CPB cannulation if emergent bypass becomes necessary. To prevent distal movement of the catheter and ensure proper placement of the device (only for the Sapien XT valve), both valvuloplasty and deployment of the valve are performed while ventilation is held (apnea) and a low CO state is induced by rapid ventricular pacing.^{82,214–218,221,225} The lack of ventricular ejection prevents migration of the balloon or stent valve that the SV from the beating heart may cause during valvuloplasty and actual device deployment.^{214,226} The CoreValve may be delivered in a beating

heart, and does not require the use of rapid ventricular pacing for deployment. Fluoroscopy and TEE are used throughout the procedure for continuous assessment of cardiac function and to guide the device into an accurate position. Once the valve has been successfully deployed, TEE is utilized to assess the degree and source of any existing AR and to examine the aorta for the presence of dissection.⁸² The transfemoral approach may be selected if there has been a previous left thoracotomy, chest radiation, or pathology in or near the LV apex.^{226,227} The transfemoral approach delivers the bioprosthetic AV in a retrograde fashion through the abdominal and thoracic aorta into the AV annulus.²¹¹ Contraindications to the transfemoral approach include the presence of an ascending aortic aneurysm and femoral-iliac arteries that have a small diameter, have stent implantations, contain a high degree of calcification, or are extremely tortuous.^{219,228,229}

In addition to achieving femoral venous and femoral arterial access for the transapical approach, a left anterior minithoracotomy incision is made through the fifth or sixth intercostal space over the LV apex (Fig. 26.21).^{211,228} The surgeon opens the pericardium and places purse-string sutures at the LV apex. A direct puncture at the LV apex is then made to allow the bioprosthetic valve to be delivered (under TEE and fluoroscopy guidance) through the LV into the AV annulus in an antegrade fashion.²²⁰ An antegrade approach is often selected for patients with severe aortic calcification or PVD, or if better surgical control is required over the balloon valvuloplasty and actual device implantation (due to the shorter distance between the LV apex and AV annulus).^{211,226}

FIGURE 26.21 Transcatheter aortic valve implantation. **A**, and **B**, Antegrade, transapical approach. A balloon is first used to compress the diseased native valve. Then, a compressed tissue heart valve is placed on the balloon catheter, inserted through the ribs into the apex of the left ventricle, and positioned directly inside the diseased aortic valve. Once in position, the balloon is inflated to secure the valve in place. **C**, Retrograde, transfemoral approach. The implantation process is similar, but the balloon and catheter are positioned retrograde from the femoral artery.

Anesthetic Considerations.

Preoperative considerations for the high-risk AS patient who is undergoing a TAVR are similar to those mentioned earlier in the chapter that apply to patients with severe AS. The anesthetist must be aware of additional considerations that are inherent in a TAVR procedure to facilitate a safe and favorable surgical outcome. These considerations begin with understanding the details of the surgical procedure, the unique set-up of a hybrid OR, and the hemodynamic challenges that arise during the procedure. [Fig. 26.22](#) shows an example of the hybrid OR setup. It must also be recognized that a TAVR procedure is a collaborative effort among many disciplines, including cardiology, anesthesia, and cardiothoracic surgery, and that all team members must clearly communicate with one

another.²¹⁹ Because fluoroscopy is used throughout a TAVR procedure, protective radiation safety equipment must be worn. Noninvasive and invasive monitoring for TAVR procedures are similar to those used for a standard cardiac case, including the use of a radial arterial catheter and PAC.²¹⁹ All IV lines should have the appropriate amount of extension to facilitate safe use of any fluoroscopic device. Patients are positioned supine, with a slight tilt to the right for surgical exposure of the left chest, if the transapical approach is selected.

FIGURE 26.22 View of hybrid cardiovascular operating room. The cardiopulmonary bypass circuit is on the far right with its own boom. The operating table is in the middle of the picture, with a floor-mounted, fixed biplanar C-arm to the left. (From Zakhary WZA, Ender JK. Procedures in the hybrid operating room. In Kaplan JA, et al. eds. *Kaplan's Cardiac Anesthesia: For Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia: Elsevier; 2017:1023.)

Recent literature has reported the increasing use of local anesthesia with sedation in experienced institutions as an anesthetic technique for transfemoral catheter aortic implantation.^{82,214,230} Transthoracic echocardiography instead of TEE is utilized in these cases. Continuous neurologic assessment, avoidance of complications associated with general anesthesia in high-risk

patients who have severe AS, and quicker recovery times are reported advantages of using local anesthesia with sedation.^{82,211,214} Advantages of utilizing a general anesthetic technique include having a protected airway, the ability to use TEE, control of ventilation during valve deployment, and the ability to urgently institute CPB if needed. A balanced general anesthesia technique is usually selected, with the goal of early emergence and extubation.²¹⁹ The slightest patient movement (even ventilation) can be disastrous during valve deployment, therefore muscle relaxants are used. Minimal doses of narcotics are needed for postoperative pain control. The use of OLV for the transapical approach is based on surgical preference.²²⁶

Vasoactive medications such as phenylephrine, norepinephrine, and epinephrine must be immediately available for administration to promptly treat hemodynamic instability. Although rapid ventricular pacing is usually limited to 10 to 15 seconds for valvuloplasty and stent deployment, preemptive boluses of a vasopressor may be administered to maintain vascular tone, maintain coronary perfusion, and ensure successful return to the baseline rhythm and MAP.^{82,211,219,226} Administration of crystalloid or colloid is usually sufficient to meet a patient's intraoperative intravascular fluid requirement during a TAVR procedure. However, typed and cross-matched blood, large-bore peripheral and central access, a fluid warming system, and a CPB team and pump should all be set up and available in case a major complication develops, such as aortic dissection or pericardial tamponade.²¹⁹ Most blood loss is associated with the initial placement and final removal of the deployment device sheath from either the femoral artery and/or LV apex.²²⁶ AV block requiring permanent pacemaker placement has been a repeatedly reported complication following TAVR, and affects 10% to 50% of patients, with a higher incidence in CoreValve use.^{211,212,222,227,231} The anesthetist must be prepared to treat the sudden onset of any intraoperative dysrhythmias, including AV block. The surgical suite should be equipped with a defibrillator and a pacemaker. Radiolucent defibrillator pads should be placed on the patient before induction. Significant perivalvular leak, stent malpositioning, coronary obstruction, and stroke caused from

atheromatous embolization are all additional perioperative complications that have been reported to occur during TAVI.^{212,220,222,232,233}

Percutaneous Mitral Valve Repair

The MitraClip system is a percutaneous catheter-based device designed to perform the Alfieri edge-to-edge repair on the mitral valve to reduce MR. The MitraClip system is the most common percutaneous mitral valve repair technique used today to treat degenerative and functional MR.^{179,227,234–237} More than 20,000 procedures have been performed worldwide since Alfieri first performed it in 1991.²³⁸ The MitraClip system was CE marked in 2008 and Food and Drug Administration (FDA) approved in 2013 for symptomatic patients with severe degenerative MR who are deemed too high risk for surgery.^{234,236}

The MitraClip system using the Alfieri edge-to-edge repair technique is a transcatheter valve procedure intended to reduce the degree of MR by delivering a clip to help secure and suture the free edge of the anterior mitral leaflet to the free edge of the posterior leaflet at the site of regurgitation if there is sufficient central leaflet surface to allow grasping by the device clip.²³⁷ The technique results in the creation of a double-orifice mitral valve (resembling a figure eight) from a central suture that connects the opposing leaflets.^{227,235} A femoral venous or transseptal approach is used, and the procedure is performed under the guidance of TEE and fluoroscopy.²³⁷ A general anesthetic is usually administered for the MitraClip procedure because continuous TEE assessment is required; however, the use of conscious sedation has also been reported.^{227,236,237,239} Results thus far for the MitraClip procedure have shown a reduction in MR (less than 2+) in the majority of patients, low rates of morbidity and mortality, and reduced hospital length of stay compared with traditional mitral valve surgical repair.^{227,234,237,239} Not only is the percutaneous mitral valve repair technique evolving, but ongoing clinical trials are also being conducted with new mitral valve therapies. These emerging therapies include percutaneous mitral valve implantations and direct mitral valve annuloplasty repair techniques.²³⁸

Devices and Procedures Developed to Manage Heart Failure

Mechanical Circulatory Assist Devices

Intraaortic Balloon Pump.

An IABP is a mechanical circulatory assist device that uses synchronized counterpulsation to enhance myocardial perfusion by reducing afterload during systole and increasing coronary blood flow to the heart during diastole.^{8,240} The IABP was first introduced in 1968, and since then its role as a key component of left ventricular support has grown in both medical and surgical settings. Medical uses include the management of cardiogenic shock, MI, intractable angina, and arrhythmias.^{8,240} In the perioperative setting, it is most commonly used to stabilize patients preoperatively and/or to help wean a patient who is having difficulty separating from CPB.^{8,240} The IABP is also used to help support coronary perfusion to patients during OPCAB procedures.^{8,240} Sepsis, descending aortic disease, severe PVD, and severe AR are contraindications to IABP placement.^{8,240-243}

The IABP consists of a flexible catheter that is attached at one end to a drive console, which contains computerized circuitry to determine proper timing for inflation and deflation. At the other end of the catheter is an inflatable, cylindrical, polyethylene balloon (containing helium) that comes in various sizes between 30 and 50 mL. It is most commonly placed percutaneously through the femoral artery via the Seldinger technique; however, alternative routes of access include the abdominal aorta and the axillary, subclavian, and iliac arteries.^{8,240,243,244} The catheter is then advanced so the tip of the balloon is situated at the junction of the aortic arch and the descending aorta (in the proximal segment of the descending aorta) and positioned 2 cm distal to the origin of the left subclavian artery.^{240,241,243,244} Proper sizing and positioning are important considerations to prevent complications such as inadvertent vascular damage or vessel occlusion. Fluoroscopy, echocardiography, or radiography is used to confirm IABP placement.²⁴⁰

The IABP should be timed with the dicrotic notch of the arterial

waveform so that the balloon inflates once the AV closes and diastole begins.²⁴⁵ The inflated balloon (during diastole) will act as a seal within the proximal descending aorta, increasing pressure and displacing blood flow antegrade toward the coronary arteries. Consequently, coronary artery perfusion is enhanced, and ultimately, myocardial O₂ delivery improves.^{241,245} Deflation of the balloon is timed immediately before the onset of systole at the beginning of the R wave of the ECG.²⁴⁵ The deflation creates a vacuum effect that lowers the aortic pressure to reduce afterload, facilitates ventricular ejection, relieves ventricular workload, and reduces myocardial O₂ demand.^{241,245} Proper timing of the IABP is essential to prevent further strain on the myocardium and to achieve a maximal counterpulsation benefit.²⁴⁰ Fig. 26.23 shows arterial waveforms with correct timing and placement, and Fig. 26.24 demonstrates arterial waveforms associated with incorrect IABP timing.

FIGURE 26.23 Arterial waveforms seen during intraaortic balloon pump (IABP) assist. The first two waveforms are unassisted, and the last is assisted. Notice the decreased end-systolic and end-diastolic pressures and augmented diastolic pressures caused by IABP augmentation and the (correct) point at which balloon inflation occurs. These are waveforms generated by a correctly positioned and timed balloon. *MVO₂*, mixed venous oxygen saturation. (Courtesy Datascope Corporation.)

FIGURE 26.24 Alterations in waveform tracings caused by errors in timing of the intraaortic balloon pump (IABP). **A**, The balloon was deflated too early. **B**, The balloon was deflated too late. **C**, The balloon was inflated too early. **D**, The balloon was inflated too late. *IAB*, intraaortic balloon; *LVEDP*, left ventricular end-diastolic pressure; *LVEDV*, left ventricular end-diastolic volume; *MVO₂*; mixed venous oxygen saturation; *PCWP*, pulmonary capillary wedge pressure. (Courtesy Datascope Corporation.)

The IABP is synchronized with either the ECG or the arterial pressure waveform. More modern consoles are unaffected by electrical noise caused by electrocautery, and they can also differentiate pacer spikes from the QRS complex when pacing is used. Timing can be difficult with irregular rhythms such as AF and faster heart rates. IABP is usually timed to inflate with each heartbeat (1 : 1) or every other beat (1 : 2) until ventricular function improves. The counterpulsation ratio can be gradually weaned to 1 : 4 and then safely discontinued. The only time it is acceptable for IABP to be abruptly discontinued when in the aorta is during CPB. To avoid risk of thrombus, anticoagulation therapy is indicated for

long-term IABP use. Vascular injuries (such as ischemia distal to the site of the balloon) are the most common complications associated with IABP use.^{8,240,244,246,247} Other frequent complications of IABP use include infection at the IABP insertion site and thrombocytopenia.^{8,240,244,246,247}

Extracorporeal Membrane Oxygenation.

ECMO is a mechanical circulatory assist device that can provide both pulmonary and systemic arterial perfusion support. It is a temporary (used for days to weeks), closed-circuit device that allows the heart and/or the lungs to recover from injury or trauma while maintaining oxygenation and perfusion.^{82,248,249} The primary conditions that call for use of ECMO are cardiogenic shock, failure to wean from CPB, RHF, heart failure that cannot be treated with a VAD, and (as a last resort, but with increasing use) resuscitation of patients requiring cardiopulmonary resuscitation.^{248,250,251} ECMO is also used to support patients with severe respiratory failure and ARDS who have failed to respond to standard treatments and advanced modes of mechanical ventilation.²⁴⁸

There are two types of ECMO, and their goals and cannulae placement are somewhat different. Venovenous ECMO is the preferred method of treatment for respiratory failure (when the cardiac function is intact) and gas exchange is impaired.^{250–252} It supports the lungs by improving gas exchange and allowing lung-protective ventilation modes. In venovenous ECMO, the femoral and internal jugular veins are often selected as cannulation sites.²⁵³ Blood is drained from the SVC and IVC through a cannula in the right internal jugular and/or the femoral vein. The blood is oxygenated by the ECMO circuit and returned to the right atrium through the same vein or a different vein (separate drainage and return cannulae or a single double-lumen cannula). If left ventricular support is required in addition to pulmonary support, venoarterial ECMO is selected.^{251,252} In contrast to venovenous ECMO, venoarterial ECMO bypasses pulmonary circulation altogether, and a higher arterial oxygenation is achieved. Cannulation for venoarterial ECMO may be centrally located (most commonly used post-CPB), where deoxygenated blood is directly drained from a cannula in the right atrium and oxygenated blood is

directly returned through a cannula inserted into the ascending aorta. Cannulation for venoarterial ECMO may also be peripheral, where deoxygenated blood is drained from a cannula in the right internal jugular and/or the femoral vein, and oxygenated rich blood is returned to the circulation (aorta) via the femoral artery. In either case, blood drains through the venous cannula to a centrifugal or roller pump that then circulates the blood at a rate of 3 to 6 L/min through a membrane oxygenator (artificial lung), where carbon dioxide is removed and O₂ is added.^{245,252} Before the blood is returned to the patient, a heat exchanger rewarms the blood that has cooled. The process is similar to CPB.

Anticoagulation with heparin administration is necessary with ECMO to prevent clot and thrombus formation. Because heparinization is required, bleeding becomes a major risk factor for patients supported with ECMO.²⁵² Other complications associated with ECMO use include stroke, infection, multiorgan dysfunction, and limb ischemia.^{245,248,251,252}

Ventricular Assist Devices

General Considerations.

Heart transplantation is the only definitive treatment for end-stage heart failure.^{82,254} It is estimated that close to 40,000 patients would benefit from a transplant; but because of the lack of donors, only 2804 heart transplants were performed in 2015. Additionally, the prevalence of heart failure increases with age, and patients over 65 years of age are not eligible transplant candidates.^{255,256} VADs are bringing new hope to this population.

Today, VADs are used to assume the function of the failing ventricle as a bridge to recovery, a bridge to transplant, or as destination therapy. Heart failure patients considered for long-term VAD support typically have become refractory to standard medical therapy. They are often symptomatic at rest and are receiving IV inotropic support.^{8,82,257} It is not uncommon for these patients to develop end-organ dysfunction caused by decreased perfusion pressure and a low CO. Cardiogenic shock from an acute MI, viral cardiomyopathies, or post-CPB can all be indications for short-term VAD support (lasting days or weeks) and bridge to recovery.^{8,258} In

this situation, the myocardium is granted time to rest while the VAD maintains circulation and decompresses the ventricle. Studies show that the decreased wall tension and myocardial O₂ demand that occur as a result of the ventricular unloading allow remodeling and recovery of the ventricle.^{259,260} Careful patient selection and intervention timing are key to achieving a successful outcome with VAD placement.⁸² Contraindications to VAD insertion include active infection or sepsis, irreversible renal or hepatic dysfunction, severe PHTN unrelated to cardiac disease, metastatic cancer, and major coagulation disorders such as hemophilia and von Willebrand disease. Since the first successful VAD implant was performed in 1966 by Dr. Michael DeBakey for postcardiotomy cardiogenic shock, VADs and their management have greatly evolved. Several studies have shown that VAD support is effective in stabilizing multiorgan failure in end-stage heart failure patients who are awaiting transplant.^{82,261} The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial compared long-term left ventricular assist device (LVAD) support to medical management for patients with end-stage heart disease who were not eligible transplant candidates. Patients who received an LVAD showed a 48% reduction in the risk of death, fewer adverse events, shorter hospital stays, lower prescription cost, and improved quality of life.²⁵⁸ VAD support for bridge to transplant has decreased mortality rates from 20.7% to 13.7% over the last 12 years. Improved outcomes have also been demonstrated in early institution of VAD support with the use of a CentriMag assist device for cardiogenic shock after cardiomy.²⁶²

Components, Types, and Heart Mate II.

The VAD is a mechanical circulatory assist device that is attached to the heart through a cannula. An LVAD collects oxygenated blood that is returned to the left atrium from an inflow cannula, usually placed at the apex of the LV. From the inflow cannula, blood enters a pumping chamber. The pumping chamber then ejects blood into the systemic circulation through an outflow cannula that is usually attached to the aorta. A right ventricular assist device (RVAD) is similarly constructed, except that it receives deoxygenated blood

from the right atrium and pumps blood into the pulmonary circulation. The RVAD inflow cannula is anastomosed to either the right atria or right ventricle, and the RVAD outflow cannula is anastomosed to the PA.

VADs are categorized according to type of blood flow (continuous or pulsatile), length of time the device can be used for support (short, intermediate, or long-term), location of device (intra-, extra-, or paracorporeal), and their source of driving power (pneumatic or electric). Two generations of VADs are currently in clinical use, and more generations are under development. A complete discussion of VADs is beyond the scope of this chapter, but [Tables 26.16](#) and [26.17](#) list some of the important characteristics of devices used for short-term and long-term support. HeartMate II is currently the most commonly used LVAD approved for intermediate- to long-term support or destination therapy in the United States ([Fig. 26.25](#)).⁸² There is currently a 79% rate of successful bridging to transplant with the HeartMate II.⁸²

TABLE 26.16

Basic Characteristics of the Devices Currently Used for Short-Term Support*

Device	Type of Support	Fill Mechanism	Drive Mechanism	System Control and Output
Abiomed BVS5000	Pulsatile	Gravity drainage	Pneumatic compression of blood chamber	Automatically adjusts rate of pumping to provide up to 5 L/min of outflow (output depends on intravascular volume status and downstream vascular resistances)
Thoratec	Pulsatile	Vacuum-assisted	Pneumatic compression of blood chamber	Depending on the mode of operation, user-defined settings determine the output (intravascular volume status is important)
Abiomed AB5000 ventricle	Pulsatile	Vacuum-assisted	Pneumatic compression of blood chamber	Automatically adjusts rate of pumping to provide up to 6 L/min of outflow (output depends on intravascular volume status and downstream vascular resistances)
Centrifugal pumps	Nonpulsatile	Gravity drainage assisted by vortex	Centrifugal force drives blood	Output is dependent on user-defined speed of impeller rotation and afterload
CentriMag	Nonpulsatile	Gravity drainage assisted by vortex	Centrifugal force drives blood	Output is dependent on user-defined speed of impeller rotation and afterload

*For example, bridge to recovery.

TABLE 26.17

Basic Characteristics of the Devices Currently Used for Long-Term Support

Device	Type of Support	Fill Mechanism	Drive Mechanism	System Control and Output
HeartMate XVE	Pulsatile; LVAD only	Gravity drainage	Electrically powered compression of blood chamber	Fixed-rate and automatic modes available; 85-mL blood chamber; maximum flow
Thoratec	Pulsatile; BiVAD possible	Vacuum-assisted	Pneumatic compression of blood chamber	Depending on the mode of operation, user-defined settings determine the output (intravascular volume status is important)
IVAD	Pulsatile; BiVAD possible	Vacuum-assisted	Pneumatic compression of blood chamber	Depending on the mode of operation, user-defined settings determine the output (intravascular volume status is important)
HeartMate II	Nonpulsatile flow; axial device; LVAD only	Gravity drainage assisted by vortex	Continuous rotation of axial pump impels blood forward	Output is dependent on user-defined speed of impeller rotation, available volume in ventricle, and afterload
CardioWest TAH	Pulsatile; replaces natural heart	All venous and pulmonary arterial blood returns to device	Pneumatic compression of blood chambers	Maximum stroke volume 70 mL; can deliver more than 9 L/min of output

BiVAD, Biventricular assist device; *IVAD*, implanted vascular assist device; *LVAD*, left ventricular assist device; *TAH*, total artificial heart.

From Stone ME, et al. New approaches to the surgical management of end-stage heart failure. In Kaplan JA, Reich JA, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Elsevier; 2011.

FIGURE 26.25 HeartMate II is an intracorporeal electrically powered axial-flow pump. Blood is drawn from the apex and pumped continuously to the ascending aorta. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

HeartMate II is an intracorporeal and nonpulsatile continuous flow device. An electrically powered axial-flow pump can generate up to 10 L/min of continuous blood flow. It can also operate at lower speeds, allowing the ventricle to assist with the workload. The HeartMate II is 60% smaller (weight: 400 g) than the HeartMate I, and is more durable.²⁶³ Common complications from VAD support such as stroke, postoperative bleeding, RV failure, and percutaneous lead infection have been shown to be far fewer with HeartMate II than with HeartMate I.²⁵⁴ Anticoagulation is required with the HeartMate II.

The HeartWare HVAD is a continuous centrifugal-flow LVAD with a magnetic levitating rotor pump that received FDA approval in 2012 for bridge to heart transplantation in patients who are at risk of death from refractory end-stage left ventricular heart failure.²⁶⁴ The HeartWare HVAD is currently the leading VAD implanted in patients outside of the United States. Its most notable difference from the HeartMate II is its smaller size. The HeartWare HVAD has a magnetic levitating rotor pump that weighs only 140 g

(5 oz). Its smaller design allows for intrapericardial placement via sternotomy or a minimal access incision.^{264,265} The HeartWare HVAD completed the second cohort of the Evaluation of the HeartWare Ventricular Assist System for Destination Therapy of Advanced Heart Failure (ENDURANCE) clinical trial in April 2015. The ENDURANCE clinical trials were a prospective, randomized, controlled, unblinded, investigational device exemption study designed to evaluate the HeartWare Ventricular Assist System as a destination therapy for patients with end-stage heart failure who are ineligible for heart transplantation. The HeartWare HVAD is approved for use as destination therapy in patients with end-stage heart failure who are ineligible for heart transplantation.

The TandemHeart system and the Impella system are percutaneous VAD systems used as short-term (hours to days) mechanical circulatory support systems in the presence of cardiogenic shock.^{245,252,253} The TandemHeart system is a left atrium to femoral artery bypass system with an external centrifugal pump.^{245,245,253} A cannula is inserted into the femoral vein across the atrial septum and into the LA, where it obtains oxygenated blood, which it then pumps into the femoral arteries at a rate up to 4 L/min.^{245,252,253} The Impella system, approved by the FDA in 2008, has an axial-flow pump; its cannula is inserted in a retrograde fashion via the femoral artery and positioned across the AV.^{245,252,253} Its pigtail catheter sits in the LV and pumps blood out to the ascending aorta, providing a CO between 2.5 and 4.0 L/min.^{245,252,253} Both percutaneous VAD devices unload the LV, decrease PCWP, increase CO, and improve peripheral tissue perfusion, thus improving overall hemodynamics.^{245,252,253} Systemic anticoagulation is required for both the TandemHeart system and the Impella system.^{245,253}

Anesthetic Management.

Anesthetic management of the LVAD candidate begins with preoperative assessment of the end-stage heart failure patient. Neurologic deficits, hepatic and renal dysfunction, and current cardiac function should be noted. Hepatic congestion from RHF, preoperative use of anticoagulation drugs, and exposure of the patient's blood to nonbiologic surfaces of the LVAD device can all

contribute to potentially substantial blood loss, and coagulopathy that may develop after placement.²⁵⁴ Blood products (platelets, FFP, and RBCs) should be available, and large-bore central and peripheral IV access should be secured before incision, in case rapid transfusion becomes necessary. Antifibrinolytic agents such as aminocaproic acid may be administered perioperatively to minimize blood loss. Placement of a radial or brachial arterial catheter and PAC in addition to standard ASA monitors prior to induction is essential to assist the anesthesia provider in achieving hemodynamic stability during induction. Decreases in preload and increases in afterload are poorly tolerated in patients with end-stage heart failure.⁸ These patients are extremely dependent on heart rate and considered to have a relatively fixed CO, with an inability to increase SV. Rapid deterioration and cardiovascular collapse can occur on induction if the patient becomes bradycardic or loses sympathetic tone.⁸ Judicious use of etomidate and a neuromuscular blocker, or a high-dose narcotic with a neuromuscular blocker, may be selected to minimize hemodynamic instability.⁸ Because sepsis is the leading cause of mortality in LVAD recipients, attention should be given to the antibiotic regimen, and strict sterile technique should be maintained.^{255,266}

A complete TEE examination assists with placement and detection of anatomic problems that can potentially complicate proper functioning of the device. AI, the presence of intracardiac shunts (PFO), MS, tricuspid insufficiency, the presence of thrombus, the level of right ventricle function, and the adequacy of VAD inflow and outflow function can all be determined from the TEE.^{8,267} Many concerns, such as AI, tricuspid regurgitation, or a PFO, will require surgical correction before LVAD placement for the device to function properly.²⁵⁵ TEE also serves as a monitor of right and left ventricular function, thereby helping to guide the anesthetist with fluid and hemodynamic management.

Before separation from CPB, ventilation is reestablished, the device is de-aired, and its function is evaluated to confirm that it will provide circulatory support. The right ventricle is assessed closely because it is needed to fill the LV. Unfortunately, 30% of LVAD recipients do develop right ventricular dysfunction after LVAD implantation, most likely because of a combination of

factors, including left ventricular decompression, myocardial stunning from CPB, fixed PHTN, and right ventricular overload from LVAD activation.^{8,254} The TEE and filling pressures are closely monitored to avoid overloading the right ventricle. Inotropes such as epinephrine, or a phosphodiesterase III inhibitor such as milrinone, help support function and decrease right ventricular afterload.⁸ Inhaled nitric oxide or Flolan (epoprostenol sodium) may be used to dilate the pulmonary vasculature. If right ventricular dysfunction ensues despite pharmacologic support, biventricular support should be considered.⁸

LVAD flow is very dependent on volume. The anesthetist should be prepared to administer volume (mainly blood and blood products) rapidly if massive bleeding and a coagulopathy develop. Patients who are potential future transplant recipients should receive blood that has been leukocyte-reduced. Vasoplegic syndrome can also develop and is best managed with vasopressin, because it causes less pulmonary vasoconstriction than norepinephrine or phenylephrine and will help prevent increases in right heart afterload.⁸ Hypertension should be treated with a vasodilator such as sodium nitroprusside to avoid causing stress and malfunction of the LVAD.²⁵⁵

Cardiac Transplantation

General Considerations.

The first human heart transplant was performed in South Africa in 1967 by Christiaan Barnard, but it was not until the introduction of cyclosporine in the 1980s that there was significant long-term survival.²⁶⁸ Today, heart transplantation is the only definitive treatment for end-stage heart failure, and survival rates (adjusted for diagnosis, sex, race/ethnicity, and age) approach 85% at 1 year and 70% at 5 years.⁸² The United Network for Organ Sharing (UNOS) is the organization in the United States that is responsible for coordinating organ procurement and allocation. An extensive multidisciplinary evaluation is required to prioritize placement on the donor list, but generally candidates must have NYHA class IV heart failure, an EF less than 20%, and a diagnosis of end-stage heart disease that is terminal in 1 to 2 years if transplant does not

occur.⁸² Once on the list, patients are assigned a priority status of 1A, 1B, or 2. Status 1A is the highest priority, and usually indicates that the patient is hemodynamically deteriorating, requiring vasopressor and/or mechanical circulatory assist support and mechanical ventilation.⁸² Ischemic or idiopathic cardiomyopathy is the most common diagnosis of heart transplant candidates, but failure can arise from many other causes.⁸² The donated organ comes from a relatively healthy patient who has been declared brain dead. The donor heart is extensively examined before being deemed suitable. Allocation of the heart is based on the UNOS priority status, ABO blood type compatibility match, weight ratio (within 20%), and distance from the donor site.⁸² The donor and recipient must be close enough geographically to ensure that the ischemic time of the heart is not prolonged.

Right ventricular failure is the major cause of short-term morbidity after transplantation. Fixed PHTN in the recipient causes acute RHF in the donor heart. The pulmonary vasculature is examined closely to determine whether it responds to vasodilator therapy. A larger donor heart, heterotopic heart transplant, or a heart-lung transplant may be considered if the recipient has a fixed PHTN (transpulmonary gradient greater than 15 mm Hg or PVR greater than 5 dynes/sec per cm⁵).^{82,268,269}

Anesthetic Management.

The preoperative period has important time constraints. Close communication is imperative among all members of the transplant center's surgical/anesthetic team and the organ procurement team to avoid prolonged donor heart ischemic time, which should be less than 4 hours.²⁷⁰ The recipient will have had an extensive evaluation so that all information necessary for a quick assessment is readily available for review. Preoperative evaluation should follow an approach similar to that of any routine urgent preanesthetic evaluation, taking particular note of any recent deterioration. Chronic systemic hypoperfusion, venous congestion, hepatic dysfunction, and abnormal coagulation profiles are common. IABP settings and timing, VAD flow rates and settings, and all inotropic drug infusions should be noted. Patients with ICDs will need them deactivated before use of electrocautery. Because most heart

transplantations are usually scheduled on short notice, most recipients will be considered full stomachs, and the last oral intake and the need for a rapid sequence or a modified rapid sequence induction should be assessed.

Induction of anesthesia for a heart transplant recipient follows many of the same principles as those for any traditional cardiac surgery on a patient with poor left ventricular function, with some noted exceptions. All medications must be administered cautiously, because patients with severe heart failure are extremely sensitive to any alterations in myocardial preload and afterload. Obtaining rapid control of the airway to prevent aspiration during induction is often indicated. To prevent cardiovascular collapse on induction, it is imperative to maintain the patient's heart rate and intravascular volume, as well as to avoid decreases in SVR. This can often be achieved with a short-acting hypnotic agent such as etomidate, which produces minimal myocardial depression; a small- to moderate-dose narcotic such as fentanyl to blunt sympathetic response to laryngoscopy and intubation; and a fast-onset muscle relaxant such as succinylcholine or rocuronium. Longer circulation times due to low EFs in transplant candidates should be anticipated.

Once surgery begins, cross-matched, irradiated blood should be available. A repeat sternotomy may warrant cannulation of the femoral arterial and venous sites or axillary cannulation, to avoid trauma to the great vessels or preexisting CABGs. Otherwise, the distal ascending aorta is cannulated, and the IVC and SVC are individually cannulated via the high right atrium.²⁶⁸ Before venous cannulation, the PAC should be withdrawn from the right atrium and left in the sterile protective sheath so that it can be refloated into the PA after CPB (Fig. 26.26).

FIGURE 26.26 Mediastinum after excision of the heart but before allograft placement. Venous cannulae are present in the superior (SVC) and inferior vena cava (IVC), and the arterial cannula is present in the ascending aorta.

A, Classic orthotopic technique. **B**, Bicaaval anastomotic

technique. (From Murray AW, et al. Anesthesia for heart, lung, and heart-lung transplantation. In Kaplan JA, et al., eds. *Kaplan's Cardiac Anesthesia: For Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia: Elsevier; 2017:976.)

A high dose of glucocorticoid (methylprednisolone) is administered either preoperatively or before release of the aortic cross-clamp to decrease the chance of a hyperacute immune response. Pharmacologic inotropic support such as an isoproterenol and/or epinephrine (direct-acting) infusion may be initiated prior to CPB separation for both inotropy and chronotropy purposes. In addition to pharmacologic agents, temporary epicardial pacing may be needed due to the presence of slow junctional rhythms and loss of sinus node function.^{82,266} Insertion of a permanent cardiac pacemaker is required in 5% to 25% of transplanted patients.^{271,272} Proper oxygenation, ventilation, and acid/base balance are necessary to adequately manage the RHF that may occur during separation from CPB. In addition, inhaled nitric oxide, prostaglandin, and/or a phosphodiesterase inhibitor such as milrinone may be used to promote pulmonary vasodilation. Once denervated, the transplanted heart no longer responds to sympathetic or parasympathetic stimulation. Consequently, indirect-acting medications like ephedrine and anticholinergic medications like atropine are ineffective in increasing heart rate or CO. The Frank-Starling mechanism is still functional, so the transplanted heart is very preload-dependent. Only pharmacologic agents such as epinephrine and isoproterenol that have direct-acting effects on catecholamines will be effective in increasing heart rate and CO.

The anesthetist should anticipate potential post-CPB bleeding and coagulopathy, which can develop for many reasons, including preoperative chronic anticoagulation, chronic hepatic congestion, extensive surgical suture lines, and CPB-induced platelet dysfunction. Anesthetic management and evaluation of ventricular function and PHTN can be further guided by the TEE and hemodynamic measurements from the PAC.

Once hemostasis is achieved, the chest is closed in the usual fashion, and the intubated transplanted recipient is transported to the ICU. Opportunistic infection, acute allograft rejection, and renal, pulmonary, and hepatic dysfunction are all possible postoperative

complications of cardiac transplantation.²⁷⁰

Surgery on the Ascending Aorta and Aortic Arch

General Considerations

The cause of aortic disease is usually congenital (e.g., Marfan syndrome, Ehlers-Danlos syndrome, bicuspid AV disease) in patients who present at younger ages for surgery, but acquired (e.g., hypertension, inflammation) in older patients.⁸ A discussion of aortic disease, as well as the classification, etiology, diagnosis, and treatment of TAs, can be found in [Chapter 25](#). This chapter focuses on anesthetic management for surgeries on the ascending aorta and arch. Care of patients having aortic surgery requires close communication between the surgeon, perfusionist, and anesthesia provider. Management will vary markedly, depending on what segment(s) of the aorta are involved and whether the AV can be preserved, repaired, or replaced. The plan for cannulation, invasive monitoring, and cerebral protection should be discussed prior to the surgery.

Most TAs are asymptomatic, so they are often found coincidentally following an x-ray or other test performed for an unrelated problem. Large TAs can cause a mass effect that leads to a variety of symptoms, including cough, dysphasia, or hoarseness due to compression on the trachea, esophagus, or recurrent laryngeal nerve. Sometimes, SVC syndrome develops.⁸ Patients with a bicuspid AV or genetic mutation associated with aortic disease should be imaged and followed at regular intervals. Surgery is indicated for all symptomatic aneurysms, and is generally indicated for ascending TAs that are dilated to 5.0 cm for congenital lesions (4.5 cm if there is a family history of dissection) or 5.5 cm for acquired lesions. TAs usually grow slowly over a period of years, but an aneurysm that is growing at a rate exceeding 0.5 cm/year should also undergo surgical repair.²⁷³ TAs of the ascending aorta and arch are usually repaired using an upper hemi or full median sternotomy, depending on the size and surgeon's preference. The type of procedure will vary depending on the extent of the aneurysm and the function of the AV. TEE is an invaluable assessment tool for determining whether the valve can

be spared or repaired, and for measuring the aorta.

Ascending Aortic Aneurysms

When the aortic aneurysm involves only the root and proximal aorta, standard aortic cannulation and CPB can be used because the distal aorta can be cannulated and a clamp placed between the cannula and the aneurysm. The femoral artery may be used as an alternate arterial cannulation site when the aortic cannula cannot be placed without jeopardizing flow to the head vessels. In this case, arterial flow is retrograde from the femoral artery to the great vessels. Additional approaches also include cannulation of the right axillary artery (or a graft sewn on the right axillary) or innominate artery.²⁷⁴ Usually a single, standard two-stage venous cannula suffices. A simple tube graft can be used to replace the aorta when the aortic root and valve are normal (Fig. 26.27). If the aortic annulus or sinuses of Valsalva (where the coronary arteries attach) are involved, the options become more complicated, and the selected technique may depend on the surgeon's expertise and preferences. When the sinuses of Valsalva are normal, the coronary arteries do not have to be reimplemented. The valve is repaired or replaced, the sinuses are spared, and a tube graft is used to repair the aneurysm. If the aortic root is dilated, a technically difficult valve-sparing operation known as a *modified David* or *Svensson reimplantation* procedure can be used (Fig. 26.28). A special instrument known as the *Hegar dilator* is placed in the LV outflow tract as the native AV (repaired if necessary) is sewn inside the graft used to repair the aneurysm. The dilator helps the surgeon correctly size the valve.²⁷⁵ The coronary arteries, which were removed along with a button of tissue from the native aorta, are then reimplemented into the graft. When the valve cannot be spared, an alternative procedure known as the *Bentall (or modified Bentall) procedure* is performed. A biologic or prosthetic AV (or pulmonary homograft) is sewn into one end of the conduit, and the resulting composite valve-graft is used to replace both the AV and ascending aorta. Again, the coronaries must be reimplemented or alternatively, an aortocoronary bypass graft can be used (Cabrol technique).^{273,274,276}

FIGURE 26.27 Ascending aortic dissection repair. **A**, The dissecting hematoma is seen and usually extends all the way to the iliac arteries. **B**, The compromised commissure of the valve is resuspended by a full-thickness pledgeted suture. **C**, The ascending aorta is replaced with a vascular graft, usually using strips of felt to reinforce the delicate adventitial tissues. (From Otto CM, Bonow RO. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 3rd ed. Philadelphia: Elsevier; 2009.)

FIGURE 26.28 David procedure. Aneurysmal root (**A**) is resected (**B**), including sinuses of Valsalva with coronary “buttons” mobilized away. **C**, Subannular sutures (six to eight) are placed. Commissural posts are drawn up inside the valve, and the annular sutures are passed through the proximal end of the graft. **D**, Annular sutures are tied gently. Then the valve is reimplanted with continuous 5-0 polypropylene suture inside the graft. Aortic continuity is reestablished with another graft of a size appropriate to the desired sinotubular junction and proximal arch. (From Otto CM, Bonow RO. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 4th ed. Philadelphia: Elsevier; 2014:210.)

Aortic Arch Aneurysms

Aneurysms that involve the arch are much more complicated. Involvement of the cerebral vessels increases the risk of neurologic

injury from both the threat of global ischemia and embolization of atherosclerotic debris. CPB is used with DHCA to protect the brain while the arch is replaced. DHCA was addressed earlier under the discussion of anesthetic management. If only the proximal aortic arch is involved, a hemiarch or partial arch replacement can be done. The origins of the arch vessels are usually dissected *en bloc* so that the three vessels lie on an island of native aortic tissue that can be anastomosed to the synthetic graft. The surgeon completes the distal anastomosis to the descending aorta first, and then sews on the island of tissue containing the arch vessels. Next, the aortic clamp is moved proximal to the arch vessels so that CPB flow can be reestablished and the cerebral vessels perfused. Finally, the proximal aortic graft anastomosis is completed (Fig. 26.29B). Aneurysms that involve the entire thoracic aorta are extremely complicated, and are often repaired in stages, combining both open and endovascular techniques. As shown in Fig. 26.29B, the distal graft is sutured circumferentially to the aorta just beyond the left subclavian artery, and the free end of the graft (“elephant trunk”) is placed within the descending aneurysm. The aneurysm repair is completed in a second procedure (as shown in Fig. 26.29C) using an endovascular stent graft attached proximally to the elephant trunk, and the distal end is secured to a Dacron graft cuff.

FIGURE 26.29 Repair of an ascending aorta, aortic arch, and descending thoracic aneurysm. **A**, Preoperative disease. **B**, Stage 1 of the repair is an open procedure. The ascending aorta and arch are replaced with a Dacron graft that is sutured circumferentially to the aorta distal to the left subclavian artery. Note that the great vessels to the head are usually resected as an island of tissue that is anastomosed to the graft. The free end of the graft (“elephant trunk”) is placed within the descending aneurysm. **C**, Completion of the procedure using an endovascular stent graft attached proximally to the elephant trunk and the distal end secured to a Dacron graft cuff. Anesthetic Management

Anesthesia implications are similar to those of other cardiac surgeries involving a median sternotomy with CPB, but with several additional concerns. The anesthesiologist must prepare for the possibility of a difficult airway if the aneurysm is large and possibly causing a mass effect. Occasionally, a reinforced ETT must be used and advanced beyond the point of compression. Caution is advised if there is resistance to passing the TEE probe or OG tube, as the aneurysm may be compressing the esophagus. An epiaortic echocardiographic examination may be necessary. If AI is present, all the anesthetic management principles previously discussed regarding acute and chronic AI will apply. In general, maintenance of a relatively high heart rate and a low SVR will enhance forward flow. Keeping the SPB lower than 120 mm Hg will minimize the chance of dissection.^{273,274} Vasodilators are often utilized to control BP and lower the SVR. PACs are usually indicated because large shifts in volume can be reasonably anticipated, especially if the arch is involved. A large-bore multilumen PAC introducer allows volume to be rapidly infused. Alternatively, several large-bore PIVs can be used with a standard PAC introducer. Blood loss can be significant, so several units of red cells should be available. FFP and platelets are transfused as needed based on coagulation studies and nonsurgical bleeding. Antifibrinolytic therapy is also sometimes used. The best location for the A-line is determined by the plan for

placement of the aortic cannula and aortic cross-clamp. For ascending aortic aneurysms, there is no consensus in the literature as to the best location for the A-line; the left brachial artery, as well as the left and right radial arteries, have been advocated. When the arch is involved, two A-lines are placed: one in either radial or brachial artery, and one in a femoral artery. If the right axillary artery is to be cannulated for CPB, then the left radial or brachial is preferred because the increased flow will cause the pressure on the right to be falsely elevated.^{274,277} Some practitioners place three A-lines: one in each upper extremity, as well as one in the femoral artery. The surgeon can then be alerted to pressure differences between the A-lines that most likely indicate inadequate flow and potential ischemia. Nasal or tympanic temperature is monitored as a reflection of brain temperature.²⁷⁸ The nasal probe should be placed before heparin is administered, to prevent bleeding in this fragile area. Usually, bladder and PA temperatures are also measured to reflect core and shell temperatures, respectively, and to help monitor the rate of rewarming.^{277,278}

Aortic Dissection

Acute ascending or aortic arch dissections are highly lethal, and timely surgical intervention correlates with survival. Descending dissections can usually be repaired on an elective basis, unless there are signs of organ ischemia. The dissection begins from an intimal tear that most often spreads antegrade, but can also dissect retrograde throughout the aorta, possibly encompassing the great vessels and/or the AV.⁸ [Chapter 25](#) discusses in detail the pathophysiology of aortic dissection and the management of descending aneurysms. Patients with ascending or arch dissections usually present with sudden severe neck and chest pain, but symptoms mimicking a stroke, MI, or arterial embolization can also occur. Syncope is an ominous sign that cerebral or cardiac circulation is compromised. Diagnosis can be made with TEE, contrast-enhanced spiral CT scan, or MRI. Acute AI, tamponade, or limb ischemia can develop at any time.^{8,274} The initial priority is to obtain adequate vascular access for both monitoring BP and transfusing the patient. Control of the BP is critical. The A-line site should be carefully selected, avoiding ischemic limbs and locations

that will be impacted by surgical cannulation. The aim of hemodynamic management is to decrease shear forces, which can cause further dissection or rupture. The heart rate and BP are most often controlled using a β -blocker first to achieve a heart rate of approximately 60 bpm, followed by cautious vasodilation to achieve an SBP lower than 120 mm Hg. Vasodilator therapy should not be initiated prior to rate control, because the reflex tachycardia that may develop can increase aortic wall stress, causing harmful expansion of the dissection.²⁷⁶ Coexisting myocardial depression can make medication titration challenging. Some institutions have the patient prepped and draped prior to induction in case urgent CPB must be initiated because of rupture. All the previously mentioned anesthetic considerations apply.

Deep Hypothermic Circulatory Arrest

Cerebral perfusion must be temporarily interrupted during repair of aneurysms involving the aortic arch. Deep hypothermia is the most important therapeutic intervention to prevent cerebral ischemia. The patient is cooled using CPB to maximally decrease the cerebral metabolic rate and O₂ consumption, thereby extending the period that the brain can tolerate circulatory arrest. As cooling on CPB is initiated, most institutions cool the brain topically by placing ice bags around the head and/or use a cooling blanket. One study demonstrated a 50% improvement in metabolic function in patients who had their heads packed in ice versus those who did not.²⁷⁷ A barrier such as a towel should be placed between the ice bags and the skin to prevent thermal damage. Care should also be taken to protect the eyes, nose, and ears from pressure. A consensus statement that details “best practices” when using hypothermia for aortic arch surgery was published in 2013.²⁷⁸ The STS also published clinical practice guidelines for temperature management during CPB. To achieve deep hypothermia, the patient is cooled to a temperature of 14.1°C to 20°C. It is recommended that the oxygenator arterial outlet blood temperature be utilized as a surrogate for cerebral temperature measurement during CPB.⁹⁷ Once the patient is cooled to the desired temperature and the EEG shows burst suppression, or the BIS reads 0, most of the blood

volume is drained into the venous reservoir, and the CPB is turned off. Arrest periods of 20 to 30 minutes are considered safe during deep hypothermia.^{274,278} Combining DHCA with cold antegrade cerebral perfusion (ACP) may prolong the safe period to as long as 80 minutes.^{277,279} The traditional goal is to have a flat EEG. The BIS and cerebral oximeters have also been used to try to detect, and thus prevent, cerebral ischemia.²⁸⁰ Other efforts to improve the safety of DHCA include reducing blood viscosity and hematocrit in an effort to counteract the increased blood viscosity that develops secondary to cooling. Pharmacologic attempts at neuroprotection include the administration of barbiturates or propofol to decrease cerebral O₂ demand. Steroids, lidocaine, and mannitol have also been used. However, because no pharmacologic intervention has proved effective, these are not considered a substitute for achieving adequate hypothermia.²⁸¹

Antegrade Cerebral Perfusion.

If DHCA is expected to last more than 30 minutes, selective ACP into the axillary, innominate, subclavian, or internal carotid artery is often used to extend the safe operative time. The perfusionist uses a roller pump to intermittently infuse blood cooled to 6°C to 12°C directly into the cerebral vessels at rates between 400 and 1000 mL/min. Many surgeons prefer to use right subclavian arterial cannulation if ACP is planned, and the BP is monitored using a right radial A-line during ACP, with the goal of maintaining the MAP between 30 and 70 mm Hg. However, the right A-line should not be used to control perfusion pressure during the cooling and rewarming period, as the pressure may be falsely elevated if the right subclavian is used for CPB arterial flow.^{7,82,274,277,279} NIRS is a relatively new, easily applied technology that measures frontal cerebral oxygenation through light transmittance. NIRS appears to be the most useful trend monitor during ascending aortic and arch surgery, particularly when ACP is employed. Significant reductions in left-sided sensor values compared with right-sided ones may indicate an incomplete circle of Willis. In this situation, ACP via the left carotid artery often restores the values.²⁷⁴

Retrograde Cerebral Perfusion.

Retrograde cerebral perfusion (RCP) was popularized in past decades as a form of enhanced cerebral protection; however, ACP has been shown to provide superior protection. Clinical use of RCP is on the decline, but is still practiced.^{277,279} RCP requires the use of individual SVC and IVC venous cannulation. During the period of arrest, the A-line of the CPB circuit is connected to the SVC cannula, and cold oxygenated blood (between 8°C and 14°C) is infused at a rate of 220 to 600 mL/min. During RCP, the patient is kept in a slight Trendelenburg position to prevent air embolism. Ideally, flow reaches the brain in a retrograde fashion through the venous system, but venous engorgement of the brain is to be avoided. The goal is to maintain an SVC pressure of less than 20 mm Hg, although this pressure is not necessarily associated with improved outcomes. The SCV pressure is usually measured by connecting the side port of the PA introducer to the CVP pressure transducer (the CVP port is capped). Advantages of RCP include relative simplicity, uniform cerebral cooling, efficient de-airing of the cerebral vessels (thus reducing the risk of embolism), and provision of O₂ and energy substrates.^{274,279}

Rewarming.

Once systemic perfusion is reestablished using CPB, a period of hypothermic reperfusion is recommended. When rewarming begins, it should be done gradually, maintaining a temperature gradient no greater than 10°C in the heat exchanger, and cerebral hyperthermia must be avoided. Temperature gradients between the arterial outlet and venous inflow on the oxygenator during CPB cooling or rewarming should not exceed 10°C, to avoid generation of gaseous emboli.⁹⁷ Even slight hyperthermia in patients with cerebral ischemia or infarction may exacerbate any damage.²⁷⁶ The STS recommendation is that surgical teams should limit arterial outlet blood temperature to less than 37°C to avoid cerebral hyperthermia.⁹⁷ The optimal temperature for coming off bypass is a matter of debate. Some believe that a bladder temperature of 36.5°C should be achieved to decrease bleeding, whereas others hold that 35°C is cerebral-protective, and that bleeding is due to the procedure and to other causes.⁹⁷

Summary

As the population ages, CAD, VHD, and heart failure will continue to be major health burdens. The risk profile of the average cardiac surgical patient and the complexity of the procedures continue to rise. Technology and innovative surgical approaches to managing CVD have changed the landscape of cardiac anesthesia. A clear understanding of the core physiologic and pathophysiologic principles that impact coronary blood flow and myocardial function will enable the anesthetist to adapt anesthetic management in this ever-evolving field. Each clinician is encouraged to stay abreast of the evidence-based outcome studies that have so greatly impacted our clinical practice. Enjoy the excitement and challenge of cardiac anesthesia, and always remember to “take care of the pipes, the pump, and the volume.”

Perioperative Management of Cardiac Implantable Electronic Devices

Judith A. Franco, Rebecca Ashlock

Due to the increasing mean age of the population in the United States and the associated cardiac pathology, many patients undergoing surgical procedures will have a preexisting cardiac implantable electronic device (CIED). The CIED may be a pacemaker, an implantable cardiac defibrillator (older model), a combination of both pacemaker and implantable cardiac defibrillator (modern device), or a cardiac resynchronization device (also referred to as a *biventricular cardiac device*). With the increasing advances in technology, there is greater device variability and newer indications for proper use. The indications for the use of each CIED differ, including the programmability. Therefore the management in the perioperative setting may be different depending on the device. Intraoperative electromagnetic interference can alter, disrupt, or damage these devices. Furthermore, rapid changes in technology are responsible for the lack of evidence-based practice guidelines and troubleshooting methodologies.^{1,2} Therefore it is extremely important not to make generalizations regarding these devices.^{1,3} It is imperative, however, that knowledge regarding the type of device, indications for placement, basic functions, programmability, response to the magnet, and device limitations are ascertained to ensure patient safety.⁴

The key objectives that will be addressed in this chapter include:

- A generalized review of various CIEDs
- Discussing the multidisciplinary team's responsibility regarding management of CIEDs

- Identifying the CIED's potential response to electromagnetic interference
- Employing intraoperative management strategies for various CIEDs

Review of Pacemakers

Pacemakers (PMs) emerged approximately 70 years ago in an effort to save the lives of patients with sinus node and atrioventricular node dysfunction. Pacemakers were initially placed via thoracotomy.⁵ These initial devices were limited to ventricular pacing at a constant rate as sensing capabilities were unavailable. These first PMs were associated with a multitude of problems such as lead fractures, randomly changing thresholds, competition between the intrinsic heart rate and the PM rate, and electromagnetic interference (EMI).

The creation of a “reed switch” enabled the PM to convert from synchronous to asynchronously pacing with the application of a magnet. A reed switch is composed of two magnetic metal strips located within the pulse generator. In the presence of a magnetic field or with the application of a magnet placed directly over the PM, the two metal strips make contact and close the reed switch, inactivating the sensing circuit. It is this change in voltage that causes the PM to asynchronously pace the myocardium.⁶ The creation of a reed switch revolutionized PM technology and secured its place as a safe and reliable intervention for sinus and atrioventricular node dysfunction.

Today's PMs are approximately the size of a quarter (Fig. 27.1). They consist of two main components: a pulse generator that houses the battery, circuitry and connectors, and insulated lead wires that conduct energy to and from the myocardium. The pulse generator is usually implanted in the pectoral pocket on either the right or left side of the chest. This is accomplished while the patient receives general anesthesia or local anesthetic with sedation (Fig. 27.2). A sensing circuit, located within the pulse generator, picks up signals transferred from the myocardium via the leads. High amplitude is seen by the PM as intrinsic activity and low amplitude is seen as interference and commonly referred to as *noise*. These signals are filtered and actual cardiac signals are sensed. The PM can read intrinsic activity correctly, and pacing is initiated appropriately. However, in the presence of EMI, this noise causes the PM to inaccurately sense intrinsic cardiac activity resulting in

PM inhibition.⁵

FIGURE 27.1 Pacemaker. (Reproduced with permission of Medtronic, Inc.)

FIGURE 27.2 A pacemaker is positioned in the pectoral pocket. (From Sorrentino SA, Remmert LN. *Mosby's Textbook for Nursing*

A PM may contain up to three lead wires. The wires are imbedded into the right atrium, the right ventricle, both the right atrium and ventricle, or the right atrium and both ventricles. The lead systems are unipolar, bipolar, or multipolar. In a unipolar configuration, the pulse generator acts as an anode (positive electrode) and the distal end of the lead wire is the cathode (negative electrode). With this lead system, there is a greater distance between the anode and cathode when compared to a bipolar lead. With a unipolar lead, the “spikes” (vertical lines that represent electrical activity) on the surface electrocardiogram (ECG) are frequently larger and the distance between the anode and the cathode places the PM at an increased risk for EMI.

Bipolar leads contain two electrodes. In a bipolar configuration, the anode and cathode are located at the distal end of the bipolar lead. As a result, there is less distance between the two poles creating a lesser chance of EMI and decreased potential for disruption to the PM function. Bipolar electrodes are visualized on a chest x-ray by identification of a distal ring located 1 to 3 cm from the tip of the bipolar lead (Fig. 27.3).⁷ Most modern PM leads are bipolar and their lead configuration exhibits smaller spikes on the surface ECG.

FIGURE 27.3 Pacemaker electrode configurations. **A**, Unipolar electrode. **B**, Bipolar electrode. (From Hillegass E. *Essentials of Cardiopulmonary Physical Therapy*. 3rd ed. St. Louis: Elsevier; 2011:389.)

Pacemakers have sensing and capturing responses that may be identifiable by the presence of spikes on the ECG. When the PM lead wire is placed in the right atrium, there is a spike followed by a *P* wave on the ECG, representing atrial depolarization (Fig. 27.4). When the lead is inserted in the right ventricle, a spike followed by a *QRS* complex on the ECG indicates ventricular depolarization (Fig. 27.5). If the device is a dual chamber pacemaker (a lead is inserted in both the right atrium and ventricle), there is a spike before the *P* wave and before the *QRS* complex followed by both atrial and ventricular depolarization (Fig. 27.6). If the pacing device is sensing the patient's intrinsic rhythm and not providing a paced response due to actual cardiac activity, only a sensing marker is visualized on the ECG. There are a multitude of indications for PM placement.⁸ Common indications are listed (Box 27.1).

Box 27.1

Indications for the Use of Pacemakers

- Sinus node disease
- Atrioventricular node disease
- Long QT syndrome
- Hypertrophic obstructive cardiomyopathy
- Dilated cardiomyopathy

Types of Pacemakers

Although the focus of this chapter describes the perioperative management of implantable PMs and cardiac defibrillators, there are various types of external PMs available. These external devices can be manipulated manually when a disruption in pacing occurs. The implantable PM requires reprogramming or, in some cases,

magnet application to remedy unreliable or disrupted pacing behavior. The following provides a brief overview of PMs that are common to the surgical patient when an implantable PM is not present.

With external pacing, transcutaneous pacing pads are applied (a) anteriorly on the right upper chest and anteriorly on the left lower chest, or (b) anteriorly mid chest and posteriorly between the scapulae. In either case, the transcutaneous pacing pads are plugged into a defibrillator/pacing machine and programmed accordingly (Fig. 27.7). In transvenous pacing, the pacing catheter is passed into the central circulation (usually via an introducer sheath) and into the appropriate cardiac chamber(s). This lead is connected to an external pacemaker generator and it is programmed as needed. Epicardial pacing leads are often inserted at the completion of cardiac surgery. These pacing wires are directly sewn, by the cardiac surgeon, onto the epicardium, passed through the skin, attached to an external pacing device, and programmed as dictated by the clinical situation.

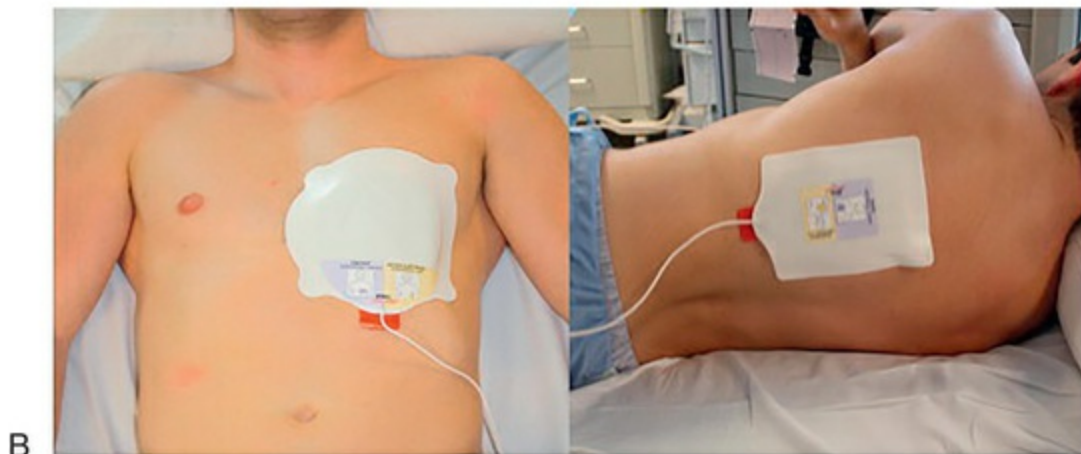

FIGURE 27.7 **A**, Pad placement for transcutaneous pacing. **B**, Alternate anteroposterior placement. (From L'Italien

AJ: Critical Cardiovascular Skills and Procedures in the Emergency Department, Emergency Medicine Clinics of North America. 2013;31(1):151–206.)

Although there are different pacemakers available, the language, terminology, and programming are similar ([Table 27.1](#)). With the non-implantable devices (external, transcutaneous, or transvenous) a practitioner can diagnose a PM problem (e.g., failure to capture or sense) and immediately intervene by manipulating the programming. For example, providers can manually change the heart rate programmed on the non-implanted pacemaker to increase oxygen delivery or increase the electrical output to improve capture. With an implantable PM, intervening in this manner is not an option without access to a device-specific programmer. Troubleshooting an implantable PM requires

recognition of the problem, knowledge of whether the device is magnet sensitive, and access to a programmer.

TABLE 27.1

Pacemaker Terminology

Heart Rate	Programmed upper and lower heart rate
Electrical output	Electrical output, measured in milliamps (mA), is the electrical output the pacemaker delivers with each charge
Synchronous mode	Paced rate matching the underlying rate of one of the heart chambers
Asynchronous mode	Cardiac pacing mode set independent of the hearts intrinsic rate
Inhibited	When the patient demonstrates an intrinsic heartbeat, the pacemaker will not deliver a paced beat.
Threshold	The minimum output that will cause the myocardial chamber (atrium or ventricle) to consistently contract or capture.
Sensitivity	The lowest amplitude P or R wave that the pacemaker will recognize as an electrical signal.
AV Interval	The time between the beginning of atrial systole (paced or intrinsic) and the beginning of ventricular systole (equivalent to the PR interval on the ECG).
Capture	Depolarization of a heart chamber in response to pacemaker electrical output.
Failure to Capture	When the pacemaker's electrical output fails to cause myocardial depolarization.
Failure to Sense	The pacemaker fails to recognize intrinsic cardiac electrical activity.

Pacemaker Codes

A three or five letter Heart Rhythm Society (HRS) code identifies the key functions of implantable PMs (Table 27.2). It is imperative that the anesthetist is familiar with the HRS codes and understands the functionality and result on the PM. The first letter in the code identifies the chamber where the pacing electrode is placed. If the first letter is A, the pacing lead is in the right atrium. If the first letter is V, the pacing lead is located in the right ventricle. If the first letter is D, then there is dual chamber pacing with wires located in both the right atrium and the right ventricle.

TABLE 27.2

Heart Rhythm Society (HRS) Pacemaker Codes

NASPE/BPEG Generic Pacemaker Codes (Revised 2002)				
Position 1	Position 2	Position 3	Position 4	Position 5
			Programmability	

Programmability				
O = None A= Atrium V= Ventricle D = Dual (A+V)	O = None A= Atrium V = Ventricle D = Dual (A+V)	O = None I = Inhibited T = Triggered D = Dual (T+I)	O=None R = Rate Modulation	O = None A = Atrium V = Ventricle D = Dual (A+V)

The second letter of the code identifies the chamber where the sensing electrode is placed. If the second letter is A, the sensing wire is located in the right atrium. If the second letter is V, the sensing lead is located in the right ventricle. If the second letter is D, the sensing wire is located in both the right atrium and the right ventricle. If the second letter is O, then there is no sensing and the PM will pace at an asynchronous rate.

The third letter of the code identifies the PMs response to the detection of a spontaneous cardiac depolarization and its effect on subsequent pacing stimuli. The device will either inhibit or trigger a pacing stimulus. If the third letter is I, then the PM response is withheld when intrinsic sensed activity is faster than the programmed lower rate limit. If the third letter is T in a single chamber mode, the PM will deliver a scheduled output pulse in response to sensed intrinsic activity. This programmed response is used for troubleshooting and electrophysiology studies. If the third letter is D, the PM will either inhibit or trigger in response to sensed intrinsic activity. For example, a sensed intrinsic atrial beat will inhibit atrial pacing output and trigger ventricular pacing.⁹ If the third letter is O, there is no sensing and the PM will asynchronously provide pacing.

The fourth letter of the code represents rate modulation. A rate-adaptive sensor, located within the generator, is programmed to respond to physiologic stimuli (compensation for physical needs, illness, or stress) and allows the pacemaker to increase its lower rate limit. For example, if a patient exercises, the PM will increase the heart rate to augment the increased need in myocardial oxygen demand. Activity-based sensors are the most prevalent and use piezoelectric (material that generates a charge in response to applied mechanical stress) crystals to detect vibration and/or accelerometers, which detect acceleration and deceleration forces. Sensors that detect minute ventilation sensors, located within the PM circuitry, measure changes in transthoracic impedance during chest expansion and deflation that are associated with respiration.

These measurements provide respiratory rate and tidal volume information and allow for calculation of minute ventilation. Changes in minute ventilation are an excellent reflection of changes in myocardial oxygen consumption and metabolic demand.¹⁰ An R indicates the presence of rate modulation capability, and O indicates its absence.

The fifth and final letter in the HRS code identifies multisite pacing. The letter A indicates one or both atria are paced. The letter V indicates that one or both ventricles are paced. The letter D indicates that there is a combination of both atrial and ventricular pacing. The letter O indicates the absence of multisite pacing.¹¹

Preoperative interrogation is recommended so that CIED indications, basic functions, programmability, response to magnet, battery life, and device limitations are known. The anesthetist must be able to recognize when the PM is not functioning or when the PM is responding inappropriately during the intraoperative period.

The following section discusses the implantable cardioverter defibrillator (ICD). The chapter will then address recent advancements, the CIEDs response to EMI, magnet utilization, and preoperative, intraoperative, and postoperative management.

Review of Implantable Cardioverter Defibrillators

Symptomatic bradyarrhythmias are treated with a pacemaker and tachyarrhythmias are often managed with an ICD. An ICD is a reliable method to restore a regular and coordinated rhythm from a lethal tachyarrhythmia.¹

Significant technological advancements have improved the efficacy of ICDs over recent years (Fig. 27.8). The first ICD, developed in the 1980s, was primitive and was energized by simple batteries.¹² This original ICD was placed through a thoracotomy or sternotomy and defibrillation patches were positioned directly on the epicardium. The lead wires were tunneled to the abdomen, which housed the defibrillator generator, and limited programming was available. When a charge was needed, the battery sent energy to the capacitor and once the capacitor was fully charged, the energy traveled through the wire to the myocardium and delivered a shock. By the 1990s, although the ICD generator still remained implanted in the abdomen, the ICD lead/shock coils (no longer an epicardial patch) were inserted via transvenous access and implanted into the right ventricle.

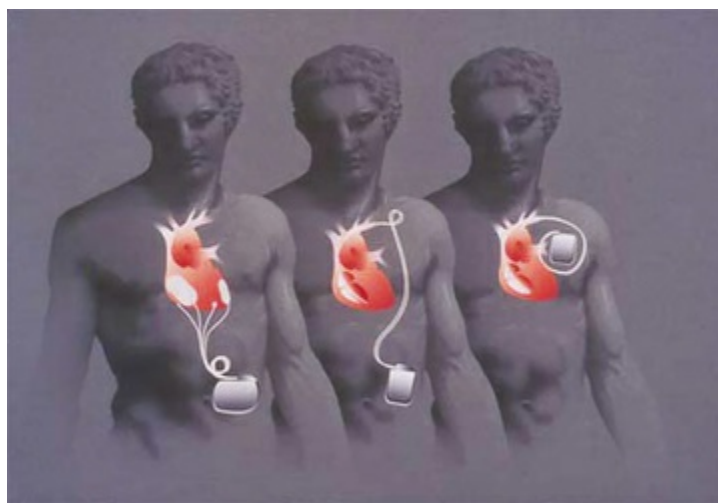

FIGURE 27.8 Transformation of ICDs. (Reproduced with permission of Medtronic, Inc.)

Today's ICDs consist of a pulse generator, a large capacity battery, a large voltage capacitor, a lead wire, and a shock coil as one unit¹³ (Fig. 27.9). The generator is most often implanted in the pectoral pocket on either the right or left side of the chest while the patient receives either general anesthesia or local anesthesia with sedation. The ICD lead/shock coil is attached to a pulse generator and positioned in the right atrium and ventricle. The capacitor delivers the current for defibrillation by receiving energy transferred from the generator's battery and discharging this energy as an electrical impulse. This impulse travels through the lead/shock coil to the myocardium and cardioverts or defibrillates the heart to treat the tachyarrhythmia. The original ICDs delivered anti-tachycardia therapy only. Modern ICDs are dual function devices and they contain back-up pacing capabilities. This chapter will focus on ICDs with dual function (ICD + PM) unless otherwise specified.

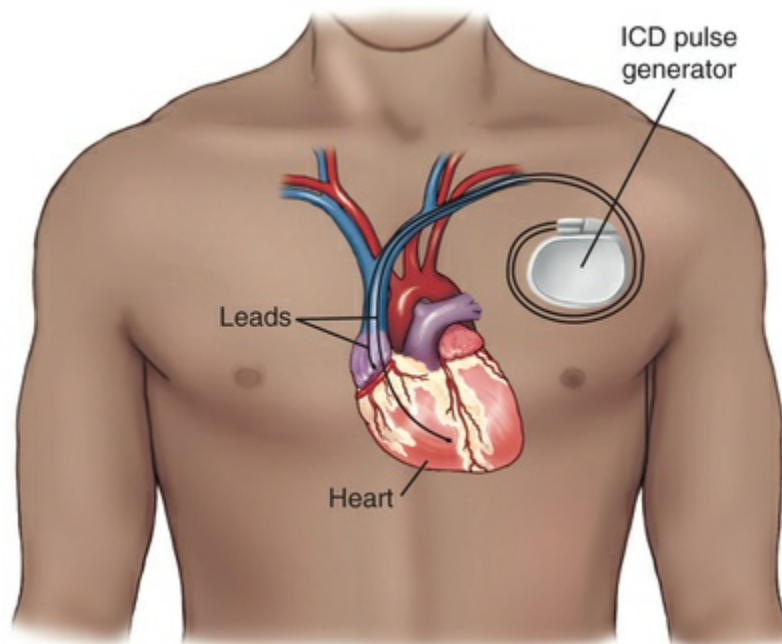

FIGURE 27.9 An implanted cardioverter-defibrillator (ICD). (Modified from Goldberger AL. *Clinical Electrocardiography: A Simplified Approach*. 8th ed. St. Louis: Elsevier; 2013.)

Implantable cardioverter defibrillators are programmed to accomplish multiple interventions. A lead/shock coil placed in the

right atrium can: (a) treat bradycardia through pacing and sensing, (b) provide rate modulation, (c) initiate antitachycardic pacing, and (d) cardiovert. A lead/shock coil placed in the right ventricle can (a) treat ventricular arrhythmias, (b) initiate anti-cardiac pacing, (c) cardiovert and defibrillate and, (d) treat bradycardia through pacing and sensing.¹⁴ If the device is a cardiac resynchronization device, a lead wire is threaded retrograde through the coronary sinus to the left side of the myocardium.

Indications and Terminology

The indications for ICDs include coronary artery disease, heart failure, arrhythmia, structural abnormalities, or conduction disturbances (Box 27.2).¹³ As with PMs, ICDs have specific codes that determine the individual devices functionality (Table 27.3). The first letter in the HRS codes describes the chamber that will be shocked, the second letter indicates the chamber where anti-tachycardia pacing occurs, the third letter denotes the device's method of rhythm detection, and the fourth letter identifies which chamber will deliver back-up pacing. The ICD pacemaker function

Box 27.2 shows the HRS pacing coding system.

Indications for Implantable Cardiac Devices

- Ventricular tachycardia
- Ventricular fibrillation
- Post-myocardial infarction with an ejection fraction (EF) < 30%
- Cardiomyopathy from any cause with an EF < 35%
- Hypertrophic cardiomyopathy
- Awaiting heart transplant
- Long QT syndrome
- Arrhythmogenic right ventricular dysplasia

- Brugada syndrome

Implantable cardioverter defibrillators can be programmed to recognize a magnet, which will disable shock therapy, although not all devices are programmed to do so.¹⁵ The magnet placed on an ICD will not initiate asynchronous pacing. This is a very important distinction and the specifics will be addressed in the previous section. Anesthetists must be familiar with the codes, terminology, and the device capabilities to properly manage and manipulate the ICD during the perioperative period.

Implantable Cardioverter Defibrillators Therapy

Sophisticated and complicated algorithms programmed in the ICD generator activate the tachyarrhythmia features when a malignant rhythm occurs. The algorithms are programmed to sense the R-to-R wave and evaluate the rate, the abruptness of the malignant pattern, and the sustainability of the rhythm.¹ The antitachycardia pacing feature will initiate short rapid pacing bursts at a rate that exceeds the intrinsic tachycardic rate and will terminate the rhythm. The ICD cardioverts ventricular tachycardia (VT) with 1–30j and defibrillates ventricular fibrillation (VF) with 10–30j.⁵ If the ICD acknowledges that the rhythm requires defibrillation, it will deliver

six shocks. Once a shock is delivered, the ICD will disable any further antitachycardia pacing activity.¹

Advancements in Technology

Over the last decade, there has been tremendous forward progress in the design and engineering of both PMs and ICDs. Two new developments have emerged and they are now available for patients. Advances in battery and miniaturization technology have led to the development of a leadless single chamber intracardiac pacemaker. These leadless pacemakers, approximately one-tenth the size of the traditional single chamber PMs, are implanted directly into the right ventricle via a femoral vein catheter (Fig. 27.10). The miniaturized devices are engineered with functionality and features comparable to their larger predecessors. Elimination of the complications associated with traditional PM implantation (e.g., infection of the subcutaneous pocket, lead fracture and dislodgment, hematoma) may decrease hospitalizations and ultimately health care costs.¹⁶⁻¹⁸ Intracardiac devices do not require removal at the end of service and they are engineered to convert to OOO mode when the battery voltage reaches the end of service.¹⁸

FIGURE 27.10 Leadless pacemaker. (Reproduced with permission of Medtronic, Inc.)

In 2012, the Food and Drug Administration (FDA) approved the use of a subcutaneous ICD (S-ICD) for the termination of life-threatening ventricular tachyarrhythmias in patients with structural or congenital heart disease, compromised venous access, or those at high risk of infection.^{19,20} The S-ICD pulse generator is implanted subcutaneously along the left lateral chest wall and the lead/shock coil is positioned along the left sternal border.^{19,20} Unlike the traditional ICD with intracardiac leads, the S-ICD delivers higher energy defibrillation shocks from outside the chest wall. The S-ICD is not indicated for patient's who require pacing for bradyarrhythmias as the device will only deliver thirty seconds of immediate post-shock pacing for bradycardia.¹⁹ This device is not sensitive to manipulation with a magnet.

Perioperative Period

Preoperative

Patients who are scheduled for surgical procedures should be medically optimized and undergo a thorough history and physical, indicated laboratory testing, and an assessment of comorbidities.⁶ The surgical patient with a CIED will require special attention. A multidisciplinary team approach (cardiologist or electrophysiologist, anesthetist, programmer, and surgeon) that considers the type of device, the location of the pulse generator, the type and length of procedure, the anticipated use of electro-surgical cautery (EC), and the patient's surgical position is warranted (Box 27.3).^{3,21} A device specific programmer and/or manufacturer contact number should be known as well (Table 27.4).

Preoperative Assessment of Cardiac Implantable Electronic Devices

CIED Inquiry

- What is the device?
- How is the CIED programmed?
- What is the indication for device implantation?
- Is the patient pacemaker dependent and if so what is the underlying rate and rhythm?
- Has the device been interrogated recently?
- Is the device functioning properly?
- If the device is an implantable cardioverter defibrillator (ICD) what is the recent number of shocks delivered? Is it safe to disable pre-operatively or to use a magnet?
- Is the device able to recognize the magnet and if so, what is the

response?

- Will monopolar electrosurgical cautery be used?
- Is the surgical site near the pulse generator?
- Does the device need to be reprogrammed?
- Do I know what to do should the CIED become inhibited or malfunction as a result of electromagnetic interference (EMI)?

TABLE 27.4

Some pertinent information may be found on the manufacturer generated wallet card. This identification card lists the (a) type of device, (b) model number and serial number, (c) date of implantation, (d) name of the implanting physician or clinic, and (e) contact information for the manufacturer.⁶ The information card will not include information about when the CIED was last interrogated or if the device has been functioning properly.

The HRS recommends routine assessment of the PM on a yearly basis and assessment of the ICD every six months.²² Device interrogation will include the: (a) date of last interrogation, (b) type of device, (c) manufacturer, (d) model, (e) indications, (f) battery life, (g) lead integrity, (h) PM function and underlying rhythm or ICD therapy, (i) magnet response, and (j) any alerts.⁶ Any recently initiated anti-tachycardia therapy should be considered when

planning the perioperative management of these patients. This information may directly determine if disabling shock therapy intraoperatively constitutes a safe plan of care.²³ An incomplete preoperative assessment or failure to investigate CIEDs programmability can lead to poor patient outcomes.²⁴

In an emergency, if the CIED function is unknown, assessing the ECG and obtaining a chest X-ray can be of use when there is insufficient time to interrogate. Evaluation of a 12-lead ECG may reveal a paced rhythm only if heart rate is currently pacing. The 12-lead ECG will not, however, inform the provider of the underlying rate, PM dependence, or type of device. The patient's chest x-ray is another source of information. Each CIED has a manufacturer identifier on its pulse generator. This identifier can be used to determine the manufacturer and possibly the model of the device. The chest x-ray can also alert the provider to whether the device is a PM (the presence of lead wires) (Fig. 27.11) or a defibrillator (the presence of 1-2 radiopaque lead/shock coils) or both (Fig. 27.12). Additional information may be obtained by placing a magnet over a CIED. If the device is a PM, asynchronous pacing may be evident. If the device is an ICD, there may be an audible tone indicating that anti-tachycardia therapy has been disabled. It is important to note that not all CIEDs respond in this manner.

FIGURE 27.11 A cardiac pacemaker battery implanted under the skin on the right chest wall is visible in this chest radiograph. The leads from the battery extend down to the right atrium and the apex of the right ventricle. (From Klatt E. *Robbins and Cotran Atlas of Pathology*. 3rd ed. St. Louis: Elsevier; 2015:51.)

FIGURE 27.12 Chest x-ray of an implanted cardioverter-defibrillator. CS, Coronary sinus; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (From Fleisher LA. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia: Elsevier; 2013:90.)

Intraoperative

Both general anesthesia or local anesthesia with sedation are acceptable techniques and they should be tailored to the patient's underlying pathology.²⁴ The American Society of Anesthesiologists (ASA) standard monitoring recommendations should be employed during all anesthetics. Attention to intraoperative physiologic alterations such as electrolyte and/or acid base imbalances, ischemia, medication levels, and hypothermia can alter device thresholds and as such should be corrected.¹

Electromagnetic Interference

The potential for CIED malfunction when exposed to EMI is a concern during the intraoperative period. EMI is defined as any

external or nonphysiologic signal that interferes with pacemaker function. Sources of EMI are present both within and outside the hospital environment. The degree to which EMI may interfere with the function of the CIED is variable. Inhibition of pacemaker function, inappropriate triggering, electrical reset, damage at the lead-tissue interface, and tracking of electrical noise are all possible responses to EMI.²²

The most prevalent source of EMI in the operating room is the electrosurgical cautery (EC) that is used to stop bleeding via cutting or coagulation of tissues. Two main types of EC are frequently employed during surgery: monopolar and bipolar. Monopolar cautery produces more energy than bipolar and therefore requires the placement of a grounding pad. The distance between the electrocautery tip and the grounding pad will determine the area in which stray current can be sensed by a CIED and misinterpreted (this is similar to the unipolar pacing lead). For this reason, the grounding pad should be positioned near the site of surgery but away from the CIED generator.

Bipolar electrocautery devices have the anode and cathode at the tip of the device. Due to the close proximity, there is less area for stray interference to be misread by the CIED. A grounding pad is not necessary with a bipolar cautery, although bipolar cautery can be converted to monopolar, which necessitates a grounding pad. Less energy is exerted with the use of bipolar electrocautery; therefore it is not usually a surgeon preference.⁵ If bipolar cautery cannot be used, then requesting that the surgeon use short bursts of energy (< 5 seconds at a time) decreases the potential of EMI effecting CIEDs.^{6,25} In an effort to eliminate the potential clinical consequences of EMI, modern CIEDs have been engineered to allow for filtering of non-cardiac signals.²⁶

Electromagnetic Interference and Cardiac Implantable Electronic Devices.

Electromagnetic interference can be interpreted as a serious cardiac dysrhythmia that can affect the activity of PMs and ICDs. A PM may interpret EMI as intrinsic electrical activity and will inhibit pacing, if it is programmed to do so. In this instance, the PM oversenses electrical activity and it will not pace the myocardium.²³ If

the patient is dependent on the PM, inhibition of pacing results in loss of mechanical cardiac activity. This can be dangerous and even life threatening unless an escape rhythm emerges.²⁷ There are additional instances in which EMI may negatively affect PM function and programmability. EMI may:

- Be viewed as noise and initiate asynchronous pacing at a rate that may cause R on T phenomena;
- Be conducted down the lead and damage the myocardium via an endocardial burn;
- Decrease battery life;
- Reset the device to an alternate rate;
- Be interpreted as a *P* wave causing the device to only pace the ventricle, thus losing potential atrial kick;
- Result in severe bradycardia or asystole;
- Reprogram and alter device settings;
- Alter thresholds eliminating proper capture.^{1,6,10,23,27}

The effect of EMI on an ICD differs from that of a PM. When EMI is present, the ICD generator may interpret the signal as a potential tachyarrhythmia (VT or VF).²⁷ If the interference (e.g., cautery) lasts long enough, the device will analyze the noise and determine if anti-tachycardia therapy is warranted. If the ICD analyzes the noise as a lethal arrhythmia, the device will deliver an inappropriate shock. A vigilant practitioner can differentiate the interference from VT/VF on a surface ECG by the presence of a pulse oximeter or arterial waveform (Fig. 27.13). The device, however, may not make a correct determination in the presence of EMI despite sophisticated algorithms and may initiate an unwarranted shock. This highlights why thorough knowledge of device programmability is so essential for the anesthetist. Information regarding what the device will and will not do is crucial to the anesthesia practitioner's decision of whether or not preoperative reprogramming is warranted or if magnet placement is a viable alternative. EMI can initiate negative effects on an ICD and:

FIGURE 27.13 ECG and arterial line with EMI. *ECG*, Electrocardiogram; *EMI*, electromagnetic interference.

- Inhibit antitachycardia therapy;
- Be conducted down the lead and damage the myocardium via an endocardial burn;
- Permanently deactivate the device, causing it to enter a “magnet mode” and fail to detect lethal rhythms;
- Change the programming and thresholds; and
- Affect the rate adaptive mode and inappropriately increase the heart rate.^{1,22,23}

In the hospital environment, there are other potential sources of EMI that can equally disrupt device function and/or programmability. Transcutaneous electrical nerve stimulators, spinal cord stimulators, extracorporeal shock wave lithotripsy, radiation therapy, electroconvulsive therapy (ECT), and magnetic resonance imaging (MRI) on CIED function vary. The anesthesia provider should be aware of the potential sources and appropriate options for minimizing and managing the consequences of CIED malfunction in these areas.

Extracorporeal shockwave lithotripsy rarely produces EMI sufficient to interfere with CIED function; however, some inappropriate sensing and pacing inhibition have been documented.²² During ECT which is used to treat severe depression, electrical current is administered to the brain. The initial cardiovascular response to ECT is bradycardia followed immediately by tachycardia, which may result in the administration of inappropriate ICD shocks. According to the HRS/ASA, if the

CIED is programmed to respond to magnet application, use of a magnet is a reasonable as a management option and reprogramming the device prior to ECT is not required.

Transcutaneous electrical nerve stimulation, used for the treatment of both chronic and acute pain, should only be used in patients with PMs (a) after extensive testing to ensure safety, (b) when exceptional improvement of quality of life is demonstrated, and (c) only intermittently. Similarly, individual testing should be performed on patients prior to initiation of spinal cord stimulator therapy to ensure no inhibition of pacemaker function or inappropriate triggering of anti-tachycardia therapy is observed.²² Radiation, both therapeutic and diagnostic, can be safely performed for patients with CIEDs. With therapeutic radiation, there is an increased risk of CIED dysfunction. Additionally, the radiation beam may have a direct effect on the pulse generator, which may result in permanent changes to the device.²¹ Diagnostic radiation frequently does not have a clinically significant impact on CIED function. However, there have been documented cases of oversensing and electrical reset with computed tomography scanning.^{28,29}

At present, medical devices are categorized into one of three groups by the American Society for Testing and Materials: (1) magnetic resonance (MR)-safe: an item that poses no known hazards in an MR environment; (2) MR-conditional: an item that has been demonstrated to pose no known hazards in a specified MR environment with specified conditions of use; and (3) MR-unsafe: an item that is known to pose hazards in all MR environments. MRI examinations can also interfere with CIED function. Possible adverse events specific to MRI include reed switch closure with subsequent asynchronous pacing, thermal injury at the electrode-myocardial tissue interface, and development of rapid pacing. Some manufacturers have developed an FDA approved "MR-conditional" device. These MR-conditional devices require reprogramming prior to an MRI scan and the manufacturers require that a facility undergo special training prior to administering patient scans. All major device companies are in the process of refining their technology. Continued monitoring of MR-conditional leads is needed to ensure that complication rates remain

reasonable in comparison with the benefit attained.^{30,31}

Reprogramming and Magnet Application

The anesthetist must consider the potential for intraoperative EMI and create an appropriate plan to mitigate the potentially harmful effects (Table 27.5).²⁷ Reprogramming is recommended when there is an expectation of increased EMI, when monopolar cautery is used, or when the surgical site is in close proximity to the device generator.^{6,22,27} Although the influence of EMI cannot be eliminated, the environment can be manipulated to identify EMI and control its impact. A device specific programmer can temporarily modify the device settings. A PM can be programmed to an asynchronous mode and an ICD can have anti-tachycardia therapy disabled.

TABLE 27.5

Preoperative Reprogramming Recommendations

Reprogramming Recommendations	Rationale
Re-programming to an asynchronous mode on a pacemaker (PM) dependent patient	<ul style="list-style-type: none">• Expected use of monopolar cautery• Expected increase in EMI• Surgical site located near the pulse generator
Disable shock therapy	<ul style="list-style-type: none">• If monopolar cautery used and anticipating increased EMI
Disable rate modulation	<ul style="list-style-type: none">• Prohibit increases in rate due to EMI
Consider a higher asynchronous rate	<ul style="list-style-type: none">• Anticipated need for increased oxygen demand
Older models may not be dual devices	<ul style="list-style-type: none">• Reprogramming is suggested

Intraoperative planning and interventions that can be used to decrease EMI and to limit its effects on cardiac devices is listed in **Box 27.4**.

Intraoperative Planning and Interventions for Patients with Cardiac Devices

- Visualization of the pulse waveform, consider arterial line
- Magnet placed or in the operating room (if the device is magnet sensitive)
- Placement of grounding pad away from pulse generator

- Bipolar cautery with short bursts
- Chronotropic pharmacologic support as needed
- Interrogator and manufacturer phone number available
- Emergency equipment readily available
- Position transcutaneous patches anterior and posterior if antiarrhythmic therapy is disabled
- Reprogram the device

The rate modulation mode is not intended to increase the heart rate indiscriminately but might do so intraoperatively in the presence of EMI. Hyperventilation, coughing or bucking, and mechanical ventilation may result in inappropriate increases in the rate of pacing.¹⁰ Therefore disabling this feature is recommended during a surgical procedure.^{3,27}

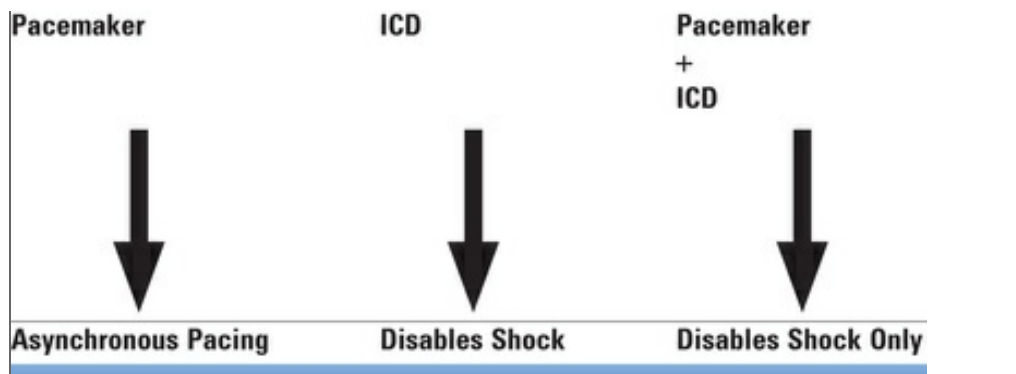

Another strategy to offset the effects of intraoperative EMI is the placement of a three-inch, round, horseshoe or rectangle magnet directly over the CIED (Fig. 27.14). Preoperative interrogation of the device manufacturer will inform the practitioner if the CIED is magnet sensitive. Most modern PMs are programmed to acknowledge the magnet, resulting in asynchronous pacing at a “magnet rate.” The magnet rate is frequently more rapid than the patient's intrinsic heart rate (85–100 beats per minute) in order to decrease the potential for R-on-T phenomenon. Magnet application will also suspend rate modulation on some PM devices.¹⁵ Unfortunately, each pacemaker is programmed differently and may or may not respond to magnet application. Some magnet responses may be disabled, and the magnet rate may not be the same as the programmed pacer rate.¹ Older devices may exhibit asynchronous paced rates at a lower than expected rate with magnet application indicating a low or depleted battery.^{25,32}

FIGURE 27.14 Device magnet.

Magnet application on an ICD closes the reed switch, suspending anti-tachycardia therapy (if the ICD is programmed to do so).¹¹ The ICD cannot shock VT or VF unless the magnet is removed. Magnet application will not suspend rate modulation on an ICD; therefore a programmer must turn off the mode.³² ICDs with a back-up pacing function will not convert to asynchronous pacing with magnet application.¹⁵ This is an important concept that must be understood and appreciated in the clinical setting. When a magnet is placed on a newer generation ICD (PM + ICD), the magnet will only suspend shock therapy and it will not asynchronously pace the heart ([Table 27.6](#)).

TABLE 27.6 Magnet Response

Three intraoperative clinical scenarios illustrate this important distinction when CIEDs are programmed to recognize magnet application:

1. Example A: EMI is inhibiting PM function. Placing the magnet directly on the PM device should initiate asynchronous pacing.
2. Example B: A surgical patient has a magnet positioned over the ICD (ICD + PM) temporarily disabling anti-tachycardia therapy. The patient suddenly converts to VF. Removing the magnet will allow the device to analyze the rhythm and intervene appropriately.
3. Example C: A surgical patient does not have a magnet placed over the ICD (ICD+PM). The patient develops a lethal rhythm. The ICD recognizes the rhythm as VF, analyzes that rhythm, determines shock therapy is warranted, and shocks the patient. The post-shock rhythm is a bradyarrhythmia and ICD pacing is not present. Placing a magnet to treat this bradyarrhythmia will not asynchronously pace the heart. This intervention merely results in disabling shock therapy, which can be hazardous to the patient who has just experienced VF.

Placement of a magnet on a CIED should not replace a thorough interrogation of the device.³² Blind magnet placement can compromise safety, especially when generalizations are made regarding device function and its response to magnet placement.¹ It is important to note: (a) not all CIEDs have similar programming,

(b) it is incorrect to assume that all CIEDs are functioning properly, and (c) placement of a magnet or reprogramming the CIED does not eliminate the potential effects of EMI.⁴ Direct interrogation remains the only reliable method of CIED assessment.⁷

Furthermore, intraoperative magnet placement has disadvantages; the position of the patient may not be optimal to accommodate the magnet or the magnet may not be effectively secured on the CIED.

Emergency Intervention

In the event of CIED malfunction during a hemodynamically unstable cardiac rhythm, transthoracic defibrillation paddles should be placed anteriorly and posteriorly however, never directly over the device. The lowest possible energy setting required to achieve cardioversion or defibrillation should be used. Transient increases in myocardial stimulation thresholds associated with external cardioversion have been documented.^{33,34} Interrogation of the device is advised following any external cardioversion or defibrillation.²

Postoperative Care

Any patient with a CIED and the potential for EMI must be monitored postoperatively. If the magnet was used to disable shock therapy, it should be removed and a complete evaluation of the device's integrity performed. A CIED is reassessed if any settings were changed and then reprogrammed to appropriate preoperative settings.⁶ If rate modulation was disabled, then it must be restored. Recommendations for postoperative interrogation are also suggested for any surgical procedure where monopolar cautery is used, any large and invasive surgery, any intraoperative adverse event, and for any emergent surgery when device interrogation did not occur.³ Consultation with a cardiologist should occur as necessary.⁶ All interventions should be recorded in the patient's medical record.

Summary

Rapidly evolving technology, expanding indications for implantation, and an aging population increase the likelihood that the anesthetist will be responsible for the care of a patient with a CIED. Complex devices, lack of standardization among manufacturers, variable programmability and response to magnet therapy, and the lack of evidence based management guidelines caused by rapid innovation and improvements in CIEDs all complicate perioperative management. A basic understanding of the indications for CIED implantation and device function is essential. Furthermore, a systematic approach for providing a safe, efficient, and an individualized plan of perioperative care is vital for optimum patient outcomes.

Anesthesia for Vascular Surgery

Sass Elisha

Peripheral Vascular Disease

Atherosclerosis is the most common cause of peripheral vascular occlusive disease. This degenerative process involves the formation of atheromatous plaques that may obstruct the vessel lumen resulting in a reduction in distal blood flow. The pathophysiologic process is systemic, progressive, and primarily affects the arteries due to plaque formation, which can lead to stenosis and potentially occlusion of the vascular lumen; thrombosis from hypercoagulability, resulting in acute organ ischemia; embolism from microthrombi or atheromatous debris; and weakening of the arterial wall, resulting in aneurysm formation. Atherosclerosis is an inflammatory condition that is partially caused by cholesterol plaques, which occur within arteries. In response to cholesterol plaques, immune cells such as macrophages and monocytes liberate proinflammatory cytokines, which leads to a progressive increase in the size of plaques. The lipid cap which envelopes the plaque can rupture, resulting in intraluminal thrombosis or plaque emboli. The most common risk factors associated with atherosclerosis are shown in [Box 28.1](#). Endothelial dysfunction is a potential cause of increased hemodynamic variability during anesthesia. Smoking, elevated proinflammatory mediators, and diabetes mellitus are major risk factors in the pathogenesis of atherosclerosis in the arterial tree. Typical symptoms associated with peripheral occlusive disease include claudication, skin ulcerations, gangrene, and impotence.¹ The extent of disability is primarily influenced by the development of collateral blood flow. The mortality rate in patients with vascular disease is two- to sixfold higher than in the general population.² Hypercoagulability resulting from platelet interaction with leukocytes and other cells that modulate the immune response plays a major role in the development of atherosclerosis.^{3,4} Researchers have discovered heritable genetic factors that predispose patients to developing vascular disease.⁵

Risk Factors Related to the Development of Atherosclerotic Lesions

- Advanced age
- Smoking
- Hypertension
- Diabetes mellitus
- Insulin resistance
- Obesity
- Family history and genetic predisposition
- Physical inactivity
- Sex (males at greater risk than females)
- Homocysteine
- Elevated C-reactive protein
- Elevated lipoprotein
- Hypertriglyceridemia
- Hyperlipidemia

Treatment for peripheral occlusive disease may range from pharmacologic therapy to surgery. Surgical therapy includes transluminal angioplasty, endarterectomy, thrombectomy, endovascular stenting, and arterial bypass. Some common surgical maneuvers used to bypass occlusive lesions are aortofemoral, axillofemoral, femorofemoral, and femoropopliteal procedures. Bypass techniques may be classified as *inflow* or *outflow* procedures, depending on the level of the obstruction, with the dividing axis occurring at the level of the groin. Temporary occlusion of the operative artery is mandatory during surgical bypass, as this temporarily further reduces blood flow and oxygen delivery. The development of collateral circulation provides alternative vascular

blood flow in patients with occlusive disease.^{6,7} Initially, angiogenesis or the development of new vessels supplies collateral blood flow that is sufficient to meet tissue oxygen demands. As the disease progresses, the blood flow is decreased, and the oxygen supply is unable to meet the tissues' demand, which could result in myocardial dysfunction, neurologic dysfunction, renal dysfunction, and/or limb ischemia.

Preoperative Evaluation

The atherosclerotic process in occlusive disease is not limited to peripheral arteries, and should be expected to be present in the coronary, cerebral, and renal arteries. More than half of the mortality associated with peripheral vascular disease results from adverse cardiac events.⁸ There is a clear association between the development of aortic aneurysms and coronary artery disease (CAD).⁹ It has been estimated that 42% of patients presenting for abdominal aortic aneurysm (AAA) repair have significant CAD.¹⁰ Preoperative cardiovascular evaluation and treatment is beneficial for reducing not only perioperative risk but also late cardiovascular events. After elective AAA repair, the 5-year survival rate and incidence of major adverse cardiovascular events is 86%.¹¹ Cardiac pathology, which often occurs in this patient population, must be managed aggressively to optimize cardiac functioning and decrease morbidity and mortality from cardiac causes.

Preoperative Pharmacologic Management

β-Blockade.

The advantages of β-blockade, as it relates to factors that affect myocardial oxygen supply and demand, have been extensively studied in patients with peripheral vascular disease. The use of β-blockers is recommended in patients at high risk for myocardial ischemia and infarction.¹² For patients having an AAA repair, there is a tenfold decrease in cardiac morbidity associated with adequate preoperative β-blockade.¹³ β-Blockade therapy should be instituted days to weeks before surgery and titrated to a target heart rate between 50 and 60 beats per minute (bpm).¹⁴ Perioperative β-

blockade started within one day or less before noncardiac surgery prevents nonfatal myocardial infarctions (MIs), but increases the risk of hypotension, bradycardia, stroke, and death. Initiating β -blockade between 2 and 7 days before surgery may be preferable, but there is a lack of scientific data to support the benefit of beginning therapy more than a month in advance.¹⁵ Vascular surgery patients with limited heart rate variability after receiving β -blockers exhibit less cardiac ischemia and decreased postoperative troponin values and have a decreased mortality from all causes 2 years postoperatively.¹⁶ For patients taking β -blockers, these medications should be continued up to the day of surgery and during the postoperative period.¹⁷

Statins.

It has been suggested that statins decrease perioperative mortality in patients with vascular disease by decreasing adverse cardiovascular and cerebrovascular events and death.¹⁸ These drugs have cardioprotective effects, as they reduce vascular inflammation, decrease the incidence of thrombogenesis, enhance nitric oxide bioavailability, stabilize atherosclerotic plaques, and lower lipid concentrations. It is reasonable to start a statin drug in this patient population. If prescribed, a statin should be instituted 30 days prior to the surgical procedure and continued throughout the postoperative period.¹⁵ Statin therapy that is started preoperatively and continued through discharge has been associated with reduced 30-day mortality and an absolute 18% improvement in 5-year survival after vascular surgery.^{18,19} Specifically, patients who were prescribed statins and then underwent endovascular aortic aneurysm repair (EVAR) had greater residual aneurysm sac regression within the first years postoperatively.²⁰

Antiplatelet Medications.

It has been unclear whether patients having noncardiac surgery who are at increased risk for MI should receive aspirin throughout the perioperative period. The results of current evidence and the Perioperative Ischemic Evaluation 2 (POISE-2) research trial indicate that perioperative aspirin does not prevent MI and does not alter the risk of a perioperative cardiovascular event.²¹ The

outcomes were unchanged for those subjects who took aspirin for a prolonged period compared to those who started aspirin prior to surgery. Aspirin did, however, increase the risk of major bleeding. In patients who have been on a long-term aspirin regimen and have aspirin withheld during the perioperative period, it is important to ensure that aspirin is restarted after the increased risk period for bleeding has passed (i.e., 8–10 days after surgery). On the basis of currently available literature, aspirin should not be administered to patients undergoing surgery unless there is a definitive guideline-based primary or secondary prevention indicated.^{22,23}

The presence of concurrent pulmonary, renal, neurologic, and endocrine dysfunction should be identified, and measures should be taken to improve organ function before surgery. Acute kidney injury (AKI) is common during the perioperative period in patients undergoing vascular surgery, and this condition is associated with a high risk for cardiovascular-specific mortality comparable to that seen with chronic kidney disease.²⁴ Strategies used to help prevent perioperative AKI are discussed later in this chapter. Preoperatively, the greater the number of comorbidities that exist, the greater the risk of morbidity and mortality during the perioperative period.

Monitoring

The extent of perioperative monitoring should be based on the presence of coexisting disease and the type of surgery. Clearly, the detection of myocardial ischemia should be a primary objective in patients with vascular disease. Methods for assessing cardiac function include electrocardiography, pulmonary artery pressure, and transesophageal echocardiography (TEE) monitoring. The effectiveness of pulmonary artery catheters (PACs) in improving patient outcomes remains controversial. Many randomized controlled trials have been performed to assess whether they offer any benefit. It was determined that PAC monitoring had no effect on mortality or length of hospital stay. Additionally, there were higher rates of pulmonary embolism, pulmonary infarction, and hemorrhage in the PAC group.^{25–27} Furthermore, PACs have not been associated with decreased inoperative mortality or morbidity, and they are associated with increases in the duration of ventilation

and length of stay in the intensive care unit (ICU) following cardiac surgical procedures.²⁶ Specific indications for the use of PAC may be indicated (e.g., complex cardiac surgery).²⁸

Due to the global nature of atherosclerotic disease, some degree of systemic cardiovascular disease in patients with peripheral vascular disease should be assumed.¹⁰ Patients with hypertension and/or angiopathy rely on increased mean arterial pressures to perfuse their vital organs. Thus, cerebral and coronary autoregulation occurs within a higher range compared to patients without peripheral occlusive vascular disease (60–140 mm Hg). Short, sustained periods of hypotension can result in cardiac or neurologic ischemia. Direct intra-arterial blood pressure monitoring allows for near–real-time determination of blood pressure values, and is warranted because information ascertained from an arterial line, such as fluid volume status, acute fluctuations in blood pressure caused by surgical intervention, and titration of vasopressor/vasodilator medications, guides treatment decisions.

In the future, the use of noninvasive hemodynamic monitoring modalities may prove to decrease morbidity and mortality by allowing the anesthetist to make anesthetic choices based on another important factor: cardiac output. Titration of vasoactive medications and guiding intravenous fluid therapy could improve survivability in this patient population. More scientific evidence will be needed on the subject prior to making practice guideline recommendations.

Anesthetic Selection

The anesthetic technique chosen for patients having vascular surgery depends on the type of surgical procedure to be performed and the presence of coexisting disease. Maintaining consistent hemodynamic control and avoiding significant episodes of intraoperative hypertension and hypotension are vital to (1) maintaining oxygen delivery to vital organs, (2) decreasing the possibility of increased myocardial oxygen consumption, and (3) decreasing the potential for hemorrhagic stroke. In certain instances, infiltration of local anesthetic and intravenous sedation may be sufficient, whereas more invasive surgical procedures require the use of general anesthesia. Regional anesthesia for

surgery on the lower extremities may decrease the overall morbidity and mortality associated with this patient population. Numerous studies have failed to yield demonstrative evidence that any single anesthetic technique decreases morbidity and mortality following vascular surgery. A comprehensive meta-analysis combining data from 141 studies involving 9559 patients suggested a 30% reduction in mortality for those patients who received a combined general anesthetic (GA) and epidural combination. A reduction in the rate of MI, stroke, and respiratory failure was found when epidural anesthesia was used in patients undergoing aortic surgery.²⁹ A major study has been conducted to evaluate various end-points associated with major vascular surgery.³⁰ None of these studies have definitively concluded that superior outcomes depend on the anesthetic technique used.³¹ A positive consideration for administering inhalation and intravenous anesthetic agents is that anesthetic medications decrease the rate of oxygen demand and help to protect neurologic and cardiac tissue in patients having noncardiac surgery.³² In addition, a meta-analysis reviewing epidural analgesia versus opioids for postoperative pain relief in patients undergoing abdominal aortic surgery showed an overall decreased rate of MI in those patients who received epidural analgesia.³³ Epidural analgesia provided during the postoperative period has significant physiologic advantages. Specific benefits of using an epidural for major abdominal vascular surgery are summarized in [Box 28.2](#). In addition, many patients having vascular surgery are receiving anticoagulant therapy and will receive heparin intraoperatively; therefore there is a risk that [Box 28.2](#) anesthesia could lead to epidural hematoma formation.³⁴

Benefits of the Epidural Technique in Vascular Surgery

Endocrine

- Inhibits surgical stress response
- Inhibits epinephrine and cortisol release
- Inhibits hyperglycemia

- Inhibits lymphopenia and granulocytosis
- Causes nitrogen sparing
- Blocks sympathetic tone
- Inhibits inflammatory mediator release

Cardiovascular

- Decreases myocardial oxygen demand and afterload
- Increases endocardial perfusion at ischemic zone
- Increases hemodynamic stability
- Decreased blood loss
- Decreases general anesthetic medication requirements
- Redistributes blood to lower extremities

Pulmonary

- Decreased effect on FVC, FEV₁, and PEFV
- Decreases ventilation perfusion mismatch
- Improves atrioventricular oxygen differentiation
- Decreases pulmonary postoperative complications
- Decreased incidence of thromboembolism

Renal

- Increases blood flow in the renal cortex
- Decreases renovascular constriction

Geriatric

- Inhibits physiologic stress
- Improves postoperative mental status

Miscellaneous

- Allows earlier extubation, ambulation, and discharge
- Improves postoperative pain control

FEV₁, Forced expiratory volume in 1 second; *FVC*, forced vital capacity; *PEFR*, peak expiratory flow rate.

Postoperative Considerations

Postoperative pain management is important to consider after peripheral vascular surgery. Most clinicians agree that postoperative administration of narcotics not only provides patient comfort, but also contributes to cardiac stability. The use of epidural opioids and local anesthetics in patients recovering from vascular surgery is an important component of postoperative care because pain can greatly enhance sympathetic nervous system stimulation. Despite a decrease in discomfort during the postoperative course, these patients must be monitored for possible adverse events, such as MI, hypotension, or respiratory depression, which could be attributed to the administration of epidural opioids and local anesthetics. Acute pain increases inflammatory mediators such as creatinine kinase, C-reactive protein, interleukin (IL)-6, and tumor necrosis factor, which can lead to regional blood flow alterations, organ dysfunction, and cell death.³⁵

Patients having vascular surgery are at increased risk for developing a venous thromboembolism (VTE) during the postoperative period. In one study, VTE was detected in 18.1% of patients with aortoiliac obstruction and 21.0% of patients after AAA repair.³⁶ The incidence of VTE continued to be elevated after discharge. All methods intended to prevent the formation of deep vein thrombosis (DVT), including pharmacologic management,

should be employed throughout the postoperative period. Low molecular weight heparin is frequently used to bridge the time between withholding oral anticoagulants and surgery. It is important to restart oral anticoagulant medications postoperatively after the risk of bleeding is decreased to minimize DVT and VTE. Increased postoperative hematocrit concentration is associated with an increased risk of 30-day mortality from DVT and pulmonary embolism.³⁷

Abdominal Aortic Aneurysms

Incidence

The incidence of AAA is estimated to be between 3% and 10% for patients over 50 years of age in the western world.³⁸ Improved detection of AAAs is the result of increased screening of asymptomatic aneurysms by noninvasive diagnostic modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography. The occurrence of AAAs has increased because of the increased age of the general population and the vascular changes that occur as a result of aging.³⁹ AAAs are two to six times more common in men than in women, and are two to three times more common in white men than in black men.³⁸ Women with AAAs are being treated at older ages and typically have AAAs that are smaller in diameter, as compared to men.⁴⁰ In men, AAAs most frequently begin to occur at 50 years of age and peak at 80 years of age.⁴¹

Risk Factors

The incidence of AAAs in a given population depends on the presence of risk factors (Box 28.3). Independent risk factors thought to be causes rather than markers for the development of an AAA include age, gender, and smoking. Smoking is the risk factor that is most highly correlated with AAA. In cigarette smokers, the incidence of AAAs increases fivefold.³⁸ There is an association between chronic inflammation and angiopathology. The specific mechanism that links inflammation and vascular disease has not been definitively established, but elevated cytokine levels appear to play a central role.⁴²

Conditions and Traits Associated With Development of Abdominal Aortic Aneurysm

- Smoking

- Older age
- Gender (more common in males than in females)
- Family history
- Coronary artery disease
- High cholesterol
- Chronic obstructive pulmonary disease
- Height (per 7 cm interval)
- Hypertension
- Peripheral vascular occlusive disease
- Caucasian

Mortality

Elective AAA repair is one of the most frequent vascular surgical procedures, with approximately 40,000 operations performed in the United States annually.⁴³ Mortality rates for elective abdominal aortic aneurysmectomies have decreased since the 1970s. The present mortality rate ranges from 1% to 11%, although it is most commonly estimated at 5%. This is compared with mortality rates of 18% to 30% in the 1950s.^{38,44–47} Even with the advent and increased frequency of EVAR, long-term mortality rates are similar, at approximately 15% to 17%.⁴⁸ Advanced detection capabilities, earlier surgical intervention, extensive preoperative preparation, refined surgical techniques, higher quality hemodynamic monitoring, improved anesthetic techniques, and aggressive postoperative management have all contributed to this improvement in surgical outcomes. Data suggest that the risk of rupture is low for AAAs less than 4 cm in diameter, but the risk dramatically increases for AAAs with a 5-cm diameter or greater. Surgical intervention is recommended for AAAs 5.5 cm or greater in diameter.⁴⁹ Unfortunately, mortality rates for patients with

undetected or untreated ruptured aortic aneurysms have not followed the trend of those who have surgical intervention. Estimates of mortality resulting from ruptured AAAs vary from 35% to 94%.^{43,50-52} Combining prehospital mortality with operative mortality, the overall mortality for AAA rupture is 80% to 90%. The 5-year mortality rate for individuals with untreated AAAs is 81%, and the 10-year mortality rate is 100%.⁵³ Other criteria for surgical intervention for AAA include ruptured AAA, a 4 to 5 cm AAA with greater than 0.5 cm enlargement in less than 6 months, patients who are symptomatic for AAA, and a 5-cm AAA or greater for elective repair for patients with a reasonable life expectancy. Early detection and elective surgical intervention can be lifesaving, because elective surgical mortality is less than 5% in most studies.⁵⁴

Diagnosis

Physical Examination

Asymptomatic aneurysms may be detected during routine examination as a pulsatile abdominal mass. Smaller aneurysms are often undetected on routine physical examination. AAA screening rates remain below 50%. AAAs are frequently discovered incidentally by primary practitioners, and some patients undergo unnecessary ultrasound screening.⁵⁵ It has been estimated that less than 30% of AAAs are identified during routine physical examination. A more extensive scoring system that includes additional risk factors such as the presence of carotid artery or peripheral arterial disease, obesity, hypertension, smoking, diabetes, and increased age may increase the rate of detection to almost 90% of AAAs.⁵⁶

Imaging

A minimally invasive method used to initially diagnose the presence of AAA is by ultrasound. Ultrasound is helpful to determine if a AAA is present, but it is not highly accurate in determining the extent of AAA or if rupture has occurred.⁵⁷ CT angiography (CTA) allows for a more precise view of the aneurysm morphology, including aneurysm size, vessel wall integrity, and

adjacent anatomic definition such as the iliac arteries. CTA has become the imaging test of choice for AAA because of its high quality resolution, rapid image acquisition, and wide availability.⁵⁸ This information gained from CTA is valuable to the surgeon and interventional radiologist for initial determination of the surgical intervention (e.g., open or EVAR) and the extent of the distal and proximal aneurysm if an endovascular stent graft is to be implanted.

Abdominal Aortic Reconstruction

Patient Selection

As a result of recent advances in surgical and anesthetic techniques, the 30-day perioperative mortality rate associated with elective open repair of AAAs is estimated to be 3% to 4.5%.⁵⁹ Most patients with abdominal aneurysms, including the elderly, are considered surgical candidates. Although advanced age contributes to an increased incidence of morbidity and mortality, age alone is not a contraindication to elective aneurysmectomy.⁶⁰ However, physiologic age is more indicative of increased surgical risk than chronologic age. Contraindications to elective repair include intractable angina pectoris, recent MI, severe pulmonary dysfunction, and chronic renal insufficiency.⁶¹ Patients with stable CAD and coronary artery stenosis of greater than 70% who require nonemergent AAA repair do not benefit from revascularization if β -blockade has been established.⁴⁴ Table 28.1 lists characteristics that define high-risk patients; however, in most cases, the presence of an AAA warrants surgical intervention.⁵³

TABLE 28.1

Criteria for High Risk in Abdominal Aortic Aneurysm Repair

Parameter	Criterion
Age	Older than 70 years
Gender	Female
Cardiac	History of myocardial infarction Angina pectoris Myocardial disease Q waves on ECG ST/T wave changes on ECG Ventricular ectopy Hypertension with left ventricular hypertrophy Congestive heart failure
Endocrine	Diabetes
Neurologic	Stroke
Renal	Chronic or acute renal failure
Pulmonary	Chronic obstructive pulmonary disease Emphysema Dyspnea Previous pulmonary surgery

ECG, Electrocardiogram.

Modified from Pairolero PC. Repair of abdominal aortic aneurysms in high-risk patients. *Surg Clin North Am.* 1989;69:765–774; Holt PJE, Thompson MM. Abdominal aortic aneurysms: evaluation and decision making. In Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery*. 8th ed. Vol. 2. Philadelphia: Elsevier; 2014; Woo EY, Damraur SM. Abdominal aortic aneurysms: open surgical treatment. In Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery*. 8th ed. Vol. 2. Philadelphia: Elsevier; 2014.

The dimensions of an aneurysm can change over time. AAAs expand by approximately 4 mm/yr.⁶² Aneurysmal vessel dimensions correspond to the law of Laplace:

$$T = P \times r$$

where T = wall tension, P = transmural pressure, and r = vessel radius.

As the radius of a vessel increases, the wall tension increases. Wall tension is directly proportional to the vessel radius and intraluminal pressure and inversely proportional to wall thickness. Therefore, the larger the aneurysm, the higher the likelihood of spontaneous rupture.

As previously stated, aneurysms measuring more than 4 to 5 cm in diameter generally require surgical intervention, but aneurysms measuring less than 4 to 5 cm should not be considered benign, and monitoring of the condition is indicated.⁴⁴ An aneurysm has the potential to rupture regardless of its size. As the diameter of the aneurysm increases in size, the risk of rupture increases, as shown in [Table 28.2](#).¹ In contradiction to the current thought that increased wall shear stress increases the risk of aortic rupture, it has been shown that aortic rupture may occur more often at sites with low wall shear stress, due to blood flow recirculation resulting in thrombus deposition, aortic wall degeneration, and eventual rupture.⁶³ Due to increased wall stress at the bifurcation of the aorta and the iliac arteries, AAAs most frequently develop in the infrarenal aorta, although approximately 5% to 15% involve the suprarenal aorta. It is estimated that approximately 40% of AAAs also involve the iliac arteries.¹

TABLE 28.2

Range of Potential Rupture Rates for a Given Size of Abdominal Aortic Aneurysm

AAA Diameter (cm)	Rupture Risk (%/yr)
< 4	0
4–5	0.5–5
5–6	3–15
6–7	10–20
7–8	20–40
> 8	30–50

AAA, Abdominal aortic aneurysm.

From Brewster DC, et al. Guidelines for the treatment of abdominal aortic aneurysms: report of a subcommittee of the Joint Council of the American Association for Vascular Surgery and Society for Vascular Surgery. *J Vasc Surg.* 2003;37:1106–1117.

Patient Preparation

Perioperative MI is the most common reason for poor outcomes in noncardiac surgery for patients with vascular disease. Optimization of myocardial oxygen supply and demand and modification of cardiac risk factors are the major goals of preoperative risk reduction. β -Blockers and statins are the important preoperative pharmacologic treatments for medical management.^{17,19}

Prophylactic coronary revascularization does not reduce the incidence of perioperative cardiac events.⁶⁴ Preoperative cardiac testing is recommended only if interpretation of the results will change anesthetic management.^{15,65,66}

Preoperative fluid loading and restoration of intravascular volume are perhaps the most important techniques used to enhance cardiac function during abdominal aortic aneurysmectomies. Reliable venous access must be secured if volume replacement is to be accomplished. Large-bore intravenous lines and central lines can be used to infuse fluids or blood. Massive hemorrhage is an ever-present threat; therefore, the availability of blood and blood products should be ensured. Provisions for rapid transfusion and intraoperative blood salvage should be confirmed.

Routine Monitoring

Standard monitoring methods include electrocardiography (with

display of lead II for detection of dysrhythmias and the precordial V₅ lead for analysis of ischemic ST-segment changes), pulse oximetry, and capnography. An esophageal stethoscope allows for continuous auscultation of heart and breath sounds, as well as temperature monitoring. Placement of an indwelling urinary catheter is necessary for continuous measurement of urinary output and renal function. Neuromuscular function should be routinely monitored.

Invasive Monitoring

Maintaining cardiac function is crucial for a successful surgical outcome. Cardiac function should be closely monitored during abdominal aortic reconstruction. Invasive blood pressure monitoring permits beat-to-beat analysis of the blood pressure, immediate identification of hemodynamic alterations related to aortic clamping, and access for blood sampling. However, information obtained from PACs has been shown to have low sensitivity and low specificity in detecting myocardial ischemia when compared with electrocardiography and TEE. As previously discussed, PACs are not routinely indicated unless a specific purpose warrants their use.²⁶

By detecting changes in ventricular wall motion, TEE provides a sensitive method for assessing ventricular wall motion abnormalities. TEE is a primary method of intraoperative cardiac assessment in patients undergoing surgery on the heart and the aorta.^{65,67} Wall motion abnormalities also occur much sooner than electrocardiographic changes during periods of reduced coronary blood flow.⁵² When TEE is used to guide intraoperative hemodynamic management, patients with left ventricular diastolic dysfunction have a decreased incidence of developing congestive heart failure and atrial fibrillation.^{68,69} The most common abnormalities detected by intraoperative TEE include hypovolemia, low ejection fraction, right ventricular failure, segmental wall motion abnormalities, and pulmonary embolus.⁷⁰ Myocardial ischemia poses the greatest risk of mortality after abdominal aortic reconstruction. Intraoperative monitoring may enable earlier detection and intervention during ischemic cardiac events.

Aortic Cross-Clamping

Abdominal aortic reconstruction is one of the most challenging situations for the anesthetist, due to the frequency and degree of hemodynamic variability during cross-clamping and unclamping of the aorta. This is further complicated by the fact that most patients having an aortic aneurysm repair are elderly and have varying degrees of coexisting disease. Perhaps the most dramatic physiologic change occurs with the application of an aortic cross-clamp. Temporary aortic occlusion produces various hemodynamic and metabolic alterations.

Hemodynamic Alterations

The hemodynamic effects of aortic cross-clamping depend on the application site along the aorta, the patient's preoperative cardiac reserve, and the patient's intravascular volume. The most common site for cross-clamping is infrarenal, because most aneurysms appear below the level of the renal arteries. Less common sites of aneurysm development are the juxtarenal and suprarenal areas.

During aortic cross-clamping, hypertension occurs above the cross-clamp, and hypotension occurs below the cross-clamp. Aortic cross-clamping increases plasma levels of catecholamines, aldosterone, cortisol, prostaglandins, and other stress hormones that are associated with a sympathetic nervous system response. There is an absence of blood flow distal to the cross-clamp in the pelvis and lower extremities.⁶ An increase in afterload causes the left ventricular myocardial wall tension to increase, which in turn increases myocardial oxygen demand. Patients with poor left ventricular function are at risk for developing congestive heart failure during this period. Mean arterial pressure (MAP) and systemic vascular resistance (SVR) also increase. Cardiac output may decrease or remain unchanged. Pulmonary artery occlusion pressure (PAOP) may increase or remain unchanged. [Table 28.3](#) summarizes the physiologic changes associated with aortic cross-clamping.

TABLE 28.3

The Physiologic Changes Associated With Aortic Cross-

Clamping

Hemodynamic Changes	Metabolic Changes	Intraoperative Interventions
Increased arterial blood pressure above the clamp	Decreased total body oxygen consumption	<i>Reduce Afterload</i> Sodium nitroprusside Inhalation anesthetics Milrinone Shunts and aorta to femoral bypass
Decreased arterial blood pressure below the clamp	Decreased total body carbon dioxide production	<i>Reduce Preload</i> Nitroglycerin Atrial to femoral bypass
Increased wall motion abnormalities and left ventricular wall tension	Increased mixed venous oxygen saturation	<i>Renal Protection</i> Fluid administration Mannitol Furosemide Dopamine N-acetylcysteine Renal cold perfusion
Decreased ejection fraction and cardiac output	Decreased total body oxygen extraction	<i>Miscellaneous</i> Hypothermia Decrease minute ventilation Sodium bicarbonate
Decreased renal blood flow	Increased catecholamine release	
Increased pulmonary occlusion pressure	Respiratory alkalosis	
Increased central venous pressure	Metabolic acidosis	
Increased coronary blood flow

Abdominal aortic aneurysms: evaluation and decision making. In Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery*. 8th ed. Vol. 2. Philadelphia: Elsevier; 2014.

Patients with adequate cardiac reserve commonly adjust to sudden increases in afterload without the occurrence of adverse cardiac events. However, patients with ischemic heart disease or ventricular dysfunction are unable to fully compensate, as a result of the hemodynamic alterations. The increased left ventricular wall stress attributed to aortic cross-clamp application may contribute to decreased global ventricular function and myocardial ischemia. Clinically, these patients experience increases in PAOP in response to aortic cross-clamping. Aggressive pharmacologic intervention is required for restoration of cardiac function during this time. An algorithm that depicts the systemic hemodynamic responses to aortic cross-clamping is shown in [Fig. 28.1](#).

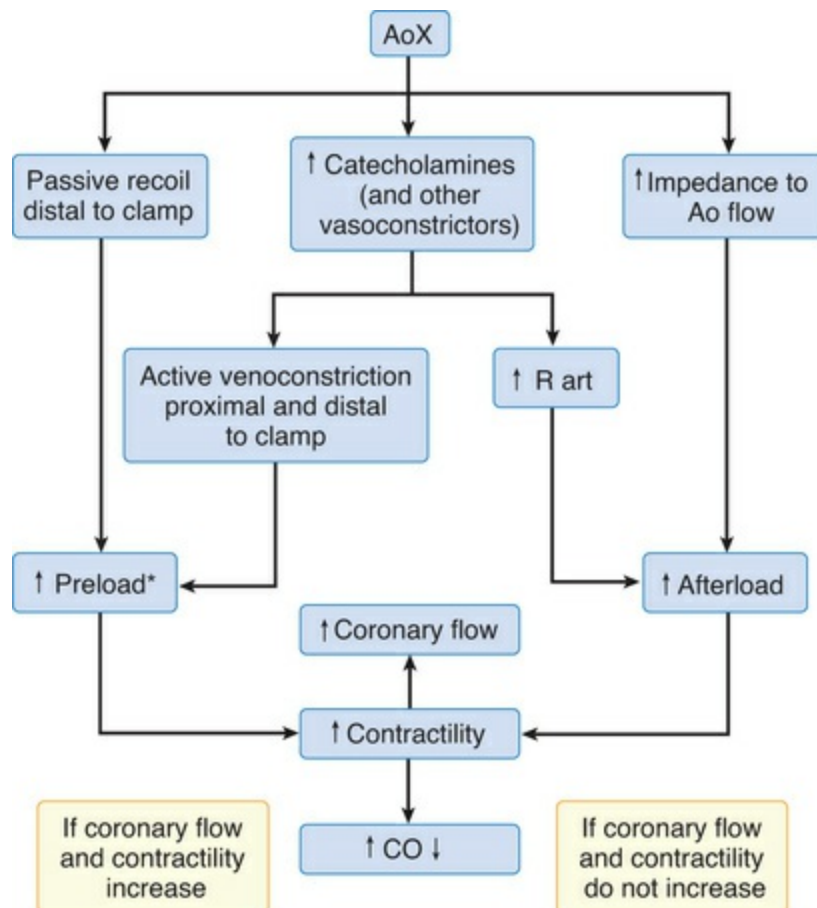

FIGURE 28.1 Systemic hemodynamic response to aortic cross-clamping. Preload (*asterisk*) does not necessarily increase with infrarenal clamping. Depending on splanchnic vascular tone, blood volume can be shifted into the splanchnic circulation, and preload will not increase. Ao, Aortic; AoX, aortic cross-clamping; *R art*, arterial resistance. (Adapted from Gelman S. The pathophysiology of aortic cross-clamping. *Anesthesiology*. 1995;82:1026-1060.)

Metabolic Alterations

After the application of an aortic cross-clamp, the lack of blood flow to distal structures creates an hypoxic and ischemic environment. In response to tissue ischemia, metabolites such as cytokines, prostaglandins, nitric oxide, and arachidonic acid are formed and released into circulation. Furthermore, anaerobic metabolism leads to the accumulation of serum lactate. The release of arachidonic acid derivatives may be a contributing factor leading to cardiac instability and myocardial depression during aortic cross-clamping.³⁸ Thromboxane A₂ synthesis, which is accelerated by the

application of an aortic cross-clamp, may be responsible for the decrease in myocardial contractility and cardiac output that occurs.

Traction on the mesentery is a surgical maneuver used for exposing the aorta. Mesenteric traction syndrome is associated with this procedure. Decreases in blood pressure and SVR, tachycardia, increased cardiac output, and facial flushing are common responses to mesenteric traction. Although the cause of this syndrome is unknown, it has been associated with high concentrations of 6-keto-prostaglandin F_{1α}, a stable metabolite of prostacyclin, at the time of mesenteric traction.⁷¹ The 6-keto-prostaglandin F_{1α} levels and hemodynamic stability return to pre-clamp values as reperfusion occurs.

The neuroendocrine response to major surgical stress is believed to be mediated by cytokines such as IL-1B, IL-6, and tumor necrosis factor, as well as plasma catecholamines and cortisol.⁷² These mediators are thought to be responsible for triggering the inflammatory response that results in increased body temperature, leukocytosis, tachycardia, tachypnea, and fluid sequestration. Patients who have an exaggerated plasma stress mediator release have longer operative and cross-clamp times and require a greater number of blood transfusions.

Effects on Regional Circulation

Acute Kidney Injury.

Tissues that are distal to the aortic clamp are underperfused. Renal insufficiency and acute renal failure are severe complications associated with abdominal aortic reconstruction. Suprarenal and juxtarenal cross-clamping are associated with a higher incidence of altered renal dynamics and can decrease renal blood flow by as much as 80%. However, significant reductions in renal blood flow occur even when aortic cross-clamping is performed below the renal arteries. Infrarenal aortic cross-clamping is associated with a 40% decrease in renal blood flow.³⁸ Thus, renal insufficiency more commonly occurs with suprarenal as compared to infrarenal cross-clamping. AKI may occur in as many as 18% of patients undergoing aortic aneurysm repair. Preoperative evaluation of renal function is the best method of assessing and anticipating which patients may

develop postoperative renal dysfunction. Preexisting renal impairment is common after elective infrarenal EVAR, and preoperative renal function appears to be the main factor associated with AKI. A complete evaluation of renal function is required during the preoperative period, and patients with a low glomerular filtration rate should be managed with more aggressive renal protection interventions.⁷³

Suprarenal cross-clamp times longer than 30 minutes increase the risk of postoperative renal failure. Even though renal blood flow is restored after unclamping, prolonged effects associated with ischemic reperfusion injury (IRI) occur. The injury caused to the renal tubular epithelium decreases the glomerular filtration rate. This effect may lead to acute renal failure, which is fatal in 50% to 90% of patients who have undergone aneurysmectomy.⁷⁴ Clamp position above the renal arteries is predictive of severe AKI in patients treated with open surgical repair (OSR).⁷⁵ AKI is common problem after elective infrarenal EVAR, and preoperative renal function appears to be the main factor associated with AKI. AKI is associated with higher mortality rates and long-term cardiovascular events after surgery.^{75,76} The administration of renal-dose dopamine, mannitol, sodium bicarbonate, and/or loop diuretics has not been scientifically proven to preserve or improve renal function postoperatively. The use of balanced crystalloid solutions and hyperchloremic solutions decreases the incidence of AKI.⁷⁷ Minimizing the use of nephrotoxic medications such as nonsteroidal antiinflammatory drugs and aminoglycoside antibiotics preoperatively is prudent. Intraoperative renal perfusion with cold solution appears to have a renal protective effect and decrease the incidence of AKI.⁷⁸ Atrial natriuretic peptide (ANP) causes vasodilatation of the preglomerular artery, inhibition of the angiotensin axis, and prostaglandin release, which promotes renal vascular dilation. During the AKI reflow period, the natriuretic effect of ANP could be useful in preventing tubular obstruction in patients undergoing major surgery such as cardiovascular surgery.⁷⁷ The most important interventions to protect from AKI are aggressive hemodynamic stabilization and minimization of aortic clamp times, which have proven efficacy.⁷⁹

Spinal Cord Ischemia.

Spinal cord damage causing paraplegia can occur during aortic occlusion. The incidence of paraplegia during thoracic and thoracoabdominal aneurysm repair is estimated to be between 1% and 13%.⁸⁰ Longitudinal blood flow to the spinal cord includes (1) two posterior and two posterolateral arteries supplying blood to the dorsal or sensory portion of the spinal cord (20% of spinal cord blood flow) and (2) one anterior spinal artery supplying blood to the anterior or motor portion of the spinal cord (80% of spinal cord blood flow). Transverse blood flow originating from the aorta is via the greater radicular artery (artery of Adamkiewicz). The exact location of this artery is variable and depends on an individual's specific anatomical characteristics. The artery most often originates between spinal segments T8–T12, but it can originate as low as L2 in a small segment of the population. This explains why the presence of paraplegia with aortic cross-clamping is unpredictable. Interruption of blood flow to the greater radicular artery in the absence of collateral blood flow has been identified as a factor that can cause paraplegia in patients having AAA repair. The incidence of neurologic complications increases as the aortic cross-clamp is positioned higher or more proximal to the heart. Somatosensory-evoked potential (SSEP) monitoring has been advocated as a method of identifying spinal cord ischemia. However, SSEP monitoring reflects dorsal (sensory) spinal cord function, and does not provide information regarding the integrity of the anterior (motor) spinal cord.⁶ Motor-evoked potential (MEP) monitoring is capable of determining anterior cord function. This monitoring modality relies on intact neuromuscular functioning for analysis, which limits its use in abdominal aortic aneurysmectomies, because neuromuscular blocking drugs are routinely used. Alternative methods for reliable evaluation of spinal cord ischemia are still under investigation.⁸¹

Spinal cord protection strategies include distal aortic perfusion, cerebrospinal fluid drainage, and mild hypothermia. Maintenance of normotension (systolic \geq 120 mm Hg) through the second postoperative day decreased the incidence of paraplegia during thoracic aortic reconstruction.^{82,83}

Ischemic colon injury is a well-documented complication

associated with abdominal aortic resections. Ischemia of the colon is most often attributed to manipulation of the inferior mesenteric artery, which supplies the primary blood supply to the left colon. This vessel is often sacrificed during surgery, and blood flow to the descending and sigmoid colon depends on the presence and adequacy of the collateral vessels. Increased intraabdominal pressure has also been implicated in ischemic colon injury. Mucosal ischemia occurs in 10% of patients who undergo AAA repair. In less than 1% of these patients, infarction of the left colon necessitates surgical intervention.⁷⁴

Aortic Cross-Clamp Release

While the aorta is occluded, metabolites that are liberated as a result of anaerobic metabolism (such as serum lactate) accumulate below the aortic cross-clamp and induce vasodilation. As the cross-clamp is released, SVR decreases, and blood is sequestered into previously dilated veins, decreasing venous return. Reactive hyperemia causes transient vasodilation secondary to the presence of tissue hypoxia, release of adenosine, and liberation of an unknown vasodepressor substance that may act as a myocardial depressant and peripheral vasodilator.⁷⁴ This combination of events results in decreased preload and afterload. The hemodynamic instability that may ensue after the release of an aortic cross-clamp is called *declamping shock syndrome*.⁸⁴ Evidence demonstrates that venous endothelin (ET), and specifically (ET)-1, may be partially responsible for the hemodynamic alterations that accompany declamping shock syndrome. Venous ET-1 has a positive inotropic effect on the heart and a vasoconstricting effect on blood vessels. [Table 28.4](#) summarizes the most commonly observed hemodynamic responses to aortic unclamping and therapeutic interventions.

TABLE 28.4

Hemodynamic Responses to Aortic Unclamping and Therapeutic Interventions

Hemodynamic Changes	Metabolic Changes	Intraoperative Interventions
Decreased arterial blood pressure	Increased lactate	Decrease anesthetic depth

Decreased myocardial contractility	Increased total body oxygen consumption	Decrease vasodilators
Decreased systemic vascular resistance	Decreased mixed venous oxygen saturation	Increase fluids
Decreased central venous pressure	Increased prostaglandins	Increase vasoconstrictor drugs
Decreased preload	Increased activated complement	Reapply cross-clamp for severe hypotension
Decreased cardiac output	Increased myocardial depressant factors	Consider administration of mannitol and sodium bicarbonate
Increased pulmonary artery pressure	Decreased temperature	
	Metabolic acidosis	

Adapted from Norris EJ. Anesthesia for vascular surgery. In Miller RD, et al., eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015; Holt PJE, Thompson MM. Abdominal aortic aneurysms: evaluation and decision making. In Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery*. 8th ed. Vol. 2. Philadelphia: Elsevier; 2014.

The magnitude of the response to unclamping the aorta may be manipulated. Although SVR and MAP decrease, intravascular volume may influence the direction and magnitude of the change in cardiac output. Restoration of circulating blood volume is paramount in providing circulatory stability before release of the aortic clamp.^{64,74,85} The site and duration of cross-clamp application, as well as the gradual release of the clamp, influence the magnitude of circulatory instability. For this reason, it is vital that communication between the anesthetist and the surgical team occurs. Partial release of the aortic cross-clamp over time often results in less severe hypotension. Vasopressors and/or inotropic agents are administered to help minimize hypotension. An algorithm depicting the systemic hemodynamic response to aortic unclamping is shown in [Fig. 28.2](#).

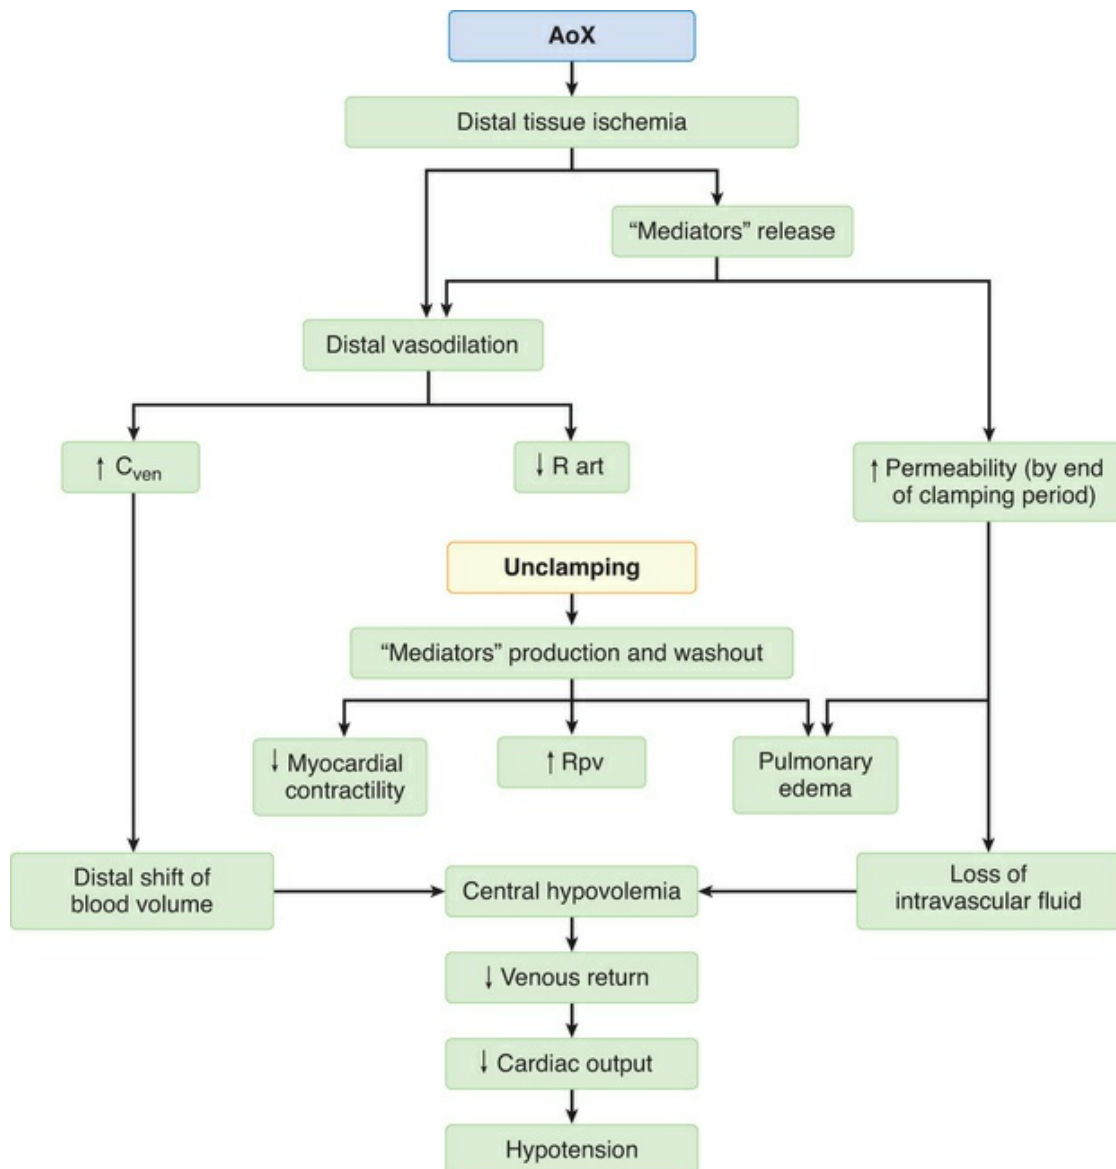

FIGURE 28.2 Systemic hemodynamic response to aortic unclamping. *AoX*, Aortic cross-clamping; C_{ven} , venous capacitance; R_{art} , arterial resistance; R_{pv} , pulmonary vascular resistance. (From Gelman S. The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology*. 1995;82:1026-1060.)

Ischemic reperfusion injury is a complex metabolic process that occurs during application of the cross-clamp (ischemia) and unclamping of the aorta (reperfusion). IRI is characterized by metabolic, thrombotic, and inflammatory components. Cells that comprise tissues remain metabolic despite low blood flow, and they liberate cytotoxic mediators during anaerobic metabolism. During cellular ischemia, reactive oxygen species and increased intracellular calcium further inhibit mitochondrial activity and adenosine triphosphate generation. Specific body tissues vary in

terms of the time it takes for their cells to become necrotic. The degree of cellular necrosis is primarily determined by the duration of ischemia. The *no-reflow phenomenon* occurs when the microvasculature is occluded by platelets, neutrophils, and thrombi, causing inadequate perfusion and further increasing cellular necrosis.¹ Reinstating blood flow increases inflammatory cell influx and cytotoxic substance wash-out into the central circulation.⁸² Myocardial stunning and dysrhythmias can occur due to decreased cellular energy, increased reactive oxygen metabolites, and increased intracellular calcium, necessitating inotropic support.⁸⁶ Other manifestations associated with IRI include tissue edema, acute respiratory distress syndrome, compartment syndrome, bacterial translocation, renal failure, and multisystem organ failure.¹

Surgical Approach

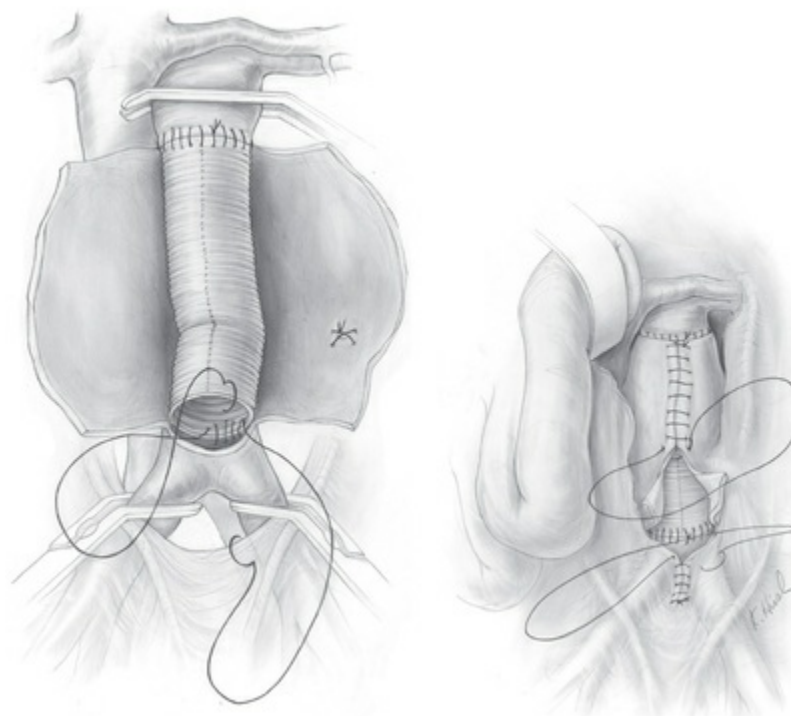

The standard surgical approach for elective abdominal aortic reconstruction is a transperitoneal incision. The advantages of this route include exposure of infrarenal and iliac vessels, ability to inspect intraabdominal organs, and rapid closure.⁸⁷ Unfavorable consequences associated with the transperitoneal approach include increased fluid losses, prolonged ileus, postoperative incisional pain, and pulmonary complications.

The retroperitoneal approach is an alternative to the standard route. Its advantages include excellent exposure (especially for juxtarenal and suprarenal aneurysms and in obese patients), decreased fluid losses, less incisional pain, and fewer postoperative pulmonary and intestinal complications. In addition, the retroperitoneal approach does not elicit mesenteric traction syndrome.⁸⁷ The reported limitations of this approach are the unfamiliarity of surgeons with this technique, poor right distal renal artery exposure, and the inability to inspect the integrity of the abdominal contents. [Table 28.5](#) compares the standard and retroperitoneal surgical approaches. After cross-clamping, the aneurysm is incised, and a synthetic graft is sewn distally and proximally to the aneurysm. The aortic adventitia is then resealed over the synthetic graft ([Fig. 28.3](#)).

TABLE 28.5**Comparison of Transperitoneal and Retroperitoneal Approaches**

Transperitoneal	Retroperitoneal
Advantages	
Familiarity	Exposure for juxtarenal and suprarenal aneurysms
Access to infrarenal aorta and iliac vessels	Decreased fluid loss
Visualization of intraabdominal viscera	Improved postoperative respiratory function
Rapid opening and closure	Better-tolerated incisional pain
Versatility	Avoids formation of intraabdominal adhesions
	Does not elicit mesenteric traction syndrome
Disadvantages	
Increased fluid losses	Inaccessibility to distal right renal artery
Less postoperative ileus	
More frequent postoperative respiratory complications	
Increased postoperative incisional pain	

Modified from Sicard GA, et al. Retroperitoneal versus transperitoneal approach of repair of abdominal aortic aneurysms. *Surg Clin North Am.* 1989;69:795–806; Woo EY, Damraur SM. Abdominal aortic aneurysms: open surgical treatment. In Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery.* 8th ed. Vol. 2. Philadelphia: Elsevier; 2014.

**FIGURE 28.3** Dacron graft used to repair an aneurysm.

Management of Fluid and Blood Loss

Extreme loss of extracellular fluid and blood should be expected during repair of AAAs. The degree of surgical and evaporative losses and third-spacing will determine the magnitude of the patient's fluid volume deficit. Furthermore, the surgical approach, the duration of the surgery, and the experience of the surgeon affect the total blood loss. Most blood loss occurs because of back-bleeding from the lumbar and inferior mesenteric arteries after the vessels have been clamped and the aneurysm is opened.⁸⁸

Anticoagulation with the use of heparin also contributes to blood loss. Excessive bleeding, however, can occur at any point during surgery, and blood replacement is often necessary during open abdominal aortic resections.

Owing to the heightened awareness of transfusion-related morbidity, the use of autologous blood via a cell saver system is a standard procedure. Presently, three options are available for administering autologous transfusions: preoperative deposit, intraoperative phlebotomy and hemodilution, and intraoperative blood salvage. Ideally, patients donate their own blood to minimize the intraoperative use of homologous blood products and the subsequent risk of transfusion-related viruses. With anemia and decreased hemoglobin, oxygen transport is decreased, thus placing the patient with systemic vascular disease at increased risk for MI and stroke. Autotransfusion blood-salvaging systems may be used for replacing intraoperative blood loss. In a study at the Mayo Clinic in which intraoperative autologous red cell salvage was used, 75% less banked blood was transfused. In a prospective study of 100 patients who underwent elective abdominal aortic resections, 80% of patients received only their own blood.⁸⁸ An increased number of banked red blood cell units infused is an independent risk factor for poor outcome after cardiac surgery.⁸⁹ Evidence suggests that there is no difference with respect to 30-day mortality between a hematocrit of 24% and a hematocrit of 30% in patients having cardiac surgery.⁹⁰

Presence of Concurrent Disease

Preoperative Management

The presence of underlying CAD in patients with vascular disease has been well documented. Reports suggest that CAD exists in more than 50% of patients who require abdominal aortic reconstruction, and is the single most significant risk factor influencing long-term survivability.^{8,91,92} MIs are responsible for 40% to 70% of all fatalities that occur after aneurysm reconstruction.^{6,46} Preoperative cardiac evaluation begins with the identification of risk factors that may contribute to adverse cardiac events and subsequent death. When preoperative CAD exists, an increased incidence of postoperative adverse cardiac complications has been demonstrated.⁹³

The end-point of any method of preoperative cardiac evaluation for aneurysmectomy is identification of functional cardiac limitations. Depending on the degree of cardiac dysfunction, preoperative optimization of cardiac function may range from simple pharmacologic manipulation to surgical intervention. The American College of Cardiology and the American Hospital Association guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery are generally followed when preparing patients for these procedures. Optimizing patient preoperative pathophysiologic states, as described in [Box 28.4](#), [Box 28.4](#) minimizes the overall rate of morbidity and mortality.

Optimization of Body Systems Prior to Abdominal Aortic Aneurysm Repair

Cardiac Evaluation

- Quantify risk factors and optimize cardiac function
- Institute appropriate β -blocker
- Institute statin therapy
- Control hypertension

- Institute appropriate anticoagulation therapy

Pulmonary Evaluation

- Advise smoking cessation
- Perform radiologic tests and pulmonary function testing as indicated
- Institute pharmacologic therapy, which may include corticosteroids and bronchodilators

Renal Evaluation

- Assess electrolytes, creatinine, and glomerular filtration rate

Adrenal Evaluation

- Provide steroid supplementation for patients at risk for acute adrenal crises

Deep Vein Thrombosis Prophylaxis

- Administer pharmacologic prophylaxis
- Provide graduated compression stockings
- Provide intermittent pneumatic compression
- Provide enous foot pumps

Musculoskeletal Evaluation

- Assess range of neck motion prior to airway management
- Assess functional limitations for positioning to avoid postoperative paresthesia

Endocrine Evaluation

- Provide short- and long-term glycemic control (mandatory), due to the increased incidence of diabetes

Miscellaneous Considerations

- Order laboratory assessments—complete blood count, coagulation panel, electrolyte panel, blood urea nitrogen, creatinine, albumin, blood sugar, liver function tests, type and crossmatch six units packed red blood cells

From Fleisher LA, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:2215–2245.]

Intraoperative Management

Anesthetic Selection

Several anesthetic techniques are available for abdominal aortic resections. Although each technique has its advantages and disadvantages, no single technique has been proven to be definitively superior. Anesthetic selection should be based on the following objectives: providing optimum analgesia and amnesia, facilitating relaxation, maintaining hemodynamic stability, preserving renal blood flow, and minimizing morbidity and mortality.

General Anesthesia.

Circulatory stability is especially desirable for patients undergoing AAA reconstruction, especially for those with CAD. All inhalation anesthetics may depress the myocardium and cause hemodynamic instability. Therefore high concentrations of inhalation agents should not be used in patients with a moderate to severe decreased ejection fraction. The degree of myocardial depression is dose-dependent, and therefore it is acceptable to administer inhalation agents at lower inhaled concentrations. Beneficial effects attributed to inhalation agents include the ability to alter autonomic responses, reversibility, rapid emergence, potentially earlier extubation, neurologic protection, and cardioprotection.³³

Cardiovascular stability provided by opioids has been well-documented, and this feature is especially attractive for patients with ischemic heart disease and ventricular dysfunction. Provision of intense analgesia for the initial postoperative period after major abdominal vascular surgery (i.e., administration of neuraxial opioid) does not alter the combined incidence of major cardiovascular, respiratory, and renal complications.⁹⁴ Despite the absence of direct myocardial depression, the sympathetic nervous system inhibition that ensues may decrease SVR and heart rate. Therefore, especially in an individual with a moderate to severely decreased ejection fraction, narcotics should be carefully titrated to the patient's hemodynamic response.

Regional Anesthesia.

The use of epidural anesthesia for abdominal aneurysmectomies is commonly considered. The benefits of epidural use include decreased preload and afterload, preserved myocardial oxygenation, reduced stress response, excellent muscle relaxation, decreased incidence of postoperative thromboembolism, increased graft flow to the lower extremities, decreased pulmonary complications, and improved postoperative analgesia. Potential disadvantages include anticoagulation and the possibility of epidural hematoma, as well as severe hypotension during blood loss or un-clamping if local anesthesia is administered intraoperatively.^{34,95}

The use of thoracic epidural analgesia (TEA) in patients having coronary artery bypass surgery decreases the incidence of postoperative supraventricular arrhythmias and respiratory complications. General anesthesia with TEA does not increase the risk of mortality, MI, or neurological complications compared to GA alone.⁹⁶

Combination Techniques.

The use of a combined general anesthesia and epidural anesthesia provides the benefits of epidural anesthesia with the ability to provide amnesia and controlled ventilation. Due to neuraxial blockade, a "light" GA can be administered. Postoperative epidural analgesia improves postoperative respiratory function and blood

flow to distal tissues. Furthermore, postoperative epidural analgesia reduces postoperative pain and pulmonary complications in patients with chronic obstructive pulmonary disease (COPD), as compared to general anesthesia alone after open aneurysm repair.⁹⁷ However, the major risks associated with neuraxial anesthesia are subarachnoid or epidural hemorrhage (resulting in hematoma after heparinization) and hypotension, which may be difficult to treat, especially during an episode of acute blood loss.

In summary, all the aforementioned anesthetic techniques can be used safely and can demonstrate positive outcomes. Even more important than anesthetic selection is the clinical management of each patient. Observation, accurate interpretation, and immediate intervention to minimize dramatic hemodynamic variability during the anesthetic process reduces morbidity and mortality to a much greater extent than selection of a superior anesthetic technique.

Fluid Management

Maintaining intravascular volume may be an extreme challenge during abdominal aortic resections. Controversy exists regarding whether the administration of crystalloids or colloids affects the overall incidence of morbidity and mortality. Crystalloids may be used for replacing basal and third-space losses at an approximate rate of 10 mL/kg per hr. Blood losses initially can be replaced with crystalloids at a ratio of 3:1. The combination of crystalloid and colloid administration is also acceptable. Regardless of the choice of fluid, volume replacement must be dictated by physiologic parameters. Fluid replacement should be sufficient to maintain normal cardiac filling pressures and cardiac output, and a urine output of at least 1 mL/kg per hr. Patients with limited cardiac reserve can develop congestive heart failure if hypervolemia occurs. As mentioned previously, cell-saver blood retrieval is commonly used, and the use of two large-bore intravenous lines in addition to a central venous catheter is warranted. Goal-directed fluid therapy may help to optimize a patient's intravascular volume and hemodynamic status.

Hemodynamic Alterations

Hemodynamic changes are likely to occur throughout the procedure. Adequate preoperative sedation should be given before the placement of invasive monitoring equipment. Fluctuations in heart rate and blood pressure should be anticipated during induction and intubation. Preoperative replacement of fluid deficits prevents exaggerated responses to vasodilating induction agents. For patients with adequate left ventricular function, hemodynamic stability can be preserved with a “slow” and controlled induction using higher doses of opioids and sympathomimetic agents if hypotension develops. The response to mesenteric traction (discussed previously) is also associated with stimulation of the celiac reflex, which results in bradycardia and hypotension.

Postoperative Considerations

Cardiac, respiratory, and renal failure are the most common complications observed postoperatively in patients recovering from abdominal aortic reconstruction. Cardiovascular function must be closely monitored in the ICU for at least 24 hours after surgery. Maintaining adequate blood pressure, intravascular fluid volume, and myocardial oxygenation is paramount during this period. MI frequently contributes to postoperative morbidity and mortality; serial cardiac enzyme analysis may be justified. Pharmacologic agents used in the treatment of hypertension or hypotension must also be available.

Most patients require ventilatory assistance during the postoperative period. Vigilant monitoring of respiratory function is mandatory, especially when epidural catheters are used for postoperative analgesia. To address the significant number of serious postoperative complications, which are noted in [Box 28.5](#), intensive and continuous assessment of the patient condition is vital. Patients are admitted to the ICU for high-acuity monitoring

Box 28.5

Postoperative Considerations for Patients Having Abdominal Aortic Aneurysm Repair

- Continue invasive hemodynamic monitoring
- Treat acute blood pressure extremes, arrhythmias (atrial fibrillation)
- Assess for postoperative myocardial infarction
- Provide ventilatory management with weaning and extubation
- Assess for abdominal compartment syndrome
- Evaluate hemoglobin, hematocrit, coagulation status, and adequacy of volume replacement
- Assess blood urea nitrogen/creatinine and urine output
- Institute deep vein thrombosis prophylaxis per protocol

Juxtarenal and Suprarenal Aortic Aneurysms

Although most AAAs occur below the level of the renal arteries, 2% extend proximally and involve the renal or visceral arteries.⁹⁸

Juxtarenal aneurysms are located at the level of the renal arteries, but they spare the renal artery orifice. More proximal suprarenal aneurysms include at least one of the renal arteries, and may involve visceral vessels. The effects of aortic cross-clamping for juxtarenal or suprarenal aneurysms are similar to those for infrarenal aortic occlusions; however, the magnitude of hemodynamic alterations increases, as the aorta is clamped more proximally.

Renal failure, although possible during infrarenal aortic cross-clamping, occurs more often because of suprarenal aortic occlusion. Maintaining adequate intravascular volume and administering osmotic and loop diuretics may minimize renal ischemia and dysfunction.

Paraplegia is possible when the blood supply to the spinal cord is interrupted by aortic cross-clamping at or above the level of the diaphragm. Increasing the MAP or decreasing cerebrospinal fluid (CSF) pressure by placing a catheter in the subarachnoid space to drain CSF may be used as a means to increase spinal cord perfusion

pressure.⁹⁸ Total body hypothermia and multimodal neurological monitoring, including SSEPs and MEPs, can be used to decrease the incidence of paraplegia. Early detection and intervention for spinal cord ischemia can decrease the incidence of permanent paraplegia after endovascular stent-grafting of the descending thoracic aorta. Neurologic deficits can become evident weeks after surgery. Routine SSEP monitoring, serial neurologic assessment, arterial pressure augmentation, and CSF drainage may benefit patients at risk for paraplegia.⁹⁹ **Box 28.6** summarizes the complications that may result from juxtarenal or suprarenal aortic occlusion.

Potential Complications of Juxtarenal or Suprarenal Aortic Occlusion

- Renal failure
- Hemorrhage
- Distal arterial occlusion
- Infarction
- Pulmonary or cardiac dysfunction
- Impotence
- Paraplegia
- Thrombosis
- Pseudoaneurysm formation
- Aortoenteric fistula

Ruptured Abdominal Aortic Aneurysm

A high mortality rate of 80% to 90% is associated with a ruptured AAA, whereas postoperative mortality is estimated to range from 40% to 50%.¹⁰⁰ The mortality after surgery to repair a ruptured AAA does not vary based on the type of surgical repair (open versus

endovascular).¹⁰¹ The most common symptoms of ruptured AAAs include a triad of severe abdominal discomfort or back pain, altered level of consciousness caused by hypotension, and a pulsatile abdominal mass.¹⁰² Other common symptoms include syncope, groin or flank pain, hematuria, and groin hernia. Risk factors associated with an increase in mortality in patients with a ruptured AAA are noted in [Box 28.7](#).

Risk Factors Associated With an Increased Risk of Mortality in Patients With Abdominal Aortic Aneurysm Rupture

- Increased age
- Women
- Nonwhite race
- Insurance status (higher for those who self-pay or are on Medicaid in the United States)
- Comorbid conditions
- Congestive heart failure
- Renal failure
- Valvular heart disease

From Cronenwett JL, Johnston W. *Rutherford's Vascular Surgery*. 8th ed. Vol. 2. Philadelphia: Elsevier; 2014.

Hypotension and a history of cardiac disease are two factors associated with the poorest prognosis.⁵¹ Patients with these symptoms should be immediately transferred to the operating room for surgical exploration. When hypotension is absent, more time is available for comprehensive preoperative assessment and testing. However, decompensation and cardiovascular collapse can occur rapidly.

Once the patient arrives in the operating suite, performing a brief

preoperative evaluation to establish peripheral and central venous access is a priority. Provisions for fluid, blood, and blood product administration is necessary, as rapid massive hemorrhage is a distinct possibility. The use of blood salvaging techniques and the ability to rapidly infuse blood and fluids are indicated. Insertion of an arterial line is essential, as significant fluctuations in blood pressure should be expected. Vasopressors such as phenylephrine and epinephrine given as a bolus and by infusion should be available. Hemodynamic stability must be the primary objective, and anesthetic induction and maintenance agents must be selected on a case-by-case basis.

Cardiovascular stability is the primary focus until blood loss from the proximal aorta is controlled by surgical intervention. Fluid resuscitation can begin with crystalloids; colloids and blood products can be administered as they become available. Intraoperative blood salvage provisions should be available. Coagulation studies and other laboratory tests including hemoglobin, hematocrit, and ionized calcium values should be obtained. Calcium is a positive inotrope, which is necessary for myocardial contractility. Large amounts of citrate used as a preservative in banked blood bind calcium ions and result in relative hypocalcemia. Decreased myocardial contractility—as evidenced by hypotension, increased left ventricular end-diastolic pressure, and increased central venous pressure—can be caused by hypocalcemia. Increased bleeding can also be caused by intraoperative hypocalcemia. If hypocalcemia occurs, calcium chloride can be administered, as guided by ionized calcium levels. Dilutional thrombocytopenia is the most common reason for coagulopathy to develop after massive intravenous fluid and blood administration. The use of fresh frozen plasma has been shown to decrease the total transfusion requirement and the incidence of coagulopathies.³⁷

The hemodynamic effects of aortic cross-clamping and release are similar to those for elective surgery; however, responses may be extreme, especially if hypotension exists when the clamp is released. Most patients require large amounts of fluid and blood replacement, and therefore postoperative mechanical ventilation is recommended. Patients experiencing hypovolemic shock are

exquisitely sensitive to the cardiodepressant and vasodilatory effects of anesthetic agents. Titration of anesthetic agents and the use of vasopressors and or positive inotropes are warranted. Additionally, ventilation may be difficult due to surgical displacement of the diaphragm cephalad. This will decrease lung expansion and functional residual capacity and increase peak pressures. Because positive pressure ventilation decreases venous return, hypotension can occur. Minimizing peak inspiratory pressures and administering higher concentrations of oxygen will help maximize venous return and maintain oxygen saturation. Manual initiation of a positive pressure breath will improve alveolar recruitment and distention.

Thoracic Aortic Aneurysms

The mortality associated with elective thoracic aneurysm repair is 22%, and if rupture occurs, it increases to 54%.¹⁰³ Patients with aortic dissections have a predicted survival of only 3 months if they do not undergo surgical repair, because the incidence of rupture is high.¹⁰⁴ Aneurysms have been described for hundreds of years, but not until 1951 did the development of the arterial prosthesis lead to successful bypass options.¹⁰⁵ The refinement of endovascular stent grafts, surgical and perfusion techniques, and intraoperative management have contributed to improved surgical outcomes.

Classification

Aneurysms of the thoracic aorta may be classified with respect to type, shape, and location. Typically, aneurysms involving all three layers of the arterial wall—tunica adventitia, tunica media, and tunica intima—are considered to be true aneurysms. In comparison, aneurysms that solely involve the adventitia are termed *false aneurysms*. The shape of the lesion also can serve as a means of characterizing aneurysms. Fusiform aneurysms have a spindle shape and result in dilation of the aorta. Saccular aneurysms are spherical dilations and are generally limited to only one segment of the vessel wall. Aortic dissection is the result of a spontaneous tear within the intima that permits the flow of blood through a false passage along the longitudinal axis of the aorta. If an aortic dissection is extensive, it is difficult for the surgeon to isolate the aneurysm and secure a graft, due to the weakened aortic wall. There are two major classification schemes for aortic dissections, based on the location. These are the DeBakey and Stanford classifications (Table 28.6). Thoracoabdominal aortic aneurysms (TAAA) are classified using the Crawford classification, as shown in Fig. 28.4.

TABLE 28.6

Classification Schemes of Acute Aortic Dissection

Classification Site of Origin and Extent of Aortic Involvement	
DeBakey	
Type I	Originates in the ascending aorta and extends at least to the aortic arch and often to the descending aorta (and beyond)
Type II	Originates in the ascending aorta; confined to this segment
Type III	Originates in the descending aorta, usually just distal to the left subclavian artery, and extends distally
Stanford	
Type A	Dissections that involve the ascending aorta (with or without extension into the descending aorta)
Type B	Dissections that do not involve the ascending aorta

From Braverman AC, et al. Diseases of the aorta. In Bonow RO, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 9th ed. Vol. 2. Philadelphia: Elsevier; 2012:1320.

FIGURE 28.4 Crawford classification of thoracoabdominal aortic aneurysms. Type I, distal to the left subclavian artery to above the renal arteries. Type II, distal to the left subclavian artery to below the renal arteries. Type III, from the sixth intercostal space to the renal arteries. Type IV, from the 13th intercostal space to the iliac bifurcation (entire abdominal aorta). Type V, below the sixth intercostal space to just above the renal arteries. (From Cronenwett JL, Johnston KW. *Rutherford's Vascular Surgery*. 8th ed. Vol. 2. Philadelphia: Elsevier; 2014:2089.)

Etiology

Atherosclerosis is the most common cause of aneurysmal pathology. Atherosclerotic lesions occur most often in the

descending and distal thoracic aorta, and are most often classified as fusiform. Less common causes include aortic dissection and various mechanical, inflammatory, and infectious processes. The [various causes of aortic aneurysms are classified in Box 28.8.](#)

Etiology of Thoracoabdominal Aortic Aneurysms

Degenerative

- Nonspecific (commonly considered arteriosclerotic), dysplastic (80%)

Mechanical (Hemodynamic)

- Dissections (15% to 20%)
- Poststenotic
- Arteriovenous fistula
- Blunt or penetrating trauma

Connective Tissue

- Ehlers-Danlos syndrome
- Marfan syndrome

Inflammatory (Noninfectious)

- Takayasu disease
- Behçet syndrome
- Reiter syndrome
- Kawasaki disease
- Microvascular disorder (e.g., polyarteritis)

- Ankylosing spondylitis
- Rheumatoid aortitis
- Periarterial inflammatory disease (e.g., pancreatitis)

Infectious

- Tuberculosis
- Bacterial
- Fungal
- Spirochetal (syphilis)

Anastomosis

- Postarteriotomy
- Postoperative pseudoaneurysm

Diagnosis

The symptomatology of thoracic aneurysms is often related to the site of the lesion and its compression of adjacent structures. Pain, stridor, and cough may result from compression of thoracic structures. A change in the quality of one's voice, resulting in hoarseness, can occur from impingement by the aneurysm on the left recurrent laryngeal nerve. This can occur because the left recurrent larynx nerve bifurcates from the vagus nerve at the level of the aortic arch. Symptoms related to aortic insufficiency may be observed in aneurysms of the ascending aorta. An upper mediastinal mass may be an incidental finding on conventional chest radiography in an asymptomatic patient. Further investigation with noninvasive methods such as CT scan and MRI can describe the specific anatomic characteristics and location of the aneurysm.

Treatment

As previously described, a high mortality rate is associated with the rupture of thoracic aneurysms. Therefore, early detection and surgical intervention make a significant contribution to long-term survival. Hemodynamic compromise and increased complexity of the aneurysm are associated with increased postoperative mortality. The surgical approach and the method of aneurysm resection vary according to the location of the lesion within the thoracic aorta. Resection of the ascending aorta and graft replacement necessitate the use of complete cardiopulmonary bypass or partial cardiopulmonary bypass (atrial-femoral: left atrial cannulation to a centrifugal pump, and reinfusion to a femoral artery cannula). If extracorporeal circulation is not indicated, heparin (50–100 units/kg) is required prior to aortic cross-clamping. For complete cardiac bypass, total systemic heparinization with 400 units/kg is necessary, and monitoring of activated clotting time is needed.¹⁰⁶ Depending on the proximity of the aneurysm to the aortic arch, the aortic valve may require replacement. Surgical resection of lesions in the transverse arch compromises cerebral perfusion, although various bypass techniques, combined with profound hypothermia and circulatory arrest, have been used.¹⁰⁷ Aneurysms of the descending aorta may be resected after application of an aortic cross-clamp. However, perfusion to distal organs can be compromised during this procedure. Arterial line and pulse oximetry monitoring should occur on the right side because impingement of the left subclavian artery, which provides blood flow to the left hand, is possible. A double lumen tube is placed, and deflation of the left lung is necessary to avoid left lung contusion and improve the surgical operating conditions. The patient is positioned in the left lateral decubitus position, and a left-sided thoracotomy is accomplished. The extent of the thoracotomy is determined by the extent of the aneurysm. A lower thoracic incision is associated with a decreased incidence of postoperative pulmonary dysfunction.¹⁰⁸

Aortic Dissection

Aortic dissection is characterized by a spontaneous tear of the vessel wall intima, permitting the passage of blood along a false lumen. Although the cause of dissections is unclear, lesions that were thought to be related to cystic necrotic processes may actually be caused by variations in wall integrity. Hypertension is the most common factor that contributes to the progression of the lesion. Manipulation of the ascending aorta during cardiac surgery may be associated with aortic dissection.¹⁰⁹ The symptoms of aortic dissection are the result of interruption of blood supply to vital organs. The most serious complication is aneurysm rupture. Diagnosis can be accomplished by the previously mentioned noninvasive techniques.

Treatment of dissecting aortic lesions depends on their location within the thoracic aorta (Fig. 28.5). Type A lesions have the highest incidence of rupture and require immediate surgical intervention. Type B lesions may initially be managed medically, with the administration of arterial dilating and β -adrenergic blocking agents.

FIGURE 28.5 Types of aortic dissection. *Type A* involves the ascending aorta and may extend into the aortic arch. *Type B* starts at the proximal descending aorta and extends distally.

In summary, surgical resection of thoracic aortic lesions enhances long-term survival. Refinement of surgical techniques and improvements in perfusion technology have reduced the overall mortality rate. The surgical method used is dependent on the location of the aortic lesion. Anesthesia for aneurysms of the ascending and transverse aorta requires cardiopulmonary bypass.

Descending Thoracic and Thoracoabdominal Aneurysms

Preoperative Assessment

Patients who undergo major vascular surgery are often elderly and have varying degrees of concurrent disease. Most patients who develop a descending thoracic aortic aneurysm (DTAA) are asymptomatic. Operative surgical decisions are based on the size, extent, and rate of expansion of the aneurysm. For patients with degenerative aortic disease, surgical repair is advised for aneurysms 6 cm or larger. Independent risk factors for DTAA include pain, increased age, COPD, renal insufficiency, aneurysm size, and aneurysm expansion rate.¹¹⁰

The importance of a thorough preoperative evaluation cannot be overemphasized. Special attention should be directed toward cardiac, renal, and neurologic function. Although most fatalities related to thoracic aortic surgery are cardiac in origin, renal and neurologic dysfunction contribute to poor surgical outcomes.¹¹¹ Preoperative renal dysfunction is directly related to postoperative renal failure, and is thought to be one of the strongest contributors to renal deterioration after surgery.^{83,111} Neurologic function should be carefully assessed in the preoperative phase. Paraplegia is one of the most devastating consequences of thoracic aortic surgery, and any alteration in lower-extremity function should be noted. Hoarseness related to compression of the recurrent laryngeal nerve should be assessed and documented. The left recurrent laryngeal nerve is most susceptible due to its close proximity to the aortic arch. Bilateral recurrent laryngeal nerve compression or damage can result in respiratory compromise.

Intraoperative Management

Monitoring

Intraoperative monitoring devices used for thoracoabdominal aneurysm resection are the same as for those used for abdominal aneurysmectomies. Direct intra-arterial blood pressure and

pulmonary artery pressure monitoring is standard during extracorporeal circulation. If the aneurysm involves the thoracic region or the distal aortic arch, right radial arterial line monitoring is preferred, because left subclavian arterial blood flow may be compromised during surgery. The use of TEE is suggested for cardiac monitoring in patients with myocardial dysfunction. An indwelling urinary catheter is used for assessing renal function. To facilitate exposing the descending thoracic aorta, a double-lumen endotracheal tube is inserted to allow for one-lung ventilation. As a result, careful monitoring of oxygenation is mandatory. Routine use of pulse oximetry may be limited if the left subclavian artery is manipulated; therefore, the right hand, the ear, or the nasal passages should be used for monitoring oxygen saturation. Finally, a lumbar intrathecal catheter is inserted to access CSF pressure. SSEPs and/or MEPs are often used to monitor and detect neurologic dysfunction.

Spinal Cord Ischemia

Neurologic dysfunction is a serious complication associated with thoracic aortic aneurysms (TAA) reconstruction. Spinal cord injury is categorized into immediate and delayed paraplegia. The incidence of immediate paraplegia with DTAA ranges from 0% to 3% if surgery is performed with adjunctive procedures or clamp times are less than 10 minutes. However, the incidence of paraplegia and/or paresis for patients having TAA repair is $7.1\% \pm 6.1\%$ (range 0%–32%).¹¹² Impending spinal cord injury depends on the type of aneurysm, surgical technique, cross-clamp time, and use of spinal cord protection interventions.¹¹³ The exact incidence of delayed paraplegia is unknown, but it is believed that as many as 25% of all spinal cord injuries are delayed. The primary preoperative risk factors for delayed paraplegia include type 2 aneurysms, emergency procedures, number of sacrificed segmental segments, and renal failure. The main postoperative factors include hemodynamic instability caused by atrial fibrillation, bleeding, multiorgan failure, and sepsis.¹¹⁰

Several techniques have been successfully applied in an effort to decrease the incidence of neurologic dysfunction after thoracic aortic surgery. These include SSEP and MEP monitoring, CSF

drainage, hypothermia, reattachment of intercostal arteries, and distal aortic perfusion. Systemic hypothermia and selective cooling of the spinal cord may lengthen ischemic time intervals; however, the clinical benefits of these hypothermia methods are unclear.¹¹⁴ The use of various bypass mechanisms and distal shunts may minimize the length of aortic occlusion time.

Spinal cord perfusion pressure can be estimated by calculating the arterial blood pressure minus the CSF pressure. During aortic clamping, CSF pressure increases whereas arterial pressure decreases distal to the clamp. The spinal cord perfusion pressure can therefore be manipulated by altering arterial blood pressure and draining CSF through the intrathecal catheter.^{114,115} The most influential interventions used to protect the spinal cord during thoracic aortic cross-clamping include (1) routine CSF drainage (CSF pressure < 10 mm Hg), (2) endorphin receptor blockade (naloxone infusion), (3) moderate intraoperative hypothermia (< 35°C), (4) avoiding hypotension (MAP > 90 mm Hg), and (5) optimizing cardiac function.¹¹⁶ It is postulated that increased levels of excitatory amino acid neurotransmitters bind to opioid receptors in the spinal cord and induce spinal cord edema. Therefore, administration of naloxone may inhibit edema formation. Avoiding the use of sodium nitroprusside is indicated, as arterial dilation may cause a “steal phenomenon,” further decreasing spinal cord blood flow.

Methods for detecting spinal cord ischemia were discussed previously. The intraoperative use of SSEPs and MEPs can provide early identification of neurologic dysfunction, but these monitoring modalities do not ensure spinal cord integrity. Factors that contribute to the development of neurologic deficits include the level of aortic clamp application, ischemic time, embolization or thrombosis of a critical intercostal artery, failure to revascularize intercostal arteries, and the urgency of surgical intervention.^{114,115} Delayed paraplegia may also be the result of IRI, although the exact mechanism of injury has not been proven.^{110,117,118} Additional complications of thoracoabdominal aortic reconstruction are listed **Box 28.9**.

Complications Following

Thoracoabdominal Aortic Aneurysm Repair

Early Complications

- Respiratory failure (most common complication)
- Hemorrhage
- Myocardial infarction
- Congestive heart failure
- Early paraplegia
- Embolization/thrombosis
- Distal artery occlusion
- Bowel ischemia
- Sexual dysfunction
- Infection
- Renal failure
- Cerebrovascular accident

Late Complications

- Delayed paraplegia
- Graft thrombosis
- Fistula formation
- False aneurysm
- Graft infection

Anesthetic Management

The principles of perioperative management of TAAs and DTAAAs are similar to those previously discussed for abdominal aortic aneurysmectomies. Anesthetic selection should be based on the presence of concomitant disease processes, with the objective of maintaining cardiovascular stability and minimizing morbidity and mortality. Intraoperative monitoring should focus on detection of myocardial, neurologic, and renal ischemia. The hemodynamic consequences of aortic cross-clamping should be attenuated by the use of pharmacologic adjuncts. Restoration of circulating blood volume minimizes the hemodynamic alterations caused by the release of the aortic clamp. For a comprehensive summary of anesthetic management for AAA repair, see the earlier section on [anesthetic management](#) for thoracic aortic aneurysm.

Postoperative Considerations

After surgery is completed, if a double-lumen endotracheal tube was used, it should be replaced with a standard endotracheal tube to provide a secure airway because postoperative ventilatory assistance is usually required. Airway anatomy may become edematous during surgery, causing difficulty with ventilation and reintubation. Under these circumstances, the double-lumen endotracheal tube may be left in place. Replacement of the endotracheal tube can proceed in the postoperative period after the airway edema has dissipated. Recurrent laryngeal nerve dysfunction can contribute to breathing difficulties after extubation.

Close observation of neurologic, circulatory, pulmonary, and renal status is warranted in the postoperative phase. Hemodynamic control is vital to maintaining perfusion to vital organs without creating excessive demands on the heart or the aortic graft. Careful monitoring of respiratory status aided by arterial blood gas analysis is indicated. Epidural analgesia with the use of local anesthetics, narcotics, or both can be administered for pain relief.

Endovascular Aortic Aneurysm Repair

In 1991, the first endovascular stent grafting (EVSG) procedure was performed to repair an infrarenal aortic aneurysm. The development of this technique allows surgeons to repair an AAA in a less invasive manner. Severe cardiac and respiratory pathology make as many as 30% of patients with aortic aneurysms poor surgical candidates.¹¹⁹ EVAR was initially developed to help patients with severe coexisting disease who were not considered viable surgical candidates. Presently, EVAR is the treatment of choice for the majority of patients with an AAA.¹²⁰ In high risk patients having elective AAA repair, the 30-day and 1-year mortality rates are significantly decreased with EVAR as compared to OSR.¹²¹ Schermerhorn suggests that the patient population who may benefit most from EVAR are high-risk patients.¹²¹ Patients who are prone to aortic aneurysm development commonly have **Box 28.10** coexisting diseases, as listed in [Box 28.10](#).

Predisposing Factors for Patients Who Are Prone to Aortic Aneurysm Development

- Hypertension
- Male gender
- Heart disease
- Smoking
- Chronic obstructive pulmonary disease
- Diabetes mellitus
- Renal impairment
- Carotid artery disease

- Peripheral arterial disease
- Family history

Data from Townsend CM, et al. *Sabiston Textbook of Surgery*. 19th ed. Philadelphia: Elsevier; 2012.

Endovascular aortic repair is associated with improved 30-day outcomes (all-cause mortality, readmission, surgical site infection, pneumonia, and sepsis) as compared to OSR.¹²²⁻¹²⁴ In one study, the 30-day mortality rate was 1.7% in the EVAR group versus 4.7% in the OSR group. Secondary interventions most often caused by endoleak were more common in the EVAR group (9.8% versus 5.8%).¹²⁵ However, there was no significant difference between the groups with respect to 2-year survival. A comparison of EVAR versus OSR showed that mortality was 0.6% and mean length of stay (LOS) was 5.8 days for EVAR, whereas in-hospital mortality for OSR was 4.6%, and the average LOS was 11.9 days.¹²⁶ EVAR is associated with decreased procedure duration, a decreased need for transfusion of blood and blood products, a shorter duration of hospitalization, and decreased morbidity compared to OSR.¹²⁷ Perioperative mortality after EVAR has remained similar in recent years despite improvements in techniques, devices, and proficiency. Randomized trials such as the Endovascular Aneurysm Repair 1 (EVAR 1), Dutch Randomized Endovascular Aneurysm Management (DREAM), and Open versus Endovascular Repair (OVER) trials showed lower 30-day mortality rates for EVAR as compared to OSR. However, late mortality rates (24–36 months postoperatively) are similar for EVAR and OSR.¹²⁸

Reinterventions occur more frequently after EVAR than after OSR.¹²⁹ The primary reason for a secondary corrective procedure is due to endoleak. Endoleak is a term that is used to describe the inability of the EVSG to isolate blood flow into the aneurysm sac. Endoleak has been determined to be a significant risk factor for late open conversion. The overall risk of late failure is approximately 3% per year.¹²⁴

EVAR is also being used to treat patients with TAAs. The mortality rate for EVAR for elective DTAA repairs range from 3.5% to 12.5%, as compared with an open approach, where mortality is

approximately 10%.¹³⁰ Reports also show that EVAR has a low incidence (0% to 6%) of spinal cord ischemia and paraplegia.¹³¹ Potential explanations for the decreased incidence of spinal cord trauma as compared to OSR are (1) no thoracic aortic cross-clamping and (2) no prolonged periods of extreme hypotension. Perioperative hypotension (MAP less than 70 mm Hg) was a significant predictor of spinal cord ischemia in patients undergoing EVAR for TAA.¹³²

The overall mortality rate for patients with a ruptured AAA who are alive when diagnosed in emergency departments is 40% to 70%.¹³³ Since the 1950s, mortality from ruptured AAAs has only decreased 3.5% per decade.¹³⁴ Patient survival after emergency repair with EVAR has increased from 2005 to 2011. A significant improvement is noted particularly in those patients who survive the first 24 hours postoperatively.¹³⁵ The 30-day mortality rate after AAA rupture is estimated to be 10% to 45%.¹³⁶ Even though secondary interventions and ESGV surveillance are required, the use of EVAR for both ruptured AAAs and TAAs in patients with suitable anatomy is a lifesaving option.¹³⁷ Medical centers that consider EVAR for ruptured AAA repair must have immediate CT imaging capabilities, trained endovascular teams, adequate endovascular supplies, and a specially arranged surgical suite.

Procedure

The most significant intraoperative advantages with EVAR as compared to OSR are the absence of aortic cross-clamping and the absence of an incision that extends from the xiphoid process to the pubis. EVAR involves deployment of an ESGV within the aortic lumen. The graft restricts blood flow to the portion of the aorta where the aneurysm exists. This procedure is also performed for patients who have TAAs or TAAAs. Cannulation of both femoral arteries is performed. As seen in [Fig. 28.6](#), a guide wire is threaded through the iliac artery to the level of the aneurysm. Next, a sheath is inserted over the guide wire and positioned at the aneurysm location through the use of fluoroscopy. The proximal end of the sheath must extend beyond the aneurysm, and care must be taken to avoid occlusion of the renal arteries. Once the sheath is deployed, radial force or fixation mechanisms such as hooks or barbs on the

stent become embedded into the aortic wall to prevent stent migration (Fig. 28.7).

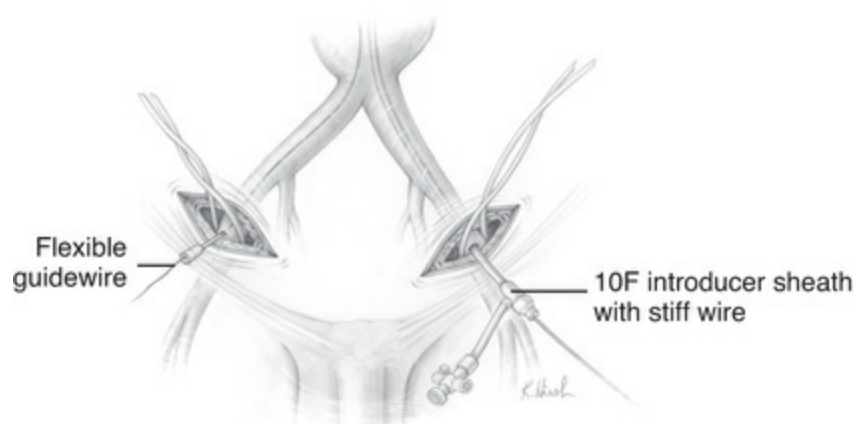

FIGURE 28.6 Femoral cutdown and insertion of introducer sheath. (From Zarins CK, Gewertz BL. *Atlas of Vascular Surgery*. 2nd ed. Philadelphia: Churchill Livingstone; 2009.)

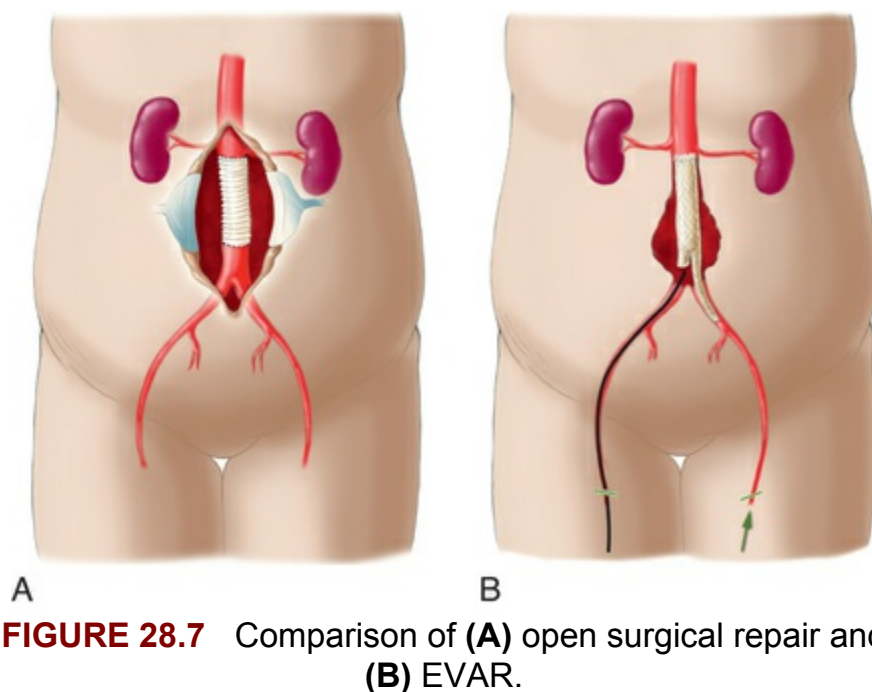

FIGURE 28.7 Comparison of (A) open surgical repair and (B) EVAR.

The surgical procedure may take place in a traditional operating room or an interventional radiology suite. Compared with the conventional surgical method, advantages of the endovascular

approach include the absence of aortic cross-clamping, improved hemodynamic stability, decreased incidence of embolic events, decreased blood loss, a reduced stress response, decreased incidence of renal dysfunction, and decreased postoperative discomfort.^{138,139} Systemic anticoagulation with heparin (50 to 100 units/kg) is administered prior to catheter manipulation.¹⁴⁰ Administration of a broad spectrum antibiotic is recommended prior to surgery. The anesthetic techniques that can be used for EVAR include general anesthesia, neuraxial blockade, or local anesthesia with sedation.¹⁴¹

Local anesthesia with sedation, as compared to general anesthesia, is associated with decreases in nonfatal cardiac morbidity, respiratory complications, renal failure, and overall mortality.^{142,143} There is also decreased pulmonary morbidity as compared with general anesthesia, and local anesthesia with sedation is associated with a shorter LOS as compared with general and neuraxial anesthesia.¹⁴⁴ The goals for intraoperative management for EVAR include maintaining hemodynamic stability, providing analgesia and anxiolysis, and being prepared to rapidly convert to an open procedure. Local or neuraxial anesthesia is associated with fewer ICU admissions, decreased length of hospitalization, and fewer systemic complications, as compared to general anesthesia.¹⁴⁵ In an alternative analysis, there was no difference in 30-day mortality associated with either local anesthesia or general anesthesia provided for EVAR. However, shorter operative times, shorter length of hospitalization, and fewer postoperative complications were associated with a local anesthetic technique.¹⁴⁶

With infrarenal or suprarenal EVAR, creatinine clearance values can decrease by 10% in the first year.¹⁴⁷ However, proximal endovascular graft migration can occur, causing renal artery occlusion and postoperative renal failure.¹⁴⁸ Fenestrated EVSGs that are constructed to allow blood to flow to the renal arteries can be used safely for those patients who have juxtarenal or suprarenal aortic aneurysms.¹⁴⁹ Plasma catecholamine concentrations and mediators of the systemic immune response are decreased in patients who undergo the endovascular approach as compared with patients who undergo conventional repair.^{150,151} Pearson

determined that plasma cortisol release was lower in patients having EVAR than in those having traditional open AAA repair.¹⁵² The EVAR group also developed significantly less sepsis and had a lower incidence of systemic immune response syndrome.

Complications that can arise from the EVAR approach include endograft thrombosis, migration, or rupture; graft infection; iliac artery rupture; and lower extremity ischemia.¹⁵³ Fatal cerebral embolism resulting in sudden respiratory arrest has occurred during EVAR.¹⁵⁴ **Box 28.11** lists potential complications associated with EVAR.

Potential Complications Associated With EVAR

Graft and Deployment Complications

- Failed deployment
- Microembolization
- Migration/occlusion of major branch arteries (i.e., renal, mesenteric)
- Aortic perforation/aneurysm rupture
- Aortic dissection
- Hematoma formation
- Endoleak
- Stenosis/kink/thrombosis
- Graft tear
- Damage to access arteries (femoral → iliac)
- Infection

Radiologic Implications

- Radiation exposure
- Allergy to contrast dye
- Renal insufficiency from contrast dye

Systemic Complications

- Neurologic (CVA, paraplegia)
- Cardiac morbidity/mortality
- Pulmonary insufficiency
- Renal insufficiency
- Postimplantation syndrome

CVA, Cardiovascular accident; *EVAR*, endovascular aneurysm repair.

Endovascular graft design and durability continue to improve. Graft devices are either unibody (come in one piece) or modular (come in multiple pieces). The endograft fabric is either woven polyester (Dacron) or polytetrafluoroethylene. There is no significant difference in biologic response when comparing these two materials.¹⁵⁵ The graft skeleton is constructed of stainless steel, Nitinol, or Elgiloy (Fig. 28.8). Nitinol stents are popular because they exhibit minimal shortening after deployment when exposed to body temperature. There is considerable interest and research involving drug-eluting stents. Researchers have shown in initial clinical trials that restenosis rates are improved with the newer-generation endovascular stents.^{156,157} EVSGs have undergone modifications to meet anatomic challenges and improve patient outcomes. In the past, endovascular repair has been limited to infrarenal AAAs and isolated TAAs. The advent of fenestrated and branched endografts have made endovascular repair of thoracoabdominal and juxtarenal aneurysms possible. Fenestrated EVSGs are safe and effective in short- and mid-term postoperative

follow-up.¹⁵⁸ Continued evolution of endograft technology will maximize the benefit and minimize complications in patients with a range of aneurysmal disease.

FIGURE 28.8 Various types of endovascular grafts.

(Adapted from Cronenwett JL, Johnston KW. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010:1363–1383.)

Endoleak ([Fig. 28.9](#)), which was noted earlier as persistent blood flow and pressure (endotension) between the endovascular graft and the aortic aneurysm, is a serious complication of this procedure. Types of endoleaks are listed in [Table 28.7](#) and shown in [Fig. 28.10](#). Endoleak diagnosed by postoperative CT scan has been reported to occur in 15% to 52% of patients.¹⁵⁹ The majority of endoleaks are type II, and 70% close spontaneously within the first month after implantation.¹⁶⁰ Type II endoleaks are caused by collateral retrograde perfusion and are associated with long-term complications. Type I and type III endoleaks are caused by device-related problems and most often occur soon after EVSG implantation.¹⁶¹ The most frequent interventions used to correct these complications include implantation of a second endograft or open repair.¹⁶² One long-term study has demonstrated that EVAR yields good results as compared to an open repair, but the overall durability of the open surgical procedure is superior.¹⁶³

FIGURE 28.9 **A**, Short aortic neck immediately before endovascular aneurysm repair. **B**, Type IA endoleak (arrow) after initial endograft placement and molding balloon angioplasty. **C**, Resolution of the type IA endoleak after placement of a 5010 “giant” Palmaz stent (arrows show proximal and distal extent). TABLE 28.7

Classification of Types of Endoleak

Classification	Description	Treatment
Type I endoleak	Attachment site leaks	Proximal or distal graft extension Secondary endograft Open repair
Type II endoleak	Branch leaks (i.e., lumbar artery, renal artery, internal iliac artery, inferior mesenteric artery)	Monitoring for enlargement Laparoscopic clip application Embolization
Type III endoleak	Graft defect (fabric tear, modular disconnection)	Secondary endograft Open repair
Type IV endoleak	Graft wall fabric porosity/suture holes	Observation Open repair

FIGURE 28.10 1, Type I endoleak; 2, Type II endoleak; 3, Type III endoleak; 4, Type IV endoleak.

As described in the EVAR 1 study, reinterventions due to endoleak were required in three times as many patients who had EVAR as compared to an open procedure. Of these endoleaks requiring reintervention, 7% were discovered within 1 month of implantation, and another 13% occurred within 4 years postoperatively.¹⁴⁸ A comparison of outcomes evaluating EVAR and open AAA repair in nearly 40,000 patients has been reported. Perioperative mortality (≤ 30 days postoperative) and the risk of mortality 3 years postoperatively were lower after EVAR compared with OSR. At 3 years postoperatively, the risk of mortality was similar to patients having an OSR. Follow-up interventions were more common after EVAR, most often due to the ESVG. Lastly, the risk of rupture was greater with EVAR within an 8-year postoperative period.¹²²

As EVSG-related endoleaks are the most likely causes of late aneurysm rupture, post-EVAR surveillance is an important factor in avoiding the risk of late aneurysm rupture.¹⁶⁴ A large proportion of late ruptures are amenable to endovascular treatment. Postoperative follow-up care for patients who have undergone

EVAR is vital, because long-term outcomes have not been quantitatively established. Physical examination and contrast-enhanced CT scans are recommended at 1, 6, 12, and 18 months postoperatively, and then annually.¹⁶⁵ Additionally, abdominal x-rays should be obtained on a regular basis. Lifelong radiographic evaluation and surveillance is necessary to monitor aneurysm size, graft migration, and endoleak. Intensive follow-up care, the need for reinterventions, and the cost of the endograft make EVAR more expensive than open repair.¹⁶⁶

Cerebrovascular Insufficiency and Carotid Endarterectomy

Carotid endarterectomy (CEA) is the second most common vascular operation performed in the United States every year (the first being coronary revascularization). Cerebrovascular accidents (strokes) are the third leading cause of death in the United States.¹⁶⁷ More strokes are caused by cerebral ischemia than by intracranial hemorrhage. In carotid atherosclerotic disease, subintimal fatty plaques can increase in size over time and incrementally occlude the vascular lumen, which results in decreased cerebral blood flow (CBF). The plaque may rupture and release fibrin, calcium, cholesterol, and inflammatory cells. This phenomenon can lead to abrupt occlusion of the lumen from thrombosis due to platelet activation, or an embolus may form and decrease CBF distal to the carotid artery. In each scenario, an abrupt decrease in CBF leads to transient ischemic attacks (TIAs) or strokes. Note the anatomic details associated with the removal of plaque and the involvement within the layers of the carotid artery in [Fig. 28.11](#).

FIGURE 28.11 **A**, Removal of plaque from carotid artery. **B**, Formulation of plaque on the intima of the carotid artery.

IEL, Internal elastic lamina; *EEL*, external elastic lamina.

(From Zarins CK, Gewertz BL. *Atlas of Vascular Surgery*. 2nd ed. Philadelphia: Churchill Livingstone; 2009.)

More than half of all strokes are preceded by a TIA. The Framingham study reported that the risk of a stroke was 30% 2 years after a TIA had occurred and approximately 55% 12 years after a TIA had occurred.¹⁶⁸ It is this increased risk of stroke associated with TIA that provides the rationale for the use of CEA, the surgical procedure in which the internal carotid artery is incised and the plaque within the carotid arterial lumen is removed to improve CBF.

Indications

Since 1954, specific indications for and expected outcomes of CEA have been the subject of heated debate. Ischemic stroke accounts for approximately 80% of first-time strokes and is primarily caused by atheromatous plaques. The initial indication for CEA was symptomatic stenosis but not complete occlusive carotid disease. This presentation occurs in most patients who undergo carotid surgery. Some centers have extended the indications to include evolved (“nondense”), nonhemorrhagic strokes and asymptomatic severe stenosis or lesser stenosis associated with contralateral occlusive disease. The North American Symptomatic CEA Trial concluded that CEA for patients with recent hemispheric TIAs and high-grade stenosis (70% to 99%) had a risk reduction of 65% for the development of an ipsilateral stroke 2 years after surgery, compared with patients whose conditions were medically managed.¹⁶⁹ The Executive Committee for the Asymptomatic Carotid Atherosclerosis Study demonstrated that asymptomatic patients with at least 60% carotid artery stenosis who underwent CEA had a 53% lower 5-year risk of ipsilateral stroke than patients who were treated medically.¹⁷⁰ Other widely reported large-scale studies including the Asymptomatic Carotid Atherosclerosis Study (ACAS) and the European Asymptomatic Carotid Surgery Trial (EACST) demonstrated a benefit of CEA with medical therapy (aspirin and atherosclerotic risk factor reduction) over medical therapy alone for patients with carotid stenosis in the 60% to 99%

range.^{171,172} These trials showed a similar absolute and relative reduction in risk for stroke of approximately 5% and 50%, respectively, at 5 years for CEA over medical therapy. Symptomatic patients are at a higher risk than asymptomatic patients for perioperative adverse events. However, the benefit of CEA in patients with recent ipsilateral carotid territory symptoms and moderate to severe carotid stenosis is much greater than the benefit of CEA in asymptomatic patients.¹⁷³

Morbidity and Mortality

The surgical outcomes reported for CEA vary due to differences in patient populations and varying degrees of surgical expertise. Other variables that cannot be stratified in studies but may affect patient outcomes include the state of collateral flow through the circle of Willis, the presence of concurrent atherosclerotic disease in the cerebral vasculature, the size and morphology of the offending plaque, the specific presenting symptoms, and the presence of concurrent cardiovascular disease.¹⁷⁴ Carotid artery stenosis is the primary cause of approximately 20% of all strokes.¹⁷⁵ The recommended acceptable perioperative stroke rates are less than 3% in asymptomatic patients, less than 5% in symptomatic patients, and 10% or less in patients with recurrent disease or existing strokes.¹⁷⁶ Morbidity rates related to CEA have been reported to be at or below these recommended limits.^{176,177} The perioperative MI rate of 2% to 5% illustrates the global nature of atherosclerotic disease and represents the greatest contribution to overall morbidity. The perioperative mortality rate for CEA is approximately 0.5% to 2.5%,^{178,179} and the long-term postoperative stroke incidence ranges from 1% to 3% per year.¹⁸⁰ In a multicenter cohort of black and white adults in the United States, the incidence and mortality rates associated with a stroke decreased from 1987 to 2011. The decreases varied across age groups, but were similar across sex and race.¹⁸¹

Patient Selection

The risks associated with CEA and stroke must be measured against the risks associated with undergoing medical management.

The patients who benefit most from CEA are those with stenosis of greater than 70%; it is less beneficial in symptomatic patients with 50% to 69% stenosis.¹⁷⁵ Surgical intervention is most beneficial in men who are older than 75 and are within 2 weeks of their last ischemic event.¹⁸² As mentioned previously, the Framingham study identified the incidence of stroke after TIAs and demonstrated an increased risk of stroke in patients with untreated disease. Preoperative neurologic dysfunction was found to be the most significant factor for predicting postoperative stroke incidence (4%). Several conditions that can increase the risk of perioperative complications include severe preoperative hypertension, CEA performed in preparation for coronary artery bypass, angina, internal carotid artery stenosis near the carotid siphon, age older than 75 years, and diabetes mellitus.^{183,184} **Box 28.12** identifies various **Box 28.12** factors that contribute to morbidity during CEA.

Factors Contributing to Morbidity During Carotid Endarterectomy

- History of stroke
- Operative timing
- Hyperglycemia
- Multiple comorbidities
- Age
- Contralateral carotid artery disease
- Progressing stroke
- Ulcerative lesion
- Intraoperative hemodynamic instability
- Surgery with shunt
- Surgery without shunt

Diagnosis

The neurologic symptoms associated with cerebral vascular dysfunctions such as TIAs and strokes are often related to decreased CBF. Whereas there are multiple causes for symptoms such as lightheadedness, altered levels of consciousness, aphasia, and acute motor deficits, these deficits warrant testing to determine if carotid stenosis is present. Asymptomatic carotid bruits may be a sign of carotid artery disease. However, not all carotid bruits indicate the presence of significant carotid artery disease. *Amaurosis fugax* manifests as monocular blindness and occurs in 25% of patients with high-grade carotid artery stenosis. This syndrome is believed to be caused by microthrombi that migrate into the internal carotid artery and decrease the blood supply of the optic nerve via the ophthalmic artery. Standard diagnostic imaging techniques used to assess the extent of carotid disease include duplex ultrasonography, digital subtraction angiography, CT angiography, and magnetic resonance angiography.¹⁸⁵

Preoperative Assessment

The presence of concurrent CAD and carotid stenosis is well documented. Although stroke is a devastating consequence of CEA, MI contributes more often to poor surgical outcomes than stroke. Although coronary angiography may not be justified in all patients undergoing CEA, a systematic approach for identifying CAD and its subsequent risks should be performed before elective surgery.

Patients with no significant medical history, normal physical examination, and normal electrocardiography should proceed directly to surgery; these patients have low surgical risks. When abnormal cardiac information is obtained, further evaluation should be performed. The presence of significant comorbidities will determine the extent to which further preoperative testing is appropriate. [Box 28.13](#) lists preoperative risk factors in patients having CEA. Preoperative pharmacologic optimization for patients with vascular and cardiac disease is discussed earlier in this chapter. Vascular surgery is associated with an increased risk of major adverse cardiac events.¹⁸⁶ For a complete discussion of cardiac optimization, see Preoperative Evaluation and preparation

of the patient. (Chapter 20) The ACCF/AHA recommendations for **Box 28.13** Preoperative cardiac assessment are in Table 28.8.

Preoperative Risk Factors for Patients Scheduled for CEA

- Neurologic (cerebrovascular accident)
- Coronary artery disease
- Hypertension
- Diabetes
- Renal disease
- Thromboembolism

CEA, Carotid endarterectomy.

TABLE 28.8

ACCF/AHA Recommendation for Perioperative Cardiac Assessment

	Scenario	Recommendation
Class I	Patients in need of emergency noncardiac surgery	Proceed directly to the operating room.
	Patients with active cardiac conditions, unstable or severe angina (not stable angina), decompensated heart failure, significant dysrhythmia (high-grade AV block, Mobitz type II block, third-degree AV block, symptomatic ventricular arrhythmias, symptomatic bradycardia, and supraventricular arrhythmias including atrial fibrillation with HR >100 beats/min), and severe valvular disease	Provide perioperative surveillance, risk stratification, and risk factor management.
	Patients undergoing low-risk procedures	Proceed with planned surgery.
	Patients with poor (<4 METs) or unknown functional capacity and no clinical risk factors	
Class IIa	Patients with functional capacity ≥ 4 METs without symptoms	Proceed with planned surgery.
	Patients with poor (<4 METs) or unknown functional capacity and three or more clinical risk factors* who are undergoing intermediate-risk surgery	Proceed with planned surgery with heart rate control.
	Patients with poor (<4 METs) or unknown functional capacity and one or two clinical risk factors* who are undergoing vascular surgery or intermediate-risk surgery	

	Patients with poor (<4 METs) or unknown functional capacity and three or more clinical risk factors* who are undergoing vascular surgery	Consider further testing if it will change management.
Class IIb	Patients with poor (<4 METs) or unknown functional capacity and three or more clinical risk factors* who are scheduled for intermediate-risk surgery	Consider noninvasive testing if it will change patient management.
	Patients with poor (<4 METs) or unknown functional capacity and one or two clinical risk factors* who are scheduled for vascular surgery or intermediate-risk surgery	

*Clinical risk factors include ischemic heart disease, compensated or prior heart failure, diabetes mellitus, renal insufficiency, and cerebrovascular disease.

Class I recommendations suggest that procedures/treatments should be performed; Class IIa recommendations suggest that it is reasonable to perform the procedure/treatment; Class IIb recommendations imply that the procedure/treatment should be considered; and in Class III the intervention should not be performed because it may not be helpful and may potentially be harmful to the patient.

Intraoperative Considerations

Cerebral Physiology

CBF can remain relatively constant at different cerebral perfusion pressures as a result of cerebrovascular autoregulation. Cerebral perfusion pressure can be expressed as the difference between MAP and intracranial pressure (ICP). During CEA, ICP is usually not elevated; therefore, MAP plays the predominant role in determining cerebral perfusion pressure. When MAP is maintained between 60 and 160 mm Hg, CBF remains constant. However, the adverse effects of chronic systemic hypertension shift the patient's cerebral autoregulatory curve to the right, and therefore a higher than normal MAP may be required to ensure adequate cerebral perfusion. CBF is also influenced by arterial carbon dioxide and oxygen concentrations, as well as anesthetic agents. Profound hypocarbia causes cerebral vascular constriction by decreasing CBF. *Cerebral steal* can occur with hypercarbia as it leads to cerebral

vascular dilation in cerebral vessels. However, in those areas of the brain that are at risk of developing ischemia caused by atherosclerotic plaques, the cerebral vessels are maximally dilated. Therefore, causing profound cerebral vascular dilation decreases CBF and increases the potential for regional ischemia. Inhalation agents increase CBF due to cerebral vascular dilation in a dose-dependent fashion. Anesthetic agents, with the exception of ketamine, decrease the cerebral metabolic rate of oxygen consumption (CMRO₂).

Normal CBF is approximately 50 mL/100 g per min. Neuronal function is generally maintained at levels greater than 25 mL/100 g per min. Blood flow that is less than this critical value jeopardizes cellular function. Decreased perfusion and ischemia can be reflected in changes in consciousness. Cellular death occurs at levels less than 6 mL/100 g per min, as evidenced by the flattening seen on an electroencephalogram.

Carotid occlusive disease jeopardizes the cerebral perfusion pressure in the ipsilateral artery. Ischemia leads to the disruption of autoregulation and compensatory vasodilation, and thus blood flow becomes pressure-dependent. During CEA, a primary goal is to ensure adequate CBF by maintaining and, if necessary, augmenting MAP.

Cerebral Monitoring

In addition to standard monitoring, direct intra-arterial pressure must be continuously assessed via arterial line placement. During CEA, hemodynamic variability frequently occurs. Owing to the high incidence of CAD and neurovascular disease in this patients having a CEA, prompt and tight control of blood pressure is imperative.

During repair, the carotid artery cross-clamp is applied distally and proximally to the carotid incision. Various monitoring techniques have been proposed for assessing the adequacy of CBF during this maneuver. A summary of select cerebral monitoring techniques is presented in [Box 28.14](#). Each of these monitoring modalities has limitations; the most sensitive and specific measure of adequate CBF is responsiveness in an awake patient.

Cerebral Monitoring Modalities During General Anesthesia for CEA

- *Electroencephalogram (EEG)*: assesses cortical electrical function
- *Somatosensory-evoked potential (SSEP)*: assesses sensory-evoked potentials
- *Carotid stump pressure (CSP)*: assesses perfusion pressure in the operative carotid artery
- *Transcranial Doppler (TCD)*: assesses blood flow velocity in the middle cerebral artery
- *Cerebral oximetry*: assesses cerebral regional oxygen saturation (near-infrared spectroscopy)

CEA, Carotid endarterectomy.

Electroencephalogram (EEG) monitoring constitutes the gold standard in identifying neurologic deficits related to carotid artery cross-clamping.^{175,187} EEG has demonstrated reliability in monitoring cortical electrical function.¹⁸⁸ Loss of β -wave activity, loss of amplitude, and emergence of slow-wave activity are all indicative of neurologic dysfunction. Limitations surrounding EEG monitoring include (1) the effect of blood pressure, temperature, and anesthetic agents on monitoring, and (2) the fact that this modality only detects EEG changes on the superficial layers of the brain and not in deep cortical structures such as the brainstem.

Carotid stump pressure has been used as a means of assessing collateral flow.¹⁸⁹ After the carotid cross-clamp is placed, blood flow from the nonoperative carotid artery and the basilar artery provides blood flow to the circle of Willis. A catheter is placed into the distal portion (above the cross-clamp) of the operative internal carotid artery, and the pressure can be monitored. Carotid stump pressure is a gross measurement of the pressure within the circle of Willis. A carotid stump pressure of less than 40 to 50 mm Hg reflects neurologic hypoperfusion and is a criterion for shunt placement.

However, there is no correlation between stump pressures and EEG changes.¹⁷⁷ In a study by Harada,¹⁹⁰ a carotid stump pressure of less than 50 mm Hg had a positive predictive value for only 36% of patients who exhibited ischemic changes on EEG during carotid artery cross-clamping. A combination of stump pressure and either Transcranial Doppler (TCD) or EEG appears to improve the detection of cerebral ischemia during carotid artery cross-clamping.¹⁹¹

Somatosensory-Evoked Potential (SSEP) monitoring can be used to identify inadequate CBF during cross-clamping; however, false-positive results can occur. In addition, SSEPs reflect the sensory integrity of the spinal cord and the brain; therefore, a motor deficit can occur despite a normal SSEP waveform. Additionally, there are no values for decreased amplitude and increased latency that definitively correlate with cerebral ischemia. Monitoring both SSEP and EEG is more sensitive for predicting perioperative deficits as compared to using either monitoring modality in isolation. Patients who experience perioperative strokes are 17 times more likely to have a change in either EEG or SSEP than other patients.¹⁹²

Transcranial Doppler (TCD) velocity monitoring has been used to detect adverse cerebral events during CEA. TCD is noninvasive and measures cerebrovascular dynamics through the CBF velocity. The use of TCD during CEA to determine if carotid shunt placement is necessary is a reliable method to decrease adverse neurologic outcomes.¹⁹³ TCD can also be used during the postoperative period to detect ischemia and the presence of cerebral hyperperfusion syndrome (CHS).

Near-infrared spectroscopy (NIRS) measures cerebral oxygenation. A greater than 20% reduction in regional cerebral oxygenation coincides with regional and global cerebral ischemia during CEA.¹⁹⁴ Despite the established advantages of using NIRS monitoring in cardiac surgery, its routine use is less established during noncardiac procedures. Both NIRS and TCD monitoring are independently accurate in predicting the need for selective shunting by detecting cerebral ischemia during CEA and general anesthesia.¹⁹⁵ As compared with stump pressure monitoring, cerebral oximetry more accurately predicts cerebral oxygenation.¹⁹⁶ [Box 28.14](#) outlines the cerebral monitoring modalities that can be used during general

anesthesia for CEA.

Cerebral Protection

The major objective during carotid artery revascularization is to maintain cerebral CBF and oxygenation. Prevention of cerebral ischemia can be accomplished in one of two ways: by increasing collateral flow (placement of intraluminal shunt) or by decreasing cerebral metabolic requirements (anesthetic medications). Multiple interventions are available for cerebral protection, including avoiding hyperglycemia, hemodilution, maintenance of normocarbia, and tight control of arterial blood pressure. Anesthetics, except for etomidate, have cerebral protective properties and may be used to minimize the degree of cerebral ischemia. Shunt placement is commonly used to allow blood to flow proximally and distally to the carotid cross-clamp during intimal plaque dissection. Potential complications associated with carotid shunt placement are depicted in [Fig. 28.12](#).

FIGURE 28.12 Pitfalls of carotid shunt placement. **A**, Potential traumatic injury to the distal internal carotid artery intima. **B**, Potential for embolization of atherosclerotic debris or air. (From Cronenwett JL, Johnston W. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010:1452.)

Cerebral ischemic events are most often the result of embolic complications, and frequently occur during the postoperative period. The need for shunt placement is based on surgeon preference and information obtained using intraoperative monitoring techniques to determine CBF. Furthermore, propofol decreases $CMRO_2$ to 40% below normal values.¹¹⁴

Dexmedetomidine also decreases cerebral oxygen consumption and CBF in animal models.¹⁹⁷ During transient focal ischemia, propofol decreases the $CMRO_2$, which results in cerebral protection. The disadvantages of administering propofol during CEA surgery include myocardial depression and hypotension. The inhalation agents also decrease $CMRO_2$ in a dose-dependent fashion. Nitrous oxide should be avoided due to the potential for pneumocephalus from microbubble expansion after carotid artery unclamping.^{175,182}

Blood Pressure Control

The presence of hypertension in patients with cerebrovascular disease is well known. Therefore, one of the most challenging aspects of care associated with anesthesia for CEA is blood pressure control. Patients with cerebral insufficiency are vulnerable to perioperative blood pressure instability. Hypotension occurs in 10% to 50% of patients who undergo CEA, and is believed to be the result of carotid sinus baroreceptor stimulation. Conversely, 10% to 66% of patients experience hypertension, which is attributed to surgical manipulation of the carotid sinus.¹⁹⁸ Preoperative blood pressure control, volume status, and depth of anesthesia can also contribute to intraoperative hemodynamic instability. During carotid artery cross-clamping, maintaining the MAP at 20% or greater of the patient's preoperative mean pressure decreases postoperative cognitive dysfunction.¹⁹⁹

Blood pressure control must begin in the preoperative phase. All patients should continue taking their antihypertensive medications

until the time of surgery. Patients with systolic blood pressure greater than 180 mm Hg may be at increased risk of stroke and death.¹⁸² Additional pharmacologic agents may be required in the preoperative period, especially during the insertion of intravenous and intra-arterial catheters, to reduce increases in heart rate and blood pressure. The induction of anesthesia, the initial incision, dissection, manipulation of the carotid sinus, and emergence from anesthesia are all events that precipitate blood pressure fluctuations. The use of pharmacologic adjuncts, such as short-acting β -adrenergic blockers, may stabilize blood pressure during induction and emergence. Continuous intravenous use of nitroglycerin or sodium nitroprusside should be available to treat hypertension. Patients with chronic hypertension are predisposed to dramatic decreases in blood pressure after the induction of general anesthesia. This condition must be treated promptly, and can be successfully managed by providing intravenous fluids or administering appropriate vasopressors. Hypotension and bradycardia, which result from carotid sinus baroreceptor manipulation, may be inhibited by stopping surgical stimulation, infiltrating the region with local anesthesia, and, if necessary, administering an anticholinergic.

Anesthetic Management

The anesthetic objectives for vascular surgery are similar to those for any type of elective procedure: to provide analgesia and amnesia, to facilitate surgical intervention, and to minimize operative morbidity and mortality. Goals that are specific to CEA include maintaining cerebral and myocardial perfusion and oxygenation, minimizing the stress response, and facilitating a smooth and rapid emergence. However, it may be difficult to maintain the integrity of one system without adversely affecting the other. For example, raising the arterial blood pressure to augment cerebral perfusion can increase myocardial oxygen demand, which may lead to ischemia. In addition, significantly decreasing blood pressure can lead to cerebral hypoperfusion. Therefore, the anesthetic goal is to optimize perfusion to the brain, minimize myocardial workload, ensure cardiovascular stability, and allow for rapid emergence. Anticoagulation is achieved via administration of

heparin (50–100 units/kg) prior to carotid artery cross-clamping. The decision to administer protamine upon completion of the surgical procedure is based on the surgeon's impression. Protamine administration is associated with a reduction in bleeding complications without increasing major thrombotic outcomes, including stroke, MI, or death after CEA.²⁰⁰ Protamine administration is associated with hypotension. Anaphylaxis is a rare but life-threatening side effect. An understanding of the physiology of the cerebrovascular system is important for optimal anesthetic management. [Fig. 28.13](#) illustrates the anatomy of structures in this region. This knowledge enables the selection of appropriate monitoring and anesthetic techniques that will protect and improve cerebral and myocardial perfusion.

FIGURE 28.13 Carotid endarterectomy. **A**, Incision site. **B** and **C**, Anatomic structures presented at the carotid surgical site. *a*, Artery; *m*, muscle; *n*, nerve; SCM, sternocleidomastoid; *v*, vein. Anesthetic Selection

The longstanding question has been whether there is an advantage of regional versus general anesthesia for CEA. The General Anesthetic versus Local Anesthetic for Carotid Surgery Trial (GALA), as well as a Cochrane meta-analysis, indicate no significant difference between the two anesthetic techniques.^{201,202} The anesthetic selection is based on the surgeon's preference, the

patient's condition, and the preoperative evaluation. Advantages of a regional technique are that an awake patient can respond to commands and allow for continuous assessment of neurologic function. If the patient's level of consciousness decreases as a result of cerebral hypoperfusion, surgeons can then place a shunt. Other potential benefits include improved patient satisfaction, decreased cost, and minimization of potential postoperative cognitive effects associated with general anesthesia.²⁰³⁻²⁰⁵ Disadvantages include patient agitation and inability to remain still, minimal airway control, seizure or stroke during carotid artery clamping, and limited ability to give anesthetic medications. Advantages of general anesthesia include the ability to perform more extensive and difficult surgical procedures, better airway control, the ability to administer cerebral protectants, and improved blood pressure control.^{175,182}

Regional Anesthesia.

A regional anesthetic (RA) technique during CEA requires a deep and superficial cervical plexus block, which is accomplished by anesthetizing cervical nerves II to IV.¹⁷⁵ Superficial cervical blocks do not anesthetize the region at the angle of the mandible, which is innervated by the trigeminal nerve. Local infiltration may be required. As noted previously, the greatest advantage of RA is the ability to directly assess neurologic function in an awake individual. Assessing level of consciousness is the most effective method of assessing the adequacy of CBF and detecting cerebral ischemia. In fact, assessment of consciousness in the awake patient may be more sensitive than conventional EEG in detecting cerebral ischemia. Corson²⁰⁶ reviewed data from 399 patients who underwent CEA in which GA and RA were used. The authors concluded that perioperative strokes occurred less often when RA was administered, especially in high-risk patients. McCarthy²⁰⁷ compared middle cerebral artery blood flow velocity using transcranial Doppler monitoring in patients undergoing CEA with either local or GA. It was determined that preservation of cerebral circulation was better maintained in patients who received local anesthesia.²⁰⁸⁻²¹¹ In addition, 67% of the GA group and 15% of the local anesthesia group received shunts.²¹² RA resulted in fewer

hemodynamic fluctuations and fewer intraoperative vasoactive medication requirements as compared with GA during perioperative management of CEA.²¹³ However, despite these seemingly physiologic advantages, no differences were observed in outcomes between the local and GA groups. The use of RA has been associated with shorter operative times, fewer cardiopulmonary complications, and a shorter duration of postoperative hospitalization.

One limiting factor for the use of RA is patient acceptance. The individual is mildly sedated; therefore, preoperative education is essential, and patient cooperation during surgery is vital. Anxiety, fear, and apprehension can initiate sympathetic stimulation, and as a result, extreme hemodynamic responses can occur. Deep sedation, which can be required in an apprehensive patient, may confound the neurologic assessment, negating the advantages of a regional technique. Additionally, hypercarbia can result from hypoventilation, and dysphoria is more likely to occur. Furthermore, converting to a GA technique once surgery has begun can be problematic. Symptoms indicating that adequate cerebral perfusion has been compromised include dizziness, contralateral weakness, decreased mentation, and loss of consciousness. In the event that this scenario occurs, immediate shunt placement is warranted. If symptoms associated with cerebral hypoperfusion do not resolve rapidly with shunt placement, emergent airway management is necessary.

General Anesthesia.

Although the use of RA has numerous advantages, GA is also used during CEA. Perhaps the greatest benefit of this technique is that it counters the most cited disadvantage of regional anesthesia: lack of patient tolerance during the procedure. GA promotes a motionless field during surgery. In addition, inhalation agents may provide hemodynamic stability and may have beneficial effects on cerebral circulation.²¹⁴ By decreasing cerebral and cardiac metabolism, the inhalation agents provide a degree of protection against ischemia, an effect that is called *anesthetic preconditioning*.²¹⁵⁻²¹⁷

There is no scientific evidence to suggest that patient outcome is improved when inhaled agents are used, compared to narcotic-

based techniques. In studies of inhalation agents, the critical regional CBF (the blood flow measurement for which EEG signs of ischemia occur) during isoflurane anesthesia was less than when other volatile anesthetics were used.^{214,218} The effects of sufentanil on cerebral hemodynamics were similar to those of isoflurane.²¹⁹ Remifentanil can be used, and its rapid metabolism improves neurologic recovery. The inhalation agents may alter the monitoring methods used for detecting cerebral ischemia, such as EEG and SSEP monitoring. In these cases, GA may require modification, and direct communication between the anesthesia and surgical teams is vital. When carotid artery cross-clamping without shunting occurs, MAP values must be 20% or greater of the patient's preoperative MAP to help ensure adequate cerebral perfusion through the contralateral carotid artery and decrease the possibility of postoperative cognitive dysfunction.¹⁹⁹ The use of nitrous oxide during CEA can potentially increase the incidence of a clinically significant pneumocephalus. During shunt placement and carotid artery cross-clamp release, microbubbles can be entrained into the carotid artery blood flow. Nitrous oxide is also known to cause hyperhomocysteinemia. Increased homocysteine can increase the postoperative cardiac risk and long-term mortality and increase the potential for carotid artery restenosis.^{220,221} If nitrous oxide is used, it should be discontinued before removal of the carotid artery cross-clamp.^{175,182}

In summary, there is no scientific consensus supporting the notion that a specific anesthetic technique is superior in decreasing perioperative morbidity and mortality post-CEA. Ensuring adequate cerebral and cardiac perfusion by treating hypertensive and hypotensive episodes aggressively is important. An anesthetic plan that allows for a rapid assessment of neurologic function at the completion of surgery should be selected.

Postoperative Considerations

Perhaps the most common problem experienced in the postoperative period is hypertension. Although the specific cause remains unclear, postoperative hypertension is likely related to changes in sensitivity of the carotid baroreceptor reflex. A systolic blood pressure greater than 180 mm Hg is associated with an

increased incidence of TIA, stroke, or MI.¹⁸³ Patients with a systolic blood pressure of 145 mm Hg or less have fewer postoperative complications.¹⁶⁹ A postoperative blood pressure of 140/80 mm Hg or less is recommended.²²² Chronic hypertension during the postoperative period can lead to the development of cerebral hyperperfusion syndrome (CHS) as described below. Postoperative hypertension often resolves within 24 hours after surgery. Postoperative hypotension is less common but can be more difficult to treat because raising the blood pressure increases myocardial oxygen demand. Reestablishing normal pressures can be accomplished by careful titration of fluids and vasopressors.

Although an uncommon complication, carotid artery hemorrhage can occur in the postoperative phase. Hemorrhage is a devastating event that requires immediate surgical intervention. One of the initial manifestations of hemorrhage may be upper airway obstruction, which may make reintubation difficult due to tracheal deviation. Emergency management of a patient with airway compromise as a result of carotid artery hemorrhage and hematoma includes immediate evacuation of the hematoma. In addition, recurrent laryngeal nerve damage can occur, which routinely manifests as inspiratory stridor. Respiratory insufficiency can be problematic for patients who have preexisting respiratory conditions. Tension pneumothorax also can occur, because the apices of the lungs extend above the clavicles toward the surgical site. Treatment includes immediate lung re-expansion via chest tube insertion or needle decompression. Damage to the carotid body can lead to blunting of the chemoreceptor reflex, and therefore supplemental oxygen should be administered. Lastly, CHS may result from increased blood flow to the brain as a result of a loss of cerebral vascular autoregulation. The mechanism of action that causes this phenomenon is unclear; however, it is hypothesized that CHS may occur as a result of chronic cerebral ischemia or altered cerebrovascular autoregulation. Signs and symptoms of CHS include severe headache, visual disturbances, altered level of consciousness, and seizures. CHS may occur more often in patients who have had a contralateral CEA within the last 3 months and undergo a second CEA for occlusion on the ipsilateral side.²²³

The incidence of postoperative stroke after CEA was discussed

previously. Unfortunately, even after successful revascularization of the carotid artery, occlusion can recur at a rate of 3% per year.¹⁷⁹ Although symptoms are present in only a small percentage of patients (3% to 5%), the incidence of recurrent carotid stenosis may be much larger than that reported, because asymptomatic cases may be overlooked.²²³ As many as 25% of patients experience a neurocognitive decline up to 1 month after surgery. Patients who are predisposed to this decline are those with diabetes and advanced age.²²⁴ The exact mechanism responsible for postoperative cognitive dysfunction has not been scientifically identified. Postoperative complications associated with CEA are listed in [Box 28.15](#).

Postoperative Complications of Carotid Endarterectomy

- Hemodynamic instability
- Myocardial ischemia/infarction
- Cerebral hyperperfusion syndrome
- Stroke
- Respiratory insufficiency
- Recurrent/superior laryngeal nerve damage
- Hematoma
- Carotid body dysfunction
- Tension pneumothorax
- Acute carotid occlusion

Owing to the anatomic location of and potential neurologic complications after CEA, post-emergence neurologic integrity should be assessed. In addition to neurocognitive functioning, clinical assessment of cranial nerve function should be performed

(Table 28.9). The anatomic locations of the cranial nerves in relation to the internal, external, and common carotid arteries are shown in Fig. 28.14.

TABLE 28.9
Cranial Nerve Assessment for the Patient Scheduled for CEA

Cranial Nerve	Function	Abnormal Response
VII (facial)	Muscles of facial expression, saliva secretion	Inability to smile symmetrically; contralateral asymmetry indicates possible stroke; nerve injury on ipsilateral side
IX (glossopharyngeal)	Swallowing, pharyngeal muscle	Difficulty swallowing with ipsilateral Horner syndrome (i.e., ptosis, miosis, exophthalmos, reduced sweating)
X (vagus) → superior and recurrent laryngeal nerves	Laryngeal muscle movement	Minor swallowing problems, fatigued voice; vocal cord paralysis, hoarseness, inadequate gag reflex; may test speech by having the patient say “EEE”
XI spinal accessory	Shoulder muscles	Ipsilateral weakness in neck and shoulder with shrugging
XII (hypoglossal)*	Muscles of tongue	Tongue sticks out and moves side to side; tongue droops to ipsilateral side; difficulty with speech and chewing, high-pitched sounds, hoarseness

*This nerve traverses the internal carotid artery.

Carotid Artery Angioplasty Stenting

A less invasive surgical approach for the treatment of carotid artery stenosis is carotid artery angioplasty and stenting (CAS).

Controversy exists regarding the degree of success that this procedure affords as an alternative to CEA. The best application of CAS is still evolving and many studies comparing stenting with endarterectomy are ongoing. Best practices regarding proper patient selection, technique, and timing of the procedure are still being explored.^{225,226} The current incidence of stroke after CEA is approximately 2%. A meta-analysis noted that, compared to CAS, CEA decreases the risk of stroke at 30 days, increases the risk of MI, and does not have an effect on the risk of death.²²⁷

The first large multicenter randomized controlled trial comparing CEA versus CAS was the Stenting and Angioplasty with Protection Patients at High Risk for Endarterectomy (SAPPHIRE) trial.²²⁸ The rate of event-free survival at 1-year post-surgery was 88% for the CAS group and 79.9% for the CEA group. The stroke rate after 1 year was lower in the CAS group as compared with the CEA group (6.2% versus 7.9%, respectively). As for cardiac morbidity, the rate of MI for CAS versus CEA was 1.9% versus 6.6% at 30 days postoperatively. Overall, cardiac morbidity was 3% for CAS and 6.2% for CEA. The conclusion drawn from the SAPPHIRE trial was that CAS does not yield inferior outcomes as compared with CEA. However, the study methodology was criticized and some experts questioned whether the results could be replicated.²²⁹ A new 3-year follow-up report of the SAPPHIRE study group indicates that in patients with severe carotid artery stenosis and increased surgical risk, no significant difference could be shown in long-term outcomes between patients who underwent CAS with an emboli-protection device and those who underwent endarterectomy.²³⁰

The Endarterectomy versus Angioplasty with Symptomatic Severe Carotid Stenosis (EVA-3S) trial was designed to compare the outcomes from CAS versus CEA. The study population included patients with symptomatic carotid stenosis of at least 60%. The study was stopped early because of a high incidence of stroke and death (9.6% compared with 3.9% for CEA at 30 days after surgery).

The conclusion was that CEA was superior to CAS for this patient population when considering risk of stroke at 30 days and 6 months postoperatively.²³¹ Another randomized controlled trial, the Stent-Protected Angioplasty versus Carotid Endarterectomy (SPACE) trial, yielded high but similar statistics for 30-day stroke death rates (6.8% for CAS and 6.3% for CEA).²³²

The goal of the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST), a randomized controlled trial, was to determine which procedure (CAS or CEA) was more effective in preventing stroke and death. Inclusion criteria were patients who were symptomatic and had greater than 50% carotid artery stenosis and those who were asymptomatic with greater than 60% carotid artery stenosis. The preliminary results from the first stage of the trial, which included 1000 patients, are encouraging and compare favorably with CEA. The rate of death or stroke from any cause during the 30 days after the procedure was 3% for asymptomatic patients under 80 years of age and 2.7% for symptomatic patients under 80 years of age.²³³ Initial indications were that CAS was associated with an increased incidence of stroke in octogenarians. However, it has now been determined that the incidence of stroke resulting from CAS is similar to the CEA results for all age groups.²³⁴ The CREST data show that the health-related quality of life in patients who underwent CAS is superior to those who underwent CEA for up to 1 year postoperatively.²³⁵ The CREST study was conducted over a ten-year period. It was determined that there were no significant differences between patients that had CEA versus CAS with respect to stroke, MI, and death.²³⁶

Case selection guidelines for CAS are listed in [Table 28.10](#). Prior to CAS, a high-resolution MRI is taken of the patient's aortic arch and carotid arteries, as well as a cerebral angiogram. This allows evaluation of the individual anatomy and angiopathology of the aortic arch, brachiocephalic artery (for right carotid artery stent), or left common carotid artery. The type of sheaths, stents, and cerebral embolic protection device needed can then be determined. Femoral artery access is obtained, and a sheath is then threaded through the aortic arch and into the operative carotid artery. The guide wire/embolic protection device is advanced through the sheath and positioned across the stenotic region. An embolic protection device

sequesters emboli during angioplasty and stenting to avoid distal occlusion in cerebral arteries (Fig. 28.15). A distal embolic protection device lowers the risk of intraoperative and postoperative adverse events.²³⁷ This filter-like device is inserted distal to the area of stenosis prior to the angioplasty and stent deployment to catch microthrombi and pieces of plaque that could lodge within the brain. Angioplasty with a 5-mm balloon dilates the carotid artery, then the stent is deployed. The guide wire/device wire is removed after angiographic confirmation that carotid artery dissection or occlusion has not occurred. Fig. 28.16 shows carotid artery patency after angioplasty and stent placement.

TABLE 28.10
Case Selection for Carotid Artery Stenting

CAS Worse	CAS Better
Clinical Features	
Advanced age (80 years or older) Intolerance of antiplatelet agents Severe renal dysfunction	COPD CHD with an abnormal cardiac stress test, unstable angina, or myocardial infarction less than 1 month ago Valvular heart disease Congestive heart failure (EF less than 30%) Contralateral recurrent laryngeal nerve dysfunction Severe obesity
Anatomic Features	
Access-related Shaggy aorta Eggshell aorta Severely angulated type III aortic arch Aortoiliac occlusive disease	Previous neck irradiation Previous radical neck surgery Tracheostomy Neck immobility Recurrent stenosis High lesions (above C2) Contralateral carotid occlusion
Target vessel-related Heavy calcification Severe tortuosity String sign Fresh thrombus Unstable plaque	

CAS, Carotid artery stenting; CHD, coronary heart disease; COPD, chronic obstructive pulmonary disease; EF, ejection fraction.

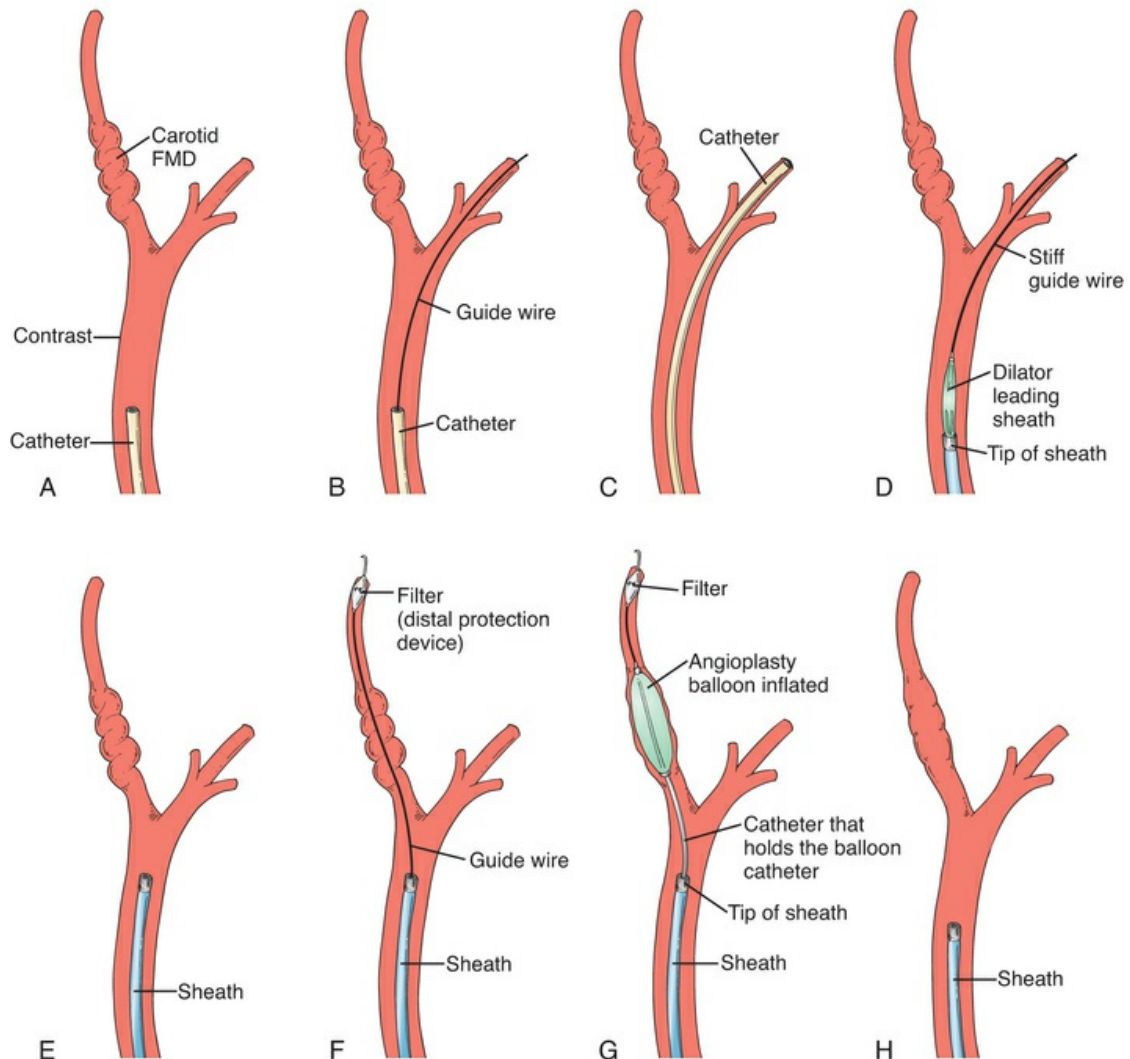

FIGURE 28.15 Endovascular technique. **A**, Internal carotid artery narrowed by fibromuscular dysplasia. An arteriogram was performed through a carotid catheter. **B**, Guide wire placed in the external carotid artery by using a roadmap of the carotid bifurcation. **C**, Cerebral catheter advanced into the external carotid artery. **D**, Stiff guide wire advanced into the external carotid artery. The carotid access sheath is advanced over the exchange guide wire. **E**, Carotid sheath in place with the tip of the sheath in the distal common carotid artery. **F**, Cerebral protection device in place in the distal internal carotid artery. **G**, Balloon angioplasty of the fibromuscular lesion in the internal carotid artery. **H**, After balloon angioplasty, the patency of the lumen has improved significantly. *FMD*, Fibromuscular dysplasia. (From Cronenwett JL, Johnston W. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Elsevier; 2010:1496.)

FIGURE 28.16 **A**, High-grade restenosis of internal carotid artery (*arrowhead*) 11 months after carotid angioplasty/stenting with a wallstent. **B**, After angioplasty alone. **C**, After placement of a Nitinol stent. Note filter protection device in distal internal carotid artery. (From Rutherford RB. *Vascular Surgery*. 8th ed. Vol. 2. Philadelphia: Elsevier; 2014.)

Anesthetic Considerations

The anesthetic technique used most often for patients having CAS is local anesthesia at the femoral insertion site, minimal sedation, antithrombotic therapy, and observation for hypotension and bradycardia.²³⁸ Anticoagulation is initiated with a heparin bolus (50–100 units/kg) to maintain an activated clotting time greater than 250 seconds.²³⁹ Balloon inflation in the internal carotid artery can stimulate the baroreceptor response, resulting in prolonged bradycardia and hypotension. Glycopyrrolate or atropine can be given prior to inflation to offset this vagal response. Fluoroscopy will be used throughout the surgery, so it is important that all operating room personnel are protected with lead shielding.

Complications associated with CAS are listed in [Box 28.16](#). The most common complication associated with this procedure is stroke caused by thromboembolism.²⁴⁰ Interventions for a patient with an

acute stroke include airway and hemodynamic management. Immediate CT scan and identification of the presence of an embolus is critical. Neurologic deficits are significantly reversible if CBF is restored within 2 hours. Treatment with catheter-directed recombinant tissue plasminogen activator is approved for acute ischemic stroke that is believed to be caused by an embolus. Catheter-based thrombectomy using snares or balloon angioplasty to restore blood flow and remove the thromboembolic material has also been used successfully.

Complications Associated With Carotid Artery Stenting

- Stroke
- Myocardial ischemia/infarction
- Bradycardia
- Hypotension
- Deformation of expandable stent
- Stent thrombosis
- Horner syndrome
- Cerebral hyperperfusion syndrome
- Carotid artery dissection
- Carotid artery rupture
- Hemorrhage resulting from anticoagulation

Patients typically remain in the postanesthesia care unit for 30 minutes after carotid stent placement and are then transferred to a monitored floor. A carotid duplex scan is performed prior to discharge, and then routinely obtained at 6 weeks, 6 months, 1 year, and then yearly. Patients remain on aspirin therapy for

anticoagulation for life.²⁴¹

Summary

As the mean age of people in the United States increases, treatment of vascular disease is one of the fastest-changing areas of medicine. Minimally invasive vascular surgical techniques are being introduced that are revolutionizing the options available for treatment. Many highly invasive surgical techniques are now being performed as interventional radiologic procedures. Anesthetic management for vascular procedures is far different from just a few years ago, and requires that we adapt to ever-new treatment strategies. As technology practice evolves, we will be better able to assess growing evidence that suggests the superiority of these procedures in decreasing patient morbidity, mortality, and convalescence.

Respiratory Anatomy, Physiology, Pathophysiology, and Anesthetic Management

Michael Rieker

Knowledge of the respiratory system is essential to the practice of anesthesia. Anesthetists are known as the airway experts, but they are also expected to possess an excellent command of the entire respiratory system. This is necessary because they administer oxygen to the majority of patients, administer inhaled anesthetics down a cascade of concentration gradients through the lungs, provide artificial ventilation for many patients under general anesthesia, and monitor and interpret blood gas analysis, capnography, and oximetry.

Besides the basic functions of the respiratory system, which include extracting oxygen (O_2) from the atmosphere and delivering it to the blood while excreting carbon dioxide (CO_2), the respiratory system functions in the processes of maintaining acid-base balance, phonation, pulmonary defense, and metabolism (synthesis and breakdown of bioactive materials). These anatomic and physiologic functions are all discussed in this chapter.

Anatomy and Physiology of the Respiratory System

Knowledge of airway anatomy is not only necessary for understanding respiratory physiology but also essential for the practice of anesthesia. The airway consists of the nose, mouth, pharynx, larynx, trachea, and lower airways.

The components of the respiratory system are the conducting airways, the lungs and their blood supply, the portions of the central nervous system responsible for control of the muscles of ventilation, the chest wall, and the thoracic muscles responsible for ventilation.

Anatomical Structures of the Respiratory System

Nose

Inhaled air enters the body through the nose or mouth. Air passing through the nose is filtered, heated to body temperature, and humidified. The external nose is only a small part of the nasal air passageway, the major portion of which lies directly behind the nose and includes three scroll-shaped turbinate bones, also called the *nasal conchae*.

The cartilage around the entrance to the nostrils that can flare during heavy breathing is called the *alar cartilage* or *ala nasae* (“nasal wings”). Each nostril opening (anterior naris) leads directly into the vestibule, which is the forwardly expanded portion of the nasal cavity. The vestibule is lined with cutaneous epithelium. In its lower half, it has sebaceous glands and coarse hairs, which serve to filter incoming air. The base of the nasal cavity is at a level higher than the opening of the nostril; therefore, during nasal intubation, the apex of the nose should be elevated superiorly with gentle pressure while the tube is inserted parallel to the roof of the mouth. The endotracheal tube should not be directed upward into the turbinates but rather along the floor of the nose formed by the superior aspect of the palatine bone, which forms the hard palate of

the mouth directly below the nose. Prolonged nasotracheal intubation is associated with obstruction of the nasal sinuses, sinus infection, and fever. Intranasal infections can produce intracranial infection via vascular connections, as discussed later in this section.

The anterior portion of the external nose, the vestibule, expands above and behind into triangular spaces, or fossae. The fossae are separated from each other by the nasal septum, which also separates the two nostrils. The septum is formed by the ethmoid and vomer bones superiorly and the vomeronasal and nasal septal cartilages inferiorly. The nasal fossae usually communicate freely with the paranasal air sinuses (frontal, ethmoid, maxillary, and sphenoid). They open into the nasopharynx by the posterior nares (also known as *choanae*) and are bordered medially by the nasal septum and laterally by three turbinates arranged one above the other. Choanal atresia is a birth defect characterized by obstruction of the posterior nasal airway. This obstruction may be life threatening in the obligate nose-breathing newborn.

The conchae are scroll-shaped prominences projecting from the lateral walls and have their free margins directed downward and inward. The conchae overlie the superior, middle, and inferior meatus, which contain the openings to the paranasal sinuses. The superior concha is the smallest of the three, and the middle concha extends forward much farther than the superior concha. The inferior concha, which lies along the inferior part of the lateral wall of the nasal cavity, is in the pathway of airflow in the nose, and it is the one most commonly injured during nasal intubation. It extends to within approximately 2 cm of the middle of the anterior naris, and its posterior tip lies approximately 1 cm in front of the pharyngeal orifice of the eustachian tube. Eustachian drainage can become obstructed when the inferior concha or adenoid tonsils become inflamed. Such obstruction can lead to middle ear pathology.

The nasal cavities are lined with mucous membranes that are continuous with those of the pharynx. The mucosa can be divided into respiratory and olfactory areas because it not only lines the tracts followed by respired air but also covers the cells that act as the receptors for smell. The olfactory epithelium occupies the apical third of the nasal cavity. This epithelium contains afferent fibers

from the olfactory nerves (cranial nerve I) that communicate through the cribriform plate of the ethmoid bone to the adjacent olfactory bulb. Signals then progress to the other parts of the rhinencephalon. The respiratory mucosa lines the lower two-thirds of the nose and consists of pseudostratified ciliated columnar epithelium interspersed with goblet cells that produce mucus. Although the morphology of cells changes progressively toward the terminal bronchioles, this general arrangement of stratified ciliated epithelium with goblet cells persists throughout the majority of the air passages of the respiratory system. The direction of motion of the cilia is toward the exterior of the nasal cavity.¹⁻⁵

The principal arterial supply of the nasal fossae arises from the ophthalmic arteries through the anterior and posterior ethmoid branches, and from the internal maxillary artery through the sphenopalatine arteries. Because of the location of the interior maxillary artery, it is sometimes ligated for the treatment of persistent nosebleed. The veins accompany the arteries; the ethmoid veins open into the superior sagittal sinus, and the nasal veins drain into the ophthalmic veins and then into the cavernous sinuses. Nasal infections can result in meningitis because of this venous communication between the intracranial and intranasal circulation. The sensory nerves from the upper respiratory tract come from the ophthalmic nerve and the maxillary nerve (both are branches of cranial nerve V). Lymphatic drainage from the cavities of the nose is via the deep cervical lymph nodes adjacent to the internal jugular vein.

Through the functioning of the nasal hairs, the mucus-producing epithelium, and the rich arterial supply, the nose has important functions that include filtration, humidification, and heating of inspired air. As long as the incoming air is not extremely cold, the nose can warm the inspired air to nearly body temperature and moisten it to nearly 100% relative humidity. The heating and humidifying functions of the nose are affected by general anesthesia. The inspiration of cold, dry gas often dries the nasal and pharyngeal passageways, causing sore throat even if no instrumentation of the airway takes place.

The hairs at the entrance to the nostrils are of minor importance to filtration because they remove only large particles. More

important is the removal of particles by turbulent precipitation. Air passing through the nasal passageways hits many obstructions, including the septum, the turbinates, and the pharyngeal wall. When the inspired air is forced to change direction, the inhaled particles cannot change course as rapidly, and they become embedded in the mucus-covered surfaces of these processes. The particles trapped in the mucus are moved by the cilia either to the naris or posteriorly to the pharynx to be expectorated or swallowed. This occurrence is important because it does not allow entry of infectious, carcinogenic, or irritating substances. Nasal filtration is extremely effective for particles above 10 μm and less than 1 nm , but filtration efficiency is inverse to particle size for particles that are between 10 nm and 1 μm .¹⁻⁵

Pharynx

The pharynx is a wide muscular tube that is a part of both the respiratory tract and the alimentary canal. Its upper border is the base of the skull, and it extends to the level of the C6 vertebra, where it becomes continuous with the esophagus. At this level, ingested foreign bodies, such as coins, are frequently lodged. The pharynx is lined by a musculomembranous coat and divided into three parts: the nasopharynx, which extends from the posterior nares (choanae) to the end of the soft palate; the oropharynx, which is bounded superiorly by the soft palate and anteriorly by the tonsillar pillars and oral cavity, and extends inferiorly to the tip of the epiglottis; and the hypopharynx (laryngopharynx), which extends from the tip of the epiglottis to the level of C6, or the beginning of the esophagus.

The pharyngeal region includes the tonsils, which are composed of three aggregations of lymphoid tissue: the palatine tonsils (major tonsils), which lie in the tonsillar fossae at the boundary of the oral cavity and oropharynx; the lingual tonsils, which extend across the tongue from the base of each palatine tonsil; and the pharyngeal tonsils (adenoids), which lie on the lateral walls of the nasopharynx. The lymphoid tissue of the tonsils forms the Waldeyer tonsillar ring, which acts as a first-line of defense against bacterial invasion of the nasal and buccal passages. If inflamed, the pharyngeal tonsils may obstruct airflow through the choanae and are sometimes

removed by an adenoidectomy. Likewise, chronic tonsillitis is an indication for removal of the palatine tonsils via tonsillectomy.¹⁻⁵

Larynx

The adult larynx extends from vertebrae C3 to C6 and is a protective structure that prevents aspiration during swallowing; vocalization evolved secondarily. The larynx consists of one bone, nine cartilages (Table 29.1), ligaments, muscles, and membranes.

TABLE 29.1

The Nine Cartilages of the Larynx

Unpaired Cartilages		Paired Cartilages	
Number	Name	Number	Name
1	Epiglottic	4 and 5	Arytenoids
2	Thyroid	6 and 7	Corniculates
3	Cricoid	8 and 9	Cuneiforms

The hyoid bone is the chief support for the larynx and it is the only bone that does not form a joint with another bone. Its anterior aspect can be easily palpated, and its location is sometimes used as a measure of airway assessment for laryngoscopy. The thyroid cartilage and the cricoid cartilage make up the principal part of the framework of the larynx, whereas internally the epiglottis protects the vocal cords and the entrance to the trachea against aspiration of food or fluids.

Laryngeal Cartilages

The epiglottis resides in close proximity to the root of the tongue and is vertical to the opening of the larynx. It is attached to the body of the thyroid cartilage by the thyroepiglottic ligament just above the vocal cords and to the base of the tongue by the glossoepiglottic folds. The furrow between the glossoepiglottic fold and the base of the tongue is called the *vallecula epiglottica* and serves as the situation point for the tip of a curved laryngoscope blade. The epiglottis serves to protect the larynx from foreign body entry. During swallowing or laryngospasm, elevation of the larynx closes the epiglottis, effectively “sealing off” the trachea.

The thyroid cartilage is the largest cartilage of the larynx, formed

by two quadrangular plates or laminae fused near the midline anteriorly. Its strength affords a great deal of protection to the larynx. The thyroid cartilage forms the Adam's apple. Being larger and covered with less subcutaneous fat, the thyroid cartilage is more prominent in adult males.

The cricoid cartilage is palpable just below the thyroid gland, and its level corresponds to the beginning of the trachea and the esophagus. It is the only true ring of cartilage encircling the airway. Anteriorly, the cricoid cartilage lies below the thyroid cartilage, with the cricothyroid membrane intervening. The cricoid is the most inferior of the nine laryngeal cartilages. The arytenoid cartilages articulate on the superior posterior aspect of the cricoid cartilage, which is slanted forward. The paired arytenoid cartilages are attached to the posterior ends of the vocal cords. The paired corniculate (median) and cuneiform (more lateral) cartilages are embedded in the aryepiglottic folds, and they provide support to these structures. These cartilages cause the two bumps seen in the aryepiglottic folds, which are often (but incorrectly) called the *arytenoids* when visualized during laryngoscopy.

In adults, the narrowest portion of the larynx is the opening between the true vocal cords (aka cricoid opening or rima glottidis) during relaxation. However, in children younger than 10 years of age, the narrowest portion of the larynx is the cricoid cartilage. This anatomic difference is of clinical significance: a tube with adequate clearance through the vocal cords may create mucosal pressure at the level of the cricoid ring in children less than 10 years of age. For this reason, uncuffed endotracheal tubes (ETTs) have traditionally been used in children less than 8 to 10 years of age. Although an uncuffed tube may offer advantages in terms of positioning,² it is becoming more commonplace to use an adjusted-size cuffed tube in pediatric patients for the added assurance of tidal volume delivery and to reduce the necessity to change the tube because of incorrect sizing.³

Membranes of the Larynx

The thyrohyoid membrane suspends the larynx from the hyoid bone. The cricothyroid membrane lies between the cricoid and the thyroid cartilages. The easiest and most rapid laryngotomy can be

performed through this membrane. Cricothyrotomy is recommended for the emergency establishment of an airway when both endotracheal intubation and mask ventilation are unsuccessful. A *transtracheal block* can be performed by puncturing the cricothyroid membrane with a needle and injecting a local anesthetic into the trachea.

Interior of Larynx

The larynx is divided into three compartments by the false vocal cords and the true vocal cords. The supraglottic area, also called the *vestibule*, extends from above the false cords to the tip of the epiglottis. On each side of the vestibule is located a pharyngeal sinus (the pyriform sinus). This recess is a potential location for lodging of foreign bodies that enter the pharynx or for noncentered ETTs. The second compartment of the larynx is the area between the false cords and the true cords known as the *laryngeal ventricles*. The third area is the infraglottic region below the true cords and above the beginning of the trachea. The rima glottidis (cricoid opening) is the space between the true vocal cords.¹⁻⁵

Movements of the Vocal Cords

The true vocal cords are fibromembranous folds attached anteriorly to the thyroid cartilage and posteriorly to the arytenoids. The focal points of movement are the arytenoid cartilages, which rotate and slide up and down on the sloping cricoid cartilage. The muscles controlling laryngeal movement ([Box 29.1](#)) are most conveniently thought of as pairs having opposing actions. The laryngeal inlet is closed by the aryepiglottic muscle and opened by the thyroepiglottic muscle. The cricoid opening is dilated by the posterior cricoarytenoid muscles and closed by the interarytenoid muscles assisted by the lateral cricoarytenoid muscles. The cricothyroid muscles lengthen the true vocal cords, and the thyroarytenoid muscles shorten them. Both sets of muscles can alter the tension on the vocal cords and are important for determining [Box 29.1](#) of the voice.⁴

Intrinsic Muscles of the Larynx

Laryngeal Inlet

- Closed by the aryepiglottic and oblique arytenoid muscles
- Opened by the thyroepiglottic muscle

Glottic Opening

- Opened by the posterior cricoarytenoid muscles
- Closed by the transverse arytenoid and the lateral cricoarytenoid muscles

True Vocal Cords

- Lengthened by the cricothyroid muscles
- Shortened by thyroarytenoid muscles

Nerve Supply to the Larynx

Both the superior and inferior laryngeal nerves are branches of cranial nerve X, the vagus nerve. The superior laryngeal nerve arises from the ganglion nodosum of the vagus and divides into two branches, the internal and external. The external segment branches to the inferior constrictor muscle of the pharynx and also to the cricothyroid muscles. These muscles change the position of the cricoid and thyroid cartilages and in doing so lengthen or increase the tension of the vocal cords. If these muscles are paralyzed, the voice becomes weak, rough, and easily fatigued. Voice hoarseness, particularly of recent onset, should be investigated in the preoperative evaluation as a potential indicator of vocal cord palsy or airway obstruction. The internal branch of the superior laryngeal nerve enters the larynx and then the thyrohyoid membrane and is distributed to the mucous membranes of the larynx and epiglottis. It provides sensation from the inferior side of the epiglottis down to the true cords (the superior side of the epiglottis is innervated by the glossopharyngeal nerve). The internal branch also innervates the interarytenoid muscles, which are important in phonation.

The inferior (or recurrent) laryngeal nerves arise from the two

vagus nerves at different levels. The left nerve descends with the vagus and then loops around the arch of the aorta, and then it courses superiorly to the trachea. The right recurrent laryngeal nerve travels with the vagus nerve as far as the right subclavian artery; it loops around this artery and then comes back up the neck. The recurrent laryngeal nerve supplies sensation to the larynx below the level of the vocal cords and innervates all the muscles of the larynx except the cricothyroid and part of the interarytenoid muscles. Damage to the recurrent laryngeal nerve(s) during surgery on the neck, or from airway devices or anesthetic blocks, can lead to unilateral or bilateral vocal cord paralysis with hoarseness or dyspnea, respectively.^{5,6} Blood supply to the larynx is provided by the superior thyroid artery (a branch of the external carotid artery) and the inferior thyroid artery (a branch of the thyrocervical trunk, which arises from the subclavian artery).¹⁻⁵

Trachea

The trachea is lined by pseudostratified ciliated columnar epithelium, and it extends from the inferior larynx to the carina, where it bifurcates into the two mainstem bronchi. In adults of normal size, the distances are fairly constant: the distance from the incisors to the larynx is approximately 13 cm, as is that from the larynx to the carina. Therefore the distance from the incisors to the carina is approximately 26 cm (note the length markings on ETTs). The blood supply to the trachea is through the inferior thyroid artery, which comes from the thyrocervical branch of the subclavian artery. Some perfusion is also received from the superior thyroid, bronchial, and internal thoracic arteries. Blood is drained by the inferior thyroid veins. Sensory innervation of the trachea is via the vagus nerve for both parasympathetic and nociceptive stimuli.

The trachea has a diameter of approximately 2.5 cm, and it is supported by incomplete rings of cartilage that open posteriorly and prevent tracheal collapse under the negative pressure generated during spontaneous respiration. The trachea extends down to the level of T4–T5, where the carina is located. This level corresponds anteriorly to the angle of Louis on the sternum, which is the articulation of the second rib. The trachea is not a rigid structure; it expands and contracts to accommodate head and neck

movement. In an intubated patient, flexion of the neck elevates the carina. As a result, the ETT moves downward and endobronchial intubation may result. During extension of the head and neck, the trachea moves downward, the ETT moves upward, and extubation can occur. In pediatric patients, the range of this movement was demonstrated to increase with patient age and height.⁷ The apparent movement of the ETT in relation to head flexion may seem paradoxical; the mnemonic “the hose follows the nose” can be used as a memory aid. Neck rotation to the left or right tends to cause tracheal elevation and risk of endobronchial intubation.¹⁻⁵

Bronchi

At the carina, the trachea divides into the right and left bronchi (Fig. 29.1). The cellular structure begins to change at this point from columnar to cuboidal epithelium, and the cartilaginous rings thin into plates once the bronchi penetrate the lungs. From the carina, the bronchi branch off at slightly different angles. The right bronchus takes a less acute angle from the trachea, approximately 25 degrees, whereas the left bronchus takes off at 45 degrees. In addition, the right mainstem bronchus is wider and shorter (2 cm) than the left one (4 cm).⁸ Because the right bronchus is more nearly vertical than the left, the tendency is much greater for ETTs, suction catheters, or aspirated foreign materials to enter the right side after passing the carina. Additionally, the beveled tip of an ETT makes right-sided intubation more likely. The side opening (Murphy's eye) located at the distal end of the ETT allows the delivery of gas if the beveled tip of the tube is closely opposed to the similarly angled right main bronchus.

FIGURE 29.1 Lobes and bronchopulmonary segments of the lungs. *Red*, upper lobes; *blue*, lower lobes; *green*, right middle lobe. The 19 major lung segments are labelled.

(From Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia: Elsevier; 2017: 6.)

Each mainstem bronchus divides into lobar bronchi (three on the right; two on the left), that lead to the major lung lobes. The right mainstem bronchus ends only 2 to 2.5 cm from the carina before giving rise to the right upper lobe (RUL) bronchus. After the RUL takeoff, the main bronchus then continues for 3 cm as the *bronchus intermedius* before giving rise to the right middle lobe bronchus and the right lower lobe bronchus. The left main bronchus is 4 to 5 cm long and terminates by bifurcating into the left upper lobe bronchus and the left lower lobe bronchus. The left upper lobe bronchus further branches into a superior division and an inferior division (the lingular branch).

Each successive division of the airways is referred to as a *generation*, with the mainstem bronchi representing the first generation, the lobar bronchi representing the second, and so on. The lobar bronchi divide into the third generation of airways, called *segmental bronchi*, which deliver ventilation to the various bronchopulmonary segments of the lung. There are 10 bronchopulmonary segments in each lung, but on the left, the apical and posterior segments and the anterior basal and medial basal segment pairs each arise from a single bronchial branch (Box 29.2). Therefore only eight third-generation bronchi are found on the left. Segments whose names contain the word *basal* are located adjacent to the diaphragm. The bronchopulmonary segments create distinct anatomic and functional units. The segments are separated by

connective tissue, so gas-exchange properties or pathology tend to be isolated to a segment. A bronchopulmonary segment can also be **Box 29-2** used as a unit.

Lung Lobes and Segments

I. Right lung

A. Right upper lobe (3 segments)

1. Apical
2. Anterior
3. Posterior

B. Right middle lobe (2 segments)

1. Medial
2. Lateral

C. Right lower lobe (5 segments)

1. Superior
2. Anterior basal
3. Posterior basal
4. Lateral basal
5. Medial basal

II. Left lung

A. Left upper lobe (4 segments)

1. Apical posterior
2. Anterior
3. Superior lingular
4. Inferior lingular

B. Left lower lobe (4 segments)

1. Superior
2. Anteromedial basal
3. Posterior basal
4. Lateral basal

Each subsegmental bronchus divides several times, giving rise to numerous bronchioles. With succeeding generations and multiplication of the number of airways, the total cross-sectional area becomes very large, and the airflow velocity decreases. There are 20 to 25 total generations before the alveoli. By the seventh generation, the diameter of bronchioles is approximately 2 mm, beyond which they are referred to as *small airways*. When the diameter has decreased to 1 mm they are referred to as *terminal bronchioles*. The terminal bronchioles are the last structures perfused by the bronchial circulation and are the end of the conducting airways (anatomic dead space, as discussed later). In the latter generations, the cross-sectional area of the airway has expanded so

much that the velocity of airflow becomes very slow, and gas moves largely by diffusion as compared to bulk flow.

With succeeding generations, the histology of the airways changes, in a progression characterized by thinning of the walls, to transition to the gas-exchanging morphology of the *respiratory zone* (Box 29.3). The terminal bronchioles divide into the respiratory bronchioles that are perfused by the pulmonary circulation and are the first place in the airway at which exchange of gas with the blood occurs. These airways are characterized by occasional outpouching of alveoli, or air sacs. The respiratory bronchioles divide into several alveolar ducts that lead to circular spaces called *atria*. Each atrium opens into two to five alveolar sacs, which are spaces lined by alveoli. The terminal airways are very small, and their walls are no longer tented open by cartilage but rather by connection with the adjacent matrix of pulmonary parenchyma in which they are situated. For this reason, they are prone to closure from compression of the pulmonary tissue during respiration or if emphysema, for example, expands the volume of adjacent air spaces and compresses the airways. The lung volume at which small airways tend to close is called the *closing volume*. In those with obesity or chronic obstructive pulmonary disease (COPD), the closing volume increases into the range of normal tidal breathing such that some airways close before the intended tidal volume has been fully expired. Small pores in the alveoli, known as the *pores of Kohn*, serve to allow collateral gas flow between alveoli and provide a mechanism of relief from gas stagnation from airway closure.⁹

Characteristics of Progressive Airway Divisions

With each succeeding generation:

- Number of airways ↑
- Cross-sectional area ↑
- Airflow velocity ↓
- Muscular layer ↑

- Cartilage ↓
- Mucous glands ↓ (absent in bronchioles)
- Goblet cells ↓
- Ciliated cells ↓
- Cuboidal, then squamous cells ↑

Respiratory Zone

The respiratory bronchioles and alveolar ducts, sacs, and alveoli comprise the *respiratory zone*, the area where gas exchange takes place. All parts of the airway prior to this (nose to terminal bronchioles) conduct gas without exchanging gas with the blood and are referred to as the *conducting zone*. Some refer to the respiratory bronchioles and alveolar ducts where limited gas exchange takes place as the *transitional zone* because structures here function both to conduct gas and also to participate in some gas exchange. The alveoli are the air sacs that are tightly packed and closely approximated with pulmonary capillaries. The typical maximum number of approximately 300 million alveoli is reached by age 9 years. The alveoli are characterized by very thin walls composed of squamous epithelium. There are three types of cells that form the alveoli: type I pneumocytes, which are the structural cells; type II pneumocytes, which produce surfactant to reduce alveolar collapse from surface tension; and type III pneumocytes, which are macrophages. The average alveolar diameter is approximately 250 μm ; therefore the total surface area available for gas exchange is 60 to 80 m^2 .¹⁰ The respiratory zone also contains non-ciliated Clara cells which serve a number of metabolic processes, as well as serving as progenitor cells for themselves and the other pneumocytes. Clara cells serve to detoxify xenobiotics and modulate inflammation. They also secrete a protein known as *uteroglobin* (because it is also found in the pregnant uterus). This protein provides a component of surfactant and the fluid lining of the distal respiratory tract. Clara cells play a role in the development of adenocarcinoma and other chronic lung diseases.

Pulmonary Hila and Coverings

The nerve supply to the bronchi and lungs arises chiefly from the sympathetic nerves and the vagus nerve (which supplies sensory and parasympathetic innervation). All conduits to the lung pass through the hilum, which is the connection of the mediastinum to the pedicle of each lung. The structures included in each hilum include the mainstem bronchus, pulmonary artery and vein, bronchial arteries and veins (which drain into the azygos system), lymphatics, lymph nodes, pulmonary nerve plexuses, and pulmonary ligament. All of this is surrounded by connective tissue. The serous membrane covering the lung is called the *pleura*. The parietal pleura lines the chest wall, mediastinum, and diaphragm, and at the hilum is then reflected back to cover the lungs as the visceral pleura. Between these two layers is a potential space called the *pleural cavity*. The touching surfaces of the two layers of pleura remain slippery by a small amount of serous fluid. Certain conditions can result in occupation of the pleural space by liquids or gas (Table 29.2) and may affect ventilation and lung expansion. Infected intrapleural blood can clot and organize to form a fibrothorax, which must be peeled from the surface of the lung (in a procedure called *lung decortication*) so the lung can reexpand.

TABLE 29.2
Conditions That Affect the Pleural Space

Material in Pleural Space	Medical Name
Air	Pneumothorax
Air under pressure	Tension pneumothorax
Blood	Hemothorax
Serous fluid	Pleural effusion
Pus	Empyema or pyothorax
Organized blood clot	Fibrothorax
Lymph	Chylothorax

Mediastinum

The mediastinum is the region located between the two pleural sacs. It exists in the center of the thoracic cavity but is slightly displaced to the left by the presence of the heart. Therefore the left lung represents 45% of the total lung capacity (TLC), whereas the

right lung represents 55%. Perforation of the larynx, trachea, pharynx, or esophagus, which sometimes occurs during esophagoscopy, bronchoscopy, or traumatic intubation, can produce mediastinitis, a life-threatening infection of an area containing the trachea, esophagus, and major blood vessels and heart. The mediastinum is divided into four divisions separated by the pericardium (Table 29.3). Common procedures involving the mediastinum include coronary artery bypass, cardiac valve replacement, aortic aneurysm repair, thymectomy for myasthenia gravis, resection of tumors, and mediastinoscopy for diagnosis and staging of cancer.

TABLE 29.3
Divisions of the Mediastinum

Subdivision	Location	Contents
Superior	Above level of the sternal angle, extending superior to the thoracic inlet	Thymus, esophagus, trachea, great vessels
Anterior	Between sternum and pericardium	Thymus
Posterior	Between vertebral column and posterior pericardium	Esophagus, thoracic aorta, thoracic duct
Middle	Between anterior and posterior divisions, bounded laterally by the parietal pleura	Heart, distal trachea, mainstem bronchi, and great vessel trunks

Pleura

The pleura is a serous membrane that lines the thoracic wall and lungs. The parietal pleura is attached to the chest wall, diaphragm, and mediastinum but is then reflected back to cover the lungs, and is afterward referred to as the *visceral pleura*. These two layers are closely opposed, with only a capillary-thin layer of pleural fluid between them in a potential space known as the *pleural space*. The parietal pleura is very sensitive to pain, and conditions that cause accumulation of pleural fluid or friction between the layers can cause discomfort. Different areas of the pleura may produce characteristic pain patterns: the costal pleura creates localized pain, the diaphragmatic pleura creates diffuse pain, and areas supplied by the phrenic nerve may radiate pain to the neck or back. Posterior to the mediastinum, the pleura doubles up and descends downward as the “pulmonary ligament.”

If communication is created across the pleura, accumulation of air in the pleural space is referred to as *pneumothorax*. In a closed chest (e.g., a pulmonary bleb ruptures, creating a communication to the pleural space), a tension pneumothorax develops as inspired air accumulates in the pleural space and is not expelled. With an opening through both pleura (such as with open chest trauma), the external wound may create a simple pneumothorax, which does not tend to cause high intrathoracic pressures. In either type of pneumothorax, the elastic recoil of the lung tends to favor lung collapse once the negative pressure of the pleural space is disrupted by the breach.¹⁻⁵

Mechanics of Breathing

Contraction of the muscles of inspiration lowers intrathoracic pressure and causes the volume of the thoracic cavity to increase. Boyle's law explains that the increase in volume creates a reduction in pressure, which causes air to enter from the atmosphere. Therefore spontaneous respiration involves passive movement of gas, as opposed to positive-pressure ventilation, which requires generation of positive pressure in the upper airway to overcome intrathoracic pressure and expand the lungs.

The diaphragm and external intercostal muscles contract during normal breathing (eupnea). Whereas the diaphragm increases the superior-inferior dimension of the chest, the external intercostals increase the anterior-posterior diameter by elevating the ribs and sternum. Each half of the diaphragm is innervated by a branch of the phrenic nerve, which arises from the third, fourth, and fifth cervical spinal nerve roots. This anatomy gives rise to the mnemonic "C-3, 4, and 5 keep the diaphragm alive." The diaphragm is almost solely responsible for quiet respiration, and loss of the function of intercostal muscles (by a thoracic spinal cord injury or high spinal or epidural block) usually does not impair respiration. However, if coupled with paralysis of the phrenic nerve and resulting paralysis of a hemidiaphragm (such as may occur with interscalene blocks), dyspnea may result. Spinal cord injuries above the level of C-5 usually lead to dependence on mechanical ventilation.

Normally, eupneic expiration results from passive recoil of the

chest wall and does not require muscular contraction, although the internal intercostal muscles may be used to augment exhalation. During forced exhalation (e.g., with coughing and the clearing of secretions), the abdominal muscles, particularly the rectus abdominis, the transversus abdominis, and the external and internal oblique muscles, are used. For forced inhalation, the intercostal muscles play a more prominent role, and accessory breathing muscles in the neck are also used. The diaphragm descends approximately 1 to 2 cm during eupneic breathing, but this excursion can increase to as much as 10 cm during forceful breathing. For air to move into the alveoli, alveolar pressure must be less than atmospheric pressure. This can be achieved either through an increase in atmospheric pressure (as in positive-pressure ventilation) or a reduction in alveolar pressure, as during spontaneous ventilation (negative-pressure breathing). During forceful inspiration, the sternocleidomastoid and scalene muscles contract in conjunction with the diaphragm and intercostals.

The muscles of ventilation are attached to the cartilaginous and bony components (ribs, sternum, and vertebrae) of the chest. Conditions that impede chest excursion, such as thoracic kyphosis, may require reduction to further increase the chest diameter. The two domes of the diaphragm separate the thoracic and abdominal cavities and function separately, such that injury to a phrenic nerve results in paralysis in the diaphragm only on that side. The central tendon on the underside of the diaphragm provides a site of rigidity, allowing the diaphragm to tense and flatten without pulling against an external insertion point, as do other muscles. The central tendon includes an orifice for passage of the inferior vena cava. There are two other prominent openings through the diaphragm; the esophagus passes through the esophageal hiatus, and the aorta, azygous vein, and thoracic duct pass through the aortic hiatus. When the diaphragm contracts during spontaneous inspiration, it flattens and moves the abdominal contents downward, raising intraabdominal pressure whilst lowering intrathoracic pressure. Pressure within the alveoli becomes slightly negative with respect to atmospheric pressure, and gas flows inward through the conducting airways to expand the lungs. When the diaphragm is paralyzed, it cannot contract; therefore it moves

upward from its normal position, owing to the effects of intraabdominal pressure and negative intrapleural pressure. When the normal diaphragm contracts (moving downward), the paralyzed diaphragm moves upward, and when the normal diaphragm relaxes (moving upward), the paralyzed diaphragm moves downward, resulting in paradoxical movements.¹⁻⁵

The diaphragm descends approximately 1 to 2 cm during eupneic breathing and as much as 10 cm during forceful breathing. For air to move into the alveoli, alveolar pressure must be less than atmospheric pressure. This can be achieved either through an increase in atmospheric pressure (as in positive-pressure ventilation) or a reduction in alveolar pressure, as during spontaneous ventilation (negative-pressure breathing).

Lung Compliance

Lung compliance is defined as the change in volume divided by the change in pressure (V/P). For a given change in pressure, a more compliant lung has a greater change in volume than a less compliant one. [Fig. 29.2](#) shows pressure-volume relationships for a lung. As with many concepts in respiratory physiology, the reader must make the jump from considering the application to a single alveolus (which aids in understanding) to conceptualizing the overall average state in the pulmonary system, which involves many regions existing along a continuum of conditions. In considering lung compliance, the curve in [Fig. 29.2](#) represents the collective contribution of alveoli that are almost collapsed at the beginning of inspiration, alveoli that are distended, and alveoli that exist at various intermediate volumes.

FIGURE 29.2 Compliance of the lung. The relationship between lung volume and lung pressure is obtained by inflating and deflating an isolated lung. The slope of each curve is the compliance. In the air-filled lung, inspiration (inflation) and expiration (deflation) follow different curves, which is known as *hysteresis*. (From Costanzo LS. *Physiology*. 5th ed. Philadelphia: Elsevier; 2014:195.)

Static effective compliance describes the pressure-volume relationship for a lung when air is not moving; that is, reflecting compliance of the lung and chest wall alone. Static compliance is decreased by conditions that make the lung difficult to inflate, such as fibrosis, obesity, vascular engorgement, edema, acute respiratory distress syndrome (ARDS), and external compression (e.g., that caused by tight dressings or a surgeon leaning on the patient's chest). Static compliance is increased by emphysema, which destroys the elastic tissue of the lung. This makes the emphysematous lung easier to inflate. The problem with emphysema is not inflation but rather deflation, because the loss of elastic tissue results in small airway collapse as the lung deflates, which causes gas trapping. It is important to note that compliance changes as lung volume changes. In other words, compliance is volume dependent. [Fig. 29.2](#) shows that the lung is less compliant

both at very low and at very high lung volumes. Alveoli require greater pressure to be inflated when they are almost empty or almost full, respectively. When an alveolus is collapsed, a great increase in pressure is necessary for inflation to begin. Observe in [Fig. 29.2](#) that the slope of the inspiratory curve is less at both low volumes and very high volumes. At low volumes, more energy is required (more negative pressure, i.e., less compliant) to begin to expand the lungs. At high volumes, the alveoli are almost at capacity, and further changes in pressure result in less change in volume (less volume per given pressure = less compliant). As you follow the curve along the expiratory side, notice that an initial increase in pressure (with slower volume change) as the chest wall relaxes is followed by a smooth reduction in volume back to the resting level. Lung compliance results from the interplay of various factors that tend to either expand the lungs or restrict lung expansion. Much of the energy required to expand the lungs, particularly at low volumes, is created by surface tension in the fluid lining of the alveoli, which tends to attract the alveoli toward a smaller volume. Perhaps counterintuitively, a lung filled with fluid (and therefore without an air/fluid interface and the resulting surface tension) has very high compliance; it requires much less energy to expand. Although not a high-fidelity measurement, static effective compliance can be calculated easily using the following equation:

$$\text{Static effective compliance} = \frac{\text{tidal volume}}{(\text{plateau pressure} - \text{PEEP})}$$

Plateau pressure is the pressure observed if you retard exhalation momentarily when the lungs are at end-inspiration. An inspiratory pause on the ventilator is an easy way to observe the plateau pressure. After subtracting the added pressure of positive end-expiratory pressure (PEEP), the plateau pressure is then divided into the measured tidal volume of that breath, producing a measure of lung compliance. A static compliance of 60 to 100 mL/cm H₂O is considered normal. However, the most useful clinical application of compliance measurement is in monitoring trends to evaluate

changing physical status or the effectiveness of PEEP or other treatment modalities. Because the plateau pressure may be contributed by both the lung elastance *and* pressure external to the lung (such as abdominal insufflation), static effective compliance has been found not to be the most accurate way to measure lung compliance in the clinical setting (refer to section that describes [transpulmonary pressure](#)).

Dynamic compliance is the compliance of the lung when the air is moving. Dynamic compliance is influenced by the forces involved in static compliance, as well as the effects of airway resistance. Airway obstruction (e.g., that caused by bronchospasm or the presence of foreign bodies in the airway) can greatly decrease dynamic compliance.¹¹ Dynamic compliance is calculated as the tidal volume divided by peak inspiratory pressure – PEEP. Modern anesthesia ventilators can calculate and trend compliance through tracing of pressure-volume curves.

Lung Elastic Recoil

The forces that cause elastic recoil of the lung are responsible for emptying the lung during exhalation and have a significant influence on lung compliance. In addition to actual elastic fibers, the surface tension of the liquid film that lines the alveoli contributes to elastic recoil of the lung. Surface tension occurs at a gas/liquid interface and is generated by the cohesive forces among the molecules of the liquid. Surface tension is what causes water to bead and form droplets.

Surface tension at the gas-fluid interface between the alveolar walls and the gas inside them contributes to reducing the size of alveoli, particularly when the alveoli are at low volumes. At end-expiration, surface tension increases the pressure required to inflate the alveoli, contributing to the flat portion of the lung compliance curve. This concept is often attributed to the law of Laplace ($P = T/r$), which states that if surface tension (T) is constant, pressure (P) would increase as radius (r) decreases. *Pulmonary surfactant* secreted by alveolar type II cells counteracts the influence of surface tension on the lungs. With surfactant present, as alveolar radius decreases, surface tension also decreases, so that pressure remains more constant. Surfactant consists of proteins and phospholipids,

primarily, dipalmitoylphosphatidylcholine. The surface active agent serves to lower the surface tension of the fluid lining the alveoli and decrease the work of breathing.

Although the law of Laplace has traditionally been applied to understanding alveolar pressure-tension relationships, there is controversy as to whether alveoli should be treated as spherical (and thus subject to the law) or not. Geometricians postulate that closely packed alveoli would not maintain the shape of spheres, but rather of polyhedrons because their sides would be flattened against each other. The classical application of Laplace described the concept of alveoli as distinct balloon-like structures wherein pressure differentials can cause small alveoli to collapse and expel their gas into larger ones. The fact that alveoli are not individually suspended, but rather part of a connective tissue mesh, argues against this concept. The presence of pores of Kohn also argues against this theory, because the pores allow pressure equalization between adjacent alveoli. Connective tissue and elastic forces probably play the most important role in preventing alveolar closure.¹²

It is clear that surfactant is crucial for reducing surface tension and preventing collapse of alveoli and, perhaps more importantly, small airways. The cylindrical shape of airways lends to the application of the law of Laplace to the role of surfactant in these structures. Surfactant probably also helps prevent fluid bridging (connection of fluid lining from opposite sides of an airway at low volumes), which could impair gas flow.¹³ In the fetus, surfactant is not produced until approximately 28 to 32 weeks of gestation and does not reach mature levels until approximately 35 weeks' gestation. The lack of surfactant is the prevalent cause of respiratory distress syndrome (RDS) in premature infants. Formation of surfactant can be hastened by the administration of glucocorticoids (particularly a steroid that crosses the placenta, such as betamethasone) to the parturient mother when premature delivery is threatened or imminent. The direct administration of synthetic surfactant to the airways of premature newborns has also greatly reduced the incidence of RDS. Amniocentesis is sometimes performed to determine whether mature surfactant levels are present in the premature fetus. The ratio of lecithin to

sphingomyelin (the L/S ratio) indicates the amount of mature surfactant (dipalmitoyl lecithin) in proportion to the amount of surfactant precursor (sphingomyelin).

Transpulmonary Pressure

Although the elastic forces of the lung tend to favor lung collapse, the chest wall is constantly under tension to expand. This is why normal inspiration requires very little energy. At the end of eupneic exhalation, the outward recoil of the chest wall is balanced by the inward elastic recoil of the lung. At this resting end-expiratory point, the opposing forces of the lungs and chest wall produce negative pressure in the pleural space.

The difference between intraalveolar pressure and intrapleural pressure is called the *transpulmonary pressure*. Under normal circumstances, the pleural pressure is always slightly negative, owing to the opposing forces of lung tissue contraction and chest wall expansion. The intrapleural pressure becomes slightly more negative during inspiration and slightly less negative during expiration. The transpulmonary pressure fluctuates as the alveolar pressure oscillates between slightly negative during inspiration to slightly positive during expiration, returning to zero whenever airflow is stopped at end-inspiration or end-expiration (Fig. 29.3). During normal inspiration, intraalveolar pressure fluctuates only by 1–2 mm Hg. Therefore very little pressure is applied during eupneic ventilation. If the lung compliance is reduced (i.e., resists inflation), during spontaneous respiration, more negative intrapleural pressure will be required to effect the same change in intraalveolar pressure and to inflate the lung. Therefore the pressure time product (PTP) rises (greater difference between intrapleural and intraalveolar pressure). Likewise, during positive pressure ventilation, the lungs' resistance to inflation is not the only contributor to dynamic or static pressure generated as a result of volume inflation. Stiffness of the chest wall, abdominal insufflation during laparoscopic surgery, obesity, trendelenburg position, and other factors can increase the pressure required to inflate the lungs. Traditional measures of lung compliance, based upon peak or plateau pressure, cannot differentiate these factors from stiffness of the lung parenchyma. High insufflating pressures or high PEEP

may cause barotrauma or volutrauma to the lung. However, if abdominal insufflation impedes lung expansion, then higher ventilating pressures may not represent high transmural pressures (intraalveolar to intrathoracic), but they may be required simply to overcome extraneous pressure from outside the lung and would not be as harmful to the lung.

FIGURE 29.3 Alveolar, pleural, and transpulmonary pressures. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:498.)

This differentiation provides the clinical application of PTP. In a patient with increased extraneous pressure (e.g., abdominal gas insufflation), the intrapleural pressure will be elevated. Therefore, although the peak inspiratory pressure may be elevated, the difference between them (i.e., the PTP) will be normal. The esophageal pressure is an accurate representation of the adjacent intrapleural pressure, and it can be measured using an esophageal measurement device which appears similar to an esophageal stethoscope. This allows calculation of the PTP. Transpulmonary pressure has been found to be an effective measure of compliance

which discounts extrapulmonary effects. This calculation can guide the selection of appropriate tidal volume and PEEP settings to achieve open lung status while avoiding over distention. Patients with acute lung injury (ALI) have demonstrated significantly improved oxygenation when ventilation was guided by maintaining PTP at 0–10 cm H₂O at end-expiration and less than 25 cm H₂O at end-inspiration.

Resistance to Breathing

In addition to the static elastic recoil of the lung, frictional resistance of lung tissues and resistance to airflow opposes inflation of the lung. Rheologic characteristics of airflow affect its ability to pass through conducting airways. Laminar flow is an orderly movement, where molecules are moving along a generally straight path. In laminar flow, the gas in the center of the stream moves faster than that closer to the wall because frictional resistance slows molecules near the vessel wall. Laminar flow is characterized by lower pressure than turbulent flow. During turbulent flow, resistance greatly increases because molecules move in various directions. The rheologic calculation of Reynolds number predicts when flow of a fluid (or gas) will be laminar or turbulent. Reynolds number (Re) is calculated as follows:

$$Re = \rho v d / \eta$$

where v = velocity of fluid flow, d = diameter of the vessel, ρ = density of the fluid, and η = viscosity of the fluid. This version of the formula would apply to flow through a tube (such as the airways). In open systems, *length* is substituted for diameter. When the inertial forces of density, velocity of flow, and diameter increase, Reynolds number increases. Increasing viscosity of the fluid reduces the product. Products up to 2000 predict laminar flow; above 4000 predict turbulent flow, and a transitional area exists when results are between those numbers.

Throughout the airways, both laminar and turbulent flows occur. True laminar flow occurs in smaller airways, where the diameter is

small and linear velocity is very low. Linear velocity is inversely proportional to cross-sectional area for any flow rate. Turbulence is greatest in large airways, and turbulence caused by branching of the airways produces the breath sounds heard on auscultation. Resistance to laminar flow follows Poiseuille's law ($R = 8\eta l/r^4$, where η equals viscosity). Resistance (R) to laminar airflow is directly proportional to the length (l) of the tube and inversely proportional to the fourth power of the radius (r). Therefore doubling the radius of the tube decreases resistance 16 (2^4) times. Normally, approximately 40% of the total airway resistance resides in the upper airways (nasal cavity, pharynx, and larynx).

Although resistance to airflow is greatest in individual small airways, the net total resistance to airflow of the small airways is very low because they represent a massive number of parallel pathways. Under normal circumstances, the greatest resistance to airflow resides in medium-sized bronchi, whose smooth muscle tone greatly affects airway resistance. During lung inflation, increasing lung volumes exert retractive forces on the airways, resulting in a reduction in airway resistance. During forced expiration, dynamic compression of the airways increases airway resistance and may promote airway collapse (most likely in small airways with no cartilaginous support).

The clinical application of these concepts resides in strategies to reduce airflow resistance. Bronchodilators will reduce resistance to airflow by increasing the radius of the pathway, as predicted by Poiseuille. Selection of an ETT size may confer greater or lesser resistance, based on the length and (much more significantly) the internal diameter of the tube. Clinical application of Reynolds number suggests that lower velocity (lower inspiratory flow or lower inspiratory:expiratory ratio) and lower density would promote laminar flow and create lower ventilating pressures. The reduction in density is the conceptual basis for combining helium with oxygen ("heliox") to improve pulmonary gas distribution in obstructive lung disease.¹⁴

Other influences on airflow include the autonomic nervous system and pathologic conditions. The autonomic nervous system affects the tone of the bronchial smooth muscle. The sympathetic nervous system, as well as sympathomimetic drugs (e.g.,

norepinephrine, epinephrine, and isoproterenol), produce bronchodilation. The parasympathetic nerves and parasympathomimetic drugs (e.g., acetylcholine) cause bronchoconstriction. Parasympatholytic drugs (e.g., atropine and ipratropium) therefore cause bronchodilation (though mildly). Irritation of the airway by foreign bodies or inhaled irritants causes reflex bronchoconstriction.

Lung Volumes

The following discussion of lung volumes uses the parameters of a normal 70-kg male. [Table 29.4](#) gives an overview of related terms and normal values. The amount of gas that enters and leaves the body with each eupneic breath is approximately 350 to 500 mL and represents the *tidal volume* (V_T). The *minute volume* (MV) equals V_T multiplied by the respiratory rate. However, because some ventilation occupies the conducting zone, only a portion of the minute ventilation (V_E) participates in gas exchange. The amount of *alveolar* ventilation in a minute equals V_T minus anatomic dead space (the volume of the conducting airways, which is approximately 2 mL/kg of body weight) multiplied by the ventilatory rate. The rate of alveolar ventilation will be indirectly proportional to the arterial CO_2 tension. The residual volume (RV) is the volume of gas left in the lung after a maximal exhalation (approximately 1.5 L). The RV cannot be removed from the lungs voluntarily and is important because it is a component of the functional residual capacity (FRC), which represents alveolar gas used for oxygenation of the blood between breaths or in periods of apnea. The expiratory reserve volume is the volume of gas expelled from the lungs during a maximal forced exhalation, starting at the end of a normal tidal exhalation. The inspiratory reserve volume is the volume of gas inhaled into the lungs during a maximal forced inhalation, starting at the end of a normal tidal inspiration (2.5 L).

TABLE 29.4

Glossary for Static Lung Volumes and Capacities

	Capacity
--	----------

			(mL)
Volumes			
Residual volume	RV	Volume of air remaining in the lungs after maximum expiration	1200
Expiratory reserve volume	ERV	Maximum volume of air expired from the resting end-expiratory level	1100
Tidal volume	V_T	Volume of air inspired or expired with each breath during quiet breathing	500
Inspiratory reserve volume	IRV	Maximum volume of air inspired from the resting end-inspiratory level	3000
Capacities			
Inspiratory capacity	$IC = IRV + V_T$	Maximum volume of air inspired from the end-expiratory level (the sum of IRV and V_T)	3500
Vital capacity	$VC = IRV + V_T + ERV$	Maximum volume of air expired from the maximum inspiratory level	4500
Functional residual capacity	$FRC = RV + ERV$	Volume of air remaining in the lungs at the end-expiratory level (the sum of RV and ERV)	2300
Total lung capacity	$TLC = IRV + V_T + ERV + RV$	Volume of air in the lungs after maximum inspiration (the sum of all volume compartments)	5800

The sum of the four basic lung volumes is the TLC. Several types of lung capacity measures exist, each of which is the sum of two or more lung volumes. TLC is the volume of air in the lungs after a maximal inspiratory effort (approximately 6 L in a 70-kg adult). The vital capacity is the amount of air that can be forcibly exhaled from the lungs after a maximal inspiratory effort (approximately 4.5 L). The FRC is the volume of gas contained in the lungs after normal quiet expiration. It is the sum of the RV and expiratory reserve volume (approximately 3 L). The inspiratory capacity is the volume of air inhaled into the lungs during a maximal inspiratory effort that begins at FRC (approximately 3 L). [Fig. 29.4](#) gives a graphic representation of lung volumes and normal flow measurements.

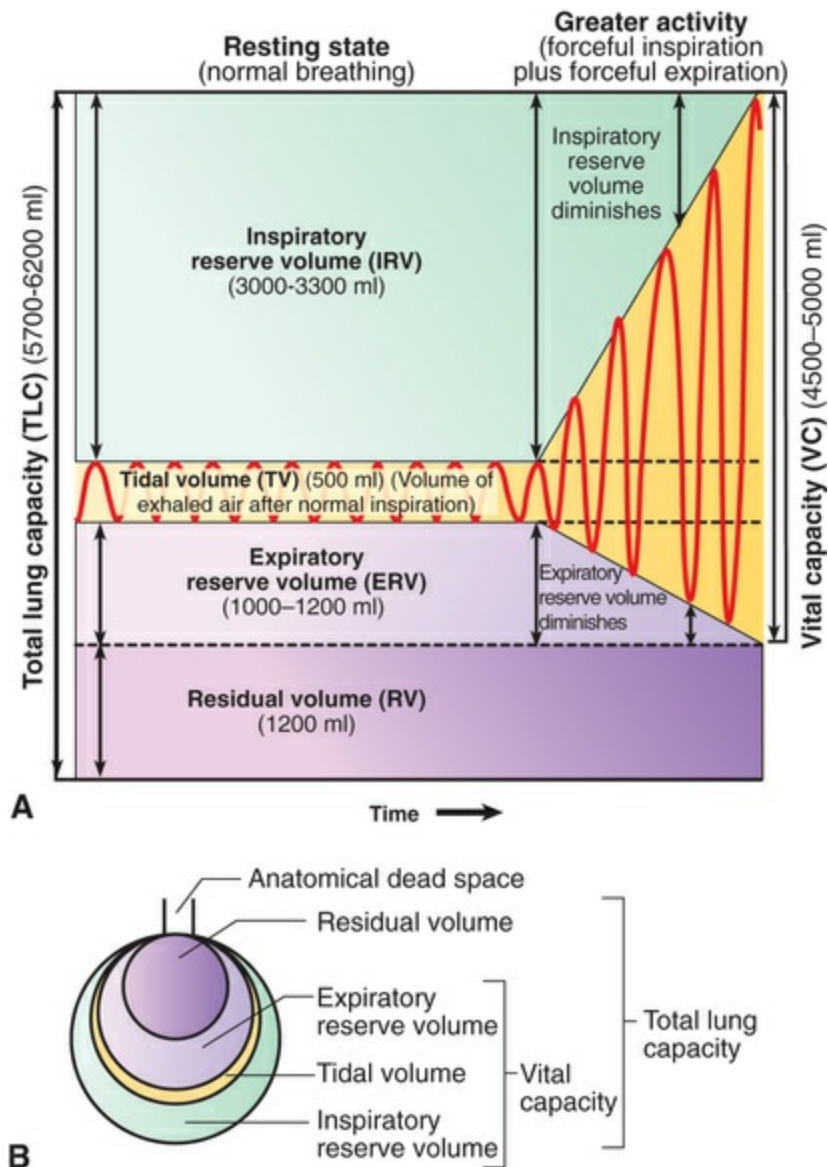

FIGURE 29.4 Pulmonary ventilation volumes. The chart in **A** shows a tracing like that produced with a spirometer. The diagram in **B** shows the pulmonary volumes as relative proportions of an inflated balloon. During normal, quiet breathing, approximately 500 mL of air is moved into and out of the respiratory tract, an amount called the *tidal volume*. During forceful breathing (like that during and after heavy exercise), an extra 3300 mL can be inspired (the inspiratory reserve volume), and an extra 1000 mL or so can be expired (the expiratory reserve volume). The largest volume of air that can be moved in and out during ventilation is called the *vital capacity*. Air that remains in the respiratory tract after a forceful expiration is called the *residual volume*. (From Patton KT, Thibodeau GA. *The Human Body in Health and Disease*. 6th ed. St. Louis: Elsevier; 2014:461.)

Closing volume describes the phenomenon during exhalation when small airways collapse, hindering further emptying of lung units distal to them. Closing volume is defined as the volume above residual volume where small airways close, whereas closing capacity describes the absolute volume of gas in the lung when small airways close (the closing capacity is the sum of the closing volume plus the residual volume). The closing volume increases from approximately 30% of the TLC at age 20 years to approximately 55% at age 70 years. Certain conditions increase the closing volume, such as supine positioning, pregnancy, obesity, COPD, congestive heart failure (CHF), and aging.¹⁵ In abnormal conditions, if the closing volume exceeds the FRC, airway closure occurs during tidal breathing, resulting in poorly ventilated or unventilated alveoli and intrapulmonary shunting. The shearing forces of repetitive airway opening and closing also leads to airway injury.¹⁶ Measurement of closing volume analyzing washout characteristics of inert gas is a more sensitive indicator of small airway disease (such as from smoking) than is measurement of spirometry.¹⁵

Gas Exchange in the Lungs

Dead Space

Dead space refers to ventilation that does not participate in gas exchange. The volume of the conducting airways represents the *anatomic dead space* and normally equals approximately 2 mL/kg of body weight. Alveoli that are ventilated but not perfused comprise the *alveolar dead space* because they do not deliver oxygen nor do they remove CO₂ from the blood. The sum of the anatomic dead space plus the alveolar dead space is the physiologic dead space (V_D). Because perfused ventilation equilibrates with arteriolar CO₂ and nonperfused (dead space) ventilation does not, the proportion of dead space ventilation can be calculated by comparing the ratio of CO₂ in the arterial blood and in the exhaled gas. This is calculated with the Bohr equation:

$$\% V_D = (PaCO_2 - PECO_2) / PaCO_2$$

where $PaCO_2$ is the arterial partial pressure of CO_2 as determined from arterial blood gas (ABG) measurement, and $PECO_2$ is the PCO_2 (partial pressure of carbon dioxide) of mixed expired gas as determined with a capnogram. Certain pathologic conditions, such as pulmonary embolus, increase the alveolar dead space and can abruptly decrease the end-tidal CO_2 ($ETCO_2$) levels monitored with capnography.¹⁻⁵

Regional Distribution of Alveolar Ventilation

Gravity and other factors influence ventilation and perfusion such that both are unevenly distributed throughout the lungs. In the normal upright lung, the alveoli at the base are more compliant than those at the apex, meaning that those at the base exhibit a greater change in volume with each breath. This is considered to be a result of the effect of gravity on the interconnected parenchyma of the lung, whereby the greatest “pull” is exerted on the more superior portions of lung. Therefore the alveoli in those areas are held in a more open state even at rest, whereas alveoli at the base are more compressed. During inspiration then, the alveoli at the bases are able to accept more new gas. Alterations to the resting volume or impingements on lung compliance may change this relationship. Pregnancy or obesity may hinder expansion of lower units or may cause compression that results in collapsed dependent areas. In that case, other lung areas become the most compliant. The sigmoidal shape of the compliance curve (see [Fig. 29.2](#)) reveals that alveoli become less compliant at higher volumes (e.g., in nondependent alveoli at high lung volume) and also at very low volumes (e.g., in dependent alveoli at very low resting lung volumes).

Alveolar Oxygen and Carbon Dioxide Levels

The levels of O_2 and CO_2 in alveolar gas are determined by several factors. These include the amount of alveolar ventilation, the inspired concentrations of O_2 and CO_2 , the flow of mixed venous blood to the lungs, and the body's consumption of O_2 and

production of CO₂. In a person spontaneously breathing room air, each breath brings approximately 350 mL of fresh air (21% of which is O₂) into the alveoli, which already contain over 2 L of gas (the FRC). Each exhalation removes approximately 350 mL of gas consisting of 5% to 6% CO₂. Every minute, approximately 250 mL of O₂ diffuse from the alveoli into the pulmonary capillary blood, whereas approximately 200 mL of CO₂ diffuse from the pulmonary capillary blood into the alveoli. The ratio of the amount of CO₂ produced to the quantity of O₂ consumed is called the *respiratory quotient* (RQ = 200 mL CO₂ produced divided by 250 mL O₂ consumed = 0.8). The proportion of CO₂ production and O₂ consumption varies with energy source (greater with more carbohydrates and lower with more fat), but 0.8 is the typical result from a mixed diet.

Approximately 21% of dry atmospheric air is O₂; therefore, at the standard barometric pressure of 760 mm Hg, the partial pressure of O₂ in atmosphere (PO_{2atm}) equals 0.21 × 760 mm Hg, or 160 mm Hg. Only 0.04% of atmospheric air is CO₂, so PCO_{2atm} = 0.3 mm Hg. As the inspired air passes through the upper airways, it is heated to body temperature and humidified to a relative humidity of nearly 100%. The partial pressure of water vapor at body temperature is a fairly constant 47 mm Hg. The PO₂ of inspired air (PIO₂) saturated with water vapor at standard atmospheric pressure = 0.21 × (760 mm Hg – 47 mm Hg), or 149 mm Hg.

The inspired gas mixes with the gas already in the alveoli (FRC) and rapidly equilibrates with the pulmonary capillary blood. The alveolar PO₂ (PAO₂) can be calculated with the alveolar air equation:

$$PAO_2 = PIO_2 - (PACO_2/RQ)$$

Thus, during breathing of atmospheric air, when alveolar PCO₂ (PACO₂) is 40 mm Hg and the RQ is 0.8, then PAO₂ = (0.21 × [760 mm Hg – 47 mm Hg]) – 40 mm Hg/0.8 = 99 mm Hg. Therefore, using the alveolar air equation, one can calculate the PAO₂ if the atmospheric pressure, inspired O₂ concentration, and PACO₂ (which is
