approximately equal both to the end-tidal PCO_2 and the arterial PCO_2 [$PaCO_2$]) are known, because water vapor pressure and RQ are fairly constant. If the inspired O_2 concentration differs from that of room air, then that fraction replaces the 0.21. PAO_2 is less than PIO_2 because the CO_2 is delivered to the alveoli by the pulmonary blood flow at the same time that O_2 is taken up from the alveoli. Therefore PAO_2 divided by the RQ approximates the amount of O_2 that was removed from the alveoli by the pulmonary capillary blood flow.¹⁻⁵

Effects of Alveolar Ventilation on Carbon Dioxide and Oxygen

Within certain limits, $PACO_2$ is inversely proportional to alveolar ventilation. If alveolar ventilation is doubled, then $PACO_2$ and $PaCO_2$ are reduced by half (if CO_2 production remains unchanged).

As alveolar ventilation increases, PAO_2 also increases slightly. However, doubling alveolar ventilation does not double PAO_2 ; according to the alveolar air equation, reduction of the $PACO_2$ raises the PAO_2 , bringing PAO_2 closer to the PIO_2 .

Pulmonary Blood Flow

The lungs have a dual blood supply: (1) the bronchial arteries (usually one on the right and two on the left), and (2) the pulmonary arteries, which bring unoxygenated blood to the lungs from the right ventricle. The bronchial arteries arise from the descending aorta and carry approximately 2% of the cardiac output (CO) to nourish the nonrespiratory tissues: lung parenchyma, bronchi, nerves, pulmonary vessels, and visceral pleura. Bronchial arteries do not participate in fresh gas exchange with the alveoli. The branches of the bronchial arteries accompany the bronchial divisions as far as the respiratory bronchioles. The bronchial veins return deoxygenated blood from the first part of the bronchi and drain into the azygos, hemiazygos, or posterior intercostal veins. The remainder of the deoxygenated blood is returned via the pulmonary veins.

The pulmonary circulation provides blood flow to the structures

distal to the terminal bronchioles, including distal nonrespiratory tissues and the respiratory units. The pulmonary artery arises from the right ventricle and branches into the right and left pulmonary arteries, which further branch to accompany the bronchi. Although the pulmonary artery receives the entire CO of the right ventricle, its walls are less muscular and more distensible than those of the aorta, and the pulmonary artery pressure (PAP) is considerably less than the pressure in the aorta. The pulmonary arteries rapidly subdivide into terminal branches, which have thinner walls, much less smooth muscle, and greater internal diameters than corresponding branches of the systemic arterial tree. Pulmonary vessels are also much shorter than systemic vessels, and according to Poiseuille's law, a decrease in length decreases resistance. Subsequently, pulmonary vascular resistance (PVR) is very low, approximately one-eighth of systemic vascular resistance (SVR).

Pulmonary vascular resistance is fairly evenly distributed among the arteries, capillaries, and veins, whereas most of the resistance in the systemic circulation is in the muscular arteries. Although pulmonary venous resistance is very low, it can decrease further when blood flow increases. This results from passive changes in resistance caused by recruitment and distensibility of the pulmonary vessels. *Recruitment* is the opening to perfusion of pulmonary vessels that were previously not perfused. *Distensibility* is an increase in diameter of a pulmonary vessel that is already being perfused, and it results from the vessel's compliance.

The sympathetic nervous system influences PVR, as do certain substances circulating in the pulmonary blood. PVR is increased by norepinephrine, serotonin, histamine, hypoxia, endothelin, leukotriene, thromboxane, prostaglandin (e.g., $\text{PGF}_2\alpha$), and hypercapnia.¹⁷ It is decreased by prostacyclin analogs (e.g., epoprostenol), endothelin receptor antagonists (e.g., bosentan), phosphodiesterase type 5 inhibitors (e.g., sildenafil),¹⁸ acetylcholine,¹⁹ and isoproterenol (minimal effect).²⁰ Short-term or limited-use medications to reduce PVR include inhaled nitric oxide, sildenafil, tadalafil, iloprost, treprostanil, and riociguat.¹⁸

The respiratory units are the site of gas exchange between alveolar air and pulmonary capillary blood. After participating in gas exchange in the respiratory zone, blood is returned to the heart

by way of the pulmonary veins. The pulmonary vessels also anastomose with the bronchial vessels at the junction of the terminal and respiratory bronchioles. Therefore the pulmonary veins carry oxygenated blood from the respiratory units and deoxygenated blood from the visceral pleura and distal bronchi. The venous bronchopulmonary anastomoses are significant in their contribution to the normal anatomic shunt (the addition of unoxygenated blood to the left chambers of the heart). Evidence of this crossover is observed during complete cardiopulmonary bypass: blood enters the left atrium, even though all blood is shunted from the right heart by the venous cannula. This occurs because blood flow continues through the bronchial vessels, which anastomose with the pulmonary veins, which in turn ultimately drain into the left atrium; this is one reason a ventricular drain may be inserted during the surgery to prevent overdilatation of the heart. Five pulmonary veins ultimately return blood to the left heart.

Influences on Pulmonary Blood Flow

Although pulmonary vessels are less muscular as compared to systemic arteries, the low pressure of the system makes pulmonary blood flow very sensitive to small changes in arterial tone. Unlike the systemic circulation, where hemodynamic influences are more global, pulmonary blood flow is more prevalently regulated locally by changes in oxygen and carbon dioxide tension. In contrast to the systemic circulation, high oxygen tension and hypocapnia vasodilates pulmonary vessels (which helps those vessels pick up more oxygen), whereas hypercarbia and acidosis cause vasoconstriction. Having the strongest influence on pulmonary local regulation, blood flow to hypoxic or atelectatic alveoli is actively diverted at a precapillary site by a process known as *hypoxic pulmonary vasoconstriction*. This protective physiologic reflex shunts blood away from focal diseased areas of the lung and improves matching of ventilation and perfusion. See [Chapter 30](#) for a discussion of the significance of hypoxic pulmonary vasoconstriction during pulmonary surgery.

Relationship of Pulmonary Blood Flow and Ventilation

In the normal upright lung, a greater portion of the blood flow is distributed to the dependent regions because of the effects of hydrostatic pressure and greater distention of dependent pulmonary vessels. Likewise, differences in compliance of the ventilating tissue also result in a general increase in the proportion of ventilation from nondependent (least ventilation) to dependent (most ventilation) of the lungs. There are two caveats to these rules. Although they describe what occurs during spontaneous respiration well, the spatial distribution of these relationships is altered during positive-pressure ventilation. In addition, the lung zones are commonly portrayed in textbooks in nicely demarcated lines of latitude, a model appreciated for its simple elegance.

Although there may be a general increase in perfusion from top to bottom of the lung, it should be noted that gravity alone does not determine physiologic perfusion. If it did, then it would be observed that the greatest blood flow in the body would be in the lower extremities, with the least in the head, a cogent point of explanation offered by Levitzki.²¹ Gravity interacts with elastic forces to influence ventilation and with vessel recruitment to alter distribution of perfusion. There is evidence that regional perfusion zones may be situated with the greatest blood flow in the lower, core areas of the lungs, with zones 2 and 1 more resembling concentric spheres radiating toward the periphery.²² Nonetheless, the classic explanation of ventilation-perfusion zones described by West in 1964 serves as a useful model for considering the relationships between ventilation and perfusion,²³ and more specifically, the conditions under which intraalveolar pressure may impede vascular flow.²⁴ In this model, regions of the lung are divided into zones, according to the relative intravascular and intraalveolar pressure (Fig. 29.5).

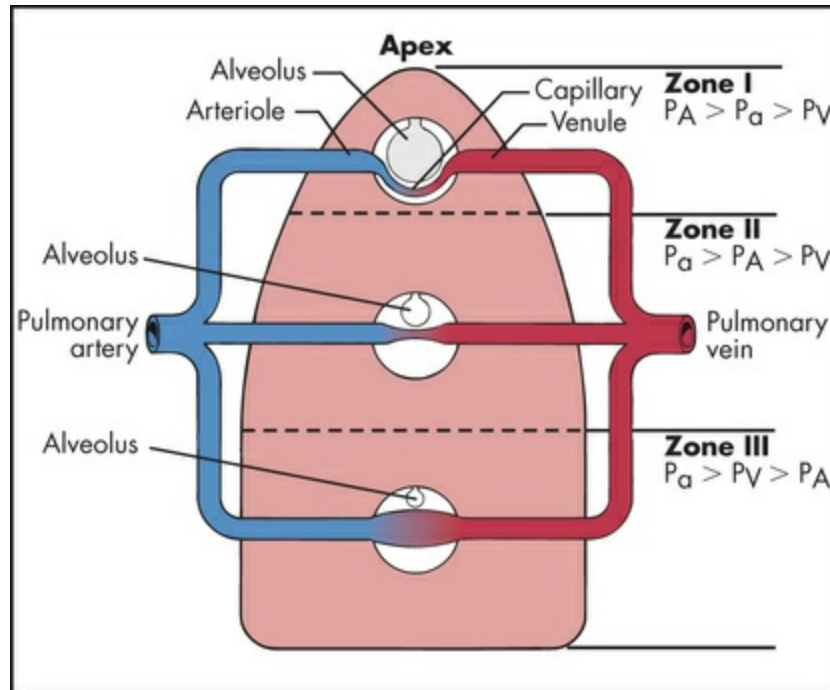

FIGURE 29.5 Gravity and alveolar pressure. Effects of gravity and alveolar pressure on pulmonary blood flow in the three lung zones. In zone I, alveolar pressure (P_A) is greater than arterial and venous pressure, and no blood flow occurs. In zone II, arterial pressure (P_a) exceeds alveolar pressure, but alveolar pressure exceeds venous pressure (P_V). Blood flow occurs in this zone, but alveolar pressure compresses the venules (venous ends of the capillaries). In zone III, both arterial and venous pressures are greater than alveolar pressure and blood flow fluctuates, depending on the difference between arterial and venous pressures. (From McCance KL, Huether SE.

Pathophysiology: The Biologic Basis for Disease in Adults and Children. 7th ed. St. Louis: Elsevier; 2014:1240.)

In the parts of the lung where alveoli exist at a greater resting volume, alveolar pressure can exceed PAP, so that perfusion is impeded. This is called *zone 1* and represents alveolar dead space because the region is ventilated but not perfused. Normally, zone 1 exists only in a very small margin of lung area around the apical border during spontaneous ventilation, but the use of PEEP or high airway pressures during mechanical ventilation can create or expand this zone.

The intermediate zone, where there is a variable relationship between vascular and alveolar pressure, is *zone 2*. A point is described in zone 2 along the continuum of decreasing intraalveolar

pressure where arterial pressure exceeds alveolar. Below that point, flow is solely dependent upon arterial flow, and unrelated to alveolar or venous pressure. This concept is described as a waterfall zone, as when rising water finally overflows a dam. At that point, the height of the dam does not influence the flow, only the upstream inflow does. The zone 2 relationship is not static, but fluctuation in alveolar pressure related to respiration can variably occlude capillary flow.

The dependent portion of the lung, where both pulmonary arterial and venous pressures exceed alveolar pressure, is known as *zone 3*. This zone represents continuous blood flow, and it is in this zone that the tip of a pulmonary artery catheter should lie, for example, to ensure continuous communication with the left heart. Alveoli in this zone rest at a lower volume than in zone 1, and so they have greater compliance and represent the greatest proportion of ventilation in the lung; however, the perfusion is also greatest in this region. Thus there is no obstruction to blood flow. West later described a fourth zone in the most dependent portions of lung, wherein extravascular pressure from mechanical compression or interstitial fluid compresses the vessels and occludes their flow.²⁵

Pulmonary Edema

The normal distance for diffusion from the alveolar air space into the pulmonary capillary blood cells is less than 1 micrometer. The gas must traverse the surfactant layer, the flat alveolar type I cells, the interstitial space, the endothelial cells that make up the wall of the pulmonary capillary, a minute amount of plasma, and then finally the membrane of the red blood cell. The pulmonary system is designed to allow free passage of gases across this series of structures, collectively called the *respiratory membrane*. However, that inherent “leakiness” does predispose this area to unintended movement of fluid.

There is a fine balance between the plasma colloid oncotic pressure, which tends to hold fluid in the pulmonary capillaries, and the capillary hydrostatic pressure, interstitial fluid colloid oncotic pressure, and negative interstitial fluid pressure, which all tend to favor fluid movement into the interstitial space. In normal circumstances, the net effect of these forces favors movement into

the interstitium, helping to divert fluid from the adjacent “leaky” capillaries away from the alveoli and thereby prevent accumulation there.²⁶ Although the interstitium has a large compliance for removing accumulating transudate fluid, derangements in the previously mentioned factors can lead to fluid accumulation in the interstitium or alveoli and disrupt gas exchange.

Pulmonary vascular congestion causes increased capillary leakage into the interstitium, resulting in increased distance for gas diffusion. If the capillary leak overcomes the compliance of the interstitial space, the fluid may then begin to pass into the alveoli. Pulmonary edema affects oxygenation more than CO₂ excretion because CO₂ is 20 times more diffusible than O₂. Many conditions can result in pulmonary edema. The high capillary pressures associated with heart failure or the excessive administration of intravenous fluids can increase water within the lungs. The size of the pulmonary capillary pores can be increased by sepsis, smoke inhalation, and other toxic conditions. Brain trauma can produce an intense sympathetic discharge, resulting in neurogenic pulmonary edema.

A condition that occasionally occurs during emergence from anesthesia is postobstructive pulmonary edema, also referred to as *negative-pressure pulmonary edema* (NPPE). After extubation, if the patient experiences laryngospasm or airway obstruction and then attempts forceful inhalation against the closed glottis, the drastic increase in negative intrathoracic pressure pulls fluid from the pulmonary capillaries and into lung tissue. The onset of pulmonary edema is rapid and treatable. The symptoms resolve rapidly; in most cases, patients are discharged within 24 hours. Treatment includes removing the precipitating condition (relieving airway obstruction) and general supportive measures: oxygen, maintenance of a patent airway, noninvasive continuous positive airway pressure (CPAP), and intubation with PEEP if required to maintain oxygenation. Unlike pulmonary edema related to fluid overload, treatment for NPPE does not routinely include diuretic therapy. However, many reported cases do include the use of diuretics and corticosteroids.²⁷ The three mainstays of treatment remain treatment of the precipitating condition, normalization of ventilation and oxygenation, and reduction of lung congestion and

Box 29.4 Treatment summary is included in [Box 29.4](#).

Management of Pulmonary Edema

- Correct underlying cause
- Support oxygenation with supplemental O₂, CPAP, mechanical ventilation, and PEEP, as necessary
- Consider steroids to stabilize capillary membranes
- For cardiogenic pulmonary edema:
 - Administer diuretics
 - Improve hemodynamics—morphine or nitroglycerin to reduce preload; inotropes or vasodilators to promote forward flow

CPAP, Continuous positive airway pressure; *PEEP*, positive end-expiratory pressure.

Ventilation-Perfusion Relationships in the Lung

Normally, ventilation (V) is approximately 4 L/min, whereas pulmonary blood flow (Q) is approximately 5 L/min. Therefore the ventilation-perfusion ratio (V/Q) for the entire lung is 0.8. However, V and Q must be matched at the alveolar-capillary level for gas exchange to occur within the lung.

Dependent portions of the lung receive a greater amount of blood flow as compared to the nondependent portions because of the effects of gravity and vessel recruitment and distensibility.

Additionally, ventilation is predominant to the more compliant portions of the lung. Normally at FRC, the dependent regions of the lung are more compliant, and the alveoli of the nondependent portions are more inflated (“tented open”) and less compliant. Therefore relatively more ventilation and perfusion favor the dependent portions, and this results in optimal gas exchange.

Although distribution of ventilation normally decreases movement from dependent to nondependent regions of the lung, the accompanying decrease in perfusion is even greater; therefore the ratio, V/Q , increases as measured progressively from dependent to nondependent lung areas (Fig. 29.6). In addition, V/Q varies: in alveoli that are ventilated but not perfused, Q equals 0, so V/Q equals infinity (i.e., dead space); in alveoli that are perfused but not ventilated, V equals 0, so V/Q equals 0 (i.e., a shunt). Similarly, alveoli that are ventilated but poorly perfused are described as “dead space,” whereas alveoli that are perfused but poorly ventilated are termed *shuntlike*; the latter contribute to the V/Q mismatch of the lung. Shuntlike alveoli (low V/Q) have relatively low PO_2 and high PCO_2 when compared with deadspace-like alveoli (high V/Q), which have relatively high PO_2 and low PCO_2 .

FIGURE 29.6 Ventilation-perfusion relationships throughout the lung.

Ventilation perfusion mismatch can result from a number of causes. A pulmonary embolus of thrombus, air, or other material that passes through the pulmonary artery to obstruct blood flow through the pulmonary capillaries creates alveolar dead space. Likewise, very high airway pressure from aggressive ventilation or PEEP can produce alveoli that are ventilated but not perfused. Similarly, very low CO results in low pulmonary blood flow and therefore increases the V/Q ratio. This is reflected by a low $ETCO_2$ on capnography and an increased gradient between the end-tidal

and the arterial PCO_2 .

Total pulmonary venous admixture (unoxygenated blood delivered to the left side of the heart) is the sum of the shunt and shuntlike states. It can be calculated with the shunt equation, which is discussed below. Bronchopulmonary anastomoses are a cause of normal anatomic shunt, along with thebesian veins, which drain into the left side of the heart and usually account for less than 2% of the CO. Airway obstruction, alveolar collapse (atelectasis), and alveolar filling processes, such as pneumonia, also produce shunt.

Some diagnostic studies can definitively identify ventilation-perfusion abnormalities. A lung scan after a single breath of xenon 133 (^{133}Xe) gas or aerosolized technetium-99m can be used to determine the location of poorly ventilated areas in the lung, whereas IV injection of dissolved radioisotope reveals areas of the lung that are poorly perfused. Together, these comprise a ventilation-perfusion scan. Pulmonary angiography (radiography with injection of intravenous [IV] contrast dye) of the pulmonary vasculature can be used to determine whether any pulmonary blood vessels are obstructed, such as with a pulmonary embolism (PE).¹⁻⁵

Effects of General Anesthesia on Respiratory Physiology

General anesthesia affects the matching of ventilation and perfusion in several ways. Changing position from upright to supine and induction of general anesthesia results in a significant decrease in the FRC (see [Chapter 23](#)). With positive-pressure ventilation, the distribution of ventilation becomes more uniform throughout the lung, so both the dependent and nondependent alveoli receive approximately the same amount of ventilation. This leads to a wider scatter of ventilation and perfusion because there is relatively more ventilation of underperfused alveoli. General anesthesia also causes a significant decrease in CO, which is exacerbated by positive-pressure ventilation, especially if it is accompanied by PEEP. This may promote an extension of zone 1 areas, although this theoretic effect is probably overstated. Atelectasis is a common finding with general anesthesia and is the main cause of the 10%

shunt commonly observed in patients under anesthesia.²⁶

Although hypoxic pulmonary vasoconstriction is partially effective in diverting blood flow away from poorly ventilated lung regions, most inhaled anesthetics (as well as potent vasodilators, such as nitroprusside and nitroglycerin) decrease the effectiveness of hypoxic pulmonary vasoconstriction, whereas most IV anesthetics have minimal effects. The inhibition of hypoxic pulmonary vasoconstriction contributes to the decrease in PaO₂ and the increase in the alveolar-arterial PO₂ difference usually occurs when volatile inhaled anesthetic agents are used in significant concentrations.

Although general anesthesia, particularly when administered in combination with muscle relaxants, increases chest-wall compliance. Laryngoscopy and endotracheal intubation can increase airway resistance by stimulating airway irritant receptors, thereby decreasing dynamic compliance. However, most inhaled anesthetics (except for nitrous oxide [N₂O]) act as bronchodilators. In addition, medications that are used to produce general anesthesia depress the ventilatory response to CO₂, metabolic acidosis, and hypoxia (as discussed later in this chapter).²⁸

Oxygen and Carbon Dioxide Exchange

As blood flows through the lungs, the mean pulmonary transit time is approximately 4 to 5 seconds, with the blood spending approximately 0.75 second in the pulmonary capillaries. However, in the normal lung, it takes only one-third of the time, or 0.25 second, for equilibration to occur between the alveolar air and the pulmonary capillary blood. During exercise, CO may be so greatly increased that the time a blood cell spends in a pulmonary capillary can be reduced to 0.25 second. This decreased time available for diffusion has a much greater effect on exchange of O₂ than on that of CO₂ because CO₂ diffuses approximately 20 times more rapidly than O₂ does. *Diffusivity* is defined as the solubility divided by the square root of the molecular weight. Carbon dioxide is a heavier molecule than O₂, but it is 24-fold as soluble in body fluids as O₂.⁴

Oxygen Transport

The blood carries O_2 in two ways: (1) physically dissolved in the plasma, and (2) bound to hemoglobin (Hgb) in the red blood cells. Normally 99.7% of the O_2 carried is bound to hemoglobin. Without adequate hemoglobin, the cardiovascular system could not transport sufficient O_2 to meet the metabolic demands of the tissues.

The solubility coefficient of oxygen in plasma is 0.003, so there is 0.003 mL of O_2 per every 1 mm Hg partial pressure of PO_2 dissolved in 100 mL of whole blood. Therefore, with a PaO_2 of 100 mm Hg, only 0.3 mL of O_2 is transported dissolved per deciliter of plasma. Each gram of hemoglobin can combine with 1.39 mL of oxygen; however, because of factors that contaminate this process (such as the presence of methemoglobin), a factor of 1.36 is applied in clinical calculations. Therefore, if the level of hemoglobin is 10 g/100 mL, then at 100% saturation, 1.36 mL of O_2 is bound to hemoglobin per 100 mL of blood. Note that a hemoglobin level of 10 g/100 mL of blood corresponds to a hematocrit of 30% as the hematocrit is normally approximately equal to the hemoglobin level multiplied by 3.

The normal hematocrit for a male is approximately 45% (Hgb 15 g/dL) and for a female is approximately 39% (Hgb 13 g/dL). Centrifugation of the blood in a capillary tube separates the cells from the plasma. A thin layer called the *buffy coat* separates the plasma and the red blood cells (erythrocytes). This thin layer (approximately 1% of the volume of the blood) consists of white blood cells and platelets.⁴

Oxyhemoglobin Dissociation Curve

The affinity of hemoglobin for oxygen fluctuates with various physiologic conditions. This unique characteristic means that hemoglobin can more efficiently carry oxygen, because in the lung, it can bind much more oxygen as compared to simple diffusion. Hemoglobin can then readily unload oxygen for delivery in the tissues. The affinity is described by the relationship between the saturation of hemoglobin at a given PO_2 in the plasma and is represented by the oxyhemoglobin ($HgbO_2$) dissociation curve (see Fig. 18.8). This relationship between PO_2 and $HgbO_2$ is described by a sigmoidal curve that is steep at lower PO_2 values and nearly flat

when the PO_2 is greater than 70 mm Hg. As the PO_2 of the plasma increases, the amount of O_2 bound to the hemoglobin also increases, but not in a linear manner. This phenomenon occurs as each of the four hemoglobin subunits combines with O_2 , and each combination facilitates the next. Similarly, when the O_2 is unloaded at the peripheral tissues, each dissociation facilitates the next. Therefore this S-shaped curve is extremely important physiologically. Interaction between O_2 and hemoglobin is also influenced by pH, PCO_2 , temperature, and the concentration of 2,3-diphosphoglycerate (a metabolite of glucose hydrolysis).

The changing affinity of hemoglobin for O_2 facilitates loading at the pulmonary capillaries and unloading of the O_2 at the peripheral tissues. The S-shaped Hgb O_2 dissociation curve is displaced to the left of the normal curve by hypocapnia, a decrease in temperature, alkalosis, and a decrease in 2,3-diphosphoglycerate levels, resulting in an increased affinity of the hemoglobin for O_2 (a higher saturation for a given PO_2). When exposed to increased temperature, hypercapnia, acidosis, and elevated 2,3-diphosphoglycerate levels, the affinity of hemoglobin for O_2 decreases. This results in a shift of the Hgb O_2 dissociation curve to the right, and therefore O_2 more readily diffuses to the tissues. Note that the conditions that favor the release of O_2 from the hemoglobin to the tissues are likely to be associated with increased tissue metabolism, which would increase the O_2 demand. The influence of pH and PCO_2 on the Hgb O_2 dissociation curve is referred as the *Bohr effect*. The position of the oxyhemoglobin curve can be quantified by the P_{50} . The P_{50} corresponds to the PaO_2 at which 50% of the hemoglobin is saturated. Under normal conditions, adult human blood has a P_{50} of 26 to 27 mm Hg. If the Hgb O_2 dissociation curve shifts to the right, the P_{50} increases; if it shifts to the left, the P_{50} decreases.

Other factors that affect O_2 transport include carbon monoxide poisoning and methemoglobinemia. Carbon monoxide binds to hemoglobin (forming carboxyhemoglobin) with 210 times the affinity of O_2 .²⁹ The carbon monoxide binds with hemoglobin at the

site that O₂ would occupy, making the carboxyhemoglobin unable to transport O₂. Without a multiple-channel oximeter, carboxyhemoglobin provides a misleadingly high reading because it interprets the hemoglobin as being “saturated,” without distinguishing the inability of the hemoglobin to unload O₂.

Methemoglobin is hemoglobin with its iron molecule in its ferric state (Fe³⁺) instead of the normal ferrous state (Fe²⁺). In the ferric state, the hemoglobin iron atoms do not combine with O₂.

Methemoglobinemia can be caused by nitrate poisoning (nitroprusside overdose) or toxic reactions to oxidant drugs, such as the local anesthetic prilocaine. Methemoglobinemia is treated with O₂ therapy and methylene blue at a dose of 1 to 2 mg/kg administered intravenously over 5 minutes.³⁰

Oxygen Content Calculations

Hemoglobin saturation is continuously monitored in anesthetized patients, but the saturation provides only a relative value; 100% saturation of a hemoglobin level that is one-half of normal represents the same amount of oxygen as a 50% saturation of the normal amount of hemoglobin. Absolute values for the amount of O₂ in arterial blood are yielded by the O₂ content equation:

$$CaO_2 = (1.36 \times \text{Hgb} \times \text{arterial Hgb saturation}) + (\text{PaO}_2 \times 0.003)$$

where CaO₂ is the arterial O₂ content, and PaO₂ and percent of Hgb saturation are obtained from ABG analysis. CaO₂ is normally approximately 20 mL of O₂ per 100 mL of arterial blood (when hemoglobin is 15 g/dL and PaO₂ greater than 90 mm Hg).

The amount of O₂ in mixed venous blood is calculated with the following equation:

$$C\bar{v}O_2 = (1.36 \times \text{Hgb} \times \% \text{ mixed venous Hgb saturation}) + (\text{P}\bar{v}O_2 \times 0.003)$$

where C \bar{v} O₂ is the mixed venous O₂ content, and P \bar{v} O₂ and percent of hemoglobin saturation are obtained from mixed venous blood

gas analysis of blood drawn from the distal lumen of a pulmonary artery catheter (the only site in the body with truly mixed venous blood). $C\bar{v}O_2$ is normally approximately 15 mL of O_2 per 100 mL of mixed venous blood when hemoglobin is 15 g/dL and $P\bar{v}O_2$ is 40 mm Hg.

Subtraction of $C\bar{v}O_2$ from CaO_2 yields the arteriovenous O_2 content difference. This difference is useful in determining the relationship between O_2 delivery to the body's tissues and the O_2 demand of the tissues. Normally the difference is approximately 5 mL/dL of blood. A difference greater than 5 mL/dL of blood can be associated with low CO because the blood takes longer to traverse the capillaries in the tissues; therefore more O_2 is extracted. A difference of less than 5 mL/dL of blood can be associated with systemic arteriovenous shunts, which allow blood to bypass the tissue capillaries; such shunts occur during hyperdynamic sepsis.

The amount of O_2 in pulmonary capillary blood is calculated with the following equation:

$$CpCO_2 = (1.36 \times Hgb \times \% \text{ pulmonary capillary Hgb saturation}) + (PpCO_2 \times 0.003)$$

where $CpCO_2$ is the pulmonary capillary O_2 content. $PpCO_2$ (partial pressure of oxygen in the pulmonary capillary) is derived from the alveolar air equation described earlier in this chapter; the assumption is made that pulmonary capillary blood equilibrates completely with the partial pressure of oxygen in the alveolar air. The pulmonary capillary oxygen saturation cannot be measured, but is estimated by plotting the $PpCO_2$ on the oxyhemoglobin dissociation curve and determining the corresponding hemoglobin saturation. $CpCO_2$ is normally approximately 21 mL of O_2 per 100 mL of pulmonary capillary blood (when Hgb is 15 g/dL and $PpCO_2$ is 99 mm Hg).

The CaO_2 , $C\bar{v}O_2$, and $CpCO_2$ are used in the shunt equation:

$$\dot{Q}S/\dot{Q}T = (C_p\text{CO}_2 - C_a\text{O}_2)/(C_p\text{CO}_2 - C_{\bar{v}}\text{O}_2)$$

In this equation, $\dot{Q}S$ is the shunt blood flow, $\dot{Q}T$ is the total blood flow (CO), $C_p\text{CO}_2$ is the pulmonary capillary O_2 content, $C_a\text{O}_2$ is the arterial O_2 content, and $C_{\bar{v}}\text{O}_2$ is the mixed venous O_2 content.²⁸ The shunt equation estimates the fraction of CO that perfuses alveoli that are absolutely nonventilated. In actuality, the shunt calculation represents the sum effects of countless lung units of varying (V/Q) relationships throughout the lung; however, the calculation is useful to monitor trends in oxygenation, help diagnose the cause of observed hypoxemia, and guide alveolar recruitment maneuvers, such as PEEP. The proof of this equation is illustrated in Fig. 29.7 and lies in the assumption that if there were no shunt (Fig. 29.7a), all arterial blood would have been fully oxygenated in the alveolar capillaries. Therefore ($C_p\text{CO}_2 = C_a\text{O}_2$) and the numerator of the equation would be zero; thus so would its quotient. On the other hand, with a theoretic 100% shunt (Fig. 29.7b), no blood would become oxygenated and thus ($C_{\bar{v}}\text{O}_2 = C_a\text{O}_2$); the difference of each from $C_p\text{CO}_2$ would be the same, and the number divided by itself would equal 1.0, denoting 100% shunt. Fig. 29.7c illustrates a theoretic 50% shunt, where the $C_a\text{O}_2$ equilibrates between the $C_p\text{CO}_2$ and the $C_{\bar{v}}\text{O}_2$, so its difference from the $C_p\text{CO}_2$ is twice that from the $C_{\bar{v}}\text{O}_2$, denoting a 0.5 shunt fraction.

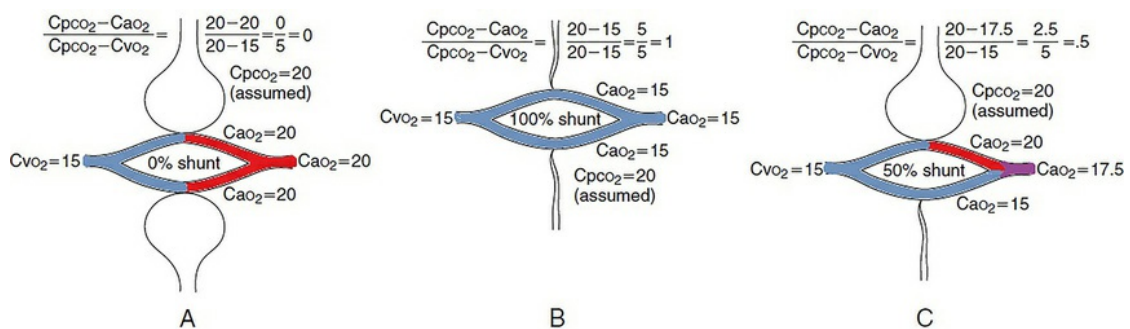

FIGURE 29.7 Calculation of the shunt fraction for various theoretic conditions. **A**, No shunt; **B**, complete shunt; **C**, 50% shunt.

One characteristic of the existence of a significant shunt

proportion is hypoxemia unresponsive to supplemental oxygen administration. When blood is passing through the lungs unoxygenated, no increase in fraction of inspired oxygen (F_{iO_2}) delivered to other regions can overcome the hypoxemia. This is because under normal circumstances, those normal lung regions are already achieving 100% saturation of the hemoglobin. Therefore they cannot overcompensate for the venous admixture contributed by the shunt areas. In assessing hypoxemia, once hypoventilation and low inspired oxygen are ruled out, improvement in P_{aO_2} in response to supplemental oxygen favors V/Q mismatch, as opposed to true shunt or possibly a diffusion disorder (the latter of which can be identified through a test of diffusing capacity of carbon monoxide in the lung [DLCO]).

Transport of Carbon Dioxide

The blood carries CO_2 in three forms: (1) in physical solution, (2) chemically combined with the amino acids of blood proteins, and (3) as bicarbonate ions. Approximately 5% to 10% of the total CO_2 transported in the blood is carried in physical solution. Chemical combination of CO_2 with the terminal amine groups of blood proteins forms carbamino compounds. The reaction occurs rapidly and does not require enzymes. Carbamino compounds constitute another 5% to 10% of the blood's total CO_2 content. The remaining 80% to 90% of the CO_2 in the blood is carried as bicarbonate. In the presence of carbonic anhydrase, CO_2 combines with water to form carbonic acid. The carbonic acid can dissociate into a bicarbonate ion and hydrogen (H^+) according to the following chemical reaction:

When HCO_3^- leaves the blood cells, chloride ions enter to maintain electrical neutrality (the so-called “chloride shift” or “hamburger shift”).³¹

Carbon Dioxide Dissociation Curve

As expected, decreases in the P_{aCO_2} correspond to a decrease in the

total CO₂ content in the blood. This is caused by corresponding decreases in the levels of bicarbonate and carbamino compounds. When the PaCO₂ falls, the amount of the total CO₂ decrease is affected by the presence of O₂ in the blood. When blood contains mainly oxygenated hemoglobin, the CO₂ dissociation curve shifts to the right, reducing the blood's capacity to hold CO₂. When the blood contains mostly deoxyhemoglobin, the curve shifts to the left, increasing the capacity to carry CO₂. This effect is known as the *Haldane effect*, and it allows the blood to load more CO₂ at the tissue level, where more deoxyhemoglobin is present, and to unload CO₂ at the lung, where more HgbO₂ is present (Fig. 29.8).

FIGURE 29.8 CO₂ dissociation curves (Haldane effect).

(From Boron WF, Boulpaep EL. *Medical Physiology*. 3rd ed. Philadelphia: Elsevier; 2017:657.)

The fact that deoxyhemoglobin is a weaker acid than HgbO₂ accounts for the Bohr and Haldane effects. Deoxyhemoglobin more readily accepts the H⁺ produced by the dissociation of carbonic acid. This permits more CO₂ to be carried in the form of bicarbonate ions (Haldane effect). Conversely, the association of H⁺ with the

amino acids of hemoglobin lowers the affinity of hemoglobin for O_2 , shifting the $HgbO_2$ dissociation curve to the right at low pH or high PCO_2 (Bohr effect).²⁸

Acid-Base Balance

The respiratory system plays an important role in maintaining normal pH balance within the body. It works along with the kidneys and the buffer systems to balance the acids and bases of the blood and other body tissues, allowing them to function normally. Hydrogen ions interact with negatively charged regions of other molecules, such as proteins, altering their structural conformation and in doing so altering their behavior. Besides affecting the $HgbO_2$ dissociation curve, blood pH alters the activity of various enzymes, thereby changing metabolic functions in all body tissues. Severe metabolic acidosis that results from prolonged cardiopulmonary arrest must be treated with sodium bicarbonate because protein-receptor sensitivity and other enzymatic functions must be restored before epinephrine can be effective in resuscitation.

Metabolism of substances ingested as food produces mainly acidic metabolic waste products. Under normal conditions, a tremendous amount of the acid produced daily can be removed from the body by the respiratory system as exhaled CO_2 . The acidic products are known as *volatile acids* because they can be converted from carbonic acid into CO_2 gas that is exhaled. Through exhalation of CO_2 , the lung eliminates over 10,000 mEq/day of carbonic acid. A much smaller amount of nonvolatile or fixed acids is also produced during normal metabolic breakdown of food at the rate of approximately 100 mEq/day; these acids are primarily removed by the kidneys.²⁸

In addition to the efforts of the respiratory system and kidneys to regulate pH levels, buffers in the human body maintain pH within the physiologic range. The buffers consist mainly of bicarbonate, phosphate, and proteins. A buffer is a mixture of substances that usually consists of a weak acid and its conjugate base. When a strong acid or base is added to a buffer system, the changes in H^+ concentration are much smaller than those that would occur if the same amount of acid or base were added to pure water or another

nonbuffered solution.

Interpretation of Arterial Blood Gases

Analysis of ABGs can provide useful information concerning the relationship of acid production and acid removal by the lungs and kidneys. Acid-base disturbances can be categorized into four major groups: respiratory acidosis, metabolic acidosis, respiratory alkalosis, and metabolic alkalosis.

Although it may seem that a great number of acid-base states are possible, actually only 11 conditions exist (Table 29.5). Blood gases in a normal individual have a pH in the range of 7.35 to 7.45, PaCO₂ ranges from 35 to 45 mm Hg, and bicarbonate concentration is normally 22 to 26 mEq/L.

TABLE 29.5
Acid-Base States

pH	CO ₂	HCO ₃	Clinical Examples
> 7.45	↓	↑	Mixed Alkalosis "Over-resuscitation" (hyperventilation and excess bicarbonate administration)
	•	↑	Metabolic Alkalosis Vomiting
	↓	•	Respiratory Alkalosis Acute hyperventilation (neurogenic, or pain)
7.45			
7.40–7.45	↑	↑	Compensated Metabolic Alkalosis Long-term hypokalemia or bicarbonate ingestion
	↓	↓	Compensated Respiratory Alkalosis Chronic hyperventilation (as in chronic ICP)
	•	•	Normal
7.40	•	•	Normal
7.35–7.40	•	•	Normal
	↑	↑	Compensated Respiratory Acidosis Chronic hypoventilation (as in COPD)
	↓	↓	Compensated Metabolic Acidosis Renal failure
7.35			
< 7.35	↑	•	Respiratory Acidosis Acute hypoventilation (opioid overdose)
	•	↓	Metabolic Acidosis Diabetic ketoacidosis
	↑	↓	Mixed Acidosis Respiratory and circulatory arrest

Upward arrow = above normal range, *downward arrow* = below normal range, *circle* = within normal range.

COPD, Chronic obstructive pulmonary disease; *ICP*, intracranial pressure.

Acidosis

Any process that leads to an elevation in PaCO_2 tends to lower arterial pH, resulting in respiratory acidosis. An acute change in PaCO_2 of 10 mm Hg is associated with a change in pH of 0.08 units. An increase in PaCO_2 with a normal bicarbonate level is termed *uncompensated respiratory acidosis*.

Metabolic acidosis should more properly be referred to as *nonrespiratory acidosis* because it does not always involve alterations in metabolism. Causes of this condition include ingestion (poisoning), infusion, production of a fixed acid (lactic acidosis), and decreased excretion of acid by the kidneys. A base change of 10 mEq/L is associated with a pH change of 0.15 unit (in the absence of a change in PaCO_2). Therefore, if the bicarbonate level increases by 10 mEq/L, then the pH also increases by 0.15 unit. A decrease in bicarbonate level when the PCO_2 remains at approximately 40 mm Hg is termed *uncompensated metabolic acidosis*. The combination of respiratory acidosis and metabolic acidosis is termed *mixed acidosis* and can produce a drastically decreased arterial pH.²⁸

Alkalosis

When alveolar ventilation exceeds that necessary to keep up with CO_2 production, both PACO_2 and PaCO_2 decrease below 35 mm Hg. As the pH rises, this hyperventilation results in respiratory alkalosis. Elevated pH accompanied by a decrease in PaCO_2 in the presence of a normal bicarbonate level is termed *uncompensated respiratory alkalosis*. The relationship between alveolar ventilation and CO_2 production that results in hyperventilation can occur because of an increase in alveolar ventilation or a decrease in CO_2 production, as occurs with hypothyroidism or hypothermia, if alveolar ventilation is maintained at normal levels.

Metabolic alkalosis occurs when fixed acid loss is increased or when the intake of bases is abnormally high. Elevated pH accompanied by above-normal increases in the bicarbonate level when the PCO_2 is maintained at approximately 40 mm Hg is termed *uncompensated metabolic alkalosis*. The combination of respiratory

alkalosis and metabolic alkalosis produces mixed alkalosis, in which the arterial pH is markedly elevated.²⁸

Compensatory Mechanisms

The respiratory system can rapidly compensate for metabolic acidosis or alkalosis by altering alveolar ventilation. It normally occurs because changes in blood H^+ concentrations affect the chemoreceptors, which in turn increases or decreases alveolar ventilation, altering $PaCO_2$ within minutes. The kidneys can compensate for respiratory acidosis and metabolic acidosis of nonrenal origin by excreting fixed acid and retaining bicarbonate. Conversely, the kidneys compensate for respiratory alkalosis or metabolic alkalosis of nonrenal origin by decreasing H^+ excretion and decreasing retention of bicarbonate. Renal compensatory mechanisms act more slowly than do respiratory mechanisms and may take several days. When evaluating blood gas analyses, *compensated acidosis* involves finding abnormalities of both the CO_2 and the HCO_3^- in the same direction, with the pH below 7.4 but above 7.35. Conversely, *compensated alkalosis* involves finding abnormalities of both the CO_2 and the HCO_3^- in the same direction, with a pH above 7.4 but less than 7.45. Ascribing the abnormality to respiratory or metabolic is then based upon which abnormality (CO_2 or HCO_3^-) in their present level would be responsible for the directional change in pH (toward acidosis or alkalosis). In spite of observing a compensatory change in CO_2 or bicarbonate, an acid-base disorder is considered *uncompensated* if that mechanism has not been able to bring the pH back into a normal range. Compensation will not “overshoot” and create a pH disorder in the opposite direction, because the drive for compensatory mechanisms is diminished as the pH approaches normal. Acid-base disorders wherein the CO_2 and HCO_3^- are both abnormal in different directions (one high, the other low) are termed *mixed acidosis* or *alkalosis*.²⁸

Treatment of Blood Gas Abnormalities

For the patient who is mechanically ventilated, respiratory acidosis

and respiratory alkalosis can be treated with a simple increase or decrease in the amount of alveolar ventilation. Respiratory acidosis should not be treated with sodium bicarbonate, because the bicarbonate dissociates into more CO_2 , worsening the acidosis. To restore stable and spontaneous circulation, mild to moderate metabolic acidosis can be treated with hyperventilation and correction of shock. Certain types of severe metabolic acidosis (pH less than 7.20) may be treated with sodium bicarbonate. The total body bicarbonate deficit is equal to the base deficit (in mEq/L) that is obtained from the blood gas values: the patient's bicarbonate level is subtracted from the normal bicarbonate level; the difference is multiplied by the patient's weight (in kilograms) and then by 0.3 (which is equal to the extracellular fluid compartment and the volume of distribution for bicarbonate). Complete correction of the base deficit is not indicated; only half of the calculated dose of bicarbonate is initially recommended. Severe lactic acidosis is treated with bicarbonate, but the acidosis associated with renal failure is better treated with dialysis. The hyperosmolarity and high sodium content of bicarbonate are usually contraindicated for patients with renal failure.²⁸

Control of Breathing

The respiratory centers in the brainstem control breathing by automatically generating a cycle of inspiration and expiration (Fig. 29.9). This spontaneously generated sequence can be modified by reflexes or by higher centers in the brain. The respiratory centers affect the nerves of the spinal cord, which innervate the muscles of respiration (the cervical branches of the spinal nerves C3, C4, and C5 form the phrenic nerves, which innervate the diaphragm). The spontaneous respiratory rhythm is generated by the medullary respiratory center, which is located in the reticular formation of the medulla under the floor of the fourth ventricle. The dorsal respiratory group and ventral respiratory group are dense collections of respiratory neurons located in the *tractus solitarius*. This region contains projections of cranial nerves IX and X and processes signals related to chemoreceptors, lung stretch receptors, gag and cough reflexes, and others. The dorsal respiratory group is

considered the pacemaker of normal breathing, that is, the area that drives respiration. The ventral respiratory group contains neurons controlling inspiration and expiration, but is quiescent during normal respiration. The pons contains the apneustic center (in the lower pons) and the pneumotaxic center (in the upper pons), both of which modify the output of the medullary respiratory center. The normal function of the apneustic center is unknown, but if it is severed, the result is “apneustic breathing” (i.e., prolonged inspiration with occasional expiration). The pneumotaxic center is thought to be the inspiratory cut-off switch, which functions to smooth the respiratory pattern.

FIGURE 29.9 Neurochemical respiratory control system. (From McCance KL, Huether SE. *Pathophysiology: The Biologic Basis for Disease in Adults and Children*. 7th ed. St. Louis: Elsevier; 2014:1233.)

The activity of the brainstem's breathing centers is modulated by information received from afferent spinal nerves and higher brain centers, as occurs in voluntary control of breathing. Additionally, a great number of sensors in the lungs, cardiovascular system, muscles, tendons, skin, and viscera can affect the control of breathing by eliciting reflex changes. Stimulation of stretch receptors in the lungs can elicit three respiratory reflexes: the Hering–Breuer inflation reflex, the Hering–Breuer deflation reflex, and the paradoxical reflex of Head. The Hering–Breuer inflation

reflex helps prevent overdistention of the alveoli at high lung volumes by inhibiting large systolic tidal volume (V_{T_s}) and may decrease the frequency of the inspiratory efforts by causing a transient apnea. The Hering–Breuer deflation reflex is responsible for the increased ventilation elicited when the lungs are deflated abnormally, such as in pneumothorax, or it may have a role in the periodic spontaneous deep breaths (sighs) that help to prevent atelectasis. The paradoxical reflex of Head results during partial block of the vagus nerves, such that lung inflation results in further deep inspiration instead of the apnea expected when the vagus nerve is fully functional. This reflex may be involved in generating the first breath of the newborn baby.³²

Chemical or mechanical irritation of the airways may elicit a reflex cough or sneeze, hyperpnea, bronchoconstriction, and increased blood pressure. The vagus nerve provides afferent pathways for all of the airway's irritant receptors, except for the nasal mucosa receptors, which send information centrally by means of the trigeminal and olfactory tracts. PE typically causes rapid, shallow breathing, whereas pulmonary vascular congestion causes hyperpnea. The vascular receptors that initiate these responses are named *J receptors* (for juxtapulmonary capillary). Stimulation of receptors in the muscles, tendons, and joints can also increase minute ventilation during exercise. Elevated blood pressure stimulates the arterial (carotid and aortic) baroreceptors, resulting in apnea and bronchodilation. Somatic pain tends to cause hyperpnea, whereas visceral pain usually causes apnea or decreased ventilation. Stimulation of the arterial chemoreceptors by decreased PaO_2 , increased $PaCO_2$, or low pH tends to increase lung inflation and cause hyperpnea, bronchoconstriction, and an increase in blood pressure. [Table 29.6](#) summarizes the respiratory control reflexes.¹⁻⁵

TABLE 29.6
Reflex Mechanism of Respiratory Control

Stimulus	Reflex	Receptor	Afferent Pathway	Effects
Lung inflation	Hering-Breuer inflation reflex	Stretch receptors within smooth muscles of large	Vagus	Respiratory—cessation of inspiratory effort, apnea, or decreased breathing frequency;

		and small airways		bronchodilation; Cardiovascular—increased heart rate; slight vasoconstriction
Lung deflation	Hering-Breuer deflation reflex	Possibly J receptors, irritant receptors in lungs, or stretch receptors in airway	Vagus	Respiratory—hyperpnea
Lung inflation	Paradoxical reflex of head	Stretch receptors in lungs	Vagus	Respiratory—inspiration
Negative pressure in upper airway	Pharyngeal dilator reflex	Receptors in nose, mouth, upper airways		Respiratory—contraction of pharyngeal dilator muscles
Mechanical or chemical irritation of airways	Cough	Receptors in upper airways, tracheobronchial tree	Vagus	Respiratory—cough; bronchoconstriction
	Sneeze	Receptors in nasal mucosa	Trigeminal, olfactory	Respiratory—sneeze; bronchoconstriction; Cardiovascular—increased blood pressure
Face immersion	Diving reflex	Receptors in nasal mucosa and face	Trigeminal	Respiratory—apnea; Cardiovascular—decreased heart rate; vasoconstriction
Pulmonary embolism		J receptors in pulmonary vessels	Vagus	Respiratory—apnea or tachypnea
Pulmonary vascular congestion		J receptors in pulmonary vessels	Vagus	Respiratory—tachypnea, possible sensation of dyspnea
Specific chemicals in the pulmonary circulation	Pulmonary chemoreflex	J receptors in pulmonary vessels	Vagus	Respiratory—apnea or tachypnea; bronchoconstriction
Low PaO ₂ , high PaCO ₂ ; low pH	Arterial chemoreceptor reflex	Carotid bodies, aortic bodies	Glossopharyngeal, vagus	Respiratory—hyperpnea; bronchoconstriction, dilation of upper airway; Cardiovascular—decreased heart rate, vasodilation, etc.
Increased systemic arterial blood pressure	Arterial baroreceptor reflex	Carotid and aortic arch stretch receptors	Glossopharyngeal, vagus	Respiratory—apnea, bronchodilation; Cardiovascular—decreased heart rate, vasodilation
Increased systemic arterial blood pressure		Muscle spindles, tendon, organs, proprioceptors	Various spinal pathways	Respiratory—provide respiratory controller with feedback about work of breathing; stimulation of proprioceptors in joints causes hyperpnea
Somatic pain		Pain receptors	Various spinal pathways	Respiratory—hyperpnea Cardiovascular—increased heart rate, vasoconstriction

P_{aO_2} , Partial pressure of O₂ in arterial blood; P_{aCO_2} , partial pressure of carbon dioxide.

Modified from Levitzky MG. *Pulmonary Physiology*. 8th ed. New York: McGraw-

Chemical Control of Breathing

The arterial and cerebrospinal fluid partial pressures of CO_2 are probably the most important inputs to the brainstem centers for establishing the ventilatory rate and V_T . Hypoxemia potentiates the ventilatory response to CO_2 . Its effect is that for any particular PaCO_2 , ventilatory response becomes greater as the PaO_2 decreases. Opioids, anesthetics and hypnotic drugs (Fig. 29.10) may profoundly depress the ventilatory response to CO_2 . COPD also depresses the ventilatory response to hypercapnia, so the hypoxic drive may be more prominently responsible for maintaining spontaneous breathing in these patients, and administering high FiO_2 may reduce their spontaneous ventilatory drive. Metabolic acidosis shifts the CO_2 curve to the left, so that for any particular PCO_2 , ventilation is increased during metabolic acidosis.

FIGURE 29.10 Carbon dioxide response curve. MAC, Minimum alveolar concentration.

A depressed or abnormal response to CO_2 during sleep may be involved in central sleep apnea (characterized by pauses of at least 10 seconds' duration between breaths, with cessation of respiratory

effort).³³ Central sleep apnea, which possibly is caused by a defect in the chemoreceptors or brainstem respiratory control center, may be an important contributor to sudden infant death syndrome.

Increased PaCO_2 and decreased PaO_2 and arterial pH stimulate the arterial (peripheral) chemoreceptors, with the carotid bodies apparently exerting a much greater influence on the medullary respiratory centers than the aortic bodies. The afferent nerve from the carotid body is Hering's nerve, a branch of the glossopharyngeal nerve. The afferent pathway from the aortic body is the vagus nerve. The central chemoreceptors are in contact with cerebrospinal fluid but are not directly exposed to arterial blood (because of the blood-brain barrier). CO_2 is rapidly diffusible through the blood-brain barrier; therefore changes in PaCO_2 are rapidly transmitted to the cerebrospinal fluid, taking less than 2 minutes. Hydrogen ions and bicarbonate ions are slowly diffusible through the blood-brain barrier, so changes in arterial pH that do not result from changes in PCO_2 take considerably longer to affect the cerebrospinal fluid. The central chemoreceptors are located just beneath the surface of the medulla. They are not stimulated by hypoxia; their activity may even be suppressed by it. The central chemoreceptors are majorly responsible for determining the resting ventilatory level and long-term maintenance of blood CO_2 levels. The central chemoreceptors contribute approximately two-thirds of the ventilatory response, whereas the peripheral chemoreceptors contribute the remaining one-third and may be more important in short-term responses to CO_2 .³⁴

Respiratory System Pathology

Obstructive Sleep Apnea

Definition

Obstructive sleep apnea (OSA) is a mechanical obstruction to breathing that occurs during sleep, when pharyngeal musculature relaxes. It is characterized by episodes of breathing cessation that last 10 or more seconds. Obesity hypoventilation syndrome is a distinct entity from OSA. It is defined as the triad of obesity, daytime hypoventilation, and sleep-disordered breathing without an alternative neuromuscular, mechanical, or metabolic cause.

Incidence and Outcome

Obstructive sleep apnea occurs in as many as 24% of males and 9% of females. Obesity is the most significant precipitating factor, with OSA being noted in 40% of obese individuals, and 80% of those presenting for bariatric surgery.³⁵ OSA is becoming increasingly prevalent in children and bears many of the same characteristics as observed in adults. Between 7% and 10% of children are habitual snorers, and OSA is estimated to exist in 1% to 4% of preschool-aged children. OSA is associated with increased postoperative complications, and is an independent risk factor for increased morbidity in the hospitalized patient.^{36,37}

Etiology and Pathophysiology

The primary causative factor for OSA is obesity, although it can exist in nonobese individuals. Factors in the pharyngeal musculature cause collapse during sleep under negative inspiratory pressure. Chronic hypoxemia and hypercarbia lead to an inflammatory state and a variety of secondary pathologies. OSA has been linked as a causative factor in atherosclerosis, hypertension, stroke, insulin resistance, diabetes, dyslipidemia, and other disorders (Table 29.7).^{38–40} Sleep apnea is associated with a decrease in FRC of the lung, so the sleep apnea patient may present with not

only a more challenging airway, but also with less oxygen reserve when they become apneic.

TABLE 29.7
Comorbidities Associated With OSA

Category	Condition	Prevalence (%)
Cardiac	Treatment-resistant hypertension	63–83
	Congestive heart failure	76
	Ischemic heart disease	38
	Atrial fibrillation	49
	Dysrhythmias	58
Respiratory	Asthma	18
	Pulmonary hypertension	77
Neurologic	First-ever stroke	71–90
Metabolic	Type 2 diabetes mellitus	36
	Metabolic syndrome	50
	Hypothyroidism	45
	Morbid obesity	50–90
Surgical	Bariatric surgery	71
	Intracranial tumor surgery	64
	Epilepsy surgery	33
Others	Gastroesophageal reflux disease	60
	Nocturia	48
	Alcoholism	17
	Primary open-angle glaucoma	20
	Head and neck cancer	76

OSA, Obstructive sleep apnea.

From Seet E, Chung F. Obstructive sleep apnea: preoperative assessment. *Anesthesiol Clin*. 2010;28(2):199–215.

Clinical Features and Diagnosis

Patients with sleep apnea often present with multiple comorbidities related to their obesity or to chronic hypoxemia from the apneic disorder. Common comorbidities include systemic and pulmonary hypertension, ischemic heart disease, and CHF. A hallmark of OSA is habitual snoring and fragmented sleep, which can lead to daytime somnolence.

Polysomnography (see later) provides an objective measure of sleep apnea, but it is expensive and impractical to apply to every patient with risk factors who presents for surgery. A number of questionnaires such as the Berlin questionnaire have been developed as screening tools for OSA. These provide a low-cost,

simple approach to identifying OSA. The components of the STOP questionnaire are as follows: S, snore loudly; T, daytime tiredness; O, observed to stop breathing during sleep; P, high blood pressure. The STOP questionnaire is often paired with four additional variables of the Bang questionnaire: B, body mass greater than 35 kg/m²; A, age older than 50 years; N, neck circumference greater than 40 cm; G, male gender. Used together, the STOP-Bang questionnaire demonstrates sensitivity of nearly 100% and specificity of approximately 40%³⁶ (see [Chapter 48, Box 48.2](#)).

Polysomnography is used to establish the diagnosis of OSA, which is based upon the number of abnormal respiratory events per hour of sleep (the apnea plus hypopnea index, AHI). Diagnostic criteria vary among institutions, but an index of greater than 5 if associated with sleep-related symptoms, or an index of greater than 15 alone, are diagnostic for the condition. The AHI also describes severity, with AHI greater than 15 being moderate, and AHI greater than 30 being severe.³⁵ Investigators are identifying a variety of at-home and in-hospital diagnostic and screening tools for the identification of sleep apnea. Whereas polysomnography is the most definitive validation of OSA, in most cases, it is not warranted to delay a surgical case solely for this test to determine the specific number of apneic episodes the patient experiences. Based upon the STOP-Bang assessment, the anesthetic plan can be formulated around a presumptive diagnosis of OSA. Unless the preoperative work-up discovers previously-unrecognized cardiovascular disease (such as pulmonary hypertension (PH), resting hypoxemia, or significant hypoventilation), there is no reliable evidence that delaying surgery or providing more detailed investigation of the degree of OSA will improve outcomes. Consideration of the interplay of baseline state of health, severity of obesity, complexity of the surgery, and anticipated requirements for postoperative opioids should inform the anesthetic plan for each individual.

Treatment

Weight loss is an important goal for the obese patient with OSA. Patients who are obese demonstrate a decreased requirement for sleep apnea therapy following bariatric surgery. The use of CPAP devices has become the gold standard in the management of OSA.

CPAP devices use a facemask held tightly to the face during sleep, which provides positive airway pressure. This pressure tents the airway open, relieves the obstruction, and promotes more continuous breathing and sleep. Although CPAP is a very effective treatment modality, sleeping with a bulky and sometimes noisy mask can be difficult to tolerate, and adherence to the therapy is as low as 50% among sleep apnea subjects. As a result, other emerging treatments include an implantable stimulator of the hypoglossal nerve to increase pharyngeal tone, and nasal end-expiratory pressure devices, positional therapy, procedures to shrink pharyngeal tissue, and pharmacologic adjuncts. Procedures to reduce tissue mass range from minor radiofrequency intervention to surgical procedures, such as uvulopalatopharyngoplasty and adenotonsillectomy in pediatric or adult patients with tonsillar hypertrophy. Adjunctive therapy includes analeptic drugs such as modafinil and armodafinil, methylxanthines, doxapram, serotonin modulators, and tricyclic antidepressants. Drug therapy is intended to reduce daytime sleepiness, reduce cardiovascular complications, strengthen pharyngeal musculature, and reduce REM sleep, among other effects.⁴¹⁻⁴³

Anesthetic Management

Continuous positive airway pressure may be implemented preoperatively to improve respiratory function, and it is even more contributory postoperatively, when respirations are compromised by opioids and residual anesthesia. Patients on CPAP at home may be instructed to bring their device to the hospital so that it can be used following surgery. Research is equivocal regarding whether perioperative CPAP therapy reduces complications, other than the obvious reduction in airway obstruction. Considering the cost and logistics involved with the process of continuing CPAP in the perioperative period, individual institutional resources can inform the decision of the extent to which CPAP is used perioperatively.

Careful airway evaluation is an important step in anesthetic preparation and management. Redundant tissue in the neck region is common in OSA (even more so than is general obesity) and it may impede effective head positioning, mask ventilation, or laryngoscopy. The anesthetist should anticipate airway difficulty

and rapid desaturation from reduced FRC. Elevation of the head and shoulders facilitates airway management and ventilation. The requirement for videolaryngoscopic or other adjunctive tools should be anticipated during anesthetic planning. Preoperatively, sedative medications should be used cautiously. As a result of central nervous system sensitization, patients may be hypersensitive to the effects of benzodiazepines and opioids. Effective doses may be extremely small, and this effect may persist even after physical symptoms have been surgically ameliorated (for example, through uvulopalatopharyngoplasty). The same concerns apply postoperatively. Patients receiving preoperative sedation should be observed, and pulse oximetry is recommended. Extubation must be undertaken carefully, when indications are that the patient will maintain a patent airway. In the recovery area, vigilance must be afforded to the potential for airway obstruction from residual anesthetic effects which heighten the preexisting sensitivity to respiratory depressant drugs. Airway obstruction occurs in 25% of pediatric patients with OSA following tonsillectomy, in contrast to 1% of those without OSA. Analgesics and general somnolence may lead to airway obstruction in the recovery area. Multimodal analgesia and regional techniques may help limit the need for systemic opioids.

Patients with moderate to severe OSA should be provided with additional monitoring postoperatively. This may include longer postanesthesia care unit (PACU) time, admission to a monitored bed, prolonged blood oxygen saturation (SpO₂) monitoring, and disqualification from same-day discharge, depending on the patient's condition. CPAP is helpful in the PACU, and patients who use this treatment at home should be encouraged to bring their device for use in the postanesthetic period. If the patient can receive CPAP therapy and monitoring for apneic episodes and desaturation, ICU admission is not indicated solely on the basis of the OSA, unless the patient has other specific indications. See [Table 29.8](#) for suggested management of the patient with OSA.

TABLE 29.8**Suggested Management of the Patient With Obstructive Sleep Apnea**

Screening	STOP-Bang questionnaire. Polysomnography for definitive diagnosis, but not required solely for anesthesia.
Preoperative	Preoperative sedation should be judicious, followed by continuous patient observation, ideally with oximetry.
Positioning	Ramp upper body for intubation.
Induction	Anticipate difficult airway; assemble video laryngoscope or other airway adjuncts.
Intraoperative	Use regional anesthesia when possible. For general anesthesia, use short-acting agents, PEEP to reduce post-op atelectasis. Limit long-acting opioids and minimize muscle relaxants as possible.
Emergence	Careful reversal with attention to residual relaxation. Elevate upper body and extubate when fully awake.
Postoperative	Use multi-modal and non-opioid analgesia. Regional techniques for analgesia. CPAP in recovery if recurring obstruction or history of home use.
Discharge	Minor surgery or regional anesthesia or sedation, and minimize opioid administration = same day discharge. Major surgery, substantial opioid need, severe OSA, or home CPAP = monitor overnight.

CPAP, Continuous positive airway pressure; OSA, obstructive sleep apnea; PEEP, positive end expired pressure.

Pulmonary Function Testing

An understanding of pulmonary function evaluation will be helpful before discussing pathologies that involve airflow limitations. A number of examinations may be performed to evaluate lung volumes and the inspiratory and expiratory flow of gas. Many of these are derived by having the patient breathe through a closed circuit with measurement of gas flow and composition.

Measurement of pulmonary volume over time is called *spirometry*. A glossary of static lung volumes and capacities is presented in [Table 29.4](#). A standard flow-volume loop is drawn in a clockwise direction, with inspiratory flow below the x-axis, and expiratory flow above it. Flow rates (in liters per second) are represented on the y-axis (see [Fig. 29.4](#)). The zero point on the x-axis represents full inspiration, because the lungs cannot be totally emptied due to the residual volume. In [Fig. 29.4](#), the scale below the x-axis provides corresponding approximate absolute values of lung volume. The most important portion of the loop in most cases is the expiratory flow and volume that begins at this point and ends when the loop reaches the x-axis again as it transitions to inspiratory flow. Values for an individual's flow and volume pattern are measured in absolute terms, and are also compared to “predicted” values based

upon performance of healthy subjects with similar anthropometric characteristics (age, gender, and height, and sometimes other factors such as weight and race).

Spirometry is based on a forced air capacity (FVC) maneuver, which requires concerted patient effort; a lack of effort may produce erroneous results.⁴⁴ The FVC is divided into several time intervals, of which the FEV₁ (forced expired volume in 1 second) is the most reproducible. The volume of air that is exhaled in 1 second from a maximal inspiration is measured as the FEV₁. Patients with increased airway resistance exhibit decreased FEV₁ and FEV₁/FVC ratios. Normal FEV₁ varies with age, declining as age increases.⁴⁵ Normally, the FEV₁ volume is at least 80% of the vital capacity, an important point that is used to differentiate low FEV₁ due to obstruction from low FEV₁ due to restrictive disease (in which latter case the vital capacity is also reduced, and the ratio of FEV₁/FVC is preserved).

Respiratory activity represented by the midportion of the expiratory curve is the most effort-independent and the most sensitive indicator of small airway disease. The parameter measured is the FEF_{25%-75%} or the forced expiratory flow rate between 25% and 75% of the exhaled breath. The normal FEF_{25%-75%} of 4 to 5 L/sec may decrease markedly in those with pulmonary disease, with early changes evident sooner in patients with obstructive disease than in those with restrictive disease. Reduction in the FEF_{25%-75%} wherein the curve begins to take a concave shape, usually appears before significant change occurs in the FEV₁.⁴⁴ It is not as reproducible as the FEV₁, but it is more sensitive to airway obstruction.⁴⁶

Flow-volume loops also provide information about disease processes through characteristic shapes (Fig. 29.11). Obstructive disease is characterized by a reduced peak flow rate and a sloping of the expiratory limb. This occurs as small airways close during expiration, noticeably reducing the flow rate during expiration. Restrictive disease is characterized by normal or heightened peak expiratory flows, but a very narrow loop, reflecting the reduced vital capacity. Obstructions to airflow may also be variable, as in tracheomalacia, such that changes in pressure may both augment

and reverse the obstruction in the course of each respiratory cycle. In this case, the location of the lesion (being intrathoracic or extrathoracic) determines whether the obstruction will be relieved or made worse by inspiration or expiration (Fig. 29.12). Airway obstructions lead to characteristic patterns on a flow-volume tracing as well (Fig. 29.13).

FIGURE 29.11 Flow-volume loops in disease. Characteristic deformities of pulmonary flow-volume loops related to obstructive and restrictive disease.

FIGURE 29.12 Variable airway obstructions during spontaneous respiration. A variable intrathoracic obstruction will be subjected to negative pressure during inspiration and will be tented open (**A**); however, as intrathoracic pressure rises during expiration, an intrathoracic obstruction will be compressed (**B**). A variable extrathoracic obstruction will be subjected to negative intratracheal pressure during inspiration and will be

compressed (**C**); however, as intratracheal pressure rises during expiration, the extrathoracic obstruction will be pushed open (**D**).

FIGURE 29.13 Flow volume loops-airway obstruction.

The dynamic effects of airway obstruction during inspiration and expiration are compared to the (**A**) normal flow volume loop. (**B**) An extra-thoracic obstruction will cause airway compression and decreased inspiratory flow.

Thus the inspiratory flow pattern will be abnormally affected. (**C**) An intra-thoracic obstruction will cause airway compression and decreased expiratory flow. Thus the expiratory flow pattern will be abnormally affected. (**D**) A fixed obstruction (e.g., foreign body in the airway) will abnormally affect both the inspiratory and the expiratory flow patterns.

The diffusion capacity (DL) is another form of pulmonary function testing which assesses the ability of gas to traverse the alveolar-capillary membrane. Factors related to Fick's law of diffusion correlate the diffusion capacity to clinical conditions; that is, thickness of the membrane (fibrosis), or surface area for diffusion (emphysema). Vascular or interstitial pathology, such as PH, will decrease the DL, whereas polycythemia will increase it. The DL is also influenced by ventilation-perfusion matching, such as PE, which would cause it to decrease. The DL test is commonly performed by having the patient inhale a single breath containing a small amount of carbon monoxide. Carbon monoxide is highly diffusible and binds avidly with hemoglobin, so that any reduction in transfer to the blood is indicative of loss of surface area of the alveolar-capillary membrane. New methods of assessing the DL now also use nitric oxide as the traced gas, as it may provide a more

sensitive indicator of interstitial disease. The DLCO is reported as the uptake of CO in mL/min per mm Hg or as a percentage of predicted value. There is no specific value correlated with perioperative complications, but reductions in DLCO are associated with increased exacerbations in COPD and a significantly increased 3-year mortality in patients with PH.⁴⁶

Chronic Obstructive Pulmonary Disease

The American Thoracic Society and European Respiratory Society define COPD as a “preventable and treatable disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases...”⁴⁷ COPD should be considered in any patient with ongoing cough, sputum production, or dyspnea with history of exposure to risk factors. Diagnosis is made by spirometric demonstration of airflow obstruction that is not fully reversible (post-bronchodilator FEV₁/FVC ratio less than 0.7).⁴⁸

The terms *chronic obstructive pulmonary disease* and *chronic obstructive lung disease* are widely used as synonyms for pathology involving airflow obstruction that does not change over months to years. COPD is caused by a mixture of small airways disease and parenchymal destruction in various combinations and proportions from one individual to the next. Two specific disorders, emphysema and chronic bronchitis, provide the prototypes of pathologic changes in COPD. Emphysema is characterized by the destruction of parenchyma that leads to loss of surface area, elastic recoil, and structural support to maintain airway patency. Bronchitis is characterized by narrowing of small airways by inflammation and mucous production. There are also numerous chronic conditions referred to collectively as *peripheral airways disease* or *small airways disease*. These entities are not mutually exclusive; peripheral airway disease often precedes onset of emphysema, and chronic bronchitis and emphysematous changes often coexist to define COPD. As a rule, COPD is observed most often in individuals with an extensive history of smoking, and the disease process takes 30 years or longer to manifest. Other chronic

diseases such as cystic fibrosis, tuberculosis, and bronchiectasis are not included in the definition of COPD,⁴⁷ nor are restrictive diseases of scoliosis, other forms of pulmonary fibrosis, or obesity. Differential diagnosis of COPD compared with other common lung disorders is present in [Table 29.9](#).

TABLE 29.9
Differential Diagnosis of COPD

Diagnosis	Suggestive Features*
COPD	Onset in midlife; symptoms slowly progressive; long-term smoking history; dyspnea during exercise; largely irreversible airflow limitation
Asthma	Onset early in life (often childhood); symptoms vary from day to day; symptoms occur at night or in early morning; allergy, rhinitis, or eczema also present; family history of asthma; largely reversible airflow limitation
Congestive heart failure	Fine basilar crackles on auscultation; chest radiograph shows dilated heart, pulmonary edema; pulmonary function tests indicate volume restriction, not airflow limitation
Bronchiectasis	Large volumes of purulent sputum; commonly associated with bacterial infection; coarse crackles or clubbing on auscultation; chest radiograph or CT scan shows bronchial dilation, bronchial wall thickening
Tuberculosis	Onset at all ages; chest radiograph shows lung infiltrate or nodular lesions; microbiologic confirmation; high local prevalence of tuberculosis, or known exposure
Obliterative bronchiolitis	Onset at younger age, in nonsmokers; may have history of rheumatoid arthritis or fume exposure; CT scan taken on expiration shows hypodense areas
Diffuse panbronchiolitis	Most patients are male and nonsmokers; almost all have chronic sinusitis; chest radiograph and HRCT scan show diffuse small centrilobular nodular opacities and hyperinflation

*These features tend to be characteristic of the respective diseases but do not occur in every case. For example, a person who has never smoked can develop COPD (especially in developing countries, where other risk factors may be more important than cigarette smoking); asthma can develop in adult and even elderly patients.

COPD, Chronic obstructive pulmonary disease; *HRCT*, high-resolution computed tomography.

Definition

Peripheral airways disease involves inflammation of the terminal and respiratory bronchioles, fibrosis and narrowing of the airway walls, and goblet cell metaplasia.⁴⁹ A small sampling of conditions that are characterized as small airways disease includes sarcoidosis,

Wegener granulomatosis, mineral dust–associated airways disease, disease from exposure to fumes and toxins, and bronchocentric granulomatosis.⁵⁰ Chronic bronchitis refers to chronic or recurrent excess mucous secretion occurring on most days for at least 3 months of the year for at least 2 successive years. A critical element is the presence of airway obstruction of expiratory airflow. Emphysema is defined as “a condition of the lung characterized by abnormal permanent enlargement of the air spaces distal to the terminal bronchiole, accompanied by destruction of their walls and without obvious fibrosis.”⁴⁹ Alveolar tissue that has been destroyed is largely incapable of regeneration, and therefore the changes that occur in emphysema are irreversible. Emphysema is subclassified as centrilobular, or panlobular. In centrilobular emphysema, dilation predominantly affects the respiratory bronchioles in the upper lung lobes. In panlobular emphysema, tissue destruction is widespread, affecting all areas of the acinus (the cells that define the “berry-bunch” shape of the alveoli) and distributed throughout the lung.⁴⁴ Destruction of lung tissue that is associated with emphysema leads to four primary alterations in pulmonary function: (1) increases in size of acini causes compression of adjacent small airways and increases airflow resistance; (2) consolidation of alveoli leads to loss of alveolar surface area and impairs gas diffusion; (3) heterogeneity of disease in different parts of the lungs leads to mismatch of ventilation and perfusion; and (4) loss of alveolar walls also decreases the amount of pulmonary capillaries, resulting in right ventricular workload.⁴

Incidence and Outcome

Chronic obstructive pulmonary disease affects more than 5% of adult Americans and is the third leading cause of death.⁴⁸ Chronic bronchitis and emphysema are the most common causes of COPD. The social and economic impacts of COPD are enormous. Patients who have advanced stages of obstructive lung diseases are unable to work and frequently cannot participate in activities of daily living. Even in milder cases, activities are often restricted. The economic cost of COPD is estimated to be over \$50 billion in the United States.⁴⁸ Death related to COPD is not only caused by respiratory failure, but it also associated with related comorbidities

such as lung cancer and heart disease.⁵¹

Etiology and Pathophysiology

In general, the development of COPD causes an exaggerated inflammatory reaction in the lungs. The principal factor that predisposes a patient to the development of COPD is cigarette smoking.⁵¹ Environmental pollution appears to have some role, but its effects are minor compared with those of cigarette smoking, particularly as the disease occurs in the United States. COPD may develop in some patients because of an imbalance between protease and antiprotease activities in the lungs; α_1 -antitrypsin deficiency is the primary genetically related cause. In people with this deficiency, smoking causes release of neutrophil elastase that is inadequately inhibited because of the deficient levels of α_1 -antitrypsin. This results in degradation of pulmonary connective tissue and in the early development of COPD.⁵² Unfortunately, α_1 -antitrypsin administration is expensive and has not demonstrated good results as a treatment.^{52,53}

The dominant feature of the natural history of COPD is progressive airflow obstruction, as reflected by a decrease in FEV₁. Three causes of decreases in FEV₁ are as follows: (1) a decrease in the intrinsic size of bronchial lumina; (2) an increase in the collapsibility of bronchial walls (this cause is the most difficult to quantify); and (3) a decrease in elastic recoil of the lungs.⁴⁴ Distinct morphologic changes can be found in the airways of patients exposed to ongoing inflammatory challenges. In chronic bronchitis, a proliferation of the compound tracheobronchial mucous glands occurs in the subepithelial layers of the airway wall. Excessive airway mucus and thickened airway walls cause a narrowing of the functional airflow channel. Airway narrowing is primarily related to a thickening of the airway walls, and not an increase in smooth muscle tone, as is more prominently observed in asthma. Destruction of parenchyma results in a loss of elastic support, which also contributes to airway narrowing.⁵⁴ Although COPD is defined as being irreversible, contemporary science is focusing on the limited amount of reversibility that can improve patients' quality of life and slow progression of the disease. Between 25%

and 50% of patients with COPD also have enhanced airway reactivity.⁵⁵ While bearing similarities to asthmatic bronchial reactivity, it appears that in COPD, airway hyperresponsiveness affects small airways more so than larger ones.⁵⁶

The defense system of a patient with COPD is disrupted by the excessive production of mucus and by paralysis of the mucociliary transport system, which leads to microbial colonization. The presence of microbial organisms in the airway secretions of patients with chronic bronchitis is common and does not necessarily imply the presence of an acute infection. Instead, chronic colonization of the airway plays a cyclic role in the ongoing pathogenesis of COPD, whereby bacteria increase mucous production, reduce ciliary motility, cause influx of neutrophils that lead to fibrosis, alter the host response to cigarette smoke, induce a chronic inflammatory response, and enhance airway reactivity.⁵⁷ General changes in lung functioning include:

1. Destruction of lung connective tissue that normally provides elastic pull on the outsides of bronchi and bronchioles reduces the tethering of airways of the pulmonary interstitium, leads to premature collapse of the airways from external pressure, and increases the unevenness of distribution of inspired air to different regions of the lungs. Consequently, the exchange of CO₂ and O₂ between the blood and alveolar air is impeded. Compensation for lower diffusion of gases is partly achieved via collateral ventilation by diffusion across alveolar walls.⁵⁸

2. Injury and inflammation of the bronchial tubes and alveoli increase the resistance to airflow during both inspiration and expiration. More forceful breaths or quicker breaths are needed for maintaining even normal levels of ventilation.⁵⁹

3. Lung compliance increases with the tissue damage, and the airways' narrowing and greater collapsibility impede the ability of the ventilatory muscles to empty the lung completely. Hyperinflation results, raising the resting end-expiratory position of the lungs. Because the lung is more expanded, the inspiratory muscles operate from a shorter initial length and produce less force when shortened.

4. The more horizontally placed diaphragm is less able to lift the rib cage. The diaphragm may contract ineffectively, such that the abdomen moves inward rather than outward with each inspiration.⁶⁰

5. Because of the increased demands for work output placed on the respiratory muscles, the energy requirement of these muscles escalates. A greater proportion of the CO goes to these muscles. If hypoxemia is present and increased ventilation is required (e.g., as in exercise), the energy supply of the muscles may become inadequate, and respiratory muscle fatigue is ultimately produced.⁶¹

6. The expansion of the lung and thorax also misaligns the intercostal muscles and accessory respiratory muscles. To compensate, patients may assume special postures, such as leaning forward.⁶²

7. Inflammation allows noxious agents in the air to reach the more deeply located tissues in the lung and gain access to blood vessels, macrophages, mast cells, and nerves in the lung. Airway irritation increases; as a result, asthmatic episodes occur because the introduction of noxious agents causes the release of spasmogenic agents from tissue cells and nerve endings.⁶²

General Gas Exchange Characteristics

The ability of compensatory mechanisms to preserve ventilation and ABG tensions varies. Ventilation is usually very well protected, even more than is gas exchange. CO₂ is 20 times more soluble than O₂ and is therefore more diffusible.⁶³ In addition, if hypercapnia should occur, pulmonary ventilation is stimulated. Minute ventilation (V_E) in COPD generally is normal to above normal. Usually, PaCO₂ does not increase beyond normal levels in COPD until FEV₁ is less than 1 L. In comparison, PaO₂ is not appreciably restored by an increase in depth of breathing, and even slight variations in V/Q ratios in the lung adversely affect oxygenation.⁴⁹ O₂ delivery (DO₂) to the tissues is preserved as much as possible by

an increase in CO, a greater extraction of O₂ from the blood, polycythemia, or some combination of these three factors. Consequently, respiratory muscle work is greater than normal, and O₂ use by the muscles is increased.

Associated Conditions

Cigarette Smoking

Cigarette smoking has been firmly established as the primary environmental risk factor associated with emphysema and bronchitis.⁴⁷ Its pathogenic mechanism is not known. The unchecked protease hypothesis holds that emphysema is caused by damage to elastic fibers because of an imbalance between elastase and antielastase in the lung.⁶⁴ In addition, evidence that oxidants have a role in lung damage is increasing. The lungs of cigarette smokers are subject to an enhanced oxidant burden. Oxidants are highly reactive electron acceptors capable of removing electrons from a variety of molecules. The process of oxidation may reversibly or irreversibly damage compounds of all chemical classes, including nucleic acids, proteins and free amino acids, lipids and lipoproteins, and carbohydrates. In this regard, oxidants can damage cells and extracellular matrix components critical for normal lung function. Cigarette smoke and activated lung phagocytes generate an increase in the level of oxidants.^{65,66} Additionally, excess sputum production and hyperplasia of the mucous glands of the trachea and large bronchi are linked to cigarette smoking.⁶⁵ The risk of COPD is not limited to cigarette smoking; smoking other types of tobacco or marijuana, exposure to secondhand smoke, and even fetal exposure to smoke during pregnancy may predispose to COPD.⁶⁷

Chronic lung hyperinflation results in diaphragmatic flattening, and a reduction in contractile force results, attributable to the Frank–Starling mechanism. Besides this gross effect, oxidative stress leads to loss of contractile proteins (i.e., myosin) and results in a reduction in contractile force.⁶⁸

Peripheral Circulation in Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease can change the determinants of systemic venous return by altering the mechanical characteristics of either the heart or lungs. When a forced expiratory breathing pattern occurs (e.g., during exercise), positive intrathoracic pressure is generated during expiration. The positive swings in pressure cyclically decrease systemic venous return, leading to an exaggeration of respiratory variation in arterial blood pressure or to pulsus paradoxus.⁶⁹ Pulsus paradoxus is present in two-thirds of patients with severe COPD, and its severity correlates with the degree of airflow obstruction.⁷⁰ Increases in lung volume may directly impede systemic venous return through compression of the vena cava or heart. Normally, inspiration augments systemic venous return because of a decrease in right atrial pressure.⁷¹

Patients with COPD often have an increase in CO mediated by an increase in catecholamine levels and by a redistribution of blood flow and volume from the high-capacitance splanchnic regions to the lower-capacitance cardiac, cerebral, and muscle regions.⁷¹

A characteristic enhanced heart rate response has also been identified. Four parameters of airway obstruction (FVC, the ratio of FEV₁ to FVC [% FEV₁], the ratio of RV to TLC [RV/TLC], and % RV) have been correlated with the heart rate response to hypoxia. This increased response appears to be the result of an unknown mechanism of diseased lung tissue.⁷²

Fluid Retention in Chronic Obstructive Pulmonary Disease.

It appears that patients with hypoxic and hypercapnic respiratory failure caused by emphysema or chronic bronchitis, or from both, have impaired renal function, with reduced renal plasma flow and decreases in glomerular filtration.⁷³

Note that cardiac responses to chronic and acute pressure increases are not the same. Chronic pressure overload causes right ventricular hypertrophy, whereas acute pressure changes cause right ventricular dilation.

Other Air Space Abnormalities

Bullae, a manifestation of some forms of emphysema, are air-containing spaces greater than 1 cm in diameter that result from the destruction and dilation of air spaces distal to terminal bronchioles.

Bullae have an outer wall consisting of the visceral pleura and an inner wall consisting of tissue derived from confluent alveoli. Bullae can grow to sizes occupying a significant proportion of the hemithorax, in which case they are referred to as *giant*.⁷⁴ A bulla or bullae that become symptomatic may warrant surgical resection. Similar to bullae, blebs are collections of air within the layers of the visceral pleura. They occur when air migrates from the lung parenchyma, and they usually form near the apices. Because blebs do not involve the acinus, they are not a form of emphysema; however, they do pose the risk of causing pneumothorax.

Clinical Features and Diagnosis

The clinical presentation associated with COPD varies markedly. Chronic productive cough and progressive exercise limitation are the hallmarks of COPD. Other common symptoms are dyspnea and wheezing, but COPD may progress to respiratory failure or cor pulmonale. Key findings in COPD are listed in [Table 29.10](#).

TABLE 29.10

Clinical Hallmarks of COPD

Assessment	Typical Finding
General appearance	Range from overweight and dusky, to thin, emaciated; pursed-lip breathing; anxious; prominent use of accessory muscles; barrel chest; jugular vein distention; rapid weight loss carries poor prognosis
Cough	Chronic, productive throughout the day (most characteristic with prominent bronchitis)
Dyspnea	Chronic, progressive increase (dyspnea precipitated by decreasing levels of activity)
Breath sounds	Rhonchi, wheezing
Heart sounds	Split S ₂ , pulmonary/tricuspid insufficiency
Radiographic features	Flat diaphragm; areas of increased radiolucency; rapid tapering of vascular markings
Spirometry	Elevated TLC, RV, FRC, RV/TLC ratio; reduced FEV ₁ , FEV ₁ /FVC ratio
Echocardiography	Increased pulmonary artery pressure, decreased RV contractility
Blood gas exchange	Reduced DLCO; Hypoxemia (most characteristic of prominent emphysema)

COPD, Chronic obstructive pulmonary disease; *DLCO*, carbon monoxide diffusion in the lung; *FEV₁*, forced expiratory volume in 1 sec; *FRC*, functional residual capacity; *FVC*, forced vital capacity; *RV*, residual volume; *TLC*, total lung capacity.

From Qaseem A, et al. Diagnosis and management of stable chronic obstructive pulmonary disease: a clinical practice guideline update from the

American College of Physicians, American College of Chest Physicians, American Thoracic Society, and European Respiratory Society. *Ann Intern Med.* 2011;155(3):179–191.

Diagnostic Testing

Pulmonary Function Tests.

Spirometry is not recommended as a screening tool, and it has limited benefit in anesthetic risk assessment, in contrast to the cost of performing the procedure.⁷⁵ Although the FEV₁ indicates the degree of airflow obstruction, it correlates poorly with symptoms and therefore may not solely indicate the severity of pulmonary disease.⁴⁴ Furthermore, severe pulmonary disease will manifest in functional limitations and characteristic physical facies, which will be evident to the anesthetist even in the absence of airflow measurement. Spirometry is most useful to primary care providers when evaluating patients with unexplained dyspnea and in those in whom COPD is suspected. Current evidence-based guidelines note that a smoking history of greater than 40 pack-years is the single best variable for predicting airflow obstruction, and the combination of greater than 55–pack-year history, wheezing on auscultation, and patient self-reported wheezing almost assures that obstruction (FEV₁/FVC ratio less than 0.7) is present.⁴⁸

Reduction in the FEV₁ is a hallmark of obstructive disease; however, it may also characterize restrictive disease. In severe obstructive lung disease, expiratory flow rates are greatly decreased and the FEV₁/FVC ratio is reduced. The ratio is evaluated in addition to the FEV₁ alone, because in restrictive disease, the FEV₁ is reduced secondary to a reduction in the vital capacity, so the reduction in FEV₁ alone does not indicate expiratory airflow obstruction. A low FEV₁ combined with a normal FEV₁/FVC is indicative of restrictive disease (Fig. 29.14). Measurement of lung volumes in obstructive disease demonstrates an increased RV and often an increased FRC. Slowing of expiratory flow and gas trapping associated with premature distal airway collapse is responsible for the increase in RV. When spirometry is used to grade the severity of COPD (FEV₁/FVC less than 0.7), the post-

bronchodilator FEV_1 compared to predicted levels is the primary determinant: $FEV_1 \geq 80\%$ = mild, 50% to 79% = moderate, 30% to 49% = severe, and less than 30% = very severe. The number of exacerbations and hospitalizations per year is also directly correlated with 3-year mortality and can be considered in the evaluation of severity of COPD.⁶⁷

FIGURE 29.14 Changes in the forced expiratory volume in 1 second (FEV_1) and the forced expiratory capacity (FVC) in obstructive and restrictive pulmonary disease. COPD, Chronic obstructive pulmonary disease. (From Naish J, Court DS. *Medical Sciences*. 2nd ed. Philadelphia: Elsevier; 2015:632.)

Arterial Blood Gas Analysis.

ABG analysis is helpful in determining the severity of gas exchange abnormality and guiding management of patients with COPD. COPD may manifest with retained oxygenation (PaO_2 greater than 60 mm Hg, $PaCO_2$ normal) or impaired exchange of oxygen and CO_2 (PaO_2 less than 60 mm Hg, $PaCO_2$ greater than 45 mm Hg, and presence of cor pulmonale), generally based upon the severity of the disease and the relative contributions of emphysema and chronic bronchitis, respectively. When emphysema predominates, compensatory hyperventilation can maintain oxygenation until the disease is very advanced. Although patients maintain adequate

ABG values, they do so at the cost of significantly increased work of breathing, and general muscle wasting occurs. In chronic bronchitis, the alveolar capillary membrane is intact, but excess mucous in the airways impedes gas flow. Chronic hypoxia in the lung causes PVR to rise and to increase work on the right ventricle. The patients become polycythemic and hypoxemic. Cyanosis is more common in patient's with chronic bronchitis.

Chest Radiography and Computed Tomography.

Radiographic abnormalities may be minimal, even in the presence of advanced COPD. Hyperlucency of the lungs (caused by arterial vascular deficiency in the lung periphery) and hyperinflation (flattening of the diaphragm with loss of the silhouette) suggest the diagnosis of emphysema.⁴ If bullae are also present, the diagnosis of emphysema is virtually certain; however, only a small percentage of patients who have emphysema have bullae. Computed tomography (CT) can delineate the pulmonary parenchyma much better than standard chest radiography. CT may also be used to quantify the amount of air trapping. Although conventional radiography has 60% to 80% sensitivity to diagnose COPD, CT scanning improves sensitivity to 90%.⁴⁶

Treatment

Treatment of COPD is focused on relieving symptoms and reducing the incidence of exacerbations. There is no treatment to reverse the course of COPD, but smoking cessation can slow the forward progression of the disease. Medical management is aimed at promoting bronchodilation using inhaled β_2 -agonists, corticosteroids, or anticholinergics. Although a low baseline level of cholinergic tone normally influences bronchial caliber, cholinergic influence is found to be elevated in COPD, with fluctuations in airway diameter attributable to changes in cholinergic tone.⁷⁶ Ideally, anticholinergics that block the M_1 and M_3 receptors would be ideal, because the M_2 acts in negative feedback to reduce acetylcholine release. However, the M_2 receptor also reduces adenylate cyclase, so blockade of the M_2 receptors also confers the advantage of enhancing the response to β -agonists.⁵⁴ Tiotropium is

a long-acting anticholinergic that is more selective for the M₃ receptor than ipratropium and atropine, and it dissociates more rapidly from the M₂ receptor. Given a 24-hour duration of action, tiotropium is gaining popularity as the ideal anticholinergic for reducing cholinergic tone in COPD.^{77,78} The choice of agents in general is largely based on individual patient response and tolerance of different agents. A joint position statement by the American College of Physicians, American College of Chest Physicians, American Thoracic Society, and the European Respiratory Society recommends the following approach to medical management of symptomatic patients⁴⁸:

1. Bronchodilators *may* be used for mild COPD (FEV₁ 60%–80%)
2. Bronchodilators are *recommended* for FEV₁ less than 60%. The specific drug prescribed is based upon patient tolerance, side effects, and cost and may consist of a long-acting β₂-agonist, anticholinergic, or corticosteroid. Combination therapy may be used, although combination therapy does not show a consistent advantage over monotherapy.
3. Pulmonary rehabilitation may be used for patients with FEV₁ greater than 50% and is recommended for those with FEV₁ less than 50%.
4. Oxygen therapy is used to maintain PaO₂ greater than 60 mm Hg (SpO₂ greater than 88%) for patients who have resting hypoxemia below this level.

At all stages of COPD progression, removal of offending and exacerbating factors is recommended (particularly cessation of smoking and administration of the influenza vaccine). Surgical treatments that are used to reduce symptoms in COPD include lung volume reduction surgery (LVRS), bullectomy, and lung transplantation. LVRS removes severely diseased portions of lung, leaving behind a greater proportion of better-functioning tissue. The result is improved elastic recoil, diaphragmatic function, and reduction in exacerbations. LVRS is most effective for

predominantly upper lobe emphysema.⁶⁷

Preoperative Evaluation

The surgical site and the preoperative status of the patient are critical factors in predicting the incidence of postoperative complications. The risk of respiratory complications is generally proportional to the proximity of the surgical site to the diaphragm.⁴⁷ Multiple factors are predictive of postoperative respiratory difficulties, but no preoperative pulmonary function test establishes absolute contraindications to surgery. The preoperative evaluation of patients with COPD should determine the severity of the disease and identify treatments for reducing inflammation, improving secretion clearance, treating underlying infection, and increasing airway caliber to ensure the best surgical outcome. Although the FEV₁ has previously been used as the primary indicator of disease severity, other factors such as body mass index, functional dyspnea, and exercise tolerance along with the FEV₁ provide useful assessment of prognosis in patients with COPD.^{51,79} The multidimensional BODE index (*Body mass index, airflow Obstruction, Dyspnea, and Exercise capacity*) is one tool used to assess disease severity.⁸⁰ Despite their heterogeneity, treatment algorithms are primarily driven by a single measurement, FEV₁ as a percentage of its predicted value (FEV₁%). In 2011, a major shift in Global Initiative for Chronic Obstructive Lung Disease (GOLD) treatment recommendations was proposed that stratifies patients with COPD on the basis of symptoms.^{47 67} GOLD recommends that spirometry is required for the clinical diagnosis of COPD to avoid misdiagnosis and to ensure proper evaluation of severity of airflow limitation. The assessment of the patient with COPD should always include assessment of (1) symptoms, (2) severity of airflow limitation, (3) history of exacerbations, and (4) comorbidities. The widely-used GOLD classification system is shown in [Table 29.11](#) and [Fig. 29.15](#). The recommendations were recently updated to add: (1) Assessment and regular evaluation of inhaler technique to improve therapeutic outcomes. (2) Examination of symptoms and future risk of exacerbations should provide the map for pharmacologic management of stable COPD (3) Patients with

persistent symptoms should be started on a long-acting bronchodilator (a LABA or a LAMA), and if symptoms persist, then dual bronchodilator therapy should be added.(4) For patients with symptoms on a long-acting bronchodilator, advancement to dual-bronchodilator therapy is preferred over the combination of an inhaled-corticosteroid and a long-acting bronchodilator.(5)A shift toward a more personalized approach to treatment with strategies for escalation and de-escalation of pharmacotherapy.

TABLE 29.11

GOLD Classification of Severity of Airflow Limitation in COPD, Based on Post-Bronchodilator FEV₁

In Patients with FEV ₁ /FVC < 0.70	
GOLD 1: mild	FEV ₁ ≥ 80% predicted
GOLD 2: moderate	50% ≤ FEV ₁ < 80% predicted
GOLD 3: severe	30% ≤ FEV ₁ < 50% predicted
GOLD 4: very severe	FEV ₁ < 30% predicted

COPD, Chronic obstructive pulmonary disease; FEV₁, forced expiratory volume in 1 second.

patient groups according to the GOLD assessment proposal. * or 1 hospitalization. *COPD*, Chronic obstructive pulmonary disease. (In Broaddus VC, et al., eds. *Murray and Nadel's Textbook of Respiratory Medicine*. 6th ed. Philadelphia: Elsevier; 2016:765; Modified from Agusti A, et al. Frequently asked questions (FAQs) about the GOLD 2011 assessment proposal of COPD. *Eur Respir J*. 2013;42:1391–1401.)

The causes of acute exacerbations of COPD are multifactorial and may be explained only partially by airway infection or inflammation. Multiple contributing factors, including bronchitis, underlying airway hyperresponsiveness, inhalation of noxious agents, mucous plugging, pneumonitis, cardiovascular disease, CHF, and generalized systemic inflammation, must be considered. Signs of COPD may be subtle. The clinician must assess for increased respiratory effort, altered breathing patterns, abnormal breath sounds, and a productive cough. A consensus statement by the American Thoracic Society defines dyspnea as “a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiologic, psychologic, social, and environmental factors and may induce secondary physiologic and behavioral responses.”^{81,82}

A history of or the presence of atopy (predisposition to allergies), childhood respiratory impairment, high serum immunoglobulin E (IgE) levels, and eosinophilia is suggestive of asthmatic bronchitis, which is generally more responsive to treatment than is smoking-induced COPD. The value of preoperative pulmonary function tests is questionable for nonpulmonary surgery.⁴⁷ Data from resting SpO₂, dyspnea-related functional limitation, exercise capacity, and body mass index will lead to useful assessment of the patient's pulmonary reserve. If pulmonary function tests are available, spirometry should be assessed before and after bronchodilator or steroid treatment (or both) so that airway disease reversibility can be evaluated. The patient's response to bronchodilators provides important information about the manageability of the COPD, with an improvement in FEV₁ of 12% to 15% from baseline indicating a significant response.⁴⁴ Other changes considered significant are improvement in FVC of at least 10% and improvement in FEF_{25%–75%}

of at least 20%, but a lack of significant improvement does not preclude use of bronchodilators during anesthesia.⁴⁶

Numerous conditions predispose a patient with COPD to infectious complications, including dehydration, decreased ability to cough, immobility, and decreased mucociliary clearance. Optimal control of airway inflammation may require antimicrobial therapy preoperatively. Increasing cough, dyspnea, chest pain, fatigue, worsening blood gas values, and other signs may indicate an acute exacerbation of COPD. The patient may report a change in sputum volume, color, or consistency. Viruses are the most frequent causative organisms in acute exacerbations of chronic bronchitis.⁸³ Acute infection is associated with epithelial desquamation and correlates with airway hyperreactivity that may persist for 3 to 6 weeks after the resolution of symptoms.⁸⁴ Measures to improve respiratory skeletal muscle strength include good nutrition and balanced fluid and electrolyte intake. Bronchodilators should be used if the patient exhibits some degree of airway obstruction (coughing may temporarily increase in frequency as greater quantities of sputum are removed). Some commonly used bronchodilators are listed in [Table 29.12](#). If pulmonary function tests are performed, the degree of reversibility ([Fig. 29.16](#)) will suggest the potential for and the means of improving ventilation in the perioperative period.

TABLE 29.12
FDA-Approved Drugs for COPD

Drug	Delivery Device	Usual Adult Dosage
Inhaled Short-Acting Anticholinergic		
Ipratropium		
<i>Altrovent HFA</i> (Boehringer Ingelheim)	HFA MDI (200 inh/unit)	2 inhalations qid PRN
Generic – single-dose vials	Nebulizer	500 mcg qid PRN
Inhaled Short-Acting Beta₂-Agonist/Short-Acting Anticholinergic Combination		
Albuterol/Ipratropium		
<i>Combivent</i> (Boehringer Ingelheim)	CFC MDI (200 inh/unit)	2 inhalations qid PRN
<i>Combivent respimat</i> (Boehringer Ingelheim)	MDI (130 inh/unit)	1 inhalation qid PRN
DuoNeb(vey) generic	Nebulizer	2.5 - 9.5 mg qid PRN
Inhaled Long-Acting Beta₂-Agonists		
Indacaterol – <i>Arcapta Noehaler</i> (Novartis)	DPI (30 inh/unit)	75 mcg once/day
Salmeterol – <i>Serevent Diskus</i> (GSK)	DPI (60 inh/unit)	50 mcg bid
Formoterol – <i>Foradil Aerolizer</i> (Merk)	DPI (60 inh/unit)	12 mcg bid

<i>Perforomist</i> (Dey)	Nebulizer	20 mcg bid
Arformoterol – <i>Brovana</i> (Sunovion)	Nebulizer	15 mcg bid
Inhaled Long-Acting Anticholinergics		
Tiotropium – <i>Spiriva HandiHaler</i> (Boehringer Ingelheim)	DPI (60 inh/unit)	18 mcg once/day
Aclidinium – <i>Tudorza Pressair</i> (Forest)	DPI (60 inh/unit)	400 mcg bid

bid, Twice per day; *inh*, inhalations; *qid*, 4 times per day; *PRN*, as needed.

FIGURE 29.16 Flow-volume loop, demonstrating expected improvement after bronchodilator therapy.

An increased plasma concentration of bicarbonate in the presence of a low or normal PaCO_2 suggests that acute hyperventilation is compensatory and it is caused by chronic CO_2 retention. If the PaCO_2 has been chronically elevated, it is important that the hypercarbia not be corrected too quickly. Sudden decreases in PaCO_2 can result in alkalemia because the kidneys cannot rapidly excrete excessive amounts of bicarbonate.

Anesthetic Management

Presently, there is a lack of scientific evidence that supports a specific anesthetic regimen for patients with COPD. However, there

are general principles should guide anesthetic planning. It is crucial to realize that COPD patients are susceptible to the development of acute respiratory failure during the postoperative period. Therefore continued intubation of the trachea and mechanical ventilation of the lungs may be necessary, particularly after thoracic and upper abdominal surgery. Postoperative ventilation is more likely to be needed in those patients with low PaO₂ and dyspnea at rest.

Assessment of respiratory function can be performed effectively and inexpensively by considering relevant factors, such as the GOLD Classification or BRODE score (see [Table 29.11](#)). In initial study, the BODE score was lower among survivors than among those who died from any cause up to 52 months postoperatively (3.7 ± 2.2 vs. 5.9 ± 2.6 , $p < 0.005$).⁸⁰ When categorized into four quartiles (BODE indices of 0 to 2, 3 to 4, 5 to 6, and 7 to 10, respectively), there was significant correlation in the mortality rates among patients in higher-scored quartiles.⁸⁵

Regional Anesthesia

Regional anesthesia is useful if sedation is not needed, and it may be less challenging than general anesthesia, to avoid manipulation of the airway and ventilation. However, anesthesiologists must nonetheless maintain a high level of vigilant monitoring if regional is administered. Complications such as pneumothorax and impaired respiratory muscle function (from phrenic nerve block or high spinal block) can lead to respiratory embarrassment quickly in the compromised patient. Neuraxial anesthetic techniques that produce sensory anesthesia above T6 are not recommended. The potential for decreasing expiratory reserve volume, impairing cough effort, and creating anxiety-provoking weakness is too great.⁸⁶

General Anesthesia

General anesthesia is often provided with a volatile anesthetic (to facilitate bronchodilation) and humidification (to prevent drying of secretions). Maintaining adequate anesthesia in patients with significant lung disease presents a challenge. General anesthesia is often associated with an increase in the alveolar-arterial difference in PO₂ (PAO₂ – PaO₂). Causes include a fairly consistent 20%

decrease in FRC when neuromuscular relaxants are used, as well as small airway closure and atelectasis. Atelectasis normally occurs after induction of general anesthesia, and it has been found to worsen with muscle paralysis and prolonged surgical duration.⁸⁷ It is interesting to note that patients with chronic hyperinflation appear to be less likely to develop atelectasis than subjects with healthy lungs, possibly because of airway closure before alveolar collapse or because of resistance to early alveolar collapse from long-standing lung hyperinflation, which prevents prompt formation of atelectasis.⁸⁸

There is some evidence that volatile anesthetics reduce the function of cilia in the respiratory tract.⁸⁹ Opioids pose less threat to disrupting ventilation-perfusion matching and may be an appealing option. However, the residual respiratory depressant effects of opioids must be managed, particularly in the COPD population, which is generally of advanced age. If N₂O is used for this purpose, bullae may enlarge and rupture; therefore presence of bullous emphysema is a contraindication to use of N₂O.

Ventilation Management

Ventilation strategies should focus on maintaining adequate oxygenation, eliminating CO₂, avoiding barotrauma from excessive inspiratory pressures, avoiding tissue injury from repetitive airway closure and reopening, and avoiding volutrauma from either excessive tidal volumes or from auto-PEEP. Oxygenation is managed first with FiO₂, but care must be taken to reduce absorptive atelectasis or damaging oxidative effects from overzealous oxygen administration. If concerns about N₂O exist, then oxygen and air provide a useful combination of carrier gases. Attention should be given to adequate hydration to prevent excessive drying of respiratory secretions. In managing CO₂ elimination, providers should avoid correction of a chronic hypercapnia during mechanical ventilation. In the face of long-term renal compensation, doing so may result in an unintended alkalemia and may make ventilator weaning difficult.

Patients with COPD have difficulty effectively moving gas into the respiratory zone and with air trapping. Airway secretions and

bronchial reactivity impede inspiration. Intermittent vital capacity maneuvers to recruit atelectatic alveoli will help improve oxygenation during surgery,⁸⁸ and PEEP will help maintain small airway patency. If the airways are noncompliant, such as with bronchitis, then slower inspiration, perhaps with an inspiratory pause, is helpful to allow time for gas to redistribute from higher compliance areas to less-ventilated areas of lung. Obstructive disease, however, may conflict with those strategies at maximizing oxygenation. With obstructive disease, longer expiratory times are useful (lower inspiration/expiration [I:E] ratio) to allow more time for expiration. The lower I:E ratio is used at the sacrifice of peak pressures, which will rise as higher inspiratory flow is used to deliver the tidal volume in a shorter inspiratory cycle. Leatherman demonstrated that there is no benefit to prolonging expiratory time beyond 4 seconds.⁹⁰ With COPD, on expiration, small airway closure and emphysematous loss of elasticity impede complete emptying of the tidal breath. As a result, inspiration begins at volumes at which the respiratory system exhibits positive recoil pressure. Thus pressure builds due to incomplete emptying at the time that the next inspiration begins. This is known as *auto-PEEP* or *intrinsic PEEP* (PEEPi).^{91,92} In the past, external PEEP (PEEPe) was generally not used in patients with COPD because hypoxemia is often improved with increases in FiO₂ and because the risk of barotrauma resulting from further hyperinflation was deemed too great. The risk of PEEP exacerbating incomplete emptying is greater in patients with COPD.⁹³ However, cyclic closure and reopening of small airways with each breathing cycle is also detrimental, and judicious use of PEEP may avoid this low-volume tissue injury.⁹³ Research suggests that a PEEPe that is less than the PEEPi in the presence of expiratory flow limitation may assist patients in overcoming the inspiratory mechanical load of PEEPi, ultimately decreasing the work of breathing and eliminating or decreasing atelectatic areas and airway closure.⁹³⁻⁹⁵ Patients whose peak cycling pressures remain essentially unaffected by PEEPe experience the greatest improvement with minimal untoward effects.⁹⁶ In the operating room, the clinician can best diagnose PEEPi by assessing whether exhalation is still taking place when the next inhalation starts.⁹⁷ Newer-generation anesthesia machines, which provide

dynamic flow and volume tracings of the respiratory cycle have improved the anesthetists ability to adequately ventilate patients with COPD (Fig. 29.17). Monitoring flow-volume tracings or the capnograph for expiratory airflow obstruction (Fig. 29.18) may also help guide decision making about whether incomplete emptying threatens the development of PEEPi. When PEEPe is added, it should be titrated in 2.5- to 5-cm H₂O increments while peak cycling pressures are closely monitored. Because PEEP is intended to avoid closure of small airways and alveoli that would exist at the lower (flat) portion of the compliance curve, the pressure-volume tracing can be used to determine the appropriate amount of PEEP to administer. Research demonstrates that PEEP set just above the lower inflection point of the compliance curve provides optimal oxygenation⁹⁸⁻¹⁰⁰ (Fig. 29.19). Although it can be difficult to determine this point clinically,¹⁰¹ the concept is important, because it connects understanding of the physiologic concept of the compliance curve with the clinical intervention of PEEP.

FIGURE 29.17 Development of intrinsic positive end-expiratory pressure (PEEPi) is suspected when the expiratory flow tracing does not reach the zero line before the subsequent inspiration begins. (From García Vicente E, et al.

Ventilación mecánica invasiva en EPOC y asma. *Med Intensiva*.

2011;35(4):288–298.)

FIGURE 29.18 Capnograph of a patient with expiratory airway obstruction. *COPD*, Chronic obstructive pulmonary disease.

FIGURE 29.19 The lower inflection point (P_{FLEX}) of the pressure-volume curve of the airway suggests an optimal pressure for setting positive end-expiratory pressure (PEEP).

Postoperative Care

Postoperative care of patients with COPD is directed at minimizing the incidence and severity of pulmonary complications, because such patients are at increased risk for developing acute respiratory failure.¹⁰² Postoperative pulmonary complications are most often

characterized by atelectasis followed by pneumonia and decreases in PaO₂.⁹⁷ These patients require close monitoring; worsening V/Q mismatch after extubation may not be detected by ABG analysis, possibly because of changes in breathing pattern and cardiovascular function. In fact, minute ventilation may not change, but often respiratory rate increases, and V_T decreases after the termination of mechanical ventilation.⁹⁶ The choice of drugs or techniques for producing anesthesia does not seem to predictably alter the incidence of postoperative pulmonary infections. Whether a relationship exists between the duration of anesthesia and the incidence of postoperative pulmonary complications is unclear.

Asthma

Definition

The National Asthma Education and Prevention Program Expert Panel Report 3 (EPR-3) defines asthma as “a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, neutrophils (especially in sudden onset, fatal exacerbations, occupational asthma, and patients who smoke), T lymphocytes, macrophages, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of coughing (particularly at night or in the early morning), wheezing, breathlessness, and chest tightness. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment.”¹⁰³ Although asthma involves chronic inflammation of the respiratory tract, it is propagated by various mediators of inflammation than in COPD, which is what primarily differentiates the pathogenesis of the two diseases.⁶⁷

Various theories underlie the cause of asthma. The three overarching theories suggest that asthma may result from the following:

1. *Deficiency of acquired immunity.* Lack of exposure to immunologic challenges in early life allows predominance of the Th2-type cytokine response and a general atopy.

2. *Genetics*.

3. *Exposure to respiratory system irritants*. These include airborne allergens (house-dust mite), irritants (tobacco smoke), and viral respiratory infections (respiratory syncytial virus).

A general approach to classification discriminates between extrinsic or intrinsic asthma. Although this system is conceptually helpful, its two groups are not mutually exclusive. Extrinsic asthma (or allergic asthma) most commonly affects children and young adults and involves exacerbation by infectious, environmental, psychological, or physical factors, whereas intrinsic asthma (or idiosyncratic asthma) usually develops in middle age without specifically identifiable attack-provoking stimuli. It is of significance that the clinical features of idiosyncratic asthma are essentially indistinguishable from the immune-mediated response.

Incidence and Outcome

Up to 25 million persons in the United States have asthma. It is the most common chronic disease of childhood, affecting an estimated 6 million children. Having asthma not only affects the lives of patients but also their families and society in terms of lost work and school, lessened quality of life, and avoidable emergency department (ED) visits, hospitalizations, and deaths.¹⁰³

Pathogenesis and Pathophysiology

Our contemporary understanding of asthma is that it is not a single entity, but rather a heterogeneous clinical syndrome characterized by episodes in which airways are hyperresponsive at times interspersed with symptom-free periods.¹⁰⁴ Bronchoconstriction is a factor long associated with the asthmatic symptom complex, but asthma is much more than bronchoconstriction. Airway inflammation and a nonspecific hyperirritability of the tracheobronchial tree are now recognized as being central to the pathogenesis of even mild cases of asthma. Permanent changes in airway anatomy, referred to as *airway remodeling*, magnify the inflammatory response.^{104,105} Some manifestations of airway

remodeling include fibrosis, mucus hypersecretion, smooth muscle hypertrophy, and angiogenesis.¹⁰³

Allergic (atopic) asthma is triggered by antigens that provoke a T-lymphocyte-generated, IgE-mediated immune response.¹⁰⁶ It is often associated with a personal or familial history of allergic disease. In susceptible patients, exposure to even minute amounts of an offending agent can cause activation of lymphocytes and cytokine release, setting into motion an immune-mediated inflammatory response. Endobronchial biopsy specimens, even from asymptomatic patients, frequently show an active inflammatory process. Eosinophils, mast cells, neutrophils, and macrophages are the most common mediators of the proinflammatory cascade.

Potent biochemical mediators released from proinflammatory and airway epithelial cells promote vasoconstriction, increased smooth muscle tone, enhanced mucus secretion, submucosal edema, increased vascular permeability, and inflammatory cell chemotaxis. Leukotrienes have been identified as especially potent spasmogenic and proinflammatory substances. Released molecules that are toxic to the airway epithelium cause patchy desquamation, exposing cholinergic nerve endings and compounding the bronchoconstrictive and hyperresponsive response. The asthmatic diathesis creates airway inflammation, edema and hypersensitivity to irritant stimuli. The degree of airway hyperresponsiveness and bronchoconstriction appears to parallel the extent of inflammation.^{107,108} When airway reactivity is high, asthmatic symptoms are generally more severe and unrelenting, and the amount of therapy required to control the episode is greater.¹⁰⁴

The mechanisms underlying nonimmunologic asthma are less clearly defined. Nonimmunologic asthma occurs in patients with no history of allergy and normal serum IgE. These patients typically develop asthmatic symptoms in response to some provocative or noxious stimulus such as cold air, airway instrumentation or irritation, climate changes, or an upper respiratory illness. Recent upper respiratory infection may precipitate bronchospasm in any patient, but the risk is higher in patients with a history of asthma. The increased bronchomotor tone associated with viral respiratory infections may persist for as long as 5 weeks.⁸⁴ Nonasthmatic

children with an upper respiratory infection are two to seven times more likely to experience an adverse event perioperatively and are more prone to postoperative desaturation.¹⁰⁹ Asthma itself, however, appears not to be a risk factor for postoperative complications, if it is controlled.¹¹⁰ Poorly controlled asthma (defined by rescue inhaler use or emergency department visits within 30 days) is associated with an increase in respiratory complications.¹¹¹

Immune mechanisms appear to be causally related or contributory to the development of asthma in more than 50% of cases, but many patients with asthma have disease mechanisms from both categories. Asthma that has its onset in childhood tends to have a strong allergic component, whereas asthma that arises in adults tends to be nonallergic or to have a mixed cause.¹⁰⁴ As a general rule, nonallergic mechanisms of exacerbation are more prevalent in the perioperative period.¹¹²

IgE-mediated asthma occurs after initial antigen exposure has resulted in IgE antibody formation. On repeat exposure, in the presence of IgE, mast cells release multiple mediators. These mediators directly constrict small and large airways, increase capillary permeability, stimulate vasoconstriction, and increase mucous gland secretion, which contributes to mucus plugging (Fig. 29.20).

FIGURE 29.20 Acute asthmatic responses. Inhaled antigen (1) binds to mast cells covered with preformed IgE.

Mast cells degranulate (2) and release inflammatory mediators such as histamine, bradykinins, leukotrienes, prostaglandins, platelet-activating factor, and interleukins. Secreted mediators (3) induce active bronchospasm (airway smooth muscle constriction), edema from increased capillary permeability, and airway mucus secretion from goblet cells. At the same time, antigen is detected by (4) dendritic cells that process and present it to Th2 cells (5), which produce interleukin-4 (IL-4) and many other interleukins (see text). IL-4 promotes switching of B cells to favor immunoglobulin E (IgE) production. Th2 cells also produce IL-5 (6), which activates eosinophils. Eosinophil products, such as major basic protein and eosinophilic cationic protein, damage the respiratory epithelium. Many inflammatory cells, including neutrophils (7), also contribute to the inflammatory process. *IgE*, Immunoglobulin E. (From McCance KL, Huether SE. *Pathophysiology: The Biologic Basis for Disease in Adults and Children*. 7th ed. St. Louis: Elsevier; 2014:1265.)

The mechanism of exercise-induced bronchospasm is unknown. One popular theory suggests that a high minute ventilation (\dot{V}_E) and the low temperature or low H_2O content of inspired gas (which requires greater heat and water transfer from the mucosal surface to the inspired gas) generates a bronchoconstrictive response. Another theory proposes that the evaporation of water from respiratory mucosa and the resultant increase in the osmolarity of the surface-lining fluid induces the degranulation of mast cells. A third theory suggests that reactive hyperemia of the bronchial mucosa occurs with rewarming, resulting in airway narrowing.¹¹³ Regardless of the mechanism, most symptoms last less than 1 hour and are usually very responsive to administration of β_2 -adrenergic receptor agonists.¹¹⁴

Occupational asthma develops when irritants directly stimulate vagal nerve endings in the airway epithelium. Infection-induced asthma with acute inflammation of the bronchi may be caused by viral, bacterial, or mycoplasmal infections. Aspirin-induced asthma occurs when, in some predisposed persons, cyclooxygenase inhibition drives arachidonic acid metabolism toward the lipoxygenase pathway, resulting in production of leukotrienes, thereby triggering the asthma attack.¹¹⁵ This peculiar response can

also occur with the use of other nonsteroidal antiinflammatory agents. The aspirin-induced asthma variant is not IgE mediated or allergic in nature. It is clinically associated with the presence of nasal polyps.

Clinical Features and Diagnosis

Airflow limitation is caused by a variety of changes in the airway, all influenced by airway inflammation¹⁰³:

- *Bronchoconstriction*—bronchial smooth muscle contraction that quickly narrows the airways in response to exposure to a variety of stimuli, including allergens or irritants
- *Airway hyperresponsiveness*—an exaggerated bronchoconstrictor response to stimuli
- *Airway edema*—as the disease becomes more persistent and inflammation becomes more progressive, edema, mucus hypersecretion, and formation of inspissated mucus plugs further limit airflow

Key hallmarks of asthma include^{103,107}:

- Recurrent wheezing
- Dyspnea (may parallel the severity of expiratory airflow obstruction)
- Cough (productive or nonproductive; frequently at night or early morning)
- Recurrent labored respirations with accessory muscle use
- Tachypnea (a respiratory rate greater than 30 breaths per minute and a heart rate of 120 suggests severe bronchospasm)
- Recurrent chest tightness
- Prolonged expiratory phase of respiration
- Fatigue
- Symptoms occur or worsen with exercise, viral infection, environmental allergens or irritants, changes in weather, stress, or menstrual cycles

Clinical classification of asthma is noted in [Table 29.13](#), and corresponding treatment protocols are shown in [Fig. 29.21](#). Typical attacks are short-lived, lasting minutes to hours. Between attacks

the asthmatic patient may be entirely symptom free; however, underlying airway remodeling is still evident.^{105,106} Severe obstruction that is refractory to bronchodilator therapy is known as *status asthmaticus*. This variant occurs in persons with a genetic predisposition¹¹⁶ and requires an escalating approach to therapy for symptoms that may persist over a number of days. Status asthmaticus also can represent an emergency situation. At times, anesthesiologists are called upon to administer ketamine or volatile anesthetics as part of the treatment for status asthmaticus.¹¹⁷⁻¹¹⁹ Use of accessory muscles of respiration and the increased work of breathing associated with a protracted asthmatic episode can result in respiratory muscle fatigue and respiratory failure.

TABLE 29.13

Classification of Severity of Asthma in Adults and Children Older Than 12 not Currently Taking Long-Term Controllers

Components of Severity	Classification of Asthma Severity (Youths ≥ 12 yr and Adults)			
	Intermittent	Persistent		
		Mild	Moderate	Severe
Impairment				
Symptoms	≤ 2 days/wk	> 2 days/wk but not daily	Daily	Throughout the day
Nighttime awakenings	< 2×/mo	3-4×/mo	> 1×/wk but not nightly	Often 7×/wk
Short-acting β ₂ -agonist use for symptom control	≤ 2 days/wk	> 2 days/wk but not daily	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal FEV ₁ between exacerbations			
	<ul style="list-style-type: none"> • FEV₁ > 80% predicted • FEV₁/FVC normal 	<ul style="list-style-type: none"> • FEV₁ > 80% predicted • FEV₁/FVC normal 	<ul style="list-style-type: none"> • FEV₁ > 60% but < 80% predicted • FEV₁/FVC reduced 5% 	<ul style="list-style-type: none"> • FEV₁ < 60% predicted • FEV₁/FVC reduced > 5%
Risk				
Exacerbations (consider frequency and severity)	0-2/yr	> 2/yr	> 2/yr	> 2/yr
	Frequency and severity may fluctuate over time Relative annual risk of exacerbations may be related to FEV ₁			

FEV₁, Forced expiratory volume in 1 second; FVC, forced vital capacity.

During exacerbations, pulmonary function tests may reflect acute expiratory airflow obstruction (\downarrow forced expiratory flow [$FEF_{25\%-75\%}$]; \downarrow FEV_1/FVC). Viscid mucus secretion may compound the airway narrowing and produce airway collapse.¹¹⁴ The asthmatic episode produces not only airflow obstruction but also gas exchange abnormalities. The resulting low V/Q state produces arterial O_2 desaturation.¹²⁰ Hypoxemia is common, but in most patients with acute bronchospasm, CO_2 elimination is relatively well preserved

until V/Q abnormalities are severe. An increased arterial CO₂ tension may indicate impending respiratory failure in the acutely ill asthmatic patient. Chronic asthma may eventually lead to irreversible lung destruction, loss of lung elasticity, PH, and lung hyperinflation.

Diagnostic Testing

Pulmonary Function Tests.

Lung function testing offers limited value to anesthetic risk assessment and should not be performed routinely based solely on the presence of asthma. Although spirometry is used to determine candidacy for lung resection surgery, it has limited value before extrathoracic surgery, even in patients with asthma or other lung disease. Even when spirometry is used to document the degree of airflow limitation, there is not a known threshold that precludes surgery.¹¹⁰

When pulmonary function tests are performed, they provide information related to the degree of impairment and the reversibility of airway limitation. RV, FRC, and TLC all increase because of an increase in volume of the gas trapped beyond closed airways, and lung deflation is less because of airway obstruction. Comparison of current and prior pulmonary function test results is useful. Tolerance of activities is used for classifying the degree of dyspnea.¹²¹ The patient in remission may have negative results on all parameters of pulmonary function and can be tested with a cholinergic agonist such as methacholine for bronchial provocation and clarification of the diagnosis of asthma.¹²² The hallmark of an incipient exacerbation of asthma is a reduction in the peak expiratory flow rate.¹⁰³

Arterial Blood Gas Analysis.

Increased diffusibility of CO₂ (compared with that of O₂) in combination with an often increased respiratory rate generally produces ABG analysis results that reflect the presence of respiratory alkalosis. Even slight hypercapnia may indicate severe air trapping and potential impending respiratory failure.

Chest Radiography.

Because nearly 75% of asthma patients have a normal chest radiograph, chest radiography is not helpful in diagnosing or determining the severity of asthma. Hyperinflation with flattening of the diaphragm may be evident.

Electrocardiography.

Changes evident on electrocardiography, such as ST-segment changes, right ventricular strain, and right axis deviation, usually manifest only in severe attacks and generally are of little significance with regard to the asthmatic condition.

Sputum Analysis.

Eosinophilia, which is common in asthmatic patients, may be manifested as the production of grossly purulent sputum. Microscopic evaluation may reveal Curschmann spirals and Charcot-Leyden crystals, rather than polymorphic neutrophils associated with infection.

Serum Values.

Eosinophilia (defined as more than 275 eosinophils per cubic millimeter of blood) is common in asthmatic patients with active IgE-mediated bronchial asthma, but its presence does not serve to differentiate extrinsic from intrinsic asthma. Asymptomatic patients with asthma generally have a total blood eosinophil count that is less than 50/mm³, with an increasing count often signaling the acceleration of bronchial asthma even before such patients experience symptoms. Determination of an increased eosinophil value in the absence of signs and symptoms of asthma requires that a differential analysis be undertaken. Tests for detection of IgE antibodies are performed only if an identifiable and avoidable substance is suspected. In this instance, consultation with a physician skilled in testing for allergic disease may be indicated.

Anesthetic Management

Several important anesthetic considerations and risk-reduction strategies have been reported. The EPR-3 recommends the

following to reduce the risk of complications during surgery¹⁰³:

- Before surgery, review the level of asthma control, medication use (especially oral systemic corticosteroids within the past 6 months), and pulmonary function.
- Provide medications before surgery to improve lung function if lung function is not well controlled. A short course of oral systemic corticosteroids may be necessary.
- For patients receiving oral systemic corticosteroids during the 6 months before surgery, and for selected patients on long-term high-dose inhaled corticosteroids (ICS), give 100 mg hydrocortisone every 8 hours intravenously during the surgical period, and reduce the dose rapidly within 24 hours after surgery.

Preoperative Evaluation

A careful preoperative history and physical examination are essential to discerning the current disease status and medication profile. Frequent nocturnal awakenings due to respiratory difficulty, recent increases in medication use, and signs of viral infection may signal an increased likelihood of intraoperative difficulties.¹²³ Elective procedures in patients who are exhibiting significant respiratory symptoms should be postponed, and the condition of such patients should be normalized as much as possible.¹²⁴

The predictive value of routine pulmonary function testing does not warrant screening use of this modality, rather, it should be used only when patient condition and surgical procedure cause concern for the patient's pulmonary recovery.⁴⁸ FEV and peak expiratory flow rate, which can be measured with inexpensive handheld devices, may be helpful in assessing current respiratory status. Values that fall 30% to 50% below expected baseline values indicate a moderate episode of bronchoconstriction. Values below 50% of normal indicate a severe episode.¹²³

Medication management of asthma is similar to that of COPD. Anticholinergics are more commonly used with COPD, whereas corticosteroids are more highly effective in patients with asthma.¹²⁵ Pretreatment with systemic corticosteroids has been advocated in asthma patients undergoing surgical procedures. Kabalin et al.¹²⁶

studied the administration of corticosteroids in asthmatic surgical patients. Of the 89 subjects in the study, 86 had no postoperative wheezing when given either prednisone or hydrocortisone preoperatively. Complications of steroid therapy such as delayed wound healing, infection, or adrenocortical insufficiency were not noted. Ensuring that a patient who is currently receiving inhaled or systemic steroids receives them immediately before surgery is prudent.

Routine preoperative medications should be given to allay anxiety. The anticholinergics atropine and glycopyrrolate exhibit mild bronchodilating effects. As noted earlier, asthmatics experience an increased parasympathetic tone, and these agents are most effective as prophylactic drugs given 20 to 30 minutes preoperatively, rather than for acute therapy.¹²⁷ Caution must be exercised when administering narcotics to patients whose respiratory difficulties are evident or when using narcotics associated with histamine release, such as morphine and the other phenanthrenes. Fentanyl and the other phenylpiperidine analogs commonly used in anesthesia (with the exception of meperidine) have been widely used and are safe.¹²⁷⁻¹²⁹ The use of histamine-2 (H₂)-receptor blocking agents such as cimetidine and ranitidine to reduce gastric volume and acidity should be avoided.^{109,129} Bronchospasm after their use has been reported, possibly resulting from loss of inhibitory feedback control via presynaptic H₂-receptor blockade, resulting in increased histamine release. Commonly prescribed drug therapy for asthma is listed in [Table 29.14](#).

TABLE 29.14
FDA-Approved Drugs for Asthma

Drug	Adult Dosage	Pediatric Dosage
Inhaled Beta₂-Agonists, Short Acting		
Albuterol – <i>Proair</i> <i>Proventil</i> <i>Ventolin</i>	90–180 mcg q 4–6 hr PRN	≥ 4 yrs; 90–180 mcg q 4–6 hr PRN
generic single – dose vials	1.25–5 mg q 4–8 hr PRN	2–4 yrs; 0.63–2.5 mg q 4–6h PRN 5–11 yrs: 1.25–5 mg q 4–8 hr PRN
Acc/Nub Single-dose vials	-	2- 12 yrs: 0.63 or 1.25 mg tid–qid PRN
Levalbuterol – <i>Xopenex</i>	90 mcg q 4–6 hr PRN	≤ 4 yrs: 90 mcg q 4–6 hr PRN

<i>Xopenex</i>	0.63–1.25 mg tid q 6–8 hr PRN	6–11 yrs; 0.31–0.63 mg tid q 6–8h PRN
<i>Pirbuterol</i> – Maxair Autohaler	200–400 mcg q 4–6 hr PRN	≤12 yrs: 200–400 mcg q 4–6 hr PRN
Inhaled Corticosteroids		
Beclomethasone dipropionate	40–320 mcg bid	5–11 yrs: 40–80 mcg bid
<i>QVAR</i>	180–720 mcg bid	6–17 yrs: 180–360 mcg bid
Budesonide – <i>Pulmicort</i>		
<i>Flexhaler Pulmicort Respules</i>	–	1–8 yrs: 0.25 mc bid or 0.5 mg once/day or bid or 1 mg once/day
Generic – single-dose vials	80–320 mcg bid	≤ 12 yrs: 80–320 mcg bid
Ciclesonide – <i>Alvesco</i>	160–320 mcg bid	16–11 yrs: 80–160 mcg bid
<i>Fluticasone propionate</i> – <i>Flovent Diskus</i>	100–1000 mcg bid	4–11 yrs: 50–100 mcg bid
<i>Flovent HFA</i>	88–880 mcg bid	
	222–888 mcg once/day in evening or 220 mcg bid	4–11 yrs: 88 mcg bid
Mometasone furoate – <i>Asmanex Twisthaler</i>		4–11 yrs:110 mcg 1x/day in evening
Oral Glucocorticoids		
Methylprednisolone – generic <i>Medrol</i> Prednisolone – generic <i>Prelone</i> <i>Orapred</i> <i>Orapred ODT</i> <i>Pediapred</i> Prednisone – generic	7.5–60 mg once/day or every other day or 40–60 mg once/day or divided bid x 3–10 days for an acute exacerbation	0–11 yrs: 0.25–2 mg/kg once/day or every other day (max 60 mg/day) or 1–2 mg/kg per day divided bid x3–10 days (max 60 mg/d) for an acute exacerbation
Inhaled Beta₂-Agonists, Long-Acting		
Salmeterol – <i>Serevent Diskus</i> (GSK)	50 mcg bid	≤4 yrs: 50 mcg bid
Formoterol – <i>Foradil Aerolizer</i>	12 mcg bid	≤5 yrs: 12 mcg bid
Inhaled Corticosteroid/Long-Acting Beta₂-Agonist Combinations		
Fluticasone propionate/ Salmeterol		
<i>Advair Diskus</i>	1 inhalation bid	4–11 yrs: 1 inhalation (100/50 mcg) bid
<i>Advair</i>	2 inhalations bid	≤12 yrs: 1 inhalation bid ≤12 yrs: 2 inhalations bid
Budesonide/formoterol – <i>Symbicort</i>	2 inhalations bid	≤12 yrs: 2 inhalations bid
Mometasone/formoterol – <i>Dulera</i>	2 inhalations bid	≤12 yrs: 2 inhalations bid
Leukotriene Modifiers		
Montelukast – generic <i>Singulair</i>	10 mg PO once/day	≤1 yr: 4 or 5 mg PO once day
Zafirlukast – generic <i>Accolate</i>	20 mg PO bid	5–11 yrs: 10 mg PO bid ≤12 yrs: 20 mg PO bid
Zileuton – <i>Zyflo</i>	600 mg PO qid	≤12 yrs 600 mg PO qid
Extended-release <i>Zyflo CR</i>	1200 mg PO bid	≤12 yrs: 1200 mg PO bid
Anti-IgE Antibody		
Omalizumab – <i>Xolair</i>	150–300 mc SC q 4 wks or 225–375 mg SC 2 wks	≤12 yrs: 150–300 mg q 4 wks or 225–375 mg q 2 wks
Theophylline		

Generic	300–600 mg/once day or divided bid	10 mg/kg per day (max 300 mg/day)
Theo-24	300–600 mg once/day	
Theochron	300–600 mg once/day

Intraoperative Management

Despite a lack of definitive controlled clinical studies, regional anesthetic techniques are generally considered to be safer than general anesthesia.¹³⁰ Spinal or epidural levels to the midthoracic area or higher, however, decrease FRC, expiratory reserve volume, and the ability to cough, and should be avoided.

The common induction drugs—propofol and ketamine—have been used successfully in asthmatic patients, but some differences exist. Ketamine is the only induction drug with bronchodilating properties, which makes it the agent of choice in patients with active asthmatic symptoms who require emergency surgery. Pizov et al.¹³¹ compared thiopental, thiamylal, methohexital, and propofol in a double-blind randomized study in patients with and without asthma. None of the asthmatic patients who received propofol exhibited wheezing 2 and 5 minutes after intubation. Wheezing after intubation occurred in 26% to 45% of the patients who received one of the three barbiturates. The authors suggested that propofol is advantageous for routine induction in asthmatic patients.

The inhalation agents produce bronchial relaxation and have all been used successfully in patients with asthma after administration of an intravenous induction drug. Isoflurane and desflurane, however, are both mild respiratory irritants, which may be a consideration during emergence. It is common practice to blunt this effect with the administration of opiates. Sevoflurane is the agent of choice for inhalation induction in children.^{132,133} Other anesthesia-related medications that should be avoided in asthmatic patients include atracurium, mivacurium and morphine because of histamine release, and β -receptor blockers, which may produce bronchoconstriction. If a β -blocker is desired, esmolol is the preferred choice, because of its relative β -1 selectivity and very short half-life. Prostaglandins, such as the F2 α subtype that is used

to stop post-partum bleeding, should be avoided in asthmatic patients, as should ergonovine and related ergot derivatives because of the risk of bronchospasm. Many practitioners avoid long-acting muscle relaxants and the associated possibility of residual muscle weakness in patients with asthma. Ketorolac and other nonsteroidal inflammatory agents should be avoided in patients with aspirin-intolerant asthma.¹³⁴

A strategy for mechanical ventilation that avoids lung hyperinflation and barotrauma while allowing for longer expiratory times should be chosen. A reduction in VE, by limiting inspiratory times and prolonging expiratory times, and moderate permissive hypercapnia have been suggested.¹³⁵⁻¹³⁷

Intraoperative Bronchospasm

The onset of an asthmatic episode may occur abruptly in surgical patients. Airway manipulation, acute exposure to allergens, or the stress of surgery can provoke wheezing in a patient who was previously asymptomatic. The lability of the disease makes assiduous observation crucial. Wheezing often suggests potentially reversible bronchoconstriction, but the extent or degree of wheezing is a notoriously poor indicator of the degree of airway obstruction.¹²¹ In addition, care must be taken to differentiate wheezing of asthmatic origin from other causes of wheezing, such as pneumothorax, ETT obstruction, endobronchial intubation, anaphylaxis, pulmonary edema, and pulmonary aspiration.¹³⁸

In anesthetized patients, prominent manifestations of the asthmatic episode are wheezing, increased mucous secretion, high inspiratory pressures, a blunted expiratory CO₂ waveform, and hypoxemia. Mechanical ventilation and positive airway pressure are associated with a higher incidence of air trapping and lung hyperinflation, and the associated inflammation can result in a pneumothorax.¹²⁰ Additionally, alveolar overdistention may lead to decreased venous return and CO. The combination of impaired ventilation and hypoxemia can precipitate increased PVR, enhanced right ventricular afterload, and finally hemodynamic collapse.

If an episode of bronchospasm occurs during anesthesia, the following steps are recommended:

1. Deepen the level of anesthesia with a volatile agent, ketamine, propofol, lidocaine, or a combination that rapidly increases anesthetic depth.
2. Administer 100% O₂.
3. Administer a short-acting β_2 -agonist (SABA).
4. In severe cases, administer epinephrine intravenously or subcutaneously (in doses of 10 mcg/kg).
5. Administer intravenous corticosteroids—hydrocortisone 2 to 4 mg/kg.
6. Consider intravenous aminophylline if long-term postoperative mechanical ventilation is planned.

Theophylline has little efficacy for the treatment of acute bronchoconstrictive episodes.¹³⁹ Episodes of severe airway obstruction may not respond to bronchodilator treatment, and cessation of wheezing may occur with the worsening of obstruction (i.e., the “ominously silent chest”).

When treating bronchospasm, SABAs may be administered by metered-dose inhaler or nebulizer, without a clear outcome advantage of either. Multiple doses may be necessary, but it should be noted that these drugs do exhibit a plateau in efficacy. Therefore extremely high doses or intravenous β -agonist do not confer additional advantage. Anticholinergic agents such as ipratropium bromide (0.25–0.5 mg nebulizer every 20 minutes \times 3) should be used in moderate to severe cases as a second-line therapy to SABA. Because inflammation is central to asthma exacerbation, corticosteroids are becoming more acceptable for acute usage, to prevent the need for longer-term therapy.^{140,141} In cases refractory to other bronchodilators, magnesium sulfate (2 gm IV over 20 minutes) has been demonstrated to be safe and effective. Magnesium is effective both as a direct smooth muscle relaxant, and also as an antiinflammatory.¹⁴² Research attention is turning to traditionally chronic-acute medications such as montelukast for their contribution to acute therapy.¹⁴⁰ In severe cases, use of helium-

oxygen and noninvasive ventilation may promote gas flow and prevent intubation in cases of impending respiratory failure.¹⁰³

Emergence

The primary issue during emergence is weighing the advantages and disadvantages of deep as compared to awake extubation. Some authors suggest deep extubation is preferable to avoid the mechanical stimulation from the ETT on awakening. Others fear that the loss of a secure airway before patient awakening may present a greater difficulty than the presence of the ETT. Either way, a judgment must be made as to when to extubate the patient, with the understanding that the earliest possible time is advantageous for prevention of mechanical bronchial stimulation. Administration of lidocaine and opiates may help diminish airway sensitivity.

The use of anticholinesterase reversal agents has also been an area of concern. The anticholinesterase should be administered in the minimum adequate dose. To ensure a more complete anticholinergic effect, a small increase in the coadministered dose of atropine or glycopyrrolate is suggested. Sugammadex does not have the cholinergic actions of neostigmine and may be preferred in patients with a reactive airway.¹⁴³

Asthma and the Pregnant Surgical Patient

Maintaining asthma control during pregnancy is important for the health and well-being of both mother and baby and for ensuring adequate oxygen supply to the fetus. Uncontrolled asthma increases the risk of perinatal mortality, preeclampsia, preterm birth, and low-birth-weight infants. It is safer for pregnant women to be treated with asthma medications than to have asthma symptoms and exacerbations. The EPR-3 report recommends the following general strategies when caring for women during pregnancy.

- The course of asthma improves in one-third of women and worsens for one-third of women during pregnancy.
- Albuterol is the preferred SABA. The most data related to safety during human pregnancy are available for albuterol.

- Inhaled corticosteroids are the preferred long-term control medication. Budesonide is the preferred ICS, because more data are available on using budesonide in pregnant women than are available on other ICSs, and the data are reassuring. However, no data indicate that the other ICS preparations are unsafe during pregnancy.
- Around the time of delivery, note that β -agonists, which promote bronchodilation, also relax the uterus and may impede the progress of labor or encourage postpartum bleeding. Conversely, prostaglandin preparations and ergot alkaloids, which reduce uterine bleeding, can lead to bronchoconstriction.

Pulmonary Hypertension

Definition

Pulmonary hypertension is defined by a mean PAP at least 25 mm Hg with a pulmonary capillary occlusion pressure of no more than 15 mm Hg. Pulmonary arterial hypertension (PAH) is a subgroup of PH characterized by vascular cell proliferation and cellular changes in low-resistance pulmonary arteries that increase the PVR.¹⁴⁴ PAH represents an advanced stage of a large number of cardiovascular diseases.¹⁴⁵

Although patients with severe PAH would not be considered candidates for nonessential surgical procedures, an anesthetist may encounter patients with PAH presenting for lung transplant or balloon atrial septostomy as treatment.^{146,147}

Incidence and Outcome

Pulmonary arterial hypertension is a rare disorder, and its true incidence is unknown; however, it is estimated to affect approximately 15 million people.¹⁴⁵ PAH is characterized by a rapidly progressive course with a 79% mortality rate within 5 years of clinical diagnosis.¹⁴⁸ The degree of increase in pressure in the pulmonary circulation has an important influence on the patient's life expectancy,¹⁴⁹ and prognosis is largely determined by right ventricular integrity.¹⁵⁰ Factors that predict perioperative complications include emergency surgery, major surgery, long

operative time, use of general anesthesia, and increased New York Heart Association functional class.¹⁴⁴ PH carries an increased risk of respiratory failure (approximately 25%), heart failure, and death following noncardiac surgery.^{151,152} The perioperative mortality rate associated with PAH is high, even in mild to moderate disease.¹⁴⁵ Reviews of outcomes among patients with PAH demonstrated perioperative death rates of 7%,¹⁴⁴ and 18%.¹⁵³ The mortality rate among obstetric patients with PAH undergoing surgery is 25%.¹⁵⁴

Etiology

Pulmonary arterial hypertension may be caused by many associated conditions including drug effects, connective tissue disorders, COPD, sarcoidosis, and idiopathic/genetic causes. Five main categories describe the type of PH: pulmonary arterial hypertension (PAH); PH due to left heart disease; PH due to lung diseases and/or hypoxia; chronic thromboembolic pulmonary hypertension; and causes with unknown mechanisms.¹⁵⁴

Pathophysiology

The normal pulmonary circulation is mostly passive, of low resistance, and highly distensible.¹⁵⁵ PAH is characterized by an increase in vascular tone and the growth and proliferation of pulmonary vascular smooth muscle. Initial reversible vasoconstriction may progress to muscle hypertrophy and irreversible degeneration.¹⁵⁶ Overload of the right ventricle can lead to cor pulmonale and inhibition of coronary perfusion.

Clinical Features and Diagnosis

Pulmonary arterial hypertension may be either acute or chronic. In almost all patients with PAH, dyspnea and exercise intolerance are usually the first complaints.^{150,157} Patients may also have angina. Right atrial hypertrophy or right ventricular hypertrophy (or both) may be evident on electrocardiogram (ECG). Chest radiography may demonstrate an enlarged pulmonary artery.¹⁵⁸ Cardiac catheterization combined with pulmonary angiography is most informative in assessment of PAH, cardiac reserve, and the effects

of pulmonary vasodilator therapy.¹⁵⁶ Vasodilator therapy is attempted when a vasoconstrictor component is identified. Vasodilator challenge may be performed with cardiac catheterization using a rapid and effective pulmonary vasodilator such as nitroglycerin, isoproterenol, nifedipine, prostaglandin E₁, prostacyclin, prostaglandin E₂, hydralazine, nitroprusside, or adenosine for evaluation of the reversibility of PAH.¹⁵⁹ Frequently, open-lung biopsy is performed for assessment of the histopathologic composition of small pulmonary arteries.¹⁶⁰ Noninvasive evaluation includes Doppler echocardiography for measurement of the velocity of tricuspid regurgitation (which correlates well with invasive PAP measurements) and pulmonic peak flow velocity.^{161,162} ETCO₂ can also serve as an indicator of the presence of PAH, due to the underlying vascular defect. ETCO₂ is significantly reduced in patients with PAH, as compared with pulmonary venous hypertension or the absence of pulmonary vascular disease.

Attempts to alleviate pulmonary hypertensive disease states have had varied success. Vasodilator agents are used most commonly and may be helpful in patients with reversible vasoconstriction (Table 29.15). Alpha- and beta-adrenergic antagonists have shown the least benefit, whereas prostacyclin has shown the best, and new drugs such as rho-kinase inhibitors show good promise.¹⁴⁶ Possible beneficial effects of pulmonary arterial dilation are preservation of lung function, prevention of right ventricle deterioration, and improved survival.

TABLE 29.15

Medications Used to Treat Pulmonary Arterial Hypertension

Drug	Route	Usual Adult Dosage
Soluble Guanylate Cyclase	Oral	1–2.5 mg tid
Riociguat – <i>Adempas</i>		
Endothelin Receptor Antagonists	Oral	5–10 mg once/day
Ambrisentan – <i>Letairis</i>	Oral	62.5 mg bid for 4 wks, then 125 mg bid
Bosentan – <i>Tracleer</i>	Oral	10 mg once/day
Macitentan – <i>Opsumit</i>	Oral	20 mg/tid
Phosphodiesterase – 5 Inhibitors		
Sildenafil	Oral	40 mg once/day
Revatio		
Tadalafil – <i>Adcirca</i>	IV	2–40 ng/kg per min continuous Infusion

Prostacyclins		
Epoprostenol <i>Veletri</i> <i>Folan</i>	Inhalation Oral	2.5–5 mcg/inhalation 6–9 times/day 0.25–21 mg bid
Iloprost – <i>Ventavis</i> Treprostinil – <i>Orenitram</i>	SC or IV Inhalation	40–160 ng/kg per min continuous Infusion 9 breaths (54 mcg) qid
Remodulin		
Tyvaso		

From Ambrisentan (Letairis) and Tadalafil (Adcirca) for Pulmonary Arterial Hypertension. *The Medical Letter on Drugs and Therapeutics*. 2016;58:1485.

Anesthetic Management

The principal objectives during anesthesia in patients with PAH are preventing increases in PAH and avoiding major hemodynamic changes.¹⁵⁷ Preoperative evaluation should include ECG, echocardiogram, chest x-ray, and ABG. Underlying medical conditions (such as COPD) should be optimized. Chronic therapy for PAH should not be discontinued for fear of its hypotensive effect. Instead, intraoperative hypotension should be treated with vasopressors.¹⁴⁵

The anesthetic plan should be based upon maintaining cardiovascular homeostasis, particularly related to the pulmonary vasculature. General or regional anesthesia may be used, but a slight tendency toward more frequent complications has been observed in patients receiving general versus regional anesthesia.¹⁴⁴ In that same review, invasive monitoring with pulmonary artery catheter or transesophageal echocardiography did not reduce complications. For induction of general anesthesia, etomidate is a likely choice, whereas ketamine, which causes an increase in PVR, should be avoided. A balanced technique will avoid unnecessary vasodilation from volatile agents, and an opioid-heavy technique should rely upon volatile agents for amnesia instead of high concentrations of N₂O. Sympathetic stimulation from desflurane should be avoided. Conditions that increase the PVR (hypoxemia, hypercarbia, acidosis, pain, hypothermia) also should be avoided.¹⁴⁴

Hypotension during surgery should be treated aggressively, and for this reason, invasive arterial pressure monitoring should be used with few exceptions. Hypotension can begin a downward spiral from which it is difficult to recover, but the anesthetist must also discriminate between a drop in SVR or right ventricular failure

as the cause of hypotension. In the former case, vasopressors are indicated, whereas in the latter, inhaled nitric oxide or iloprost would be used.^{163,164}

Cor Pulmonale

Definition

The term *cor pulmonale* refers to right heart failure secondary to pulmonary pathology. Typically, this results from PH that leads to progressive right ventricular hypertrophy, dilation, and eventual cardiac decompensation. This situation arises from a variety of disorders that affect the structure and function of the lungs (Box 29.5). COPD is the leading cause of cor pulmonale.¹⁶⁵

Diagnostic Classification of Pulmonary Hypertension

Group 1: Pulmonary Arterial Hypertension (PAH)

1. Idiopathic PAH

2. Heritable PAH

1. *BMPR2*

2. *ALK1, ENG, SMAD9, CAV1, KCNK3*

3. Unknown genes

3. Drug- and toxin-induced

4. Associated with:

1. Connective tissue diseases

2. HIV infection
3. Portal hypertension
4. Congenital heart disease
5. Schistosomiasis

Group 1': Pulmonary Veno-Occlusive Disease (PVOD) and/or Pulmonarycapillary Hemangiomas (PCH)

Group 1'': Persistent Pulmonary Hypertension of the Newborn

Group 2: Pulmonary Hypertension due to Left Heart Disease

1. Left ventricular systolic dysfunction
2. Left ventricular diastolic dysfunction
3. Valvular disease
4. Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies

Group 3: Pulmonary Hypertension due to Lung Diseases and/or Hypoxia

1. Chronic obstructive pulmonary disease
2. Interstitial lung disease
3. Other pulmonary diseases with mixed restrictive

and obstructive pattern

4. Sleep-disordered breathing
5. Alveolar hypoventilation disorders
6. Chronic exposure to high altitude
7. Developmental lung diseases

Group 4: Chronic Thromboembolic Pulmonary Hypertension (CTEPH)

Group 5: Pulmonary Hypertension With Unclear Multifactorial Mechanisms

1. Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
2. Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangiomyomatosis
3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
4. Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

ALK1, Activin receptor-like kinase type 1; *BMPR2*, bone morphogenetic protein receptor type 2; *CAV1*, caveolin-1; *ENG*, endoglin; *HIV*, human immunodeficiency virus; PAH, pulmonary arterial hypertension.

Incidence and Outcome

In individuals older than 50 years of age, cor pulmonale is the third most common cardiac disorder (after ischemic heart disease and hypertensive cardiac disease). The male-to-female ratio of incidence of the disease is 5 : 1, and 10% to 30% of patients admitted to the hospital with coronary heart failure exhibit cor pulmonale.¹⁶⁶ The incidence of PH among patients with advanced COPD is estimated to be 50%.¹⁶⁷

Prognosis is determined by the pulmonary disease responsible for the increased PVR. In patients with COPD in whom PAO₂ can be maintained at near-normal levels, the prognosis is favorable. However, cor pulmonale combined with hypoxic lung disease is associated with a 70% rate of mortality within 5 years after onset of associated peripheral edema.¹⁶⁸ Prognosis is poor for those patients in whom cor pulmonale is the result of gradual obstruction of pulmonary vessels by intrinsic pulmonary vascular disease or pulmonary fibrosis. These anatomic changes cause irreversible alterations in the pulmonary vasculature, resulting in fixed elevations in PVR.

Etiology

Chronic obstructive pulmonary disease is associated with the functional loss of pulmonary capillaries and subsequent arterial hypoxemia; these events initiate pulmonary vasoconstriction, which is the leading cause of chronic cor pulmonale. The World Health Organization has proposed a classification of conditions associated with cor pulmonale. Diseases associated with hypoxic pulmonary vasoconstriction include the following:

- COPD
- Bronchiectasis
- Chronic mountain sickness
- Cystic fibrosis
- Idiopathic alveolar hypoventilation

- Obesity-related hypoventilation syndrome
- Neuromuscular disease
- Kyphoscoliosis
- Pleuropulmonary fibrosis
- Upper airway obstruction

Diseases that produce obstruction or obliteration of the pulmonary vasculature include the following:

- Pulmonary embolism (PE)
- Pulmonary fibrosis
- Pulmonary lymphangitic carcinomatosis
- Idiopathic PAH
- Progressive systemic sclerosis
- Sarcoidosis
- Intravenous drug abuse
- Pulmonary vasculitis
- Pulmonary venoocclusive disease

Pathophysiology

Pulmonary hypertension is always an underlying pathology of cor pulmonale. In COPD, polycythemia, hypoxic pulmonary vasoconstriction, hyperinflation, and the reduction in size of the pulmonary vascular bed lead to PH.¹⁶⁹ Sustained PH produces hypertrophy of the smooth muscle in the tunica media, and remodeling of the vascular smooth muscle leads to irreversible increases in PVR. An imbalance in nitric oxide and endothelin is also contributory, with the balance tipped toward the vasoconstrictive effects of endothelin.¹⁶⁹ The rate at which right ventricular dysfunction develops depends on the magnitude of pressure increase in the pulmonary circulation and on the rapidity with which this increase occurs. For example, PE may lead to right ventricular failure in the presence of a mean PAP as low as 30 mm Hg. By contrast, when PAH occurs gradually, as it does in COPD, right ventricular compensation occurs; CHF rarely occurs before mean PAP exceeds 50 mm Hg.

The normal pulmonary circulation can accommodate a maximal

right ventricular output with minimal increase in pulmonary pressure via distention of existing vessels or recruitment of unused vessels. The compensatory mechanism for pressure overload on the right ventricle involves enhancement of contractility and an increase in preload, which result in an increase in right ventricular end-diastolic volume.¹⁷⁰ In response to chronic pressure overload imposed by the PAH, right ventricular hypertrophy occurs. Brain natriuretic peptide shows a positive correlation to ventricular stretch, which occurs in cor pulmonale.¹⁶⁹ Cor pulmonale can be precipitated acutely. For example, patients with COPD have larger than normal increases in PAP when executing maneuvers that increase pulmonary blood flow (e.g., exercise, even if resting hemodynamic status is normal).¹⁷¹ Cor pulmonale can be produced acutely by sudden increases in PVR, such as from exercise, PE, or ARDS.¹⁷²

Clinical Features and Diagnosis

Clinical manifestations of cor pulmonale are often nonspecific and obscured by COPD. Echocardiography may be useful,¹⁷² but right-sided heart catheterization is usually required for diagnosis. Cardiac catheterization combined with pulmonary angiography provides the most definitive information on the degree of PAH, cardiac reserve, and the effects of pulmonary vasodilator treatment.¹⁵⁶

Symptoms associated with cor pulmonale include retrosternal pain, cough, dyspnea on exertion, weakness, fatigue, early exhaustion, and hemoptysis.¹⁵⁶ Occasionally, hoarseness secondary to left recurrent laryngeal nerve compression by the enlarged pulmonary artery is present.¹⁶⁶ Syncope on exertion may occur, reflecting the inability of the right ventricular stroke volume to increase in the presence of a fixed elevation of PVR.

Physical signs of cor pulmonale include the following:

- Elevation of jugular venous pressure
- Cardiac heave or thrust along the left sternal border and S₃ gallop
- Presence of an S₄ heart sound secondary to significant right ventricular hypertrophy

- A widely split S₂ heart sound
- Possible murmur of pulmonic and tricuspid insufficiency
- Hepatomegaly, ascites, and lower-extremity edema (late signs)

Diagnostic Testing

Electrocardiography.

Right atrial displacement, right ventricular hypertrophy, right atrial hypertrophy, and right atrial enlargement may be observed. *P pulmonale* (tall, peaked p-waves) are a characteristic sign. Patients may develop concomitant supraventricular tachycardic arrhythmias (i.e., tachycardic atrial fibrillation, sinus tachycardia, and paroxysmal atrial tachycardia).

Imaging Studies.

On chest radiography, enlargement of the pulmonary arteries is observed, followed by right ventricular hypertrophy. Meeting criteria for pulmonary artery dilation has 98% sensitivity for diagnosing PH.¹⁶⁹ Echocardiography may be helpful to demonstrate enlargement, dilation, or thickening of the right ventricle, with or without tricuspid valve regurgitation, and elevated pulmonary artery systolic pressure. All these findings suggest that at least acute or possibly chronic PAH is present. Shifting of the intraventricular septum as a result of increased right ventricular end-diastolic volume is another characteristic finding.¹⁶⁹ Magnetic resonance imaging provides better evaluation of the ventricular wall thickness than does echocardiography.

Treatment

The three major drug classes for treatment of PAH are prostanoids, endothelin receptor antagonists, and phosphodiesterase inhibitors. The goals of treatment include decreasing the workload of the right ventricle, reducing PVR, preventing increases in PAP, and avoiding major hemodynamic changes. Diuretics may be used to reduce cardiac workload, but caution must be employed to avoid causing inadequate preload.¹⁶⁹ Improvement of gas exchange is the primary focus of treatment in COPD patients with cor pulmonale.^{156,173}

Treatment includes supplemental administration of O₂ to maintain a PaO₂ of greater than 60 mm Hg or an arterial O₂ saturation of greater than 90%. O₂ is the only vasodilator with a selective effect on pulmonary vessels that is not associated with a risk of worsening hypoxemia.¹⁷⁴ Ventilation under anesthesia should focus on maintaining low airway pressures and avoiding PEEPi.¹⁷²

Heart-Lung Transplantation

A heart-lung transplantation may ultimately be needed when cor pulmonale progresses despite the provision of maximal medical therapy.

In general, preoperative preparation of the patient with cor pulmonale includes the following:

- Elimination and control of acute or chronic pulmonary infections
- Reversal of bronchospasm
- Improvement in clearance of secretions
- Expansion of collapsed or poorly ventilated alveoli
- Hydration
- Correction of any electrolyte imbalance

Anesthetic Management

Regional anesthesia technique may be appropriate as long as a high sensory level of anesthesia is not required, because any decrease in SVR in the presence of a fixed PVR may produce undesirable degrees of systemic hypotension.¹⁷⁵

General Anesthesia

Volatile agents decrease PVR. Studies have demonstrated that PAP is decreased by isoflurane. N₂O has been shown to increase PVR in patients with primary pulmonary hypertension. Intravenous agents, with the exception of ketamine, appear to have little effect on PVR. During all stages of anesthesia, hemodynamic manipulation that increase PAP must be avoided. Five key principles should be followed¹⁵⁶:

- Maintain good oxygenation.

- Avoid acidosis.
- Avoid the use of exogenous and endogenous vasoconstrictors.
- Avoid presenting stimuli that increase sympathetic tone.
- Avoid hypothermia.

A complete discussion of heart and lung transplants can be found in [Chapters 26](#) and [41](#).

Pulmonary Embolism

Definition

Pulmonary embolism is caused by a dislodged thrombus that travels into the pulmonary vascular bed. A significant thrombus obstructs blood flow and causes forward ischemia and rearward cardiac overload. Classification of acute PEs is given in [Table 29.16](#).

TABLE 29.16

Classification of Acute Pulmonary Embolism

Category (Frequency)	Presentation	Therapy
Massive PE (5%–10%)	Systolic blood pressure < 90 mm Hg or poor tissue perfusion or multisystem organ failure plus extensive thrombosis, such as “saddle” PE or right or left main pulmonary artery thrombus	Anticoagulation (usually starting with intravenous UFH), plus consider advanced therapy: systemic thrombolysis, pharmacomechanical catheter-directed therapy, surgical embolectomy, or inferior vena cava (IVC) filter
Submassive PE (20%–25%)	Hemodynamically stable but moderate or severe right ventricular dysfunction or enlargement, coupled with biomarker elevation indicative of right ventricular microinfarction and/or right ventricular pressure overload	Anticoagulation usually with intravenous UFH until decision made regarding implementation of advanced therapy; controversy centers on this group. For systemic thrombolysis, reducing the rate of cardiovascular collapse and death must be balanced against the increased rate of hemorrhagic stroke. For patients at low bleeding risk with severe right ventricular dysfunction, consider same interventions as for massive PE
Small to moderate PE (70%)	Normal hemodynamics and normal right ventricular size and function	Anticoagulation with parenteral therapy as a bridge to warfarin or, alternatively, with oral rivaroxaban regimen as monotherapy

UFH, Unfractionated heparin. *PE*, pulmonary embolism

From Goldhaber SZ. Pulmonary embolism. In Mann DL, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 10th ed. Philadelphia: Elsevier; 2015:1666.

Incidence and Outcome

Being a major source of morbidity and mortality, PE affects between 300,000 and 600,000 people in the United States annually. One-third of these develop post-thrombotic syndrome (long-term complications such as swelling, pain, and discoloration in the affected limb), one-third of people with PE die within 1 month of diagnosis, and one-fourth of them present with sudden death as the first symptom.¹⁷⁶ Pulmonary emboli originate from deep vein thrombosis (DVT) of the iliofemoral vessels in approximately 90% of patients, although other sites of thrombus formation include the pelvic veins, the renal and hepatic veins, the axillary veins in the upper extremities, and the right atrium.¹⁷⁷ PE occurs in approximately 1% of surgical patients overall,¹⁷⁸ but the incidence is as high as 30% among high-risk orthopedic procedures.¹⁷⁹ Mortality from perioperative PE is approximately 10%.^{178,180}

Etiology

Pulmonary embolism is considered by some to be a clinical manifestation of DVT rather than a separate entity, because almost all incidents of PE result from an embolized vein thrombosis. The incidence of symptoms from DVT is greater with more proximal sites of thrombosis. Three major factors promote the formation of venous thrombi: stasis of blood flow, venous injury, and hypercoagulable states. These three components are described as the Virchow's triad and underlie the risk factors for venous thrombosis (Box 29.6). Smoking and obesity have been shown to be independent risk factors for PE in women¹⁸¹ and malignancies are a particularly high risk for PE. Cancer patients are found to have over twice the incidence of venous thromboembolism as that in the general population, and this risk is heightened further when indwelling central venous catheters are in place.¹⁸² Other, less common causes of PE include air, tumor, bone, fat, catheter fragments, and amniotic fluid. Fillers used in illicit drug preparations by intravenous drug abusers also may cause PE. Of particular concern to anesthesia providers are air emboli caused by the opening of venous structures during surgery or by disconnected

Box 29.6 Central venous lines.

Thromboembolic Risk Factors

Hereditary Thrombophilias

- Protein C deficiency
- Protein S deficiency
- Antithrombin III deficiency
- Factor V Leiden mutation
- Prothrombin 20210 G → A variation
- Hyperhomocysteinemia
- Dysfibrinogenemia
- Familial plasminogen deficiency

Acquired Surgical Predispositions

- Major thoracic, abdominal, or neurosurgical procedures requiring general anesthesia and lasting > 30 min
- Hip arthroplasty
- Knee arthroplasty
- Knee arthroscopy
- Hip fracture
- Major trauma
- Open prostatectomy
- Spinal cord injury

Acquired Medical Predispositions

- Prior venous thromboembolism
- Advanced age (> 60 yr)
- Malignancy
- Congestive heart failure
- Cerebrovascular accident
- Nephrotic syndrome
- Estrogen therapy
- Pregnancy and the postpartum period
- Obesity
- Prolonged immobilization
- Antiphospholipid antibody syndrome
- Lupus anticoagulant
- Inflammatory bowel disease
- Paroxysmal nocturnal hemoglobinuria
- Behçet syndrome

From Morris TA, Fedullo PF. Pulmonary Thromboembolism. In Broaddus VC, et al., eds. *Murray and Nadel's Textbook of Respiratory Medicine*. 6th ed. Philadelphia: Elsevier; 2016:1002

Most pulmonary emboli resolve within 8 to 21 days of the initial presentation; 10% to 20% are estimated to develop into unresolved emboli, and 0.5% to 4% lead to the development of chronic PAH. Chronically unresolved emboli that lodge in major pulmonary arteries may become incorporated into the vascular walls and obstruct blood flow. Patients with such emboli are surgical candidates, representing approximately 1000 cases in the United

States each year.¹⁸³

Pathophysiology

Once a thrombus has formed, it rarely remains static. It can be dissolved through fibrinolysis, become “organized” into a vessel wall, or be released into the circulation. Because thrombi are most friable early in their development, it is then that the greatest risk for embolization exists.

If the fragment is released from its site of formation, it can be rapidly swept into one of the pulmonary arteries. It may pass through the vasculature completely, disintegrate, and block several smaller pulmonary vessels; or if the thrombus is sufficiently large, it may impact against one or both pulmonary arteries and cause pulmonary collapse, massive infarction, and ultimately cardiac arrest.¹⁸⁴

Within the pulmonary capillaries, hemorrhage is frequently seen distal to the site of the embolism. The alveolar structures in this area can remain viable for a period.¹⁸⁴ However, if the clot does not dissolve or if it is not quickly squeezed through the vasculature, the alveolar structure will be permanently damaged. Bronchial circulation limits the possibility of pulmonary infarction, and substantial damage is unusual unless an embolus completely blocks a large artery or preexisting lung disease is present.¹⁸⁵ In fact, less than 10% of emboli actually cause any type of infarction.¹⁸⁶

Mechanism

When a pulmonary artery is occluded, ventilation distal to the obstruction is decreased. This is a result of the direct effect of alveolar PCO₂ (PACO₂) on the smooth muscle of the local small airways. The reduction of airflow to the unperfused lung reduces the amount of wasted ventilation. This mechanism is very short lived, with distribution of ventilation returning to normal within several hours.^{184,186} The elastic properties of the embolized region may change some hours after the event; localized atelectasis is believed to result from a loss of pulmonary surfactant, the rapid turnover of which requires adequate blood flow.¹⁸⁶

Pulmonary Function

Pulmonary Circulation.

Normally the pulmonary circulation has a very large reserve capacity. However, when PAPs increase, previously unfilled capillaries are recruited, and distention occurs. This allows for obstruction of at least half of the pulmonary circulation before a substantial increase in PAP becomes manifest.¹⁸⁴ Obstruction of blood flow is further reduced by serotonin and platelet-activating factor from platelets of the embolus, vasoactive peptides from plasma, and histamine from mast cells.¹⁸⁷ Occlusion of approximately 70% of the pulmonary vascular bed results in PAH with subsequent right ventricular failure, increased end-diastolic pressures, and development of arrhythmias and possibly of tricuspid valve incompetence.¹⁸⁵ Pulmonary edema may follow, because blood flow is diverted to alternate areas of lung.^{184,188} Acute pulmonary edema develops when hyperperfusion from intact circulation to the perfused lung results in extravasation of fluid into the alveoli. If the clot fractures and passes quickly, or if the affected area is minimal, the PAPs gradually decrease with embolus resolution by fibrinolysis or transformation onto the vessel wall as a scar.¹⁸⁵

The right ventricle will initially increase stroke volume through adrenergic activation. Eventually, though, the increased ventricular volume shifts the intraventricular septum and reduces left heart output. The reduction in left ventricular output can compromise coronary filling, and lead to ischemia, which further degrades contractility.¹⁸⁷

Gas Exchange.

An embolus can have a significant effect on gas exchange. Moderate hypoxemia without CO₂ retention is often seen after PE as both physiologic shunt and dead space increase. In spontaneously breathing patients, PaCO₂ is maintained at the normal level after PE by increasing the respiratory rate. The resultant increase in ventilation may be substantial because of the large physiologic dead space. Because the anesthetized patient who is not spontaneously breathing cannot increase his or her ventilation, the PaCO₂ rises and O₂ saturation decreases more quickly.^{186,189}

The difference between PaCO₂ and end-tidal PCO₂ (P_{ET}CO₂) is a

very useful indicator in PE, with high sensitivity and specificity.¹⁸⁶ The mixed $P_{ET}CO_2$ tends to be low because of the high V/Q (ventilation/perfusion) ratio in the embolized region. Particularly if underlying ventilation and perfusion prior to embolization were well matched, the $P_{ET}CO_2$ is an accurate and immediate indicator of the status of pulmonary gas exchange. In anesthetized patients, the $PaCO_2$ continues to increase more quickly because of this increase in dead space without ventilatory compensation. If the embolus does not completely occlude the vessel, the discrepancy between $P_{ET}CO_2$ and $PaCO_2$ may not be as great.¹⁸⁴

Clinical Features and Diagnosis

The patient's clinical presentation depends largely on the size of the embolus. Signs and symptoms of PE vary and are common to a number of disorders. Therefore the differential diagnosis may be difficult (Box 29.7). The Wells Clinical Model for predicting the pretest probability of PE is commonly used to determine which patients may be at risk for PE (Table 29.17). Dyspnea of sudden onset appears to be the only common historic complaint. Sudden hypotension and tachycardia, wheezing, tachypnea, and signs of right ventricular overload are common. Hypoxemia is a constant feature of PE, possibly owing to intrapulmonary shunting. Because PE often occurs without premonitory signs and the symptoms are not highly specific, in the acute setting, diagnosis is often presumptive and by exclusion. Box 29.8 outlines common clinical findings (history and symptoms) in patients who developed PE.

Differential Diagnosis of Acute Intraoperative Pulmonary Embolism

- Anaphylactic reaction
- Aortic dissection
- Aortic stenosis
- Brain stem stroke

- Bronchospasm
- Heart failure
- Hypertrophic cardiomyopathy
- Myocardial infarction
- Pulmonary hypertension
- Tension pneumothorax

TABLE 29.17

Wells Clinical Model for Predicting the Pretest Probability of Pulmonary Embolism

Variable	Points Assigned
Clinical signs and symptoms of deep venous thrombosis	3.0
An alternative diagnosis is less likely than pulmonary embolism	3.0
Heart rate > 100 beats/min	1.5
Immobilization or surgery in the previous 4 wk	1.5
Previous deep venous thrombosis or pulmonary embolism	1.5
Hemoptysis	1.0
Malignancy (on treatment, treated in the past 6 mo, or palliative)	1.0
Score	Clinical Assessment Probability
< 2 points	Low probability
2–6 points	Intermediate probability
> 6 points	High probability

Box 29.8

Most Common Symptoms and Signs of Pulmonary Embolism

Symptoms

- Otherwise unexplained dyspnea
- Chest pain, either pleuritic or “atypical”
- Anxiety
- Cough

Signs

- Tachypnea
- Tachycardia
- Low-grade fever
- Left parasternal lift
- Jugular venous distension
- Tricuspid regurgitant murmur
- Accentuated P2
- Hemoptysis
- Leg edema, erythema, tenderness

From Goldhaber SZ. Pulmonary embolism. In Mann DL, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 10th ed. Philadelphia: Elsevier; 2015:1669.

Small emboli often go unrecognized; however, multiple small emboli can produce extensive obstruction of the pulmonary capillary bed, possibly causing PAH and cardiac failure. Generally, however, small thromboemboli are incorporated into the arterial wall and have little effect on either parenchyma or the circulation. Patients may complain of dyspnea on exertion that may lead to syncope; sometimes, a right ventricular “heave” or a split-second heart sound can be detected on examination. Patients with medium-sized emboli may present with pleuritic pain accompanied by dyspnea, a slight fever, and a productive cough that yields blood-streaked sputum. These patients usually are tachycardic. A small pleural effusion can develop and mimic the appearance of pneumonia.

Massive emboli can produce sudden cardiac collapse. Preceding symptoms range from pallor, shock, and central chest pain to sudden loss of consciousness. In patients with cardiac collapse, the pulse becomes rapid and weak, blood pressure decreases, neck

veins become engorged, and cardiogenic shock may be present or impending. In addition, a decrease in $P_{ET}CO_2$ and an increase in $PaCO_2$ occur, with the difference between the values increasing as conditions worsen. If a pulmonary artery catheter is in place, PAPs are observed to increase rapidly. A right ventricular strain pattern may be seen on an ECG. The prognosis for these patients is very poor.¹⁸⁴

Diagnostic Testing

Few of the common preoperative tests indicate the presence of PE. A number of imaging and laboratory tests are available for diagnosis (Table 29.18). The most common electrocardiographic signs are noted in Box 29.9 and Fig. 29.22. In addition, echocardiography may demonstrate right ventricular dilation or dyskinesia, septal shift, tricuspid regurgitation, or dilation of the pulmonary artery. In the patient with PE, ABG analysis generally reveals hypoxemia and increased differences between $PaCO_2$ and $P_{ET}CO_2$, which result from ventilation of unperfused alveoli.¹⁸⁹ Massive PE is associated with severe hypoxemia and hypocapnia. An initial difference between $PaCO_2$ and $P_{ET}CO_2$ is common early during the embolic event.¹⁸⁶ Some common conditions associated with an increased risk for DVT are given in Tables 38.8 and 38.9.

TABLE 29.18

Diagnostic Tests for Suspected Pulmonary Embolism

Test	Comments
Oxygen saturation	Nonspecific, but suspect PE if there is a sudden otherwise unexplained decrement
Electrocardiogram	May be normal, especially in younger, previously healthy individuals; may provide alternative diagnosis, such as myocardial infarction or pericarditis
Echocardiography	Best used as a prognostic test in patients with established PE, rather than as a diagnostic test; many patients with larger PE will have normal echocardiograms
Lung scanning	Usually provides ambiguous results, used in lieu of chest CT for patients with anaphylaxis to contrast agent, renal insufficiency, or pregnancy
Chest CT	Most accurate diagnostic imaging test for PE; beware if CT result and clinical likelihood are discordant
Pulmonary angiography	Invasive, costly, uncomfortable; used primarily when local catheter intervention is planned
D-dimer	An excellent “rule out” test if normal, especially if accompanied by non-high clinical suspicion
Venous ultrasonography	Excellent for diagnosing acute symptomatic proximal DVT, but a negative test does not rule out PE, because a recent leg DVT may have embolized completely; calf vein imaging is operator dependent

Magnetic
resonance
imaging

Reliable only for imaging proximal segmental pulmonary arteries; requires gadolinium but does not require iodinated contrast agents

CT, Computed tomography; DVT, deep vein thrombosis; PE, pulmonary embolism.

From Goldhaber SZ. Pulmonary embolism. In Mann DL, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 9th ed. Philadelphia: Elsevier; 2012:1686.

Box 29.9

Electrocardiographic Signs Associated With Pulmonary Embolism

- Tachycardia
- Negative T wave in V1–V5
- McGinn-White S1Q3T3
- Right axis deviation $> 90^\circ$
- Negative T wave in II, III, aVF
- Pulmonary P wave
- R $>$ S or Q in aVR
- Right ventricular ischemia
- Complete or incomplete RBBB

RBBB, Right bundle branch block.

FIGURE 29.22 Classic electrocardiogram of pulmonary embolus. Note the “S1, Q3, T3” pattern. (From Goldman L, et al. *Goldman's Cecil Medicine*. 25th ed. Philadelphia: Elsevier; 2016: 623.)

There are limited laboratory analyses useful to support the diagnosis of PE. The D-dimer assay cannot rule in PE, but a normal result makes diagnosis of PE very unlikely. Troponin I and troponin T levels are elevated in less than one-half of cases of significant PE. Therefore their presence is not useful for diagnosis, but elevation of troponins is associated with adverse outcomes, including death and the need for aggressive resuscitation.¹⁹⁰

Prevention

Aggressive efforts at prevention have been successful in reducing the incidence of DVT in surgical patients. Use of compression stockings, intermittent pneumatic compression devices, administration of various anticoagulants and thrombolytics, and ambulation are typical measures for preventing embolus formation. Because surgery is a risk factor for venous thromboembolism, care should be taken to reduce risk for every surgical patient. Anesthesia for patients at risk for PE is aimed at avoiding venous stasis, hypercoagulability, and vessel injury. This involves ensuring

administration of lower extremity circulatory aids or anticoagulants before anesthetic induction. Anesthetic planning also may contribute to risk reduction. For example, the use of neuraxial anesthesia, which causes vasodilation in the lower extremities, reduces the incidence of DVT by 50% in comparison to general anesthesia.^{191,192}

Medical and Surgical Treatment

Guidelines for treatment of PE are summarized in [Box 29.10](#). Anticoagulation is the most common intervention, aimed at preventing further insult. Clot removal is most often accomplished with thrombolytic agents. Surgical intervention is indicated for patients who are unresponsive to other measures; however, this represents a small number of patients.¹⁹³ Currently, the most common surgical procedure for patients with PE is placement of an umbrella filter, which traps thromboemboli. Vena cava filters are usually indicated for patients with bleeding disorders who are not able to tolerate standard anticoagulant therapy, or for those who are refractory to anticoagulant therapy. The filter is placed in the inferior vena cava under fluoroscopic guidance, usually below the renal veins at the level of the L2 to L3. Suprarenal placement is required when a thrombus directly involves the renal veins or has propagated above the level of the renal veins. The presence of an infrarenal filter in a pregnant woman may place her and her fetus at risk because of the possibility that the filter will come in to contact with the gravid uterus. Suprarenal placement prevents this risk.¹⁹²

Medical Management for Acute Pulmonary Embolism

- Begin UFH intravenous therapy as soon as massive PE is suspected
- Goal of UFH infusion should be an aPTT of at least 80 seconds
- Limit volume resuscitation to 500–1,000 mL as excessive volume may worsen right ventricular failure

- Administer vasopressors and inotropes if there is evidence of hemodynamic instability
- Determine risk of thrombolytic therapy
- Consider placement of IVC filter, catheter embolectomy, or surgical embolectomy if thrombolytic therapy is too risky
- Avoid the combination of thrombolytic therapy and IVC filter insertion
- Consider immediate referral to medical institution that specializes in massive PE

aPTT, Activated partial thromboplastin time; *IVC*, inferior vena cava; *PE*, pulmonary embolism; *UFH*, unfractionated heparin.

Adapted from Goldhaber SZ. Pulmonary embolism. In Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 10th ed. Philadelphia: Elsevier; 2015:1666.

Thromboendarterectomy is the treatment of choice for chronic large vessel thromboembolic PAH.¹⁹⁴ Desired results include decreased PVR, improved CO, restoration of exercise tolerance, and resolution of hypoxemia. Improvements in RV function and hemodynamics may be prompt, whereas improvements in gas exchange occur over weeks to months. Although the role of pulmonary embolectomy remains controversial, in the few patients who do not benefit from optimal medical therapy, it remains an acceptable procedure.¹⁹⁵

Anesthetic Management

Anesthetic management for a patient with a pulmonary embolus is primarily aimed at preventing further embolism and providing respiratory and cardiovascular support.¹⁹⁶ Table 29.19 outlines preventative prophylactic measures for patients at risk of PE. The use of a high F_iO_2 supports pulmonary vasodilation. If PAP is monitored, the anesthesia provider will have additional information to optimize right-sided heart function and assess the

effects of anesthetic management on PVR.¹⁸⁸ However, the risk-benefit ratio of a pulmonary artery catheter should consider the possibility that these catheters may dislodge clots in the right side of the heart. Induction is often performed with etomidate. Ketamine may appear to be a compelling choice in the face of cardiovascular compromise, but ketamine may increase PVR.¹⁸⁶ The use of N₂O is generally believed to be acceptable. However, the use of N₂O may be limited by the desire to administer high F_iO₂ and concerns for increasing the PVR. The use of N₂O is contraindicated in patients with venous air embolism, because of the potential for N₂O to rapidly expand the volume of the embolism.¹⁸⁵ Patients with moderate to severe PE are often experiencing acute right-sided heart failure. Cardiac function can be optimized by the use of minimally depressing cardiac agents such as opioids.

TABLE 29.19
Prevention of Venous Thromboembolism

Condition	Strategy
Total hip or knee replacement; hip or pelvis fracture	Warfarin (Coumadin) (target INR 2.5) × 4–6 weeks LMWH/subcut (e.g., fondaparinux 2.5 mg subcut [except for total knee replacement]) or rivaroxaban 10 mg daily or dalteparin 2500–5000 units daily subcut where available
	IPC ± warfarin
Gynecologic cancer surgery	LMWH consider 1 month of prophylaxis
Thoracic surgery	IPC or GCS plus unfractionated heparin, 5000 units bid or tid
High-risk general surgery (e.g., prior VTE, current cancer, or obesity)	IPC or GCS plus unfractionated heparin, 5000 units bid tid or LMWH
General, gynecologic, or urologic surgery (without prior VTE) for noncancerous conditions	GCS plus unfractionated heparin 5000 units bid or tid
	Dalteparin 2500 units subcut once daily
	Enoxaparin 40 mg subcut once daily
Neurosurgery, eye surgery, or other surgery when prophylactic anticoagulation is contraindicated	GCS ± IPC
Neurosurgery	Unfractionated heparin 5000 units bid or tid
	Enoxaparin 40 mg subcut once daily
	GPC or IPC
	Consider surveillance of lower extremity by ultrasonography
Orthopedic surgery	Enoxaparin 30 mg twice daily
	Enoxaparin 40 mg once daily*
	Dalteparin 5000 units once daily*
	Fondaparinux 2.5 mg subcut daily
	Warfarin (target INR = 2-3)
General surgery	GCS plus IPC
	Unfractionated heparin 5000 units bid or tid
	Enoxaparin 40 mg daily
	Dalteparin 2500 or 5000 units once daily
	GCS plus IPC

Pregnancy	Enoxaparin 40 mg daily Dalteparin 5000 units daily
Medical patients	Unfractionated heparin 5000 units bid or tid Enoxaparin 40 mg daily Dalteparin 5000 units once daily Fondaparinux 2.5 mg subcut daily in patient who cannot tolerate heparin Consider surveillance of lower extremity by ultrasonography
	GCS <i>plus</i> IPC
Long distance air travel	LMWH for high-risk patients

* Approved only for total hip replacement prophylaxis.

GCS, Graduated compression stockings; *INR*, international normalized ratio; *IPC*, intermittent pneumatic compression; *LMWH*, low-molecular weight heparin; *subcut*, subcutaneous; *VTE*, venous thromboembolism.

New York: McGraw Hill; 2015:1631–1636; Goldhaber SZ. Pulmonary embolism. In Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 10th ed. Philadelphia: Elsevier; 2015:1664.

Persistent, severe hypotension, such as that accompanying a massive PE, may necessitate the use of a cardiotoxic agent or partial or full cardiopulmonary bypass. The goal is preservation of perfusion to the brain and heart until cardiopulmonary bypass is started and surgical removal of the clot attempted.¹⁸⁸ Patients with PE are extremely sensitive to any anesthetic agent. It is critical to have heparin ready to support initiation of bypass if necessary. Although separation from bypass is beyond the scope of this chapter, the anesthetist should anticipate that difficulties may be encountered. Reports of operative mortality during pulmonary embolectomy range from 11% to 55%, with much higher rates among patients experiencing cardiac arrest.¹⁹⁷

Detection of Pulmonary Embolism During Anesthesia

In the intubated patient under general anesthesia, clinical presentation is limited to objective signs. A decreasing $P_{ET}CO_2$ and tachycardia usually are the first signs of PE.^{188,189} These can be followed by a decrease in blood-oxygen saturation (SaO_2) and ABG results indicative of unexplained arterial hypoxemia. In the case of massive PE, abrupt, unexplained hypotension and tachycardia are the classic (albeit, nonspecific) signs. Increased PAP and central venous pressure (CVP) are observed in combination with a

decrease in systolic and diastolic blood pressures.¹⁸⁹ Bronchospasm may occur.¹⁸³ Finally, ECG changes that indicate right axis deviation, incomplete or complete right bundle branch block, or peaked T waves may be observed in the presence or absence of an accompanying systolic ejection murmur^{184,189} (Fig. 29.22 Box 29.9).

Intraoperative Management of Acute PE

In the case of suspected PE in the anesthetized patient, treatment requires rapid intervention because cardiovascular decompensation can occur quickly. First and most importantly, an airway must be established if the patient is not already intubated. Second, delivery of the anesthetic agent must be discontinued, and administration of a 100% FiO₂ initiated.¹⁸⁸ Next, the circulatory system should be supported with the infusion of intravenous fluids or blood (or both) as needed, and sympathomimetics initiated if necessary.

Norepinephrine may be the vasopressor of choice, because of its ability to support contractility, as well as improve brain perfusion through vasoconstriction.¹⁸⁷ Epinephrine, dopamine, or dobutamine + norepinephrine may also be helpful. Ventricular dysrhythmias should be treated with intravenous administration of lidocaine or amiodarone, and the patient should receive PEEP for optimization of oxygenation.¹⁸⁵ If symptoms are refractory to treatment, thrombolysis or pulmonary embolectomy may be necessary. Severe hemodynamic difficulty should be anticipated and resuscitative efforts continued. In severe cases, cardiopulmonary bypass may be necessary until the obstruction can be relieved.

Patients with PE present particular management challenges during their postoperative course, including reperfusion edema, persistent hypoxemia, pericardial effusion, psychiatric disorders, and pulmonary blood flow steal. The areas of the lung to which pulmonary artery flow has been restored are subject to development of reperfusion pulmonary edema, presumably as a manifestation of oxidant- and protease-mediated ALI. Other possible causes are extracorporeal circulation, anticoagulation, and an increase in perfusion pressure in a previously obstructed pulmonary artery. Complications include immediate pulmonary hemorrhage and respiratory disturbance, and death may occur.¹⁹⁷

This syndrome may develop 3 to 5 days after surgery.¹⁹⁸ Olman et al.¹⁹⁹ have observed that after pulmonary thromboendarterectomy for relief of chronic thromboembolic PAH, perfusion lung scans often reveal new perfusion defects in segments served by undissected pulmonary arteries. This phenomenon has been labeled *pulmonary blood flow steal*, and it is believed to be caused by postoperative redistribution of regional PVR due to the altered (widened) architecture of the dissected vessels that received arterectomy. No evidence of embolism was found in the previously normal areas.

Restrictive Pulmonary Diseases

Definition

Restrictive pulmonary disease is defined as any condition that interferes with normal lung expansion during inspiration, and it is characterized by a TLC below the 5th percentile.⁴⁴ Typically, it includes disorders that increase the inward elastic recoil of the lungs or chest wall (Table 29.20). Consequently, the alteration in pulmonary dynamics results in decreases in lung volumes and capacities and in lung or chest-wall compliance. Some restrictive diseases produce ventilation abnormalities and V/Q mismatching, whereas others lead to impairment of diffusion. FEV₁ and FVC are both decreased, owing to a reduction in TLC or a decrease in chest-wall compliance or muscle strength. However, the FEV₁/FVC ratio is normal or elevated.

TABLE 29.20

Common Causes of Restrictive Lung Disease

Cause	Example
Interstitialium	
Interstitial fibrosis, infiltration	Asbestosis
Pulmonary edema	Left ventricular failure
Pleura	
Pleural disease	Fibrothorax
Thoracic Cage and Abdomen	
Neuromuscular disease	Poliomyelitis
Skeletal abnormalities	Severe kyphoscoliosis
Marked obesity	Gross obesity

Modified from Grippi MA. et al. Approach to the patient with respiratory symptoms. In Grippi MA, et al., eds. *Fishman's Pulmonary Disease and Disorders*. New York: McGraw-Hill; 2015:382.

Impairment-producing restrictive pulmonary diseases can be classified as: (1) acute intrinsic, (2) chronic intrinsic, or (3) chronic extrinsic. Acute intrinsic disorders are primarily caused by the abnormal movement of intravascular fluid into the interstitium of the lung and alveoli secondary to the increase in pulmonary vascular pressures occurring with left ventricular failure, fluid overload, or an increase in pulmonary capillary permeability.

Examples of acute intrinsic disorders include pulmonary edema, aspiration pneumonia, and ARDS. Chronic intrinsic diseases are characterized by pulmonary fibrosis. Conditions that produce fibrosis of the lung include idiopathic pulmonary fibrosis (IPF), radiation injury, cytotoxic and noncytotoxic drug exposure, O₂ toxicity, autoimmune diseases, and sarcoidosis. Chronic extrinsic diseases can be defined as disorders that inhibit the normal lung excursion. They include flail chest, pneumothorax, and pleural effusions. They also include conditions that interfere with chest-wall expansion, such as ascites, obesity, pregnancy, and skeletal and neuromuscular disorders.

The pulmonary system and its functions are directly manipulated by the administration of anesthesia. The effect of intraoperative pulmonary insult or preexisting pulmonary disease on respiratory function during anesthesia and the postoperative period is predictable: greater degrees of pulmonary impairment lead to marked alterations in intraoperative respiratory status and higher rates of occurrence of postoperative pulmonary complications. This section illustrates the pathophysiologic changes involved in these clinical disorders and discusses their clinical presentation, diagnosis, treatment, and anesthetic implications.

Pulmonary Edema

Pulmonary edema is not an independent disease entity, but rather the result of a variety of disease processes. Pulmonary edema is the accumulation of excess fluid in the interstitial and air-filled spaces of the lung. The mechanisms responsible for its development include an increase in hydrostatic pressure within the pulmonary capillary system, an increase in the permeability of the alveolocapillary membrane, and a decrease in intravascular colloid oncotic pressure.²⁰⁰

To understand the etiology and pathophysiology of pulmonary edema, Starling's law of transcapillary fluid exchange must be clearly understood. The pulmonary capillary endothelium is semipermeable. Pulmonary interstitial fluid pressures, both hydrostatic (peak inspiratory flow [P_{if}]) and osmotic (π_{if}), along with the hydrostatic pressure in the pulmonary capillaries (P_c) and

the osmotic pressure of the plasma (π_p), are the primary determinants that balance fluid exchange across this semipermeable barrier.²⁰¹ These factors, which ultimately determine the amount of fluid that actually leaves the pulmonary vascular space, are incorporated into what is known as the *Starling equation*. A simplified version of this equation is as follows:

$$\dot{Q} = k[(P_c - P_{if}) - (\pi_p - \pi_{if})]$$

where Q is the total amount of fluid that traverses the endothelial membrane and k is the fluid filtration coefficient, which describes quantitatively the permeability of the membrane.^{200,201}

The P_c , the force favoring fluid movement out of the vessel wall, is in direct opposition to the P_{if} . The P_{if} , when positive, tends to force fluid inward through the capillary membrane; when it is negative, it tends to force fluid outward.⁴ The π_p and P_{if} also oppose each other, with the π_{if} keeping fluid within the capillary and the P_{if} pulling it outward into the interstitium. Overall, the balance of forces shown in the Starling equation favors fluid filtration into the interstitial space. Fluid filtered out into the alveolar interstitial space does not enter the alveoli, because under normal conditions, the alveolar epithelium is composed of very tight junctions that prevent fluid and protein from entering the alveolar air spaces. The fluid moves to the extravascular interstitial space, where the lymphatic vessels remove all the filtered fluid and return it to the systemic circulation.²⁰²

Pulmonary edema can occur if any variable in the Starling equation is altered in the direction favoring increased fluid filtration. High pressure (P_c) and increased permeability (k) are the two most important components of the Starling equation that are altered in states of pulmonary edema. Because of this, pulmonary edema is classified as being either cardiogenic (high pressure, hydrostatic) or noncardiogenic (permeability is increased).

Cardiogenic pulmonary edema occurs whenever the P_c is increased. Increased P_c is the most common form of pulmonary edema. Cardiogenic pulmonary edema is initiated by some type of left-sided heart incompetence or failure. The term *left ventricular*

failure implies that a decrease has occurred in left ventricular contractility, which ultimately leads to a reduction in both stroke volume and CO. Incomplete left ventricular emptying elevates left ventricular end-diastolic volume, which in turn elevates left ventricular end-diastolic pressure. Increased left ventricular end-diastolic pressure is “reflected back,” causing elevation of the left atrial, pulmonary venous, and pulmonary capillary pressures. When pulmonary capillary pressure reaches levels of 20 to 25 mm Hg (normal range, 10 to 16 mm Hg), the rate of fluid transudation often exceeds lymphatic drainage capacity, and alveolar flooding occurs.

Coronary artery disease, hypertension, cardiomyopathies, mitral regurgitation, and mitral stenosis are a few of the cardiac conditions that may increase pulmonary intravascular hydrostatic pressure (P_c) and predispose a patient to developing pulmonary edema. Although an elevated left ventricular end-diastolic pressure is the major cause of an increase in P_c , and therefore pulmonary edema, it is important to realize that several noncardiac problems also may increase P_c . These include pulmonary venoocclusive disease, fibrosing mediastinitis, head trauma, cerebrovascular accident, exposure to high altitudes, and overhydration.

Noncardiogenic pulmonary edema is associated with an increase in endothelial permeability caused by an insult that disrupts the barrier function of the blood-tissue interface. Unlike cardiogenic pulmonary edema, in which the capillary endothelium remains intact and no leakage of protein is noted, noncardiogenic pulmonary edema is associated with leakage of both fluid and protein from the vascular space.²⁰¹ Because this respiratory membrane disruption cannot be easily or directly measured, noncardiogenic pulmonary edema is said to exist when suspicious chest radiographic evidence coexists with insufficient hemodynamic basis. The presence of a pulmonary wedge pressure less than 12 mm Hg and the absence of a significant history of cardiac disease generally suffice for exclusion of a hemodynamic mechanism.

Although a multitude of disorders are associated with noncardiogenic pulmonary edema, the most commonly encountered cause is systemic sepsis that leads to ARDS. Other

clinical conditions associated with noncardiogenic pulmonary edema include the aspiration syndromes, inhalation of toxic fumes ([Box 29.10](#)) and the embolization phenomena ([Box 29.11](#)).

Conditions Associated with ARDS, Categorized by Possible Mechanisms of Injury

Direct Injury	Indirect Injury
Pneumonia	Sepsis
Aspiration	Major trauma
Pulmonary contusion	Multiple blood transfusions
Toxic inhalation	Pancreatitis
Near-drowning	Cardiopulmonary bypass
Reperfusion injury (e.g., after lung transplantation)	Drug overdose
	Adverse effect of medication

From Lee WL, Slutsky AS. Acute hypoxemic Respiratory failure and ARDS. In Broaddus VC, et al., eds. *Murray and Nadel's Textbook of Respiratory Medicine*. 6th ed. Philadelphia: Elsevier; 2016:1744.

Pulmonary edema is nearly always associated with some type of preexisting disease state or insult. If a patient with pulmonary edema has a history of CHF, hypertension, or ischemic heart disease, the presence of cardiogenic pulmonary edema can be assumed. In addition to systemic sepsis, anaphylaxis, pancreatitis, disseminated intravascular coagulation, trauma, multiple transfusions, and near-drowning can all result in noncardiogenic pulmonary edema.

Neurogenic Pulmonary Edema

Neurogenic pulmonary edema begins with a massive outpouring of sympathetic nervous system stimulation triggered by central nervous system insult. This centrally mediated central nervous system overactivity typically occurs in the hypothalamic area. Excessive sympathetic activation induces remarkable hemodynamic alterations, primarily systemic and pulmonary vasoconstriction. The left ventricle fails because of the inordinate pressure work imposed by the systemic hypertension, and pulmonary blood volume increases because of the functional imbalance between the failing left ventricle and the normal right ventricle.²⁰¹ Although this

sequence seems to parallel that of hemodynamic pulmonary edema, a permeability component exists, as evidenced by the high protein concentration found in the pulmonary secretions of affected patients.

Uremic Pulmonary Edema

Uremic pulmonary edema is seen in those patients with renal insufficiency or failure. Overhydration and expansion of the circulating blood volume lead to increases in pulmonary capillary pressures. Again, a “leaky” component exists because of the metabolic abnormalities associated with uremia. Reducing the circulating blood volume of these patients via hemodialysis promotes resolution of this type of pulmonary edema.²⁰¹

High-Altitude–Related Pulmonary Edema

High-altitude–related pulmonary edema can occur in the absence of left ventricular failure whenever an individual overexerts before acclimating to a high altitude. The pathogenesis of this form of pulmonary edema is unclear, but it may be the result of intense hypoxic pulmonary arterial vasoconstriction or massive sympathetic discharge triggered by cerebral hypoxia.²⁰²

Pulmonary Edema Due to Upper Airway Obstruction

Pulmonary edema caused by upper airway obstruction results from prolonged, forced inspiratory effort against an obstructed upper airway. The most common cause of this type of pulmonary edema in adults is laryngospasm after extubation and general anesthesia. In children, pulmonary edema after obstruction caused by croup, epiglottitis, and laryngospasm is also well documented. Vigorous inspiration against airway obstruction creates high negative intrathoracic, transpleural, and alveolar pressures, enlarging the pulmonary vascular volume and subsequently the interstitial fluid volume. The capacity of the lymphatics becomes overwhelmed, and interstitial fluid transudes into the pulmonary alveoli. Hypoxia causes a massive sympathetic discharge that results in systemic vasoconstriction and a translocation of fluid from the systemic circulation to the already expanding pulmonary vascular and interstitial spaces. Hypoxia also increases pulmonary capillary

pressures. Because hypoxia alters myocardial activity, left atrial function and left ventricular function are reduced.

During obstruction, vigorous inspiratory efforts are unsuccessful because of the airway obstruction. Unsuccessful expiration produces an increase in intrathoracic and alveolar pressures. PEEP_i is also produced during this stage. Relief of the obstruction results in cessation of PEEP_i.

The consequence of these events is the sudden massive transudation of fluid from the pulmonary interstitium into the alveoli, which results in pulmonary edema. The malignity of pulmonary edema is determined by the extent of prior alveolar and capillary damage and the immensity of hemodynamic and cardiovascular alterations.

Not all of those who experience an acute airway obstruction develop pulmonary edema, and no specific risk factors for its occurrence have been identified. Factors that may predispose to its formation after obstruction include youth, male gender, long periods of obstruction, overzealous perioperative fluid administration, and the presence of preexisting cardiac and pulmonary disease.

Treatment includes prompt recognition of the condition, securing a patent airway, supportive therapy with oxygenation, and administering diuretics. Although the onset of pulmonary edema after laryngospasm is usually immediate, cases have been reported of the occurrence of pulmonary edema several hours after laryngospasm. Therefore it is recommended that patients who develop laryngospasm be closely observed postoperatively. The diagnosis of pulmonary edema and its differentiation into cardiogenic and noncardiac categories necessitates taking a detailed medical history and performing a physical examination, chest radiography, and ABG analysis.

Physical examination reveals increased respiratory effort. As water accumulates, the lungs become heavy and noncompliant, and a decrease in FRC occurs. This increase in the volume of extravascular lung fluid provides a potent stimulus for surrounding interstitial stretch receptors (J-receptors), the activation of which results in tachypnea. Tachypnea is not relieved by the administration of O₂ and the return of PaO₂ to normal. Intercostal

retractions and use of accessory muscles are apparent on physical examination. Signs of sympathetic stress stimulation, such as hypertension, diaphoresis, and tachycardia, are often noted. The expectoration of pink, frothy sputum is indicative that alveoli have been flooded.²⁰¹

The detection of basilar crackles on auscultation is the traditional hallmark of early pulmonary edema. In reality, by the time crackles become audible, excess water has already flooded the alveoli and overflowed into the terminal bronchioles.¹⁹⁹ It is in the bronchioles, not in the alveoli, that the crackles of pulmonary edema are generated. The earliest and most often disregarded clinical sign associated with pulmonary edema is rapid, shallow breathing.

In cardiogenic pulmonary edema, heart size may be increased. High CVPs, an S₃ or S₄ gallop, and jugular venous distention are often observed.²⁰⁰ Chest radiography is still the most reliable and expedient tool for early detection of pulmonary edema. In cardiogenic pulmonary edema, the cardiac silhouette may appear abnormal or enlarged; in noncardiogenic pulmonary edema, it can be enlarged or remain normal. Interstitial edema can be observed before the alveoli flood and the onset of clinical signs occurs. Pleural effusions are common, and a “whited-out” or “butterfly” appearance may be noted.²⁰¹

Arterial blood gas analysis reveals hypoxemia secondary to V/Q abnormalities. When right-to-left shunting is great, the PaO₂ can be affected by any change in the central venous O₂ content. Increases in O₂ consumption or decreases in CO further reduce the PaO₂. The PaCO₂ may be low, normal, or elevated. The initial hypocarbia is related to tachypnea and high MVs; at later stages, hypercarbia is frequently secondary to muscle fatigue and exhaustion. Changes in pH usually reflect changes in PaCO₂, but metabolic or lactic acidosis or both may occur from tissue O₂ deficiency, low CO, or sepsis.

Anesthetic Management

Pulmonary edema is considered a medical emergency, and immediate intervention is required for treatment of the underlying disease, support of other failing organ systems, and optimization of O₂ delivery.²⁰⁰ O₂ should be administered either by nasal cannula,

facemask, or ETT. If oxygenation does not improve with the administration of high FiO_2 , positive-pressure ventilation with either PEEP or CPAP must be initiated. Institution of positive-pressure mechanical ventilation in patients with acute pulmonary edema usually results in a prompt increase in oxygenation and, in some cases, in CO. Improvement occurs because of superior inflation and V/Q matching. Improvement in left ventricular function (CO) may occur secondary to four possible mechanisms: (1) improvement in arterial oxygenation and therefore improvement of myocardial O_2 supply; (2) reduction in the extreme pleural pressure swings present with spontaneous ventilation and hence reduction in afterload on the left ventricle; (3) decrease in the workload of the failing heart because of a reduction in work of breathing (and therefore a reduction in O_2 requirement) effected by a mechanical ventilator; and (4) decrease in preload (and a subsequent reduction in venous return) occurring secondary to the use of positive-pressure ventilation.

Pharmacologic therapy includes the use of vasodilators, inotropes, steroids, and diuretics. For more than 50 years, morphine sulfate has been used in the treatment of cardiogenic pulmonary edema because of its venodilatory and preload-reducing properties.²⁰¹ Nitroprusside is effective at decreasing preload and afterload. By reducing systemic blood pressure and afterload, nitroprusside decreases left ventricular impedance to ejection. This may result in better cardiac function, with a subsequent lowering of left atrial pressures. Inotropic agents such as dopamine or dobutamine improve myocardial contractility and lower cardiac filling pressures. In patients with chronic CHF and pulmonary congestion, digitalis augments contractility and promotes decreases in left atrial and ventricular filling pressures. (The use of steroids is discussed later in this chapter in the section on ARDS.)

Fluid balance is managed with both fluid restriction and diuresis. This therapy helps achieve a “negative” fluid balance in hydrostatic pulmonary edema, in which P_c is high. Even in permeability pulmonary edema, in which P_c is thought to be low, any decrease in the hydrostatic pressure further reduces the net movement of pulmonary microvascular fluid outward.²⁰⁰ Potent diuretics such as furosemide not only lower left atrial filling pressure by decreasing

systemic venous tone but also induce diuresis of the expanded extravascular volume.

The type of fluid, whether crystalloid or colloid, that should be used in the presence of pulmonary edema remains controversial. Regardless of type used, it is generally agreed that administration should proceed slowly.

Aspiration Pneumonitis

Definition

Aspiration is a rare yet serious complication associated with general anesthesia. Much effort is expended to prevent this untoward occurrence and minimize sequelae if it does occur. It can occur at any time during the course of anesthesia administration, and if it is severe, a multitude of serious complications may follow. Pneumonitis adds an average of 15 hospital days' stay and over \$20,000 to the course of care of a patient who suffers this complication.²⁰³

Pneumonitis from perioperative aspiration (Mendelson's syndrome) was described by Curtis Mendelson in 1946 after he observed a number of deaths among obstetric patients.²⁰⁴ Mendelson's laboratory investigations led him to the conclusion that two entirely separate clinical aspiration disorders existed. One followed the aspiration of solid food and produced a picture of laryngeal or bronchial obstruction, whereas the other resulted from direct acid injury to the lung and produced the "asthmalike" syndrome that now carries his name.²⁰⁵ Aspiration pneumonitis in patients receiving anesthesia results from the intersection of three components: first, gastric contents escape from the stomach into the pharynx; second, those contents enter the lungs; and third, they are of a caustic nature, which results in lung tissue injury. This results from preexisting disease, airway manipulation, and the inevitable compromise in protective reflexes that accompany the anesthetized state. Aspirates may be categorized as contaminated, acidic, alkaline, particulate, and nonparticulate. Pneumonitis is a chemical injury and is not synonymous with pneumonia. Less than half of all aspirations lead to pneumonia, which occurs most often in patients who aspirate infected material or who are immunocompromised.

Ingestion of highly acidic or particulate aspirate may cause severe respiratory damage without an infectious component. Patients who initially show no signs of infection, however, may develop pneumonia over time because of the severity of the lung injury and prolonged respiratory support.²⁰⁶

Incidence and Outcome

Although the incidence of regurgitation is estimated to be frequent (as high as 15%, according to some authors), pulmonary aspiration complicates only approximately 1 out of 3000 anesthetics.²⁰⁷ This incidence is roughly doubled for cesarean section surgery²⁰⁸ and emergency surgery.²⁰⁹ Fortunately, the majority of aspiration incidents require little or no treatment. Warner et al.²¹⁰ reviewed 215,488 general anesthetics and studied the outcomes of pulmonary aspiration. They noted that approximately 60% of episodes were asymptomatic, 20% were symptomatic but required only conservative treatment or short-term ventilation, 15% required mechanical ventilation for more than 6 hours, and 5% of episodes led to death (Fig. 29.23). The overall mortality was 1 in 71,829 anesthetic procedures. Several of their findings were interesting. Complications developed in equal percentages among those who received and those who did not receive pharmacologic acid aspiration prophylaxis. Patients who aspirated but did not develop symptoms within 2 hours could be discharged. If signs or symptoms did not emerge in that time frame they would not occur subsequently. Not surprisingly, the largest number of aspirations occur during induction and intubation or on emergence within 5 minutes of extubation. They found no serious morbidity from pulmonary aspiration in nearly 120,000 elective procedures in American Society of Anesthesiologists (ASA) class I or II.

FIGURE 29.23 Outcomes of patients with perioperative aspiration. (Percentages approximate.) (Data from Warner MA, et al. Clinical significance of pulmonary aspiration during the perioperative period. *Anesthesiology*. 1993;78(1):56–62.)

In a later study, the same group reported on the incidence of aspiration in infants and children.²¹¹ Although pediatric patients are often reported as having a higher incidence of aspiration than adults,²⁰⁹ the researchers found no increase in the incidence among young patients. They noted 24 aspirations in a series of 63,180 general anesthetic procedures. Fifteen of the 24 children did not develop symptoms within 2 hours, and no treatment was required. Five children required respiratory support, three for more than 48 hours. No deaths occurred. Common risk factors for aspiration are

Box 29.12 Box 29.12.

Risk Factors for Gastric Aspiration

- Emergency surgery
- Full stomach

- Obstetrics
- Gastrointestinal obstruction
- Ascites
- Diabetic gastroparesis
- Gastroesophageal reflux
- Hiatal hernia
- Peptic ulcer disease
- Difficult airway management
- High gastric pressure or reduced lower esophageal sphincter tone
- Impaired airway reflexes
- Head injury
- Depressed level of consciousness
- Seizures
- Obesity
- Scleroderma, CREST, or other connective tissue disorders affecting the esophagus
- Trauma or stress
- Nausea and vomiting
- Opioid administration
- Cricoid pressure
- Residual neuromuscular relaxation
- Cardiac arrest, severe hypotension

CREST, Calcinosis, Raynaud phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasia.

The Anesthetic Incidence Monitoring Study database in New Zealand noted 133 cases of aspiration out of 5000 reported anesthesia incidents.²¹² Five deaths occurred. Aspiration was confirmed by clinical signs or radiography. Predisposing factors included abdominal pathology, obesity, diabetes, neurologic deficit, lithotomy position, difficult intubation, reflux disease, hiatal hernia, and inadequate anesthesia leading to straining and bucking.

In an interesting study, researchers examined general anesthesia administered by mask in obstetric patients who required surgery immediately after vaginal delivery.²¹³ Procedures included placental extraction; repair of vaginal, cervical, and perineal tears; and uterine manipulation. This database in Israel involved 1705 anesthetic procedures and only one case of mild pneumonitis occurred.

Etiology

Although vomiting and gastroesophageal reflux are common clinical events, aspiration usually occurs only when normal protective reflexes (swallowing, coughing, gagging) are inhibited.²¹⁰ Reflex responses to aspiration are automatically blunted with depression of consciousness. The most common time period for depression of protective airway reflexes is during anesthetic induction and emergence.²¹⁰

Three aspiration syndromes have been identified: (1) chemical pneumonitis (Mendelson's syndrome); (2) mechanical obstruction; and (3) bacterial infection. Because acute chemical pneumonitis poses the greatest difficulty to anesthesia providers, the pathophysiology, presentation, and anesthetic implications of Mendelson's syndrome are discussed.

The type and amount of the aspirate that causes aspiration pneumonia is often characterized according to the pH, volume, and type of gastric material aspirated. It has long been considered that gastric fluid volume (GFV) greater than 0.4 mL/kg (25 mL/70 kg) and a pH less than 2.5 are significant indicators of risk for

aspiration sequelae. In 1974, Roberts and Shirley²¹⁴ published a classic article advocating these arbitrarily defined surrogate endpoints in patients undergoing cesarean section. These markers became widely accepted in clinical practice, and efforts to reach these levels preoperatively in many patient groups included insertion of nasogastric tubes, as well as multidrug pharmacologic intervention. Unfortunately, the experiment by Roberts and Shirley by far lacked adequate scientific design to derive recommendations on assessing risk or administering prophylaxis to patients to reduce aspiration. Questions have therefore been raised as to the validity of the data behind these recommendations, with the suggestion that a reappraisal is in order.²¹⁵

A gastric fluid volume of greater than 0.4 mL/kg is more common, even in fasting individuals, than the overall incidence of aspiration would suggest, if this were a major risk factor for aspiration. In a 1998 report comparing gastric content differences in healthy obese versus lean patients, a GFV greater than 25 mL and pH less than 2.5 were noted in 26.6% of obese and 42% of lean patients.²¹⁶ These data suggest that healthy obese patients do not exhibit delayed gastric emptying and that many patients routinely fall into the arbitrary range of GFV greater than 25 mL and pH less than 2.5 without experiencing aspiration. Although the volume *aspirated* correlates with the severity of pulmonary damage, there is less correlation between the volume in the stomach and the risk of pneumonitis. A review of the value of routine nasogastric tube use after abdominal surgery demonstrated a slight *increase* in pulmonary complications among patients nonselectively treated with a nasogastric tube. The applicability of this information to short-term use under anesthesia is unknown, but it should be noted that gastric tubes not only provide evacuation but also may provide a conduit for regurgitation. Their value in patients not at risk for aspiration is unclear.²¹⁷

Acidity plays a role in aspiration-induced lung damage; however, preoperative pharmacologic manipulation of gastric pH has not been proven to be clinically effective.^{210,211} It is time to shift the focus away from GFV and pH and toward patient characteristics, patient condition, and anesthetic practices that place the patient at risk for pulmonary aspiration. Attention to the presence of factors listed in

Box 29.12 and in particular to the presence of *multiple* factors from that list will prove more fruitful to the anesthetist's ability to predict aspiration risk than will over-attention to the questionable and nonspecific factors of GFV and gastric pH. Gastric content and volume assessment is a new point-of-care ultrasound application that can help determine aspiration risk. Ultrasound assessment is being used more frequently to quantify gastric content and volume.²¹⁸

Pathophysiology

The pathophysiology of aspiration pneumonitis is typically characterized by four stages. (1) The aspirated substance causes immediate damage to the lung parenchyma, resulting in tissue damage. (2) Atelectasis results within minutes, owing to a parasympathetic response that leads to airway closure and a decrease in lung compliance. (3) One to two hours after the injury, an intense inflammatory reaction occurs, characterized by pulmonary edema and hemorrhage. Inflammatory cytokines, including interleukin-8 (IL-8) and tumor necrosis factor-alpha (TNF- α) released by alveolar macrophages, play a central role. The attracted neutrophils also play a key role in this phase by releasing oxygen radicals and proteases. (4) By 24 hours after the insult, secondary injuries result from fibrin deposits and necrosis of alveolar cells.

When aspiration is severe, damage to the entire alveolar-capillary barrier, including the basement membranes and capillary endothelial cells, may occur. It is important to note that physical damage is done to the lung endothelium instantly on contact with caustic aspirate. Therefore there is no benefit in performing bronchoscopy or deep tracheal suctioning with the intent of halting the damage. Unless the patient has aspirated a particulate substance that can be retrieved, deep suctioning after aspiration will probably cause more irritation than any benefit from reversing the process. Suctioning the mouth and pharynx to prevent further aspiration is indicated.

Hypoxemia occurs secondary to a shunting effect due to atelectasis. Initially, PaCO₂ tends to be low because of

hyperventilation from hypoxic drive and because of the mechanical and irritative stimuli to the large airways and parenchyma. Hypercarbia associated with hypoventilation is a negative prognostic sign. Because atelectasis is common, PEEP is commonly a useful treatment modality for patients who require mechanical ventilation. Damage to the lung parenchyma causes an increase in the permeability of the pulmonary blood vessels followed by a profound capillary leak syndrome. This capillary leak produces flooding of the interstitium and alveolar spaces with a protein-rich fluid (permeability pulmonary edema). Mucus rapidly buffers the acidic fluid entering the lungs. Despite this, initial contact with highly acidic material has still been shown to increase the vascular permeability in a very predictable fashion. In addition to the inactivation of surfactant by the gastric aspirate itself, the loss of protein through the impaired capillary wall can cause changes in surfactant production and, in turn, can contribute to a loss of lung compliance. Hemodynamic changes may include hypotension and reduction in CO from hypoxemia-induced myocardial ischemia and acidosis.

In the inflammatory stage, there is a release of various phagocyte-derived substances such as reactive oxygen metabolites, nitric oxide, and proteases. This stage is characterized by neutrophil infiltration, which has been found to be an important negative factor in the eventual outcome after aspiration. Research has demonstrated that inhibition of alveolar macrophages will decrease the levels of inflammatory mediators and neutrophil recruitment to the area of injury.²¹⁹ Direct inhibition of neutrophils with neutrophil aggregation inhibitors, such as pentoxifylline and lidocaine, are gaining research interest for their potential to improve outcomes of pneumonitis. Lidocaine has been demonstrated to inhibit neutrophil chemotaxis,²⁰⁹ suppress superoxide production,²²⁰ reduce reperfusion injury,²²¹ and improve outcomes following acid aspiration.²²²

Clinical Features and Diagnosis

Arterial hypoxemia, the hallmark sign of aspiration pneumonitis, is frequently the first sign of aspiration. Because the majority of aspiration incidents are asymptomatic or mildly symptomatic,

unexplained hypoxemia occurring in otherwise healthy patients postoperatively may often be a vague sign of silent aspiration. Other signs of aspiration include tachypnea, dyspnea, tachycardia, hypertension, and cyanosis.

Diagnosis may be difficult to establish unless the aspiration is witnessed or gastric contents are visualized directly in the airway or suctioned from an ETT. ABG analysis and chest radiography are needed for evaluation. Infiltrates in perihilar and dependent regions along with pulmonary edema are the most common findings on radiography.

Anesthetic Management

Preoperative Management

Recognizing risk factors and decreasing the overall risk (including avoidance of general anesthesia) are important steps in preventing aspiration. When the use of general anesthesia is unavoidable in at-risk patients, taking the following steps may help minimize the risk of aspiration, or at least limit its consequences.

Nil per os (NPO) policy has been a mainstay of prophylaxis against aspiration, by aiming to reduce patients' intragastric volume by the time they undergo anesthesia. The suggestion by Roberts and Shirley that a GFV greater than 0.4 mL/kg would predispose to aspiration gave credence to this approach. Following this concept, practitioners have instructed patients to refrain from oral intake for 8, 12, and sometimes as much as 16 hours (e.g., afternoon-scheduled surgeries, for which the patient is told to remain "NPO after midnight"). However, these NPO periods are unnecessarily long to ensure stomach emptying of most low-fat foods, and the prolonged NPO periods contribute more to patient discomfort, dehydration, and insulin resistance than to ensuring an empty stomach.²²³ It has become evident that clear liquids leave the stomach within 2 hours of ingestion, but gastric acid secretion continues, even in the absence of food intake. Therefore, in the absence of prokinetic stimulation by oral intake, a fasting patient may have a higher gastric volume and acidity than one who was allowed clear fluids closer to the time of surgery. The effects of gastrin and cholecystokinin on stimulating gastric emptying in response to

clear liquid ingestion are greater than the effect of the migrating motor complex in emptying the stomach in the absence of food or liquid intake. As a result, patients who are allowed liberal intake (without upper limit of volume) of clear fluids up to 2 hours before a procedure have higher gastric pH and lower volume than those who fasted for more than 4 hours.^{224,225} Contemporary understanding of this concept has led to revision of blanket NPO guidelines in favor of food-specific guidelines, particularly a much more liberal approach to clear liquid ingestion preoperatively (Fig. 29.24).

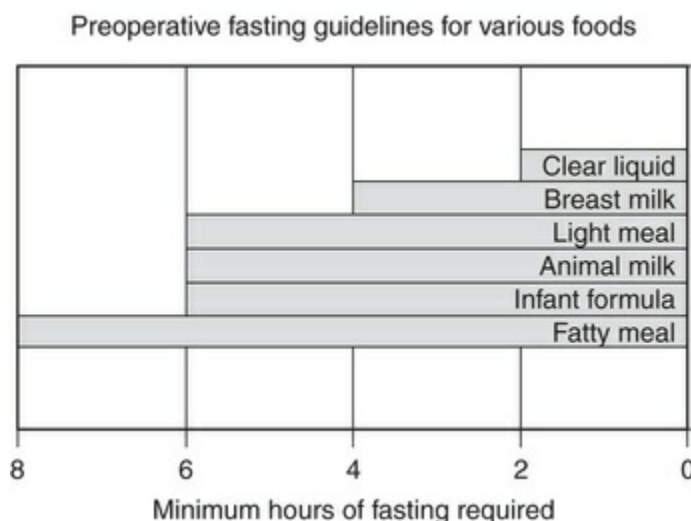

FIGURE 29.24 Preoperative fasting guidelines. (Data from American Society of Anesthesiologists Committee on Standards and Practice Parameters. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective surgery. *Anesthesiology*. 2011;114:495–511.)

Pharmacologic prophylaxis for aspiration may be considered to reduce risk factors for pneumonitis. Agents such as gastrokinetics, histamine blockers, anticholinergics, antacids, proton pump inhibitors, and antiemetics are all used alone or in various combinations to raise gastric pH, lower gastric volume, and reduce the incidence of emesis (Table 29.21). Although scientific evidence does not support the routine use of prophylactic agents, practitioners may administer them when indicated for patients who are at risk. Although previously used to inhibit gastrointestinal

activity, anticholinergic agents are no longer supported for prophylactic use, and they may even antagonize other useful agents. For example, metoclopramide raises barrier pressure (which opposes gastric regurgitation) by increasing the tone of the lower esophageal sphincter; however, anticholinergics inhibit this effect. Metoclopramide stimulates gastric emptying and acts as an antiemetic.

TABLE 29.21

Medications for Aspiration Prophylaxis*

Medication Type	Common Examples
Gastrointestinal stimulants	Metoclopramide
Histamine-2 antagonists	Cimetidine
	Famotidine
Proton pump inhibitors	Omeprazole
	Lansoprazole
Antacids	Sodium citrate
	Sodium bicarbonate
	Magnesium trisilicate
Antiemetics	Droperidol
	Ondansetron
Anticholinergics†	Atropine
	Scopolamine
	Glycopyrrolate

*The routine preoperative use of these medications to decrease aspiration risk in patients with no apparent increased risk is not recommended.

†The use of anticholinergics to decrease aspiration risk is not recommended.

Data from American Society of Anesthesiologists Committee on Standards and Practice Parameters. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective surgery. *Anesthesiology*. 2011;114:495–511.

Clear, nonparticulate antacids such as sodium citrate or sodium citrate with citric acid (“bicitra”) have been shown to be clinically effective in increasing the pH of gastric contents. Desired onset of action occurs within 15 minutes, and duration of action is 1 to 3 hours. Although citrate preparations may last up to 6 to 7 hours, some patients will also experience a rebound increase in gastric acid production, so if surgery is delayed more than 1 hour after citrate administration, it may be prudent to repeat the dose.²²⁶

Intravenous administration of the H₂-receptor blockers such as

cimetidine, ranitidine, or famotidine 45 to 60 minutes before surgery can raise gastric pH. Of the H₂ blockers, famotidine provides the best profile of duration of action and low incidence of side effects.²²⁷ Although the H₂ blockers reduce gastrin-induced acid production, they are less effective against vagal or muscarinic influence. In contrast, proton pump inhibitors irreversibly bind to H⁺/K⁺ ATPase, blocking the final pathway for acid production. They are therefore more effective in reducing acid production, but for maximal effectiveness, they must be administered as a dose the night before surgery and then repeated preoperatively. In emergency cases or where the prior-night dose was not performed, H₂-receptor blockers may provide a better option for single-dose therapy.

Although cricoid pressure has long been considered a foundation of management of aspiration risk, the effectiveness of this technique has recently been called into question.^{228–231} Confounding findings include that in a significant number of patients, the esophagus is not aligned directly posteriorly to the trachea,^{232,233} so there are numerous reports of aspiration despite application of cricoid pressure.²³⁴ Other suggestions are that cricoid pressure is inconsistently applied, or cricoid pressure itself will reduce lower esophageal sphincter pressure (LESP), thereby increasing the gradient for gastric regurgitation.^{235,236} This LESP reduction appears to be a reflex mechanism in response to cricoid pressure and can be blunted by remifentanyl.²³⁷ Other nonpharmacologic mechanisms such as elevating the patient's head may offer limited benefit. In a small study of non-obese, awake, non-fasted patients, Jeske et al.²³⁸ found no difference in gastric regurgitation, regardless of 20-degree head elevation or depression. Proponents of cricoid pressure believe that whereas the procedure may not exactly compress the esophagus as Sellick envisioned, it may nonetheless provide a barrier against regurgitation.^{239,240} Although the overall benefit of cricoid pressure is questionable, it is still widely considered a standard of care.²⁴¹

Intraoperative Management

If intubation is not expected to be difficult, a rapid-sequence induction (rather than awake endotracheal intubation) is acceptable

in the patient with aspiration risk. There is little evidence that “modified” rapid sequence technique (which allows for gentle mask ventilation) worsens aspiration incidence, and this approach may be preferable in patients at risk for rapid oxygen desaturation.²⁴² Because difficult intubation itself is a risk factor for aspiration, there should be a low threshold for performing awake intubation in a patient with aspiration risk who may also pose airway challenges. Endotracheal intubation is considered the optimal approach for airway isolation, but regurgitated material can seep around the ETT cuff, particularly if it is not lubricated.^{243,244} Preventive measures in the anesthetic plan include ensuring that the patient is fully awake before extubation and manifesting protective reflexes, residual neuromuscular blockade is minimized to the extent possible, the degree of narcosis does not impair the level of consciousness postoperatively, and that the stomach has been evacuated.

If vomiting or aspiration occurs during induction, immediate treatment includes tilting of the patient's head downward or to the side, rapid suctioning of the mouth and pharynx, and endotracheal intubation. There is little benefit in performing tracheal or bronchial suctioning in most cases, and bronchoscopy should be reserved for those patients suspected of having aspirated solid material. If aspiration is severe, surgery may be postponed. ABG analysis should be performed for determination of the extent of hypoxemia. Early application of PEEP is recommended for improving pulmonary function and combating atelectasis.²¹⁵

Oxygenation should be supported with supplemental oxygen only to the minimum extent necessary. The damage to pulmonary parenchyma from caustic aspiration predisposes the tissue to oxygen toxicity. Indiscriminate administration of oxygen may worsen tissue damage.²⁴⁵ For pharmacologic treatment of aspiration pneumonitis, the use of steroids is controversial. Long considered a mainstay of treatment, steroid therapy is associated with more rapid resolution of radiologic evidence of pneumonitis but also with longer intensive care unit (ICU) stays for some patients. Lidocaine 1.5 mg/kg is probably not harmful, but may be helpful as a neutrophil aggregation for improving long-term outcome after aspiration.²²² Although most cases of aspiration are of sterile

material (such as typical gastric acid), leukocytosis, fever, and infiltrate on x-ray are common findings in aspiration pneumonitis. The clinical findings resemble but do not indicate bacterial colonization (i.e., pneumonia). For this reason, the routine use of antibiotics is not recommended. Antibiotics are indicated only if the fever does not resolve within 48 hours, or there is risk for bacterial colonization (e.g., a patient on high-pH gastric tube feedings) or protected-sample bronchial or blood cultures indicate infection. [Box 29.13](#) gives standard treatment protocol for aspiration pneumonitis.

Treatment of Aspiration Pneumonitis

- Suction mouth and pharynx
- Deeper suctioning only for particulate material
- Administer oxygen; only to extent needed
- Lidocaine to inhibit neutrophil response
- Steroids of questionable benefit
- Intubate as needed to support oxygenation
- Bronchodilator, PEEP to support ventilation
- Antibiotics only if indicated or for fever or \uparrow WBC count > 48 hours

PEEP, Positive end-expiratory pressure; *WBC*, white blood cell count.

The common time course of symptoms after aspiration has been characterized. Warner et al.²¹⁰ noted that the condition of the patient at 2 hours after the aspiration was prognostic of the patient's eventual course. Patients could be discharged if they did not manifest significant symptoms within 2 hours of the incident. Their criteria were as follows: (1) patients did not develop symptoms that included a new cough or a wheeze; (2) no decrease in SpO₂ of greater than or equal to 10% of preoperative levels occurred when

the patient was breathing room air; (3) patients did not exhibit an A-a gradient of greater than or equal to 300 mm Hg; and (4) no radiographic evidence of pulmonary aspiration was present.

Acute Respiratory Distress Syndrome

Definition

The term *acute respiratory failure* is often used synonymously with *acute* (formerly *adult*) *respiratory distress syndrome*. Although ARDS may be caused by or associated with a variety of clinical conditions, most patients with this disease demonstrate similar clinical and pathologic features, regardless of the cause of lung injury. Common features include a history of a preceding noxious event that served as a trigger for the subsequent development of ARDS and insult to the alveolar–capillary membrane that results in increased permeability and subsequent interstitial and alveolar edema.²⁴⁶ Clinical presentation is characterized by dyspnea, severe hypoxemia, diffuse bilateral pulmonary infiltration, and stiffening and noncompliance of the lungs.

In 2012, the Berlin definition of ARDS was developed (Table 29.22). The degree of hypoxemia was stratified into mild, moderate, and severe based on the arterial PO_2/FiO_2 ratio and a requirement for PEEP of 5 cm H_2O or greater was included (whether applied by ETT or, in the setting of mild disease, by noninvasive ventilation). The term ALI was eliminated. Given that the use of pulmonary artery catheters has decreased dramatically due to a demonstrated lack of benefit, the need for a pulmonary arterial wedge pressure measurement was eliminated and instead it was recommended that objective testing (e.g., echocardiography) be performed to exclude cardiogenic edema if no risk factor for ARDS could be identified. *Acute* was explicitly defined as ARDS developing within 1 week of a known risk factor.²⁴⁷

TABLE 29.22

Berlin Definition of ARDS

Criterion	Definition
Timing	Within 1 week of a known precipitant, or new/worsening respiratory

	symptoms
Chest imaging (chest radiograph or CT scan)	Bilateral opacities—not fully explained by effusions, lobar/lung collapse, or nodules
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload If no risk factor for ARDS is present, need objective assessment (e.g., echocardiogram) to exclude hydrostatic edema
Oxygenation	
Mild	200 mm Hg < arterial PO ₂ /FiO ₂ ≤ 300 mm Hg with PEEP or CPAP ≥ 5 cm H ₂ O
Moderate	100 mm Hg < arterial PO ₂ / FiO ₂ ≤ 200 mm Hg with PEEP ≥ 5 cm H ₂ O
Severe	Arterial PO ₂ / FiO ₂ ≤ 100 mm Hg with PEEP ≥ 5 cm H ₂ O

ARDS, Acute respiratory distress syndrome, CPAP, continuous positive airway pressure; *Fio*₂, fraction of inspired oxygen; PEEP, positive end-expiratory pressure.

Adapted from Ranieri VM, et al: Acute respiratory distress syndrome: The Berlin Definition. *JAMA*. 2012;307(23):2526–2533.

Incidence and Outcome

Risk factors for the development of ARDS appear to be additive. The incidence of occurrence is 25% with the presence of one risk factor, 42% with the presence of two, and 85% with the presence of three.²⁴⁸ The mortality rate for ARDS remains high, at approximately 50%.²⁴⁹ However, the mortality rate often exceeds 90% when gram-negative septic shock precedes ARDS development.²⁵⁰

Etiology

The most common events and risk factors associated with the development of ARDS include: (1) sepsis; (2) bacterial pneumonia; (3) trauma; and (4) aspiration pneumonitis.²⁵¹ Other causes include diseases of the central nervous system, metabolic events (e.g., pancreatitis and uremia), disease states that result in the release of inflammatory mediators (e.g., extrapulmonary infections, disseminated intravascular coagulation, anaphylaxis, coronary bypass grafting, and transfusion reactions), and other forms of shock (cardiogenic, or hypovolemic) (see [Box 29.11](#)).²⁴⁷

Pathophysiology

The pathophysiology of ARDS is centered on severe damage and

inflammation to the alveolar-capillary membrane. Research has focused on the release of cytokines and membrane-bound phospholipids from the capillary endothelium and the activation of leukocytes and macrophages (via the complement system) within the lungs.²⁵² As in pneumonitis, neutrophils play a role in the pathology of ARDS, and IL-8 has been identified as the main chemotactic factor for neutrophils.²⁵³

Phospholipids are converted into prostaglandins and leukotrienes by the enzymes cyclooxygenase and lipoxygenase, respectively. It is believed that prostaglandin metabolites mediate pulmonary vasoconstriction, alter vascular reactivity (i.e., decrease hypoxic pulmonary vasoconstriction), and cause airway constriction.

In addition, microembolus formation is a common manifestation of ARDS. Complement system activation and the release of thromboplastin from soft-tissue injury can trigger the coagulation system. Damage to the alveolar-capillary membrane impairs oxygenation, and loss of lung compliance makes it difficult to effectively ventilate patients. The effect of microemboli, prolonged alveolar hypoxia and hypercapnia, and injury to the alveolar tissue leads to increases in PVR. High alveolar pressures from aggressive positive pressure ventilation further contribute to increased right ventricular afterload. This afterload increase leads to cor pulmonale in 25% of cases,²⁵⁴ and shunting across a patent foramen ovale occurs in 20%.²⁵⁵ Associated right ventricular dysfunction increases the associated mortality from ARDS,²⁵⁶ particularly when plateau pressures are high.²⁵⁷

Clinical Features and Diagnosis

The clinical presentation of ARDS resembles that of pulmonary edema and aspiration pneumonitis. Patients are dyspneic, hypoxemic, and hypovolemic and often require intubation and mechanical ventilation. Noncardiogenic pulmonary edema is a hallmark finding. Findings on histologic examination are similar to those of aspiration pneumonitis, with the exception that fibrosis of lung is more pronounced. Recovery of lung function is unpredictable. Milder cases resolve quickly, whereas others progress to fibrosis and death.

Treatment

Treatment is supportive and includes correction of hypoxemia, afterload reduction, and inotropic support as indicated.

Maintaining tissue oxygenation and reducing further lung damage are the main goals of therapy. Preserving end-organ perfusion is of utmost importance. There is no definitive treatment for ARDS, but some approaches to reducing the inflammatory reaction and improving oxygenation include corticosteroids, inhaled nitric oxide, exogenous surfactant, and extracorporeal gas exchange.^{258,259}

Anesthetic Management

Anesthetic preparation includes evaluation of the patient's respiratory, cardiac, and renal status. The anesthesiologist should carefully manage vascular volume to avoid transudation of water into the lungs and give meticulous attention to avoiding air in vascular lines, due to the potential for right-to-left shunting. Useful monitoring should include cardiac filling pressures, CO, invasive blood pressure, and a urinary catheter.

Ventilator settings should be noted and special attention devoted to peak inspiratory pressures and PEEP levels. Considering the prominence of cor pulmonale, the ventilation strategy must balance the need for alveolar recruitment with the potential for overloading the right ventricle. As PEEP is added, alveoli are recruited, improving oxygenation and reducing afterload on the right ventricle. However, at a point, alveolar overdistention will tip the balance beyond benefit and into detrimental effects, as the intrapulmonary pressure provides impedance to CO.²⁶⁰ The concept of *permissive hypercapnia* offers license to limit aggressiveness of ventilation in the interest of minimizing mean airway pressures; however, the effects of hypercapnia on increasing the PVR are varied. Some report a significant reduction (20%) in right ventricular ejection,²⁶¹ whereas others have found the hemodynamic effects temporary and nondetrimental.²⁶² In any case, right ventricular function should be monitored along with blood gas results as outcome goals for any ventilation strategy used in ARDS. Rising CVP as well as chamber dilation, reduced ejection fraction, and septal deviation or paradoxical motion as shown by

echocardiography are means of identifying RV dysfunction.²⁶³

A protective ventilation strategy is often used, aimed at minimizing airway pressures and avoiding barotrauma and volutrauma in the face of severely reduced compliance. Some approaches are referred to as *open lung* strategies, inferring a primary goal of preventing atelectasis and airway closure. Open lung approaches have tended toward use of high levels of PEEP, but there is growing evidence that more modest levels may be equally effective.^{260,264} Protective ventilation strategies vary in their details. In some cases, very unconventional ventilation approaches such as high-frequency oscillation must be used. Oscillation has been demonstrated to reduce mortality and improve gas exchange over conventional ventilation.^{265,266} Strategies focused on supporting right ventricular performance may include prone positioning.²⁶³ Prone positioning improves airway pressures, gas exchange, and reduces the indicators of cor pulmonale.²⁶⁷⁻²⁶⁹ Some common modes of ventilation are shown in [Tables 29.23](#) and [29.24](#); however, [Table 29.25](#) provides a sampling of some protective ventilation protocols that have been used in ARDS research or as guidelines.

TABLE 29.23

Features of Pressure Controlled Versus Volume-Controlled Ventilation

	Set Parameters	Variable Parameters	Clinical Implications	Clinical Conditions
Pressure-controlled ventilation (PCV)	Peak pressure target, inspiratory time, RR, PEEP	Tidal volume, inspiratory flow	Controls airway pressure, but tidal volume becomes a function of lung compliance (no guaranteed tidal volume or minute ventilation). Allows estimation of end-inspiratory alveolar pressure based on ventilator settings. Variable inspiratory flow helpful for patients with high respiratory drive.	Severe asthma COPD Salicylate toxicity
Volume-controlled ventilation (VCV)	Tidal volume, RR, inspiratory flow pattern, inspiratory time	PIP, end-inspiratory alveolar pressure	Guaranteed delivery of tidal volume, but may result in high or injurious lung pressures. End-inspiratory alveolar pressure cannot be reliably estimated and must be measured (plateau pressure).	Acute lung injury ARDS Obesity Severe burns

ARDS, Acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; PIP, peak inspiratory pressure; PEEP, positive-end expiratory pressure; RR, respiratory rate.

TABLE 29.24

Ventilator Strategies: Features of Potential Options

Mode	Parameters Set by Provider	Clinical Scenario
Continuous Mechanical Ventilation (CMV)		
Assist-control (A/C)	Pressure or volume control, RR	Paralyzed or deeply sedated patient, sedated patients with intermittent spontaneous respiratory effort; can lead to hyperventilation
Intermittent Mandatory Ventilation (IMV)		
Synchronized intermittent mandatory ventilation (SIMV)	Pressure or volume control, RR (backup rate)	Patients with regular but poor spontaneous respiratory effort; if used in deeply sedated patients, set RR will need to be higher
Continuous Spontaneous Ventilation (CSV)		
Pressure-support ventilation (PSV)	Level of pressure support, PEEP	Spontaneously breathing patients with good respiratory effort requiring minimal ventilatory support
Continuous positive airway pressure (CPAP)	Level of CPAP	Alert, spontaneously breathing patients with immediately reversible causes of respiratory distress; COPD and ACPE are classic indications for noninvasive ventilation
Bi-level positive airway pressure (BL-PAP)	IPAP and EPAP	Similar to CPAP

ACPE, Acute cardiogenic pulmonary edema; *COPD*, chronic obstructive pulmonary disease; *EPAP*, expiratory positive airway pressure; *IPAP*, inspiratory positive airway pressure; *PEEP*, positive end-expiratory pressure; *RR*, respiratory rate.

TABLE 29.25

Ventilation Protocol Used in the ARDS Network Study

Parameter	Protocol
Mode of ventilation	Volume assist control
Tidal volume	≤ 6 mL/kg predicted body weight
Plateau pressure	≤ 30 cm H ₂ O
Frequency	6–35 breaths/min, titrated for pH 7.3–7.45
I : E ratio	1 : 1 to 1 : 3
Oxygenation goal	Arterial PO ₂ 55–80 mm Hg, or SpO ₂ 88%–95%
FiO ₂ /PEEP (cm H ₂ O) combinations allowed	0.3/5, 0.4/5, 0.4/8, 0.5/8, 0.5/10, 0.6/10, 0.7/10, 0.7/12, 0.7/14, 0.8/14, 0.9/14, 0.9/16, 0.9/18, 1/18–24

ARDS, Acute respiratory distress syndrome; *I:E ratio*, inspiratory:expiratory ratio; *Fio₂*, fraction of inspired oxygen; *PEEP*, positive end expiratory pressure.

Transfusion-Related Pulmonary Disease

With increasing awareness of a host of complications related to blood transfusion, the connection to pulmonary complications has become a significant area of concern. The primary transfusion-related pulmonary complication is transfusion-related acute lung injury (TRALI).

Definition

Transfusion-related acute lung injury is a form of acute lung injury that is associated with blood transfusion and that is characterized by pulmonary infiltrates and hypoxemia. TRALI is defined as acute onset hypoxemia, bilateral lung infiltrations on the chest radiograph, and no evidence of circulatory overload, which occurs during or within 6 hours of blood transfusion in a patient with no other risk factor for ALI. TRALI resembles ARDS in clinical presentation, but unlike ARDS, it has a lower mortality and is self-limiting with spontaneous resolution usually occurring within 96 hours.²⁷⁰

Incidence and Outcome

Transfusion-related acute lung injury is a leading cause of transfusion-related fatalities, and it is the most common cause of major morbidity and death after transfusion^{271–274}; 5% to 10% of cases are fatal.^{275,276} There is a prevailing sense that TRALI is underdiagnosed, and so the incidence may be much higher than that stated figure. A 2012 study noted an incidence 0.81 (95% confidence interval, 0.44–1.49) per 10 000 units transfused.²⁷⁵

Etiology

Transfusion-related acute lung injury is thought to occur because of an interaction between transfused blood products and the recipient's white blood cells. Attention first focused on an immune mechanism, particularly surrounding the human leukocyte antigens (HLAs) and human neutrophil alloantigens (HNAs) in the recipient. The finding that some victims did not demonstrate elevated antibody titers, and that TRALI could be induced in excised lungs indicated that there is at least one other mechanism. In cases of nonimmune TRALI, reactive lipid products released from the donor blood cells may act as the trigger. In either form of TRALI, neutrophils play an important role. Theories often entertain a “two hit” hypothesis, assuming that a preexisting factor is present in victims and leads to the abnormal reaction to the allograft blood.^{277,278} This hypothesis helps explain why TRALI occurs only in some individuals.

Predisposing factors for TRALI frequently surround events that may prime the immune system; for example, recent surgery, malignancy, and sepsis, as well as alcoholism and liver disease. Increased levels of HLA and previous ALI as a risk factor point to immunologic predisposition as another factor.²⁷⁹ Donor risk factors also play an important role in development of TRALI. For example, pregnancy causes an elevation in HLA in many women and a high proportion of TRALI cases arise in individuals who receive blood products donated by women with leukocyte antibodies. For this reason, the United Kingdom halted use of plasma from female donors in 2003, and a significant reduction in the incidence of TRALI ensued. The US Food and Drug Administration is considering methods to implement a similar policy.²⁷⁴ Although TRALI has occurred in association with a wide variety of blood products, the greatest incidence follows platelet transfusion.²⁷⁰

Pathophysiology

Upon activation, neutrophils become trapped within the pulmonary microvasculature, causing congestion and leading to noncardiogenic pulmonary edema. Complement activation and release of oxygen free radicals and proteases then cause damage to

the capillary endothelium, which also promotes fluid leak into the alveoli. Platelets also play an important role in TRALI, because they are activated and then sequestered in the lungs through some interaction with neutrophils.²⁸⁰

Clinical Features and Diagnosis

Transfusion-related acute lung injury, by definition, is associated with blood transfusion, so symptoms begin during or up to 6 hours after transfusion of any blood product. Acute onset and hypoxemia are key findings, with $\text{PaO}_2/\text{FiO}_2$ ratio less than 300. Bilateral infiltrates are found on chest radiography. Clinical symptoms include fever, chills, and dyspnea. Hypertension and hypotension occur with equal frequency.

It is important to distinguish TRALI from other causes of lung dysfunction; therefore diagnosis must exclude any other precipitating factor for ALI. Cardiogenic causes and acute hypersensitivity reactions or ABO incompatibility reactions must also be excluded. TRALI appears with similar symptomatology as transfusion-related circulatory overload (TACO). TACO usually presents with tachycardia, dyspnea, and pulmonary edema. The key differentiating factor is that signs of circulatory overload or predisposition to circulatory overload (e.g., CHF) exist in TACO but not in TRALI. For patients with coronary artery disease, CHF, or who are status post lung resection (particularly with peripheral edema, jugular vein distension, S_3 heart sound), circulatory overload should be ruled out before presuming a diagnosis of TRALI. Patients who develop TACO often show signs of circulatory overload prior to the blood infusion.

Treatment

Treatment is largely supportive, as is the treatment for ARDS. A lung-protective ventilation strategy is used for patients requiring mechanical ventilation.

Anesthetic Management

Management of the patient who develops TRALI requires

immediate cessation of the transfusion. IV fluids are used to support blood pressure if the patient is hypotensive, and diuretics are not indicated, because the respiratory distress is due to microvascular injury rather than fluid overload; 70% of cases require mechanical ventilation, but resolution occurs more quickly than does ARDS.

Appropriate attribution of cause is important to guide the correct treatment. Finding of anti-HLA or HNA antibodies in plasma support the diagnosis of TRALI, whereas signs of fluid overload (clinical signs or elevated brain natriuretic peptide) support the diagnosis of TACO.^{281,282}

Drug-Induced Pulmonary Disease

Currently, more than 100 pharmacologic agents are known to produce adverse effects on the lung parenchyma, the pleura, and the airway. Drug-induced pulmonary injury occurs in several hundred thousand people each year in the United States.

Knowledge of doses and the potential adverse effects of the prescribed medications may prevent or minimize drug-induced damage. The rapid development of nanotechnology also lends concern for new forms of pulmonary toxicity. Nanoparticles, because of their extremely small size, can gain access to physiologic areas that traditional molecules cannot. In particular, in the respiratory tract, carbon nanotubes cause damage to alveolar cells, form granulomas, and led to fibrosis. This damage leads to release of proinflammatory cytokines and generation of oxygen free radicals.²⁸³⁻²⁸⁵ With the growing use of nanotubes in medications, cosmetics, disease treatment, and other applications, it is likely that new forms of pulmonary toxicity will grow in incidence.

Mechanism

The mechanism of drug-induced pulmonary injury is not well defined. It has been shown that cytotoxic drugs used in the treatment of cancer cause pulmonary insult by a combination of the direct toxic effects of a drug or its metabolite and of their indirect effects; that is, the enhancement of inflammation or immune processes. The clinical features produced by different cytotoxic

agents are similar, but chronic pneumonitis and fibrosis are the most commonly associated clinical syndromes. [Box 29.14](#) lists various agents that may produce pulmonary toxicity. The pathogenesis of pulmonary toxicity is uncertain but has been found to include disruption of the endothelial cells and changes in calcium homeostasis that lead to toxic injury. The mechanisms of drug-induced pulmonary injury associated with noncytotoxic drugs are less well defined but may involve changes in pulmonary homeostasis. Noncytotoxic agents can induce the development of numerous clinical syndromes. Several commonly implicated agents are discussed in the following sections.

Classification of Drug-Induced and Related Pulmonary Diseases by Type of Medication

Chemotherapeutic

Cytotoxic

- Azathioprine
- Bleomycin
- Busulfan
- Chlorambucil
- Cyclophosphamide
- Etoposide
- Interleukin-2
- Melphalan
- Mitomycin C*
- Nitrosoureas

- Procarbazine
- Vinblastine
- Zinostatin

Noncytotoxic

- Bleomycin*
- Cytosine arabinoside*
- Gemcitabine*
- Methotrexate*
- Procarbazine*

Antibiotic

- Amphotericin B*
- Nitrofurantoin
- Acute*
- Chronic
- Sulfasalazine

Anti-Inflammatory

- Acetylsalicylic acid*
- Gold
- Interferons
- Leukotriene antagonists

- Methotrexate
- Nonsteroidal anti-inflammatory agents
- Penicillamine*

Analgesic

- Placidyl*
- Propoxyphene*
- Salicylates*

Cardiovascular

- Amiodarone*
- Angiotensin-converting enzyme inhibitors
- Anticoagulants
- β -Blockers*
- Dipyridamole
- Flecainide
- Protamine*
- Tocainide

Illicit

- Heroin*
- Methadone*
- Methylphenidate
- Cocaine

- Talc granulomatosis

Inhalant

- Aspirated oil
- Oxygen*

Intravenous

- Blood products*
- Sodium morrhuate*
- Ethiodized oil (lymphangiogram)

Miscellaneous

- Appetite suppressants
- Bromocriptine
- Complement-mediated leukostasis*
- Dantrolene
- Hydrochlorothiazide*
- Methysergide
- Radiation
- Systemic lupus erythematosus (drug-induced)
- Tocolytic agents*
- Tricyclics*
- L-Tryptophan

*Typically present as acute and subacute respiratory insufficiency

From Dulohery MM, et al. Drug-induced pulmonary disease. In Broaddus VC, et al., eds. *Murray and Nadel's Textbook of Respiratory Medicine*. 6th ed. Philadelphia: Elsevier; 2016:1276.

Noncytotoxic Drug-Induced Pulmonary Disease

Amiodarone

Amiodarone is one of the most frequently prescribed medications for ventricular dysrhythmias. Pulmonary disease from amiodarone occurs with 5% to 15% prevalence and takes the form of chronic interstitial pneumonitis, organizing pneumonia, ARDS, or a solitary mass of fibrosis.²⁸⁶ Toxicity may be related to direct toxicity, immunologic mechanisms, or related to activation of the renin-angiotensin system.²⁸⁷

Clinical diagnosis of amiodarone-induced pulmonary toxicity is based on the presence of two or more of the following signs and symptoms²⁸⁸:

1. New onset of pulmonary symptoms such as dyspnea, cough, or pleuritic chest pain
2. Detection of new chest radiographic abnormalities such as an interstitial or alveolar infiltrate
3. A decrease in DLCO of 20% from the pretreatment value; if no pretreatment values are available, then a value equal to less than 80% of the predicted value
4. Abnormal gallium-67 uptake by the lungs
5. Characteristic histologic changes of lung tissue obtained by bronchoscopic or open-lung biopsy

Amiodarone-induced pulmonary toxicity is commonly characterized by an insidious onset with nonproductive cough, hypoxemia, progressive dyspnea, weight loss, pleuritic chest pain, pleural effusion, and occasional fever.^{286,289} Some patients present with a rapidly progressive dyspnea, high fever, and hypoxemia.

Chest radiographs demonstrate parenchymal infiltrates with a predominant diffuse alveolar, interstitial, or mixed pattern that may progress to fibrosis.²⁹⁰ Pleural thickening and effusions also have been reported. Pulmonary function tests performed at the onset of pulmonary toxicity reveal abnormalities typical of restrictive lung disease. Onset usually occurs after 2 months and is dose-related, occurring most commonly if doses greater than 400 mg/day are used.²⁸⁶ Toxicity is rare when given acutely. Therapeutic options are limited. In cases where drug withdrawal is not desirable, corticosteroids are helpful at ameliorating the disease.²⁹¹ When the drug is discontinued, resolution of toxic signs is gradual due to the drug's half-life of approximately 40 to 70 days. Fibrosis, when it occurs, is not irreversible.²⁸⁶

Cytotoxic Drug-Induced Pulmonary Disease

Three clinical syndromes are associated with cytotoxic drug-induced pulmonary injury and include: (1) chronic pneumonitis and fibrosis, (2) acute hypersensitivity lung disease, and (3) noncardiogenic pulmonary edema.²⁹² These syndromes may coexist.

Chronic Pneumonitis and Fibrosis

Interstitial pneumonitis and fibrosis is the most frequently encountered pattern in drug-induced pulmonary injury. The mechanism of injury is a direct cytotoxic effect of a drug or its metabolites on the endothelial, interstitial, or alveolar epithelial cells. On lung parenchyma, the cytotoxic effect elicits an inflammatory response characterized by the proliferation of macrophages, lymphocytes, and other inflammatory cells. This inflammatory response leads to the deposition of fibrin within the alveoli, which produces interstitial inflammation and fibrosis.

Interstitial pneumonitis can be classified as acute, subacute, or chronic; the chronic form is the most frequently encountered. Common manifestations of these subgroups include dyspnea, dry cough, low-grade fever, fatigue, and malaise that develop over several weeks to months. Chest radiography demonstrates diffuse interstitial infiltrates. Bleomycin is the causative agent most often implicated in interstitial pneumonitis. Treatment includes

discontinuation of the offending agent with or without institution of corticosteroid therapy; prognosis is variable. Other antineoplastics implicated in pneumonitis and fibrosis are trastuzumab, gemcitabine, temsirolimus, everolimus, paclitaxel, docetaxel, irinotecan, gefitinib, oxaliplatin, topotecan, and imatinib.²⁹³

Syndrome of Hypersensitivity Lung Disease

Hypersensitivity lung disease has been associated with the cytotoxic agents bleomycin, methotrexate, L-asparaginase, procarbazine, etoposide, teniposide, and mitoxantrone.²⁹³ Common pulmonary manifestations include a nonproductive cough, dyspnea, and chest pain. The systemic allergic response is manifested as fever, urticaria, arthralgias, hypotension, and eosinophilia. Chest radiography may reveal pneumonitis, pleuritis, and pleural effusion. Corticosteroid use may or may not be indicated, and prognosis is generally favorable.

Drug-Induced Pulmonary Edema

The development of noncardiogenic pulmonary edema is an acute but rare phenomenon that occurs after the administration of some antineoplastic agents. Cytotoxic drugs that contribute to its development include methotrexate, cytosine arabinoside (cytarabine), gemcitabine, imatinib, and cyclophosphamide.

Numerous pharmacologic agents used in the treatment of cancer have been implicated in the development of toxic pulmonary side effects. The agents most commonly implicated in pulmonary insult include bleomycin, busulfan, carmustine, and methotrexate. Pulmonary toxicity in the use of antineoplastic agents is defined as the development of clinical signs and symptoms of pulmonary distress that were not present during the pretreatment studies. The prevalence of diffuse pulmonary infiltration occurring as a result of drug toxicity is reported to be as high as 20%.

Prototype Agents Implicated in Pulmonary Insult

Bleomycin.

Bleomycin, an antitumor antibiotic, is the most common

chemotherapeutically induced potentiator of pulmonary injury. Despite the benefits of bleomycin therapy, the development of pulmonary toxicity is the limiting factor of its use.²⁹⁴ The most common adverse effect of bleomycin is the development of interstitial fibrosis. The incidence of pulmonary fibrosis is approximately 20%, with a 1% mortality rate. Anesthesia-related problems occur postoperatively and are associated with exposure to high O₂ concentrations. Symptoms of toxicity initially include a dry hacking cough and dyspnea on exertion. Progression of lung disease is associated with dyspnea at rest, tachypnea, fever, and cyanosis. Changes on chest radiography usually occur later and manifest as bibasilar reticular infiltrates that may progress to frank consolidation.

Several investigators have suggested that patients undergoing general anesthesia who have a concurrent history of bleomycin therapy should receive the lowest possible O₂ concentrations that allow maintenance of adequate PaO₂.^{295,296} The use of steroids has been effective in some patients.

Anesthetic Management of Bleomycin-Treated Patients.

Although universally accepted guidelines for the management of a bleomycin-treated patient undergoing general anesthesia are lacking, the following suggestions have been made:

- O₂ saturation should be monitored continuously and ABG analysis performed intermittently.
- Immediately before anesthesia, 100% O₂ should be administered for 1 to 4 minutes.
- After induction, a target PaO₂ should be chosen and the FiO₂ maintained at the lowest level that allows adequate oxygenation.
- The use of PEEP should be considered.
- Crystalloid solutions should be administered carefully and the use of colloid solutions considered if large fluid volumes are required.
- The patient should be informed of the possible need for postoperative ventilation.
- Postoperatively, the FiO₂ should be kept at the lowest possible

setting that maintains the target PaO₂.

The choice of anesthetic technique varies, but as with all surgical procedures, careful evaluation and management are essential. There are no reports suggesting the superiority of regional anesthesia in patients treated with bleomycin.

Methotrexate.

Methotrexate is an analog of folic acid that inhibits cellular reproduction by causing an acute intracellular deficiency of folate coenzymes. Methotrexate is used in the treatment of malignant and benign conditions, including leukemia, osteogenic sarcoma, choriocarcinoma, polymyositis, psoriasis, and connective tissue disorders (particularly rheumatoid arthritis). Regardless of the route of administration, pulmonary toxicity has been reported to occur with all forms of delivery, with an incidence of 7.6%. Clinically, the onset of pulmonary dysfunction may be chronic, but more commonly it is acute. The syndrome often develops over 7 to 14 days and is characterized by fever, dry cough, dyspnea, hypoxemia, and bilateral pulmonary infiltrates. Improvement may begin 10 to 14 days after onset.

Pulmonary Oxygen Toxicity

Etiology

As with all prescribed drugs, the risks of the adverse effects of O₂ administration must be considered, despite its beneficial effects. The prolonged use of high concentrations of O₂ (greater than 50% for longer than 24 hours) is potentially toxic and may result in irreversible lung damage.²⁹⁵ The rate of development of O₂ toxicity is directly related to the exposure: partial pressure of inspired O₂ and duration of administration. Deleterious effects have been reported with more brief administrations.²⁹⁷

Normobaric hyperoxia can result in four clinical syndromes: (1) acute tracheobronchitis, (2) absorption atelectasis, (3) acute alveolar lung injury (ARDS), and (4) bronchopulmonary dysplasia. When nitrogen is replaced with O₂, absorption atelectasis occurs in the alveoli that are poorly ventilated. The loss of the so-called “nitrogen

splint” promotes alveolar collapse.

Pathophysiology

The pathogenesis of pulmonary O₂ toxicity is linked to the excessive production of free O₂ radicals.²⁹⁸ Free radicals are molecules that contain one or more unpaired electrons. Free radicals are highly reactive metabolites of O₂ (e.g., superoxide anion, hydrogen peroxide, and hydroxyl radical) that overwhelm antioxidant systems, including cellular enzymatic defenses (superoxide dismutase, catalase, glutathione peroxidase) and nonenzymatic scavengers (α -tocopherol acetate). Free radicals exert their toxic effect on cell and organelle membranes; they interfere with vital cellular functions, causing inactivation of enzymes and transport proteins, membrane lipid peroxidation, and inhibition of cell growth and division. Factors predisposing to oxygen toxicity are increased exposure (concentration \times duration), advanced age, and radiation therapy to the thorax and use of chemotherapeutic agents that alter antioxidant defense mechanisms or generate oxidants.

Clinical Features and Diagnosis

The earliest manifestations are related to the effects on the tracheobronchial mucosa. Symptoms may occur after 6 hours of O₂ exposure and include substernal chest pain that is prominent with inspiration, tachypnea, and a nonproductive cough. By 24 hours, paresthesia, anorexia, nausea, and headache occur. Physiologic changes include a decrease in tracheal mucous velocity, vital capacity (VC), pulmonary compliance, and diffusing capacity and increased PAO₂ – PaO₂. Some individuals develop signs of mild airway obstruction. Chest radiography demonstrates an alveolar and interstitial pattern.

Management

Both hyperoxia and hypoxemia have undesirable effects. The goal is to deliver the lowest level of FiO₂ needed for maintaining adequate arterial O₂ saturation (generally, a PaO₂ of greater than 90 mm Hg).

Measures such as PEEP should be used for decreasing the need for high FiO₂. In cases of frank oxygen toxicity, corticosteroid therapy reduces antioxidant enzyme activity and may be useful.

Autoimmune Disorders

Autoimmune diseases, connective tissue diseases, collagenosis, and rheumatologic diseases are terms used interchangeably in clinical medicine. These entities are often characterized by multiple-organ involvement and inflammation. Most of these disorders have unknown causes; however, the inflammatory process is immunologically mediated, as evidenced by the presence of autoantibodies, rheumatoid factor, and immune complexes, as well as by elevation of the sedimentation rate and the observation of certain clinical characteristics. Pulmonary manifestations are common and often assume a major role in the disease process. Characteristic restrictive lung changes may result if pulmonary impairment is sufficiently severe. [Box 29.15](#) lists pulmonary manifestations of various collagen vascular diseases.

Pulmonary Manifestations of Collagen Vascular Diseases

Rheumatoid Arthritis

- Pleural disease (effusions)
- Diffuse interstitial pneumonitis
- Necrobiotic nodules
- Caplan syndrome
- Pulmonary hypertension (arteritis)
- Apical fibrobullous disease
- Bronchiolitis obliterans with and without organizing pneumonia
- Cricoarytenoid arthritis

Systemic Lupus Erythematosus

- Pleural disease (pleuritis, effusions)
- Atelectasis
- Acute lupus pneumonitis
- Diffuse interstitial lung disease
- Pulmonary hemorrhage
- Respiratory muscle dysfunction

Progressive Systemic Sclerosis

- Diffuse interstitial fibrosis
- Pulmonary vascular disease
- Aspiration pneumonia
- Chest-wall restrictions secondary to thoracic skin sclerosis
- Pleural disease

Polymyositis – Dermatomyositis

- Interstitial pneumonitis
- Aspiration pneumonia
- Respiratory myositis
- Pulmonary hypertension
- Bronchiolitis obliterans organizing pneumonia

Mixed Connective Tissue Disease

- Diffuse interstitial lung disease
- Pulmonary hypertension (vasculitis)
- Pleural disease
- Diaphragmatic muscle dysfunction

Sjögren Syndrome

- Respiratory mucosal dryness
- Pleurisy
- Chronic airway disease
- Lymphocytic interstitial pneumonia
- Pseudolymphoma
- Lymphoma
- Amyloid
- Pulmonary hypertension (vasculitis)

Sarcoidosis

Sarcoidosis is a multisystemic disorder characterized by the presence of epithelioid-cell granulomata. It is described as an intense interaction of activated lymphocytes and macrophages that results in tissue injury. The disease most often involves the lungs, reticuloendothelial system, skin, eyes, and myocardium. The prevalence of disease globally is 16.5/100,000 men and 19/100,000 women. The disease predominantly occurs in those aged 20 to 40 years.²⁹⁹ A preponderance of the disease among African Americans and varying phenotypes among other ethnic groups points to a strong genetic influence.³⁰⁰ The cause of sarcoidosis is unclear; no organic or inorganic causative agent has been consistently found. The route of transmission also is uncertain and may be related to

human lymphocyte antigen polymorphisms, which lead to granuloma formation after various interactions of antigens, HLA molecules, and T-cell receptors.³⁰¹ Interferon-gamma and cytokines such as TNF- α , IL-12, and IL-18 play a critical role in the formation of granulomatous lesions.³⁰²

Most sarcoid granulomata resolve spontaneously, leaving no scar. Others persist for a longer duration, with little or no fibrosis, and still others become hyalinized, fibrotic areas that cause tissue damage. Pulmonary involvement is primarily in regions rich in lymphatic vessels, such as the subpleural, perivascular, and peribronchial areas. Often, adjacent nonspecific inflammatory changes, as well as alveolitis with cellular infiltrates, are noted.³⁰³

Parenchymal infiltration and fibrosis result in a decrease in lung compliance, impairment of diffusing capacity, and a reduction in lung volumes. A restrictive pattern of ventilation is usually observed, but many patients exhibit a reduced FEV₁/FVC and increased airway resistance. V/Q imbalance and an increase in PaO₂ occur in response to a nonuniform decrease in lung compliance. An obstructive pattern resulting from endobronchial disease or peribronchial fibrosis may occur simultaneously. PH occurs in varying percentages, but is reportedly as high as 50% to 70% in some groups (particularly lung transplant patients).³⁰⁴ Cor pulmonale may develop in the presence of severe pulmonary fibrosis. Inhaled prostacyclin and sildenafil may be used to reduce PH.

Clinical presentation is varied and may be categorized as asymptomatic (occurring in 20% of individuals investigated and based on the detection of abnormality of chest radiography) or symptomatic (characterized by nonspecific features ranging from fever, fatigue, anorexia, weight loss, chills, and night sweats to dyspnea and blindness). The lung is the most commonly affected organ, with pulmonary involvement occurring in more than 90% of individuals with sarcoidosis.³⁰¹ Respiratory symptoms are those typical of interstitial involvement and include dyspnea, dry cough, and retrosternal chest pain (35% to 50% of patients). Less common symptoms include wheezing, hemoptysis, pleural effusion, and clubbing of the fingers. Sarcoidosis is one of the few chest diseases that concurrently involve lymph nodes in the lung (hilar region)

and the mediastinum. On radiography, intrathoracic involvement has been classified into three categories. Stage I is characterized by bilateral, symmetric, hilar, and mediastinal adenopathy; stage II by hilar adenopathy and diffuse pulmonary infiltrates; stage III by diffuse pulmonary infiltrates without adenopathy; and stage IV by pulmonary fibrosis.³⁰¹ Stage I is associated with the most favorable prognosis, and stage IV with the poor outcomes.

The diagnosis of sarcoidosis requires evidence of multisystem disease (i.e., multiorgan presence of granulomas). Extrathoracic involvement typically involves lymphatics, skin, liver, eye, spleen, and bone. Salivary glands, heart, nervous system, and larynx involvement occur in small percentages. Although not a common site, laryngeal involvement should cause concern about possible difficulty with airway instrumentation. Laryngeal involvement is signaled by hoarseness, dyspnea, dysphagia, dysphonia, cough, or stridor. When laryngeal involvement exists, it affects the supraglottic area in 80% and the subglottic area in 20%.²⁹⁹ Tracheotomy, transoral resection, corticosteroids, and laser resection may be used to treat laryngeal granulomas.

The overall prognosis in sarcoidosis is good. The acute onset is usually followed by a self-limiting course of approximately 2 years' duration with spontaneous resolution in approximately 20%. Treatment with corticosteroids (topical, inhaled, enteral, or parenteral) is frequently used and produces relief of symptoms, clinical remissions, and suppression of inflammation and granuloma formation. Conversely, because spontaneous and permanent remissions occur in 50% of patients, the use of corticosteroids in these individuals is controversial. Other therapies include methotrexate, azathioprine, leflunomide, and mycophenolate.³⁰¹ Considering a prominent role of TNF, infliximab, a monoclonal antibody to TNF, has been found effective in treating sarcoidosis.^{305,306}

The mortality rate for patients with sarcoidosis after 5 years is approximately 4% to 10% and is attributed to respiratory failure, azotemia from renal injury caused by chronic hypercalciuria, cardiac arrest resulting from myocardial involvement, and massive hemoptysis due to colonization of bullae by *Aspergillus fumigatus*.

Flail Chest

Flail chest, a condition that results from chest trauma and multiple rib fractures, is reported to occur in 5% of patients who sustain thoracic injury (Fig. 29.25).³⁰⁷ The hallmark of flail chest is paradoxical movement of the chest wall at the site of the fracture. During inspiration, the chest wall is drawn inward, owing to the negative intrathoracic pressure; and outward during expiration, when the intrathoracic pressure increases above atmospheric pressure (Fig. 29.26). Inefficient lung inflation caused by rib fracture and paradoxical breathing limits alveolar ventilation and may progress to hypoventilation, hypercapnia, and progressive alveolar collapse.³⁰⁸ Treatment includes pain control with interventions that may include intercostal nerve block with a local anesthetic or insertion of an epidural catheter with a local anesthetic or opioid, and, in severe cases, tracheal intubation with mechanical ventilation and PEEP (Box 29.16). Ventilator settings are adjusted so that wide fluctuations in pleural pressure are decreased or avoided. Surgical fixation of the rib cage may be indicated in some patients for persistent pain, severe chest wall instability, or a progressive decline in pulmonary function testing in a patient with flail chest.³⁰⁹ The mortality rate is directly related to the underlying and associated injuries. It has been reported to be between 8% and 35%.³⁰⁸

FLAIL CHEST

FIGURE 29.25 Fracture of several adjacent ribs in two places with lateral flail or central flail segments. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 8th ed. Philadelphia: Elsevier; 2014:433.)

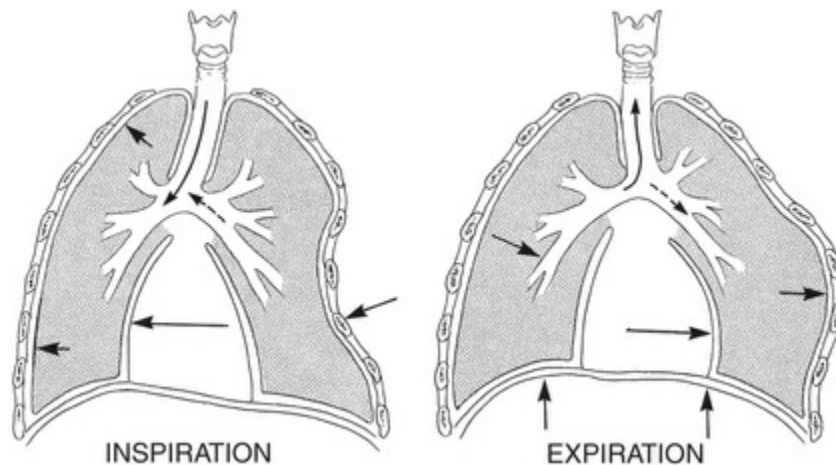

FIGURE 29.26 Flail chest: Paradoxical respiration. On inspiration, flail section sinks in as chest expands, impairing ability to produce negative intrapleural pressure to draw in air. Mediastinum shifts to uninjured side. On expiration, flail segment bulges outward, impairing ability to exhale. Mediastinum shifts to injured side. Air may shift uselessly from side to side in severe flail chest (*broken arrows*). (Redrawn from Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Elsevier; 2010:394.)

Box 29.16

Indications for Treatment of Flail Chest With Mechanical Ventilation

Respiratory failure manifested by one or more of the following criteria:

- Clinical signs of respiratory fatigue
- Respiratory rate > 35/min or < 8 min
- $PAO_2 < 60$ mm Hg at $FiO_2 \geq 0.5$
- $PaCO_2 < 55$ mm Hg at $FiO_2 \geq 0.5$

- Alveolar-arterial oxygen gradient > 450
- Clinical evidence of severe shock
- Associated severe head injury with lack of airway control or need to ventilate
- Severe associated injury necessitating surgery

Pneumothorax

Pneumothorax can be subdivided into three categories, depending on whether air has direct access to the pleural cavity.

Simple Pneumothorax

In simple pneumothorax, no communication exists between the atmosphere and the pleural space (Fig. 29.27). Additionally, no shift of the mediastinum or hemidiaphragm results from the accumulation of air in the intrapleural space. The severity of pneumothorax is graded on the basis of the degree of collapse: collapse of 15% or less is small; collapse of 15% to 60% is moderate; and collapse of greater than 60% is large. Treatment of a simple pneumothorax is determined by the size and cause of injury and may include catheter aspiration or tube thoracostomy; close observation of the patient with simple pneumothorax is essential.

FIGURE 29.27 Closed pneumothorax. Simple pneumothorax is present in the right lung, with air in the

pleural cavity and collapse of right lung. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Elsevier; 2014:437.)

Communicating Pneumothorax

With a communicating pneumothorax, air in the pleural cavity exchanges with atmospheric air through a defect in the chest wall (Fig. 29.28). A communicating pneumothorax represents a severe ventilatory disturbance because the affected lung collapses on inspiration and expands slightly on expiration. The exchange of air in and out of the wound results in a large functional dead space and a decrease in the efficacy of ventilation.

FIGURE 29.28 Communicating pneumothorax. The right lung has collapsed, and air is present in the pleural cavity, with communication to the outside through the defect in the chest wall. In sucking chest wounds, lung volume is greater with expiration. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Elsevier; 2014:438.)

The wound should be covered with an occlusive dressing immediately. The dressing should prevent influx of air, but should allow egress of air from inside the thorax to avoid development of tension pneumothorax (see next section). Treatment measures include administration of supplemental O₂, tube thoracostomy, and

intubation; mechanical ventilation may be indicated.

Tension Pneumothorax

Tension pneumothorax develops when air progressively accumulates under pressure within the pleural cavity (Fig. 29.29). If the pressure becomes too great, the mediastinum shifts to the opposite hemithorax, and this causes compression of the contralateral lung and great vessels. Subsequently, venous return is decreased, and air enters the pleural space but cannot exit. Respiratory and cardiac disturbances ensue, exhibited by a decrease in CO, a decrease in blood pressure, an increase in CVP, and a shunting of blood to nonventilated areas. The hallmark signs associated with a tension pneumothorax are hypotension, hypoxemia, tachycardia, increased CVP, and increased airway pressure. Other findings include absence of breath sounds on the affected side, asymmetric chest wall movement, tracheal shift, displacement of the cardiac impulse, and hyperresonance to percussion in the affected hemithorax. The patient may exhibit extreme anxiety.

FIGURE 29.29 Tension pneumothorax. Hyperlucency is noted, mostly toward the left lung base, because the x-ray is a supine exposure. Shift of the mediastinum toward the right is noted. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Elsevier; 2014:438.)

Tension pneumothorax is potentially lethal; therefore immediate treatment is essential. Decompression of the chest can be performed with the insertion of a 14-gauge angiocatheter into the second or third interspace anteriorly or the fourth or fifth interspace laterally. A rush of air is heard when decompression occurs. The angiocatheter converts the tension pneumothorax to a simple pneumothorax.

Hemothorax

A hemothorax is caused by the accumulation of blood in the pleural cavity. It is usually a result of trauma (Fig. 29.30), but other causes include the rupture of small blood vessels in the presence of inflammation, pneumonia, tuberculosis, or erosion by tumors.

FIGURE 29.30 Hemothorax secondary to gunshot wound. Note haziness over right hemithorax with bullet seen in right upper lobe. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 8th ed. Philadelphia: Elsevier; 2014:441.)

The treatment of hemothorax consists of airway management as necessary, restoration of circulating blood volume, and evacuation of the accumulated blood. Thoracostomy may be indicated if the initial bleeding rate is greater than 20 mL/kg per hr. If bleeding subsides but its rate remains greater than 7 mL/kg per hr, if chest

radiograph worsens, or if hypotension persists after initial blood replacement and decompression, thoracostomy is indicated.

Pathogenesis

Different presentations may be distinguished, according to the mechanism of injury.

Spontaneous.

Pneumothorax is usually caused by rupture of alveoli near the pleural surface of the lung after a forceful sneeze or cough. This mechanism is most common in individuals with a long narrow chest and in those with emphysema.

Traumatic.

Hemothorax, pneumothorax, and flail chest may occur after blunt chest trauma; however, they most often occur after rib fracture. Hemopneumothorax also may occur with penetrating injury.

Iatrogenic.

Hemothorax and pneumothorax may occur after any of the following:

- Subclavian central line insertion (incidence 2% to 16%)
- Supraclavicular brachial plexus block (interscalene and intercostal block are possible, but less prevalent causes)
- Barotrauma (resulting from overdistention of the alveoli by PEEP or high peak pressure; abrupt deterioration of PaO₂ and cardiovascular function during mechanical ventilation should arouse suspicion of pulmonary barotrauma, especially pneumothorax)
- Other surgical procedures (e.g., mediastinoscopy, radical neck dissection, mastectomy, axillary lymph node dissection, or nephrectomy)

Nitrous Oxide and Pneumothorax

The blood-gas partition coefficient of N₂O (0.47) is 34 times greater than that of nitrogen (0.014). This differential solubility means than

N₂O can leave the blood to enter an air-filled cavity 34 times more rapidly than nitrogen can leave the cavity and enter the blood. As a result, the volume or pressure of the air-filled cavity surrounded by a compliant wall increases. An often-cited study determined that 75% N₂O doubles the volume of a pneumothorax in 10 minutes.³¹⁰ If in the presence of pneumothorax the chest tube is patent and functioning, N₂O is theoretically acceptable, because little pleural air should be present, and any accumulation should be evacuated by the chest tube. A closed pneumothorax is a contraindication to administering N₂O. Decreased pulmonary compliance (increased pulmonary inspiratory pressure) during administration of anesthesia to patients with a history of chest trauma may reflect the expansion of an unrecognized pneumothorax.

Atelectasis

Definition

Atelectasis is an abnormal condition characterized by a collapse of pulmonary tissue that prevents the alveolar exchange of CO₂ and O₂. Atelectasis can involve a small localized area or an entire lung. Atelectasis is common with all general anesthetics. It commonly develops within the first few minutes of induction of anesthesia, regardless of the mode of ventilation used, and persists for hours to days after anesthesia, depending on the extent and location of surgery.³¹¹ Atelectasis commonly forms adjacent to the diaphragm in dependent lung regions. Compression of lung tissue, absence of diaphragmatic-induced negative pressure, impaired surfactant, and absorption of oxygen from nitrogen-free alveoli are common causes of atelectasis. Affecting 90% of patients under general anesthesia, atelectasis and airway closure are responsible for the vast majority of gas exchange impairment observed under anesthesia.³¹²

Etiology and Pathophysiology

Atelectasis results from a blockage or obstruction of many small bronchi or of a major bronchus. The loss of diaphragmatic tone and function during general anesthesia is a major contributing factor to atelectasis, which characteristically develops within minutes after

anesthesia induction. As small airways close due to maldistribution of ventilation under positive-pressure breathing, or due to the cephalad migration of abdominal contents, the gas within the affected alveoli is absorbed, and there is no further ventilation to reopen those alveoli. Reduction in the FiO_2 can help reduce the degree of atelectasis (as measured by the shunt fraction).³¹³

Incidence and Outcome

Atelectasis occurs almost universally under general anesthesia and is the most common cause of postoperative respiratory dysfunction. Postoperatively, it occurs most often after thoracic and upper abdominal procedures, with rates of incidence reaching 80%. In lower-risk surgeries, postoperative atelectasis is most often subclinical and resolves spontaneously within 24 to 48 hours. No recent data support that atelectasis predisposes one to the development of pneumonia.

Treatment

Historically, practitioners used large tidal volumes (10 to 15 mL/kg) to combat atelectasis intraoperatively. Although the concept of injury related to high-pressure barotraumas has been long understood, the understanding of ventilator-associated lung injury being related to high ventilating volumes, even in the presence of moderate-peak inspiratory pressures (volutrauma) has changed the approach to establishing ventilator tidal volumes.^{273,314} To reduce the deleterious effect of high volumes, smaller tidal volumes of 6 to 8 mL/kg are more beneficial for mechanical ventilation, particularly in cases of RDS. There is evidence that this reduction in tidal volume does not worsen the degree of atelectasis.³¹⁵ Instead, PEEP and various maneuvers to reopen (“recruit”) and maintain alveoli have been proposed to reduce atelectasis.³¹⁶ Most common of these are vital capacity maneuvers, where the lungs are intermittently expanded to vital capacity or 30 cm H_2O and held in that state for approximately 10 seconds.^{313,317} Such recruitment maneuvers are most effective when combined with other strategies, such as reduction in FiO_2 or open-lung ventilation approaches.

Open-lung ventilation describes myriad approaches to providing

mechanical ventilation with the goal of preventing atelectasis. Pressure-control inverse ratio ventilation (PC-IRV) and, more recently, airway pressure release ventilation (APRV) are approaches designed to maintain a higher mean lung volume and thereby reduce airway closure and atelectasis. APRV is analogous to CPAP, with intermittent release phases that allow the lung volume to drop briefly. APRV has an advantage over more “controlled” ventilation modes (such as PC-IRV) in that it is useful in spontaneously breathing patients to reduce neuromuscular blockade, preserve respiratory effort and protective reflexes, and cause less patient-ventilator dyssynchrony.³¹⁸

Standard postoperative measures for improving pulmonary function include incentive spirometry, deep breathing, intermittent positive-pressure breathing, and administration of CPAP. The use of CPAP is the most effective method for increasing FRC from the interventions previously listed.

Pleural Effusion

Pleural effusion is the abnormal accumulation of fluid in the pleural space. It is usually an indication of disorders or disease complications in the surrounding structures. Possible causes of effusion are: (1) blockage of lymphatic drainage from the pleural cavity; (2) cardiac failure, which causes an increase in pulmonary capillary pressures and eventual movement of fluid into the pleural cavity; (3) reductions in plasma colloid osmotic pressure; and (4) infection or any other inflammatory process of the pleural membranes that alters capillary membrane permeability.

Treatment modalities include tube thoracostomy, thoracentesis, and pleurodesis. Pleurodesis is a procedure used to prevent the reaccumulation of pleural fluid. Inflammation is produced with injection of a sclerosing agent, usually tetracycline, into the chest tube; adhesion formation and fusion of the pleural membranes result.

Skeletal Disorders

The primary pathophysiology of skeletal disorders is an alteration in the structure of the thorax that diminishes chest-wall excursion.

Disorders commonly producing this restriction of breathing include sternal deformities, kyphoscoliosis, and ankylosing spondylitis (AS).

Pectus Deformities

Pectus Excavatum

Pectus excavatum, also referred to as *funnel chest*, is the most common chest wall deformity, occurring in 1 in 400 children.³¹⁹ It is a congenital anomaly characterized by depression of the sternum (usually above the xiphoid-sternal junction) and symmetric or asymmetric prominence of the ribs on either side. Pectus excavatum is a genetically heritable abnormality that is associated with adolescent scoliosis.³²⁰ If uncorrected, the disease usually worsens at adolescence. A widely used surgical procedure, the Nuss procedure, inserts a metal rod behind the sternum to reverse the concavity.³²¹

Clinically, the majority of patients are asymptomatic unless pectus excavatum is extreme. Patients with pectus excavatum have reduced chest cavities and TLC compared with normal individuals; however, pulmonary function is often normal except in severe cases, in which VC, TLC, and maximum breathing capacity may be diminished. The indications for repair of pectus excavatum are the subject of controversy. Conflicting data have been presented regarding whether the repair of pectus excavatum is performed only for cosmetic purposes or whether it actually improves cardiorespiratory function and exercise tolerance.³²¹ Patients with Marfan syndrome have a high incidence of chest-wall deformities. They are usually seen in their most severe form and are often accompanied by scoliosis. Other musculoskeletal diseases may be present in patients with pectus excavatum. Congenital heart disease, mitral valve prolapse, and asthma also occur more frequently in patients with pectus excavatum. Electrocardiographic abnormalities are common and attributable to the abnormal chest-wall configuration and to the displacement and rotation of the heart into the left thoracic cavity. A systolic ejection murmur of grades II to III or IV is often identified.

Pectus Carinatum

Pectus carinatum is characterized by a longitudinal protrusion of the sternum. It is the second most common chest deformity, occurring in 1 or 2 persons per 1000. A familial tendency exists, and the disorder is more frequent in males than in females (4 : 1). The pathogenesis is unclear, and the disorder may be congenital or acquired. The development of pectus carinatum is thought to result from the overgrowth of the costal cartilages, which results in displacement of the sternum. The development of pectus carinatum has also been associated with severe childhood asthma and rickets.³²² The physiologic effects are probably related to the restriction of thoracic excursion. Patients with pectus carinatum have an increased incidence of congenital heart disease, including ventricular septal defect, patent ductus arteriosus, atrial-septal defects, and mitral valve abnormalities.³²³ Surgery is the only effective treatment for pectus carinatum, and it is performed to alleviate possible cardiopulmonary dysfunction and to prevent progressive postural deformities, as well as for cosmetic reasons.

Kyphoscoliosis

Definition

Kyphosis is a deformity marked by an accentuated posterior curvature of the spine. Scoliosis is a lateral curvature. Kyphoscoliosis results when kyphosis and scoliosis occur concomitantly, causing a lateral bending and rotation of the vertebral column. Scoliosis alone, despite its severity, does not cause sensory or motor impairment. In contrast, kyphosis and kyphoscoliosis may induce cord damage because of the sharp angulation of the spine. Respiratory dysfunction is associated with scoliosis, significant kyphosis, and severe kyphoscoliosis.

Incidence and Outcome

Scoliosis is the most common spinal deformity, with an incidence of 4 persons per 1000.³²⁴ The etiologic classification of scoliosis is divided into five categories: idiopathic, congenital, neuropathic (e.g., poliomyelitis, cerebral palsy, syringomyelia, and Friedreich ataxia), myopathic (e.g., muscular dystrophy and amyotonia

congenita), and traumatic. Idiopathic scoliosis is the most common deformity, accounting for 80% of all cases. The presence of cervical scoliosis should alert anesthesia personnel to potential difficulties in airway management. Any significant curvature involving the thoracic spine may alter lung function. Unless deformity is severe, patients with kyphosis are able to maintain normal pulmonary function. In contrast, even mild forms of scoliosis can result in impaired ventilatory function.

Although not totally consistent, VC and FEV₁ less than 50% of that predicted during initial testing suggest an increased risk of pulmonary complications postoperatively.^{325–327} The Cobb angle (being greater than 100–110 degrees) is also moderately predictive of complications.^{325,326}

Severe thoracic deformity may result in respiratory alterations during sleep. Several types of breathing abnormalities have been documented, including obstructive apnea and hypopnea. The lowest HgbO₂ saturations occurred during REM sleep.^{328,329} Because of chronic effects on the pulmonary system, surgical correction results in immediate and short-term deterioration of respiratory mechanics in anesthetized patients.³³⁰

Clinical Features and Diagnosis

Diminution of pulmonary function occurs with curvatures of greater than 60 degrees, and pulmonary symptoms develop with curvatures greater than 70 degrees (as measured by the Cobb technique; [Fig. 29.31](#)). Curvatures of greater than 100 degrees may be associated with significant gas exchange impairment.³³¹ In general, the greater the curvature, the greater the loss of pulmonary function. As a result, mechanical ventilation becomes inefficient; this inefficiency is the major factor causing respiratory embarrassment.³²⁹ At the time of diagnosis, it is often possible to document a reduction in lung capacity. The characteristic deformity seen in scoliosis causes one hemithorax to become relatively smaller than the other.

FIGURE 29.31 Cobb method of measuring scoliosis curves. The most tilted vertebrae above and below the curve are identified. Horizontal lines are drawn parallel with the plane of each vertebra. Perpendicular lines intersecting those horizontal lines intersect at the angle of curvature.

Skeletal chest wall deformity in kyphoscoliosis leads to a reduction in lung volumes and the pulmonary vascular bed.³³² Ventilatory failure associated with severe kyphoscoliosis produces a lung size that is 30% to 65% of normal. As the patient ages, the chest wall becomes less compliant; this increases the work of breathing and leads to hypoventilation and respiratory muscle weakness.

The main features of lung mechanics in the patient with early-stage scoliosis are reduced lung volumes (VC, TLC, FRC, and RV) and reduced chest wall compliance; in the late stages of disease, V/Q mismatching with hypoxemia (attributed to alveolar hypoventilation because of a decrease in VT), increased PAP, hypercapnia, abnormal response to CO₂ stimulation, increased work of breathing, and cor pulmonale occur and eventually lead to cardiorespiratory failure.³³² Reduction in VC to 60% to 80% of the predicted value is a typical finding.³³¹ FEV₁/FVC is normal unless other pulmonary diseases are present. Although normocarbia prevails for most of the clinical course, an elevated PaCO₂ signifies

the onset of respiratory failure. The severity of hypercapnia most closely correlates with the patient's age and inspiratory muscle strength.

Associated Conditions

Scoliosis may be associated with several cardiovascular abnormalities, of which mitral valve prolapse is the most common. If mitral regurgitation is present, antibiotic prophylaxis is indicated before surgical manipulation. Other common changes include an increase in PVR and ensuing PAH, which leads to the development of right ventricular hypertrophy. Several contributing factors are thought to be responsible for the development of increased PVR. First, arterial hypoxemia results in pulmonary vasoconstriction. Second, changes in the pulmonary arterioles as a consequence of the increased pulmonic pressure may cause narrowing and result in irreversible PAH. Third, a compressed chest wall may increase vascular resistance in affected areas. Lastly, development of scoliosis at an early age inhibits growth of the pulmonary vascular bed.

Treatment

The management of scoliosis may include: (1) observation of the problem without active medical treatment; (2) treatment by nonoperative methods that include the use of braces or electronic stimulators; and (3) operative methods such as anterior or posterior spinal fusion and instrumentation, such as Harrington rod insertion.³³³ Debate continues regarding the long-term effectiveness of various treatment modalities vis-à-vis short- and long-term complications that can also arise after surgery.³³⁴

Anesthetic Management

Preoperative Evaluation.

Preoperatively, a thorough review of systems is essential. The severity of scoliosis and any underlying conditions must be noted. Any reversible pulmonary involvement such as pneumonia should be corrected before elective surgery. ABG analysis may be indicated if there is suspicion of significant pulmonary impairment. Because

these procedures can potentially involve large blood losses, young, healthy, asymptomatic patients may donate autologous blood. Blood typing and cross match also are required.

When sedatives are used in the preoperative area, care must be taken to ensure that respiratory status is not depressed. The need for intraoperative monitoring is dictated by the type of surgery and the physical status of the patient. No specific anesthetic techniques have been shown to be superior in patients with scoliosis, but N₂O may increase PVR by direct vasoconstrictive effects on the pulmonary vasculature. It has been suggested that scoliosis is associated with an increased incidence of malignant hyperthermia.³³⁵

With significant manual distraction of the spine during the procedure, assessment of neural integrity may be required. Although increasingly less common, a “wake-up” test may be requested after placement of surgical instrumentation. This should be communicated between surgeon and anesthesiologist before the procedure. At the designated time, the anesthetic is lightened and the patient is observed to follow commands and demonstrate motor function. The anesthetic must be planned to allow the patient to become able to hear and follow commands, while still tolerating the ETT in the prone position. After successful demonstration, anesthesia is rapidly reinstated to facilitate the conclusion of the procedure. The use of somatosensory evoked potentials and motor evoked potential monitoring has reduced the requirement for the wake-up test. Neural monitoring, however, also necessitates customization of the anesthetic plan to reduce interference with the signals. High-dose volatile agent concentration or wide swings in anesthetic depth can influence sensory evoked potential monitoring. Muscle relaxants interfere with motor evoked response monitoring. All anesthetic agents depress somatosensory evoked potentials to a varying degree. Administration of volatile anesthetics should not exceed a minimum alveolar concentration of 1 MAC. A technique using primarily N₂O or propofol for hypnosis and continuous infusion of opioid is a common approach. Communication between the monitoring technician and anesthesiologist is essential.

Intraoperative Management.

Considerable fluid and blood loss may occur during surgery. The surgeon may request the institution of deliberate hypotension. Deliberate hypotension can be produced with the use of one or more of the following: potent inhalation anesthetics; vasodilators (e.g., sodium nitroprusside, or nitroglycerin), or β -adrenergic blocking agents (e.g., propranolol or esmolol). The risks and potential benefits should be weighed against the effects of deliberate hypotension. Traditional wisdom was that the mean arterial blood pressure can be safely maintained at a lower level of 60 mm Hg. However, the lower limit of cerebral autoregulation is highly variable. Discrepancies between blood pressure measurement devices and the actual perfusion pressure of the brain may be significant. The incidence of both blindness from retinal hypoperfusion in the prone position and cerebral injury from deliberate hypotension call for extreme caution in driving the blood pressure down during this procedure.³³⁶⁻³³⁸ Interventions for prevention of hypothermia, such as use of an air warming blanket, should be used. Careful positioning is essential.

Postoperative Care.

The decision of whether to use mechanical ventilation postoperatively is based on the severity of scoliosis, the patient's preoperative physical status, and the occurrence of intraoperative events. Most patients with mild to moderate pulmonary dysfunction are able to undergo safe extubation in the operating room. Those with severe deformity should be weaned slowly.

Ankylosing Spondylitis

Definition

Ankylosing spondylitis, also known as *rheumatoid spondylitis* and *Marie-Strumpell disease*, is a chronic inflammatory disorder that primarily affects the spine and sacroiliac joints and produces fusion of the spinal vertebrae and the costovertebral joints.

Etiology and Incidence

The cause of AS remains unclear. However, it is strongly associated

with the histocompatibility antigen HLA-B27, the presence of which is detected in more than 90% of Caucasians with the disease.³³⁹ It is a disease of adults younger than 40 years, and it demonstrates a predilection for males (male-to-female ratio, 9 : 1). The disease is rare in non-Caucasians.

Clinical Features and Diagnosis

Ankylosing spondylitis is diagnosed on the basis of clinical criteria that include: (1) chronic low back pain with limitation of spinal motion (less than 4 cm as measured by the Schober test); (2) radiographic evidence of bilateral sacroiliitis; and (3) limitation of chest wall expansion (less than 2.5 cm increase in chest circumference measured at the fourth intercostal space).

Extraskelatal manifestations of this disease include iritis, cardiovascular involvement (cardiac conduction defects, aortitis, and aortic insufficiency in 20% of individuals), peripheral arthritis, fever, anemia, fatigue, weight loss, and fibrocavitary (fibrobullous) disease of the apexes of the lungs. The most limiting factors associated with AS are pain, stiffness, and fatigue.

Complications

Pulmonary complications are reported to occur in 2% to 70% of patients with AS. Apical fibrosis is the most commonly occurring abnormality, followed by interstitial lung disease, respiratory impairment due to chest wall restriction, sleep apnea, and spontaneous pneumothorax. In apical fibrosis, the pulmonary lesion begins with apical pleural thickening and patchy consolidation of one or both apexes, and often progresses to dense bilateral fibrosis and air space enlargement. Patients with apical fibrosis usually have advanced AS. Cardiac complications associated with AS include aortic valve diseases, conduction disturbances, cardiomyopathy, and ischemic heart disease.³⁴⁰

The most common thoracic complication is fixation of the thoracic cage as a result of costovertebral ankylosis, which can lead to pulmonary dysfunction.³⁴¹ In patients with this complication, motion of the thoracic cage is restricted due to fusion of the costovertebral joints; this restriction leads to a decrease in thoracic excursion. Respiratory function typically demonstrates a restrictive

pattern with mild diminution of TLC, VC, and DLCO and normal or slightly increased RV and FRC. Pulmonary compliance, diffusion capacity, and ABG values are usually normal.³⁴¹ Despite having abnormal pulmonary function, the majority of patients with AS are able to perform normal physical activities without exhibiting pulmonary symptoms.

Bone ankylosis may occur in the numerous joints around the thorax (i.e., the thoracic vertebrae and the costovertebral, costotransverse, sternoclavicular, and sternomanubrial joints), resulting in limitation of chest-wall movement. Patients with AS rarely complain of respiratory symptoms or functional impairment unless they have coexisting cardiovascular or respiratory disease. Progressive kyphosis is equivalent to progressive rigidity of the thorax. Increased diaphragmatic function compensates for decreased thoracic motion, allowing lung function to be well preserved. Regional lung ventilation in patients with AS is normal unless they have preexisting apical fibrosis.

Cervical spondylosis most often affects levels C5 to C6 and C6 to C7. The distributions of C4 to C5, C7 to T1, and C3 to C4 are less frequently affected. The degenerative changes may result in nerve root entrapment by foraminal encroachment. The phrenic nerve, which innervates the diaphragm, is supplied primarily by the C4 nerve root, and to a lesser extent, by the C3 and C5 nerve roots. A case of hemidiaphragmatic paralysis secondary to C4 nerve root compression has been reported.

Cricoarytenoid involvement may exist and can lead to respiratory dysfunction and upper airway obstruction. Cricoarytenoid dysfunction can manifest as a hoarse, weak voice. Respiratory failure from cricoarytenoid ankylosis has necessitated therapeutic tracheostomy. In all reported cases, laryngeal symptoms were present before cricoarytenoid arthritis caused airway compromise. A case of acute respiratory failure and cor pulmonale resulting from cricoarytenoid arthritis has also been reported in a patient with AS.

Treatment

Medical therapy for adult patients with AS is supportive and preventive. Most patients with AS are asymptomatic. Depending on the severity of disease involvement, management may consist of the

use of corticosteroids and nonsteroidal antiinflammatory agents.

Anesthetic Management

Patients with AS have specific anesthetic requirements.³⁴²

Management of the upper airway is the priority because of the potential for obstruction. Cervical spine involvement may result in limitation of movement. The ankylosed neck is more susceptible to hyperextension injury, and cervical fracture may occur. Intubation awake with or without the use of a fiberoptic bronchoscope is indicated. In rare situations, tracheostomy must be performed with the patient under local anesthesia before anesthesia can be induced. A regional anesthetic technique may not be feasible because of skeletal involvement that precludes access or because of neurologic complications such as spinal cord compression, cauda equina syndrome, focal epilepsy, vertebrobasilar insufficiency, and peripheral nerve lesions. Patients with cardiovascular system involvement may require antibiotic coverage, treatment of heart failure, or insertion of a temporary pacemaker before surgery. Restriction of chest expansion and, rarely, pulmonary fibrosis necessitate performance of a thorough preoperative assessment and immediate postoperative mechanical ventilation. Careful attention for proper positioning is essential.

Summary

To conduct an accurate patient assessment and manage relevant pathophysiology, knowledge of the anatomy and physiology of the respiratory system is imperative for the anesthetist. Anatomic idiosyncrasies (such as the shorter, straighter, right mainstem bronchus), physiologic derangements from anesthesia (such as the atelectasis and ventilation-perfusion mismatch that occur), perianesthetic complications (such as aspiration pneumonitis), preexisting illness (such as COPD), and iatrogenic illness (such as pulmonary toxicity from chemotherapeutic agents) are all concerns for the anesthetist when caring for the pulmonary system.

Anesthesia for Thoracic Surgery

Michael Rieker

Thoracic surgery is greatly facilitated by the contribution of anesthesia care, which can isolate the movement of one lung during ventilation and create a quiet surgical field. Although this procedure requires advanced techniques related to airway management, it has been in existence almost as long as tracheal intubation itself. In 1928, Guedel, Magill, Waters, and other pioneers first achieved closed endotracheal anesthesia. The treatment of tuberculosis and empyema, however, required isolation of the infected lung, and in 1931 Joseph Gale and Ralph Waters first described "closed endobronchial anesthesia." Bronchial blockade for selective ventilation and lung isolation was reported by Magill in 1936. In 1950, Björk and Carlens were credited with the first use of a double lumen endotracheal tube (ETT) for thoracic surgery, the bronchspirometric double lumen tube (DLT), which Carlens described the year before.^{1,2} DLTs evolved in design, and the use of the Fogarty embolectomy catheter for bronchial blockade gave way to the Univent tube invented by Inoue and colleagues.

Development of airway devices is continuously evolving, and anesthesiologists caring for patients undergoing thoracic surgery must be skilled at insertion, maintenance, and monitoring of these devices for proper function. However, the process of lung isolation facilitates the surgical procedure, but compounds a central concern in thoracic anesthesia: maintaining effective gas exchange in the face of ventilation and perfusion mismatch. General anesthesia creates atelectasis, which is compounded by muscle relaxants and lateral positioning, but ventilation and perfusion are further mismatched when the thorax is opened, and ceasing ventilation of one lung is the final insult. Fortunately, physiologic processes such as hypoxic pulmonary vasoconstriction combat the inherent shunt, and anesthetic management is geared toward supporting those

processes while fostering oxygenation through various ventilation modalities. The general incidence of hypoxemia is 5% to 10% during one-lung ventilation (OLV).³

Besides managing the complexities of a double lumen ETT, the anesthetist must also be cognizant of the effects of underlying disease as it relates to management of ventilation (bullous disease contraindicating nitrous oxide [N₂O]), interactions with anesthetic drugs (small cell carcinoma being associated with myasthenic syndrome), and even concerns about oxygen toxicity (in patients treated with bleomycin and other chemotherapeutics).

Preoperative Preparation

Bronchogenic carcinoma is the leading cause of cancer deaths in the United States.⁴ Lung cancer is most often discovered only once the patients exhibit symptoms, and even with aggressive multimodal treatment, prognosis is poor. A review of patients with non-small cell carcinoma found a 5-year survival rate of less than 7%.⁵ However, resection of the affected lung tissue offers a better prognosis as compared to radiation and chemotherapy, and so cancer is a common indication for lung surgery. There is a strong association between lung cancer and chronic obstructive pulmonary disease (COPD), such that the incidence of lung cancer is four times higher among COPD sufferers than it is in the general population, and underlying COPD almost doubles the 3-year mortality from lung cancer.⁶⁻⁸ Many patients presenting for lung surgery will have complex underlying pathology. Therefore, evaluating respiratory function and predicting postresection function are crucial to anticipating the patient's intraoperative and postoperative care needs.

The surgical risk assessment for patients in need of pulmonary resection surgery focuses on the risk of potential postoperative complications and whether postoperative pulmonary function will be sufficient to allow for an adequate quality of life. Between 20% and 30% of patients with lung cancer are found to be surgical candidates,⁹ and almost 40% of these candidates are disqualified based on poor lung function alone.¹⁰ The anesthetic risk assessment specific to pulmonary surgery focuses on how the underlying pathology will challenge the maintenance of adequate gas exchange and general homeostasis under OLV, and the potential for postoperative respiratory failure to make weaning and extubation difficult. However, mortality from unresected carcinomas is sufficiently high that the risks of postoperative complications would need to be extraordinarily significant before they would preclude surgery. COPD is the progressive destruction of alveoli and lung architecture that occurs over the course of years. Considering the ageing nature of our population and the increase in the incidence of obesity, it is not surprising that lung resection

surgeries are now being performed on more patients who have end-stage COPD, morbid obesity, or who are of advanced age.^{11,12} Evidence shows that these patients can be treated safely. The American College of Chest Physicians (ACCP) does not set a maximal age cutoff for pulmonary surgical candidacy.¹³ Changes in surgical techniques, especially the use of video-assisted thoracoscopic surgery, have markedly decreased the incidence of postoperative pulmonary complications, and will necessitate a reevaluation of the testing required for preoperative assessment.¹⁴ Given the large physiologic changes that occur after pneumonectomy, complete pulmonary function testing, as well as cardiac testing, is indicated.

Fear of creating pulmonary insufficiency by lung resection is an important concern, and numerous studies have attempted to determine the lowest limit of pulmonary function that will allow surgery to be safely performed. However, research findings are limited in their ability to predict particular complications. Studies performed to predict postoperative pulmonary complications after lung resection demonstrate that patients develop both pulmonary and cardiac complications such as dysrhythmias, myocardial infarction, pulmonary embolism, pneumonia, and empyema. These complications influence the duration of mechanical ventilation and outcome; however, none of these complications can be predicted by preoperative studies of pulmonary function. [Box 30.1](#) presents some commonly-used preoperative assessment criteria for lung resection.

Summary of Preoperative Factors That Predict Postoperative Complications

Factors That Characterize Average Risk

- $FEV_1 > 2 \text{ L}$ or 80% of predicted
- PPO $FEV_1 > 80\%$ of predicted
- PPO $FEV_1 + \text{PPO DLCO}$ both $> 40\%$
- $VO_2 \text{ max} > 15 \text{ mL/kg per min}$

- Ability to climb three flights of stairs

Factors That Characterize Elevated Risk

- $FEV_1 < 2 \text{ L}$ or $< 40\%$ of predicted
- PPO $FEV_1 < 40\%$ of predicted
- PPO DLCO $< 40\%$ of predicted
- PPO product ($FEV_1 \times DLCO$) $< 1,650$
- $VO_2 \text{ max} < 10 \text{ mL/kg per min}$
- Inability to climb one flight of stairs
- Oxygen desaturation $> 4\%$ during exercise

DLCO, Diffusing capacity of the lungs for carbon monoxide; *FEV₁*, forced expiratory volume 1; *PPO*, predicted postoperative, *VO₂ max*, maximum volume of oxygen.

History and Physical Examination

Cancer patients who undergo lung resection typically have a history of multiple risk factors and signs of respiratory disease. Risk factors include cigarette smoking, air pollution, and industrial chemical exposure. The smoking history that is so commonly associated with these patients increases the incidence of ischemic heart disease or hypertension. Therefore patients must be evaluated for exertional dyspnea, productive cough, hemoptysis, cyanosis, poor exercise tolerance, and chest pain.

The presence of ischemic cardiac disease that is severe, unstable, or associated with dysrhythmias should indicate consultation from a cardiologist to help mitigate the risk of cardiac complications. Because severe COPD may significantly limit physical activity, a provocative pharmacologic cardiac stress test may be helpful to identify coronary insufficiency.¹⁵ The use of perioperative beta blockade is controversial, and nonselective agents may be

particularly detrimental if they inhibit bronchodilation. However, cardioselective β -blockers have been found to be beneficial in COPD patients undergoing vascular surgery.¹⁶ Beta blockade may be considered to reduce cardiac risk;¹⁷ at the least, patients currently taking β -blockers should continue their regimen throughout the surgical encounter. The surgical plan must be carefully considered for patients with coronary diffusion defects that show greater than 20% reversibility. In cases of high risk cardiac disease, lung surgery may be delayed for 6 weeks to allow coronary artery bypass first.¹⁵ With the increasing popularity of off-bypass coronary revascularization, the two procedures can more easily be performed in a single surgical encounter.¹⁸

Patients with lung cancer should be assessed for effects of the primary tumor, as well as effects of secondary pathologies and side effects of therapy (Table 30.1). Supine dyspnea may result from COPD or compression of the airway by a mediastinal mass. A high index of suspicion should also be maintained for hormonal abnormalities, because many lung tumors cause paraneoplastic syndromes characterized by the secretion of endocrine-like substances such as adrenocorticotrophic hormone,¹⁹ antidiuretic hormone,²⁰ serotonin, parathyroid-like hormone,²¹ and insulin-like growth factor,²² causing a variety of metabolic abnormalities.²³ Cushing disease may lead to metabolic alkalosis, hypokalemia, and hyperglycemia.^{24,25} Hypercalcemia occurs in 10% to 25% of patients with lung cancer related to parathyroid-like hormone, increased calcitriol, or overactivity of osteoclasts. The finding of hypercalcemia carries a very poor prognosis. Clinical signs may include polyuria, polydipsia, confusion, vomiting, abdominal cramps, bradycardia, and mental status changes. Neuroendocrine tumors comprise 20% of lung cancers, and 5% of them produce carcinoid syndrome.²⁶ In those patients, histamine-stimulating drugs and adrenergic agonists may precipitate the flushing, hypotension, and tachyarrhythmias related to serotonin release. Paraneoplastic neurologic syndromes represent autoimmune dysfunctions associated with cancers. In total, 1% to 2% of patients with small cell lung cancer develop Lambert-Eaton myasthenic syndrome (LEMS).²⁷ In this syndrome, antibodies are formed that inhibit voltage-gated calcium channels. This decreases the release of

acetylcholine from presynaptic nerve terminals,²⁸ resulting in weakness and sensitivity to nondepolarizing muscle relaxants. Usually, the initial presentation with autonomic dysfunction (80% of patients with LEMS) includes orthostatic hypotension followed by weakness that progresses upward from the legs.²⁹ In contrast to myasthenia gravis, LEMS involves dysfunction of the calcium channels. Repetitive stimulation or activity improves function (as more acetylcholine is mobilized), and anticholinesterase drugs are not an effective treatment. Treatment includes immunoglobulin, corticosteroids, or 3,4-diaminopyridine (3,4-DAP), which opens potassium channels and increases calcium concentrations in the nerve terminal. Other autoimmune channelopathies can affect voltage-gated potassium channels and prolong acetylcholine release, causing myotonia, or affect autonomic ganglia, causing orthostatic hypotension and arrhythmias.³⁰

TABLE 30.1

Anesthetic Considerations in Lung Cancer Patients: “The 4 Ms”

Mass effects	Obstructive pneumonia, lung abscess, superior vena cava syndrome, tracheobronchial distortion, Pancoast syndrome, recurrent laryngeal nerve or phrenic nerve paresis, chest wall or mediastinal extension
Metabolic effects	Lambert-Eaton syndrome, hypercalcemia, hyponatremia, Cushing syndrome, syndrome of inappropriate antidiuretic hormone secretion
Metastases	Particularly to brain, bone, liver, and adrenal glands
Medications	Chemotherapy-induced lung changes (bleomycin = pulmonary toxicity, doxorubicin = cardiac toxicity, cisplatin = renal toxicity)

Modified from Slinger PP, Johnston MR. Preoperative assessment and management. In Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.

Physical examination findings in COPD are commonly barrel chest deformity, accessory muscle use or paradoxical breathing movement, pursed-lip breathing, and tympanic percussion notes on the chest. Auscultation reveals rhonchi or wheezing. Signs of cor pulmonale include jugular vein distention or peripheral edema, split S2 heart sound, pulmonary or tricuspid valve insufficiency murmurs, and rales auscultated over the lungs.³¹ Nutritional status, commonly compromised in patients with cancer, is also important to note because hypoalbuminemia and malnutrition are associated

with increased postoperative complications such as pneumonia.³²
Box 302 lists important elements of the preoperative evaluation.

Preoperative Evaluation of Patients for Pulmonary Surgery

1. Evaluate comorbidities:

- Smoking-related complications
- Cor pulmonale
- Effects of paraneoplasms
- Cardiovascular disease (unstable angina, MI within 6 weeks, or significant dysrhythmias = high risk of cardiac complications)
- Treatment side effects (particularly from cytotoxic drugs and radiation)

2. ECG and chest x-ray for signs of cardiovascular dysfunction and effects of lung pathology

3. Laboratory assessment of electrolytes, blood count, albumin, and renal function indicators

4. Lung function testing: 80-40-15 rule:

- FEV_1 and DLCO > 80% predicted = no additional testing needed. If < 80 or dyspnea present, diffusing capacity and postoperative function should be predicted

- PPO FEV₁ and DLCO < 40% predicted = increased risk; exercise testing should be evaluated
- VO₂ max < 15 mL/kg per min = increased risk.

5. For COPD, consider blood gas and response to bronchodilators

COPD, Chronic obstructive pulmonary disease; *DLCO*, diffusing capacity of the lungs for carbon monoxide; *ECG*, electrocardiogram; *FEV1*, forced expiratory volume 1; *MI*, myocardial infarction; *PPO*, predicted postoperative, *VO₂ max*, maximum volume of oxygen.

Diagnostic Data

Chest Radiograph

A chest radiograph should be obtained to determine the presence of associated disease and COPD complications (tumor infringement on airway or vascular structures, bullous disease, congestive heart failure, or pneumothorax). The radiograph does not provide abundant information regarding the degree of COPD, but findings characteristic of COPD include hyperinflation, increased anteroposterior thoracic diameter, and diaphragm flattening. Emphysema-related bullae may be present, and infection or pleural effusions may be noted preoperatively and treated to improve the postoperative course. The locations of masses can be identified. In some patients, it can be ascertained whether lesions compress mediastinal structures, cause tracheal shift, or invade the airway. This information is important to predict whether intubation will be difficult, whether induction of anesthesia could cause collapse of the airway, or whether surgical dissection may be difficult and potentially involve excessive bleeding. Evidence of increased pulmonary vascular resistance (PVR) resulting from compression of the vascular bed increases the likelihood of right ventricular failure and worsens the prognosis following lung resection. Relevant signs include prominent pulmonary arteries with rapid tapering of the vasculature, and a widened right heart border.

Electrocardiogram

An electrocardiogram (ECG) is useful for assessing signs of right ventricular hypertrophy. In such a case, the ECG shows a tall R wave in V_1 (> 6 mm), R/S ratio greater than 1 in lead V_1 , and a ratio less than 1 in V_6 , along with a right-axis deviation and diminished amplitude limb leads.³³⁻³⁵ Right atrial hypertrophy causes the initial component of a biphasic P wave in lead V_1 to be larger than the second component. Strain characteristics such as ST segment depression and T-wave inversion, as well as incomplete or complete right bundle branch block, may be observed. The ECG has excellent specificity for identifying left ventricular hypertrophy (LVH), but less sensitivity for detecting it.^{36,37} Therefore, if ECG criteria are inconclusive, echocardiography may be helpful to further elucidate the status of the right ventricle. Findings of pathologic Q-waves and evidence of LVH preoperatively correlate with an increased incidence of postoperative ischemia and infarction.³⁸

Echocardiogram

Echocardiographic findings that are consistent with pulmonary disease are increased thickness of the right ventricular free wall, chamber enlargement, septal shift, tricuspid regurgitation, and a decreased right ventricular ejection fraction. In response to chronic hypoxia, hypoxic pulmonary vasoconstriction causes elevated pulmonary artery pressures. This results in increased right ventricular afterload, which can lead to right ventricular dysfunction. Increased PVR and right ventricular strain cause concern in patients undergoing pneumonectomy or extensive partial resection because of the added resistance produced by clamping the vasculature of one lung in the surgical procedure. Echocardiography is the best initial tool for assessing pulmonary hypertension, but additional studies with pulmonary angiography, ventilation-perfusion scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI) may also be used for more in-depth evaluation.³⁹

Laboratory Assessment

Measurement of preoperative room air arterial blood gases should be considered for patients with COPD, and it is useful in guiding postoperative ventilation. Carbon dioxide (CO₂) retention with an arterial partial pressure (PaCO₂) greater than 45 mm Hg is an indicator of poor ventilatory function. However, hypercapnia is not a reliable predictor of increased risk of perioperative pulmonary complications.⁴⁰ Preoperative hypoxemia (blood oxygen saturation [SpO₂] < 90%) and, particularly, desaturation during exercise, may be predictive of increased complications following thoracic surgery.^{41,42} However, in general, blood gas analysis is not a reliable tool for predicting postoperative pulmonary complications,⁴³ and the correlation between desaturation during exercise and postoperative complications is not a consistent finding.⁴⁴

Hypoalbuminemia is the most common laboratory finding, and serves as an important predictor of pulmonary complications. Numerous studies have demonstrated increases in postoperative pulmonary complications among patients with low serum albumin levels (generally < 3.6 g/dL).⁴⁵⁻⁴⁸ This factor increases risk as much as 2.5 times,⁴⁷ and albumin level maintenance is a measured factor in the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP).⁴⁹ The blood urea nitrogen level is also identified by NSQIP data as a predictive factor for pulmonary complications when it is greater than 22 mg/dL.^{47,48}

Other laboratory analyses should include renal function indicators (particularly for patients treated with nephrotoxic drugs such as methotrexate, gemcitabine, and cisplatin),^{50,51} sodium (related to syndrome of inappropriate antidiuretic hormone secretion),²³ and calcium (due to parathyroid hormone-like protein).^{21,52}

Pulmonary Function Tests

Patients presenting for lung resection should undergo pulmonary function testing to assess for airflow limitation, diffusion defect, and cardiopulmonary reserve.⁵³ Assessment should include the response to bronchodilators for patients who demonstrate obstructive disease (see [Fig. 29.18](#)). The American Thoracic Society

considers a 12% improvement in forced expiratory volume 1 (FEV₁) post-bronchodilator therapy to be significant. Whereas this parameter has a low sensitivity to diagnose asthma,⁵⁴ the relative responsiveness of the patient to bronchodilators can suggest the utility of using bronchodilators for intraoperative management. Pulmonary assessment by spirometry should be based upon values obtained post-bronchodilator therapy, as these would represent the patient's potential lung function once optimized on medications. No single pulmonary function measurement provides an overall risk assessment. For example, although the FEV₁ is the most prevalent spirometric measurement, one case series of 100 thoracic surgery patients with very low FEV₁ values (less than 35%) demonstrated a low rate of mortality and ventilator dependence (although the patients did show a prolonged duration of hospitalization and air leak).⁵⁵ In another series of 109 elderly patients, stair-climbing ability was better correlated (inverse relationship) with postoperative cardiopulmonary complications than was forced vital capacity (FVC) or predicted postoperative (PPO) FEV₁.⁵⁶ Therefore, a multimodal approach must be taken, considering airflow (PPO FEV₁), parenchymal function (diffusing capacity of the lungs for carbon monoxide, DLCO), and cardiopulmonary reserve (maximum volume of oxygen [VO₂ max]). The general cutoff points indicating increased risk among these parameters is below 40% for PPO FEV₁ and DLCO, and 15 mL/kg per min for VO₂ max. However, the surgical approach must also be considered as part of the risk evaluation. A large study involving more than 13,000 subjects validated that PPO FEV₁ and PPO DLCO estimates were inversely proportional to the rate of complications and mortality. However, the absolute rate of complications and mortality was significantly lower in patients undergoing thoracoscopic, rather than open, lobectomy, even when the PPO FEV₁ and PPO DLCO were less than 40%.⁵⁷

It should be noted that guidelines used to assess surgical candidacy are not intended to dictate candidacy for anesthesia. If the patient is a candidate for surgery, it is less likely that there will be anesthetic-specific concerns about pulmonary function that would override the surgical decision, particularly as many of these

surgeries are performed to treat cancer. Notwithstanding this, it is helpful for the anesthetist to understand the patient's risk stratification to plan for the level of ventilatory support required during and after surgery. Assessment must consider multiple functional variables. Similar to standards set by the American Thoracic Society and the European Respiratory Society, the ACCP proposes the following assessment of risk factors for patients with lung cancer undergoing lung surgery: preoperative FEV₁ greater than 80% of the predicted value (or > 2 L for pneumonectomy or > 1.5 L for lobectomy) indicates average risk, and no further assessment of lung function is required. The DLCO should be assessed if diffuse parenchymal disease or dyspnea on exertion is noted. If the FEV₁ or DLCO is less than 80% of the predicted value, then the predicted postoperative FEV₁ and DLCO are assessed.⁴⁰ This is accomplished either through radionuclide scanning, or mathematically (based on the proportion of total lung that will remain after the planned resection). The PPO FEV₁ can be calculated by multiplying the current FEV₁ by the fraction of functioning lung or the fraction of lung segments that will remain after surgery.¹⁵ For high-risk patients, more detailed assessment via radionuclide scanning, CT scanning, or MRI is advisable. Postoperative PPO FEV₁ values greater than 40% of the predicted value for the patient indicate average risk. Values less than 30% of the predicted value indicate increased risk, and intermediate values warrant exercise testing to assess oxygen consumption (VO₂ max). A VO₂ max of less than 15 mL/kg per min indicates high risk, whereas a value greater than 15 mL/kg per min indicates average risk.⁴⁰ The European Respiratory Society places VO₂ max more prominently in the assessment, and considers high-risk cutoffs as being less than 30% for PPO FEV₁ and DLCO, and less than 10 mL/kg per min for VO₂ max.⁵³ Regarding anesthetic planning, average-risk patients (e.g., PPO FEV₁ > 40%) are likely to be extubated immediately following surgery. High-risk patients (e.g., PPO FEV₁ < 30%) have a higher likelihood of requiring some degree of postoperative ventilation. Planning for intermediate-risk patients (e.g., PPO FEV₁ 30% to 40%) is further individualized based upon other assessment

parameters.

Ventilation-Perfusion Assessment

When the preoperative lung function tests indicate that the patient is at an increased risk for perioperative complications, split lung function tests of ventilation and perfusion are valuable for predicting postresection lung function.^{53,58} Removal of a diseased portion of lung may not decrease overall lung function; in fact, it may improve it. The extent of pulmonary surgery has been found to correlate inversely with the intraoperative partial pressure of arterial oxygen (PaO_2), where patients undergoing pneumonectomy had higher PaO_2 than those undergoing lobectomy, which in turn were higher than those undergoing segmentectomy.³ This paradox is related to the corresponding amount of perfusion of the diseased lung. With larger, central tumors (such as would require a pneumonectomy), perfusion, and thus shunting under OLV, is diminished in comparison to a more peripheral lesion requiring a limited resection. Likewise, the results of perfusion scanning can predict the degree of hypoxemia during OLV, as the degree of perfusion to the operative lung is proportional to the degree of potential shunt produced when ventilation to that lung ceases.³

Ventilation can be measured by having the patient inhale one vital capacity breath of a radioisotope and measuring isotope counts with multiple scanners placed over the chest wall. Intravenously injected radioisotope can be imaged to show the distribution of perfusion to all areas of the lung. After determining function in various areas of the lung, calculations can then estimate postresection function by multiplying the current function by the fraction of functioning lung that will remain postoperatively. Calculations based on segmental lung regions may help predict outcomes for patients undergoing lung volume reduction surgery. This procedure of removing emphysematous portions of lung to improve overall lung function has proved efficacious and particularly beneficial in allowing resection of cancerous lung tissue from patients in whom overall lung function studies would have contraindicated surgery.⁴⁰ Lung volume reduction surgery is most useful in patients with heterogeneous emphysema (particularly

when the emphysematous lobe is also the one containing the tumor), where removal of a lung segment or lobe will result in better pulmonary function overall. Incidentally, this effect is appreciated more often with upper rather than lower lobectomy, in which patients with a low preoperative FEV₁ tend to demonstrate improvement in the FEV₁ following upper lobectomy.⁵⁹

Dynamic MRI and quantitative CT are newer modalities used to determine postresection pulmonary function.^{60,61} Dynamic MRI traces the movement of oxygen or sulfur hexafluoride to reflect diffusing capacity.⁶² Quantitative CT is intended to provide more specific data than global measurements such as FEV₁. This scan can be used to quantify low-attenuation (emphysematous) areas of lung to determine both overall proportion and regional distribution of disease. Results are comparable to FEV₁ in predicting obstruction.⁶³

Diffusion Capacity

Diffusion capacity tests the lungs' ability to allow transport of gas across the alveolar-capillary membrane. It is difficult to measure the diffusing capacity of oxygen, and thus carbon monoxide (CO) is used. The patient inhales a small amount of CO, holds the breath for 10 seconds, exhales, and the amount of CO in the exhaled breath is measured. After subtracting the amount of CO that should be expired with dead space air, the amount exhaled provides an indicator of the diffusion of gases in the lung. A DLCO less than 40% of the predicted value has been associated with increased complications following pulmonary surgery. However, DLCO has been found to have good specificity but low sensitivity as an independent measurement. The product of the predicted values for DLCO and FEV₁ may provide better reliability than single measures. This measurement, called the *predicted postoperative product*, was found by Pierce to be less than 1650 in 75% of those who died.⁶⁴

Cardiopulmonary Reserve

Maximal oxygen consumption (VO₂ max) testing during exercise is also a strong predictor of patient outcome.^{31,40,65} A VO₂ max less

than 10 mL/kg per min (or 40% of the predicted value) is associated with increased mortality, whereas a VO_2 max greater than 20 mL/kg per min is a favorable finding.⁶⁶ These values may be roughly estimated by evaluating the patient's physical ability, in which the ability to climb five flights of stairs suggests a VO_2 max greater than 20 mL/kg per min, and the inability to climb one flight of stairs suggests a VO_2 max of less than 10 mL/kg per min.⁶⁷

Cardiopulmonary exercise testing may be applied to evaluate patients prior to pulmonary surgery. For example, the inability to walk 500 meters in a 6-minute walk test was correlated with a significant increase in the duration of hospital stay, atrial fibrillation, and blood transfusion in patients undergoing pulmonary lobectomies.⁶⁸

Patient Optimization

Aggressive treatment of acute or reversible components of respiratory disease greatly decreases the risk of postoperative complications. Treatable preoperative conditions include infections, excess bronchial secretions, bronchospasm, dehydration, electrolyte imbalance, cigarette smoking, alcohol abuse, and malnutrition.

Smoking is not only a major risk factor for chronic lung disease, but is also a strong predictor of perioperative complications. Among patients undergoing noncardiac surgery, pulmonary complications occurred in 22% of smokers, 13% of past smokers, and only 5% of nonsmokers.⁶⁹ In a study of lung cancer patients, 87% were smokers, and the smokers had a 1.5% rate of mortality, whereas nonsmokers had only a 0.4% rate of mortality. Smokers in that study demonstrated twice the rate of complications as did nonsmokers.⁷⁰ The correlation of complications with the duration of smoking history can be calculated using the pack-year index (the product of the packs per day smoked times the years of smoking at that rate). Patients with greater than a 20 pack-year history have demonstrated increased incidence of complications compared with those who have a more modest smoking history.^{71,72}

Smoking cessation may reduce postoperative complications; however, the timing of this intervention is important. Most research indicates that smoking cessation for less than 4 weeks prior to

surgery does not alter risk of complications at all.^{69,73,74} Some data suggest that short-term smoking cessation (less than 1 month) may cause increases in mucus production, which may actually increase complications^{69,75}; however, research findings are equivocal on the concept of increasing complications.^{74,75} Carboxyhemoglobin levels have shown a significant decrease rapidly after smoking cessation, and improvement of nasal mucociliary clearance occurs within 1 to 2 weeks; however, the implications of these findings for postoperative complications are unclear.^{76,77} The rates of complications are reduced in proportion to the amount of time after quitting, with a threshold of at least 4 weeks to observe improvement and even more improvement noted after 8 weeks.^{73,74} Only in one very large study was a trend toward slight reduction in complications noticed with less than 1 month of smoking cessation, and complications further decreased in proportion to the total duration of cessation.⁷⁰ Smoking cessation counseling and intervention is a widely recommended strategy for medical management of COPD patients; however, owing to the urgent nature of treating pulmonary carcinoma, delaying surgery to allow for an adequate period of smoking cessation is an impractical goal.

Monitoring Plan

The purpose of monitoring during thoracic surgery is the quick recognition of sudden and severe changes in ventilation and hemodynamics that can accompany positioning, OLV, and surgical manipulation of the airway and thoracic structures. According to American Association of Nurse Anesthetists (AANA) guidelines, standard monitors should be used.⁷⁸ Airway pressure monitoring helps detect changes in airway compliance and assists in identifying the proper placement of DLTs. Capnography is useful for determining the adequacy of when one lung is deflated, and also for detecting abrupt changes in cardiac output, which may accompany positioning or surgical manipulation. Considering pre-existing ventilation derangements and changes with lateral position, the gradient of end-tidal to arterial CO₂ may be wider than the typical 5 mm Hg. There is evidence that, even if the gradient is determined early, it may not remain the same throughout the

intraoperative course.

Electrocardiogram

All patients require continuous monitoring of the ECG. Typically, anesthesiologists monitor a limb lead (II) for easy rhythm recognition and a precordial lead to add sensitivity for detection of ischemia. A landmark article by London identified V₅ as the precordial lead which would add the most sensitivity to ischemia detection.⁷⁹ That article noted that monitoring a combination of leads II and V₅ will help detect more than 85% of myocardial ischemic episodes. A more recent study (2014), which accounted for both the changing pattern of ischemia over time (onset vs. peak), as well as comparison to preoperative values, found lead V₄ to be the most sensitive for detecting ischemia, followed by V₅.³⁸ In practice, concerns for positioning, surgical site prep, and access to the skin electrode may result in the precordial lead not being placed in the precisely correct location. Various studies have determined that myocardial ischemia frequently occurs in leads V₃ through V₆.^{38,80,81} A consistent finding is that monitoring a combination of leads is significantly more effective than monitoring a single lead.^{38,79,82} A second intraoperative lead monitored in the V4-5 position or in whatever anterolateral position provides the most isoelectric ST segment is desirable.³⁸

Arterial Pressure Monitoring

Arterial blood pressure monitoring allows the anesthesiologist to identify acute hypotension during surgical manipulation. It also facilitates sampling of arterial blood for blood gas analysis. For thoracotomies, the arterial cannula is generally placed in the dependent arm, where it is more easily stabilized. For mediastinoscopy, the arterial monitoring site is selected to provide indication of innominate artery occlusion (see section on [mediastinoscopy](#) later).

Central Venous Pressure Monitoring

Central venous pressure (CVP) monitoring is not required for

routine thoracotomies, but may be indicated if the patient's volume status is unclear or if large fluid shifts are anticipated. In complex cases, a CVP line may help manage fluid status. Increased filling pressures (CVP or pulmonary capillary wedge) have been associated with greater lung injury and prolonged mechanical ventilation following complex pulmonary surgery.⁸³ In addition, a large-bore CVP line can provide access for rapid infusion, and an access site should transvenous pacing or pulmonary artery pressure monitoring become necessary.

The CVP line can be inserted via the external or internal jugular veins or the subclavian veins. An external jugular line is more easily kinked in the lateral position. One should remain alert to the possibility of pneumothorax with the insertion of central lines. A pneumothorax on the ventilated (nonoperative) side can lead to severe hypoxemia during OLV. If a subclavian approach to venous cannulation is planned, the insertion site should be on the same side as the planned thoracotomy.

Cardiac Performance Monitoring

Pulmonary artery pressure monitoring is intended to provide estimation of left ventricular pressures and guide the support of cardiac performance with fluids and cardiovascular drugs. In spite of its past popularity, pulmonary artery catheterization has not been demonstrated to improve patient outcomes in either cardiac or noncardiac surgery,⁸⁴ nor is it helpful in predicting postoperative complications.^{53,85} There have even been suggestions that right heart catheterization may promote cardiac complications.⁸⁶ If pulmonary artery monitoring is deemed useful, the anesthetist must be cautious in interpreting values when pulmonary disease is present because the normal correlation of right and left ventricular pressures may be inaccurate. The use of pulmonary artery catheters has specific limitations during OLV. Lung pathology or hypoxic pulmonary vasoconstriction may alter the resistance in pulmonary vessels and reduce the correlation between pulmonary artery occlusion pressure and left ventricular pressure.⁸⁷ More than 90% of pulmonary artery catheters float into the right lung.⁸⁸ During right thoracotomy, then, the catheter will likely be in the nondependent, collapsed lung and give a false low reading for cardiac output.

Finally, care must be taken to ensure that a pulmonary artery catheter is not situated in a vessel that will be clamped during the course of lung resection. A better evaluation of cardiac filling, contractility, and valvular performance would come by way of echocardiography. Preoperative echocardiography is indicated when suspicion exists of valvular disease, outflow tract obstruction, ventricular dysfunction, or pulmonary hypertension.^{17,53}

Lateral Decubitus Position

The most frequent position chosen for surgical exposure during thoracotomy is the lateral decubitus position. A roll is placed beneath the torso just caudal to the axilla to prevent compression of the neurovascular bundle and forward rotation of the humeral head. It is important to note that, whereas this roll is commonly called an *axillary roll*, is better considered an *axillary support roll*, because positioning it in the axilla may cause neurovascular compression. Hyperabduction of the arms is prevented to keep the brachial plexus from stretching against the humeral head. Arms can be separately padded and extended forward on arm boards. Strategies for supporting the nondependent arm may include a pillow between the arms, a padded Mayo stand (which provides good access to intravenous (IV) or arterial lines in the dependent arm), or specially made double arm boards. Pulse oximetry or frequent palpation of the radial pulse ensures the integrity of circulation to the hand.

The head is supported on pillows to maintain alignment of the head and neck with the spine. Lateral flexion of the neck can cause compression of the jugular veins or vertebral arteries, compromising cerebral circulation. The dependent ear can be compressed by the weight of the head. Careful padding or use of a foam doughnut relieves this pressure, but care must be taken to prevent corneal abrasion and retinal ischemia by avoiding pressure on the eyes. Because the brachial plexus arises from the cervical vertebrae, stretching of one side of the neck can occur if the head is not maintained in a neutral position resulting in neuropathy. A complete discussion of positioning and potential nerve injuries is presented in [Chapter 23](#). Another pressure point of concern with the lateral position is the region near the common peroneal nerve. These pressure points are located near the fibular head of the dependent leg and the femoral head of the nondependent leg if a stabilizing strap is placed over the patient.

Physiology of the Lateral Decubitus Position

Positional changes and alterations in chest wall integrity produce significant alterations in ventilation and perfusion of the lungs during thoracic surgery. Due to the critical nature of the procedure and the degree of pulmonary pathology that is frequently associated with these patients, a thorough knowledge of positioning, ventilation, perfusion, and strategies to minimize the potential for hypoxia are discussed. A thorough discussion of pulmonary anatomy and physiology is present in [Chapter 29](#).

Upright Position

The distribution of perfusion in the lungs depends on gravity in relation to the level of the heart and on pressures transmitted through alveoli. In a spontaneously breathing, upright patient, perfusion increases from the apex to the base of the lung ([Fig. 30.1](#)). Ventilation also increases from apex to base, based on the relative compliance of alveoli. Owing to downward traction from gravity, negative pleural pressure is greatest at the apex of the lung, and this factor keeps alveoli distended ([Fig. 30.2](#)). Dependent alveoli are less distended and therefore more compliant (can expand by a greater volume for a given pressure change because they are starting at a lower resting volume). Therefore, most of a tidal volume (V_T) breath is distributed to the dependent alveoli ([Fig. 30.3](#)). The increase in both ventilation and perfusion from apex to base is not parallel, and is certainly more complexly arranged than in neatly-divided zones. However, the general increase in ventilation and perfusion from top to bottom results in efficient gas exchange.

FIGURE 30.1 The lung is divided into three zones according to the relative magnitudes of the pulmonary arterial, venous, and alveolar pressures (P_a , P_v , and P_A , respectively). In *zone 1*, alveolar exceeds arterial pressure, so the collapsible vessels are held closed and there is no flow. In *zone 2*, arterial exceeds alveolar pressure, but alveolar exceeds venous pressure. Under these conditions, a constriction occurs at the downstream end of each collapsible vessel, and the pressure inside the vessel at this point is equal to alveolar pressure, so the pressure gradient causing flow is arterial-alveolar. This gradient increases linearly with distance down the lung, and therefore so does blood flow. In *zone 3*, venous exceeds alveolar pressure, and the collapsible vessels are held open. Here, the pressure gradient causing flow is arteriovenous, and there is constant perfusion of alveoli. (From West JB. Explanation of the uneven distribution of blood flow in the lung, based on the pressures affecting capillaries. In West JB. *Respiratory Physiology: The Essentials*. 10th ed. Philadelphia: Lippincott Williams & Wilkins; 2013:50.)

FIGURE 30.2 Schematic diagram of the lung within the chest wall, showing the tendency of the lung to assume a globular shape because of its viscoelastic nature. The tendency of the top of the lung to collapse inward creates a relatively negative pressure at the apex, and the tendency of the bottom of the lung to spread outward creates a relatively positive pressure at the base. Therefore, pleural pressure (P_{pl}) increases by 0.25 cm H₂O per centimeter of lung dependency. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

FIGURE 30.3 Due to gravity, alveoli in the most dependent portions of lung are compressed by the tissue above, whereas those in the most nondependent portions are suspended open. At end-inspiration and end-

expiration, the pressure inside all alveoli is equalized with atmospheric pressure; however, an increasing gradient of pleural pressure toward dependent areas creates a gradient in transpulmonary pressure at rest. Whereas the change in transpulmonary pressure during inspiration is equal for all alveoli, alveoli in dependent regions are on the steep portion of the compliance curve, and therefore receive the largest share of the tidal volume. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

Awake Lateral Position

In the lateral position, less vertical distance is present to cause differences in the intrapleural pressure and blood pressure gradients (Fig. 30.4). Abdominal contents displace the diaphragm in a cephalad direction on the dependent side. Starting from a higher position in the thorax, the dependent hemidiaphragm can contract further. During inspiration, therefore, contraction of the diaphragm causes more of the V_T to fill the dependent lung. Perfusion is dependent upon gravity and, when in the lateral position, it is also greatest in the dependent lung (Fig. 30.5). Overall, the relationship of greater ventilation and perfusion in the dependent lung is unchanged, and gas exchange remains efficient.

FIGURE 30.4 Schematic representation of the effects of gravity on the distribution of pulmonary ventilation and

blood flow in the lateral decubitus position. The vertical gradient in the lateral decubitus position is less than in the upright position; consequently, blood flow in zones 2 and 3 is less. Nevertheless, pulmonary blood flow increases with lung dependency and is greater in the dependent lung than in the nondependent lung. *PA*, Alveolar pressure; *Ppa*, pulmonary arterial pressure; *Ppv*, pulmonary venous pressure. (From Triantafillou AN, et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

FIGURE 30.5 **A**, An increasing gradient of intrapleural pressure from top to bottom of lungs creates different resting volumes of alveoli and variation in regional compliance, as described in Fig. 30.4. **B**, In the lateral decubitus position, gravity-related effects translate to greater compliance of the dependent lung and lesser compliance of the nondependent lung. Therefore, in the spontaneously breathing individual, more ventilation is delivered to the dependent lung. *P*, Transpulmonary pressure; *PPL*, intrapleural pressure; *V*, alveolar volume. (From Triantafillou AN et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

Anesthetized Lateral Position, Chest Closed, With Spontaneous Ventilation

A change in the distribution of ventilation is seen with the induction of anesthesia, even when spontaneous respiration is maintained. Functional residual capacity (FRC) decreases almost

immediately upon the induction of anesthesia. The weight of the mediastinum and the cephalad displacement of the diaphragm by abdominal contents further decrease FRC in the dependent lung and reduce the proportion of the favorable zone 3 area. Lower volumes in each lung shift their place on the compliance curve. The lungs are less compliant when they are either at a very high volume (distended alveoli) or a very low volume (atelectasis). In the anesthetized patient, the nondependent lung moves from a flat, noncompliant portion of the compliance curve to a more compliant position. Although anesthesia results in a net loss of FRC, the relative proportion of FRC in the nondependent lung increases in contrast to the dependent lung.⁸⁹ As the dependent lung loses FRC, its volume becomes so low as to decrease its compliance. It shifts to a less compliant, flatter portion of the curve (Fig. 30.6). Ventilation is therefore preferentially distributed to the nondependent lung, whereas gravity-dependent blood flow preferentially goes to the dependent lung, resulting in a mismatch of ventilation and perfusion.

FIGURE 30.6 **A**, Regional compliance of lungs in the awake patient in lateral decubitus position and, **B**, regional compliance of lungs in the anesthetized patient in the lateral decubitus position. Induction of anesthesia causes a loss of lung volume in both lungs, with the nondependent lung moving from a flat, noncompliant portion of the pressure-volume curve to a steep, compliant portion. The dependent lung moves from the highly compliant portion toward the lower flattening of the curve. In some areas of the dependent lung, resting alveolar volume is so low that atelectasis and airway closure impede inflation. Therefore,

in the anesthetized patient in the lateral decubitus position, more tidal ventilation shifts toward the nondependent lung (where there is the least perfusion), creating ventilation-perfusion mismatch. P , Transpulmonary pressure; V , alveolar volume. (From Triantafyllou AN et al. Physiology of the lateral decubitus position, the open chest, and one-lung ventilation. In Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003.)

Anesthetized, Paralyzed, Mechanically Ventilated

Under mechanical ventilation, the diaphragm no longer contributes to ventilation of the lower lung, and FRC further declines as the compression from abdominal viscera is no longer counteracted by the force of the contracting diaphragm (Fig. 30.7). With the initiation of mechanical ventilation and the absence of diaphragmatic contraction, ventilation further shifts to follow the path of least resistance, favoring the nondependent lung. The ventilation-perfusion relationship further deteriorates. The addition of positive end-expiratory pressure (PEEP) to mechanical ventilation may help restore FRC and improve the ventilation-perfusion ratio.

FIGURE 30.7 Anesthesia and surgery may cause a progressive cephalad displacement of the diaphragm. The sequence of events involves assumption of the supine position, induction of anesthesia, causation of paralysis, and lateral decubitus positioning (wherein abdominal contents mostly press upon the dependent

hemidiaphragm). This movement of the diaphragm and the downward displacement of the mediastinum result in decreased functional residual capacity and contribute to pushing the dependent lung to the lower flattening of the compliance curve. *FRC*, Functional residual capacity; *P_{ab}*, pressure of the abdominal contents. (Adapted from Benumof JL. *Anesthesia for Thoracic Surgery*. 2nd ed. Philadelphia: Elsevier; 1995.)

Anesthetized, Open-Chest

Upon opening the thorax, there is an immediate decrease in resistance to gas flow in the nondependent lung, as the lung detaches from the chest wall. This causes further loss of ventilation to the dependent lung, in preference for the nondependent lung. The mediastinum also further shifts downward because of loss of negative intrapleural pressure in the nondependent lung, which helped to distend it. Ventilation to the dependent lung is decreased in proportion to the displacement of the lung by the mediastinal structures. Compression of the great vessels may cause a decrease in cardiac output and circulatory compromise. Any spontaneous respiration becomes very inefficient as paradoxical movement of air occurs on inspiration from the open-chest lung into the dependent lung, which has greater negative intrapleural pressure. Upon expiration, gas exits the dependent lung and enters both the trachea and the open-chest lung, causing the lung to expand (Fig. 30.8). Paradoxical respiration compromises fresh gas exchange in the dependent lung as part of the V_T moves between the lungs. Positive-pressure ventilation diminishes the effects of mediastinal shift and paradoxical respiration. However, during mechanical ventilation, the open chest provides no resistance, and the greatly increased compliance of that lung allows a higher proportion of ventilation to go to the nondependent lung, which is the least perfused area of the thorax. The less ventilated, better-perfused, dependent lung contributes to physiologic shunt, as blood flows through atelectatic areas without acquiring oxygen. Although the prevalence of different zones is not as evenly distributed as diagrams would suggest, the lateral, anesthetized, paralyzed, open-chest patient does exhibit the epitome of significant regional areas of disparity between ventilation and perfusion.

FIGURE 30.8 Inspiration: The diaphragm contracts causing negative intrathoracic pressure (*arrow 1*) that draws air through the sucking chest wound in the pleural cavity (*arrow 2*) and causing the mediastinal structures to shift to the patient's left (*arrow 3*). Expiration: the diaphragm recoils (*arrow 1*) causing air to exit the chest (*arrow 2*) and allowing the mediastinum to shift back to normal position (*arrow 3*). The collapsed lung paradoxically shrinks on inspiration and expands on expiration. (From Marx

J, Hockberger R, Walls R. *Rosen's Emergency Medicine*. 8th ed. Philadelphia: Elsevier; 2014:438.)

Anesthetized Open-Chest, With One-Lung Ventilation

The succeeding cascade of changes leading up to the anesthetized open-chest results in significant ventilation-perfusion mismatch. There is little resistance to ventilation of the nondependent lung, whereas the effects of gravity promote perfusion to the dependent lung. When ventilation to the nondependent lung is ceased, ventilation is directed to the dependent lung. The remaining perfusion to the nondependent lung creates a shunt, but hypoxic pulmonary vasoconstriction reduces the shunt by 50% by diverting much of that blood toward the dependent lung. The PaO₂ is higher during OLV in the lateral position than it is in the supine position, as clamping the airway to the nondependent lung reverses some of the changes that cause the ventilation-perfusion (V/Q) disparity in

the anesthetized patient.

One-Lung Ventilation

Indications for Lung Separation

The ability to provide distinct ventilation to the separate lungs facilitates pulmonary surgery by providing a quiet surgical field. This is particularly helpful in the case of thoracoscopic surgery, in which visualization and the ability to manipulate the operative lung are limited. Thoracic surgeons will commonly consider lung separation an absolute requirement for pulmonary surgery. However, surgery can be performed on a lung that is being ventilated, and thoracic surgery alone is not an absolute indication for OLV. In fact, in the case of pediatric patients, gentle dual-lung ventilation is indicated and appropriate in either the presence of airway concerns that preclude use of a lung-separating device or the inability to maintain oxygenation with OLV. Certain situations, such as infectious contamination of one lung, are absolute indications for OLV, but most common thoracic surgeries create relative indications for lung separation in that they can safely be accomplished without it. Indications for lung separation are noted

Box 303.3.

Indications for Lung Separation

I. Absolute

A. Isolation of one lung from the other to avoid spillage or contamination

1. Infection

2. Massive hemorrhage

B. Control of the distribution of ventilation

1. Bronchopleural fistula

2. Bronchopleural cutaneous fistula
3. Surgical opening of a major conducting airway
4. Giant unilateral lung cyst or bulla
5. Tracheobronchial tree disruption
6. Life-threatening hypoxemia related to unilateral lung disease

C. Unilateral bronchopulmonary lavage

1. Pulmonary alveolar proteinosis

II. Relative

A. Surgical exposure—high priority

1. Thoracic aortic aneurysm
2. Pneumonectomy
3. Thoracoscopy
4. Upper lobectomy
5. Mediastinal exposure

B. Surgical exposure—medium (lower) priority

1. Middle and lower lobectomies and subsegmental

resections

2. Esophageal resection

3. Procedures on the thoracic spine

C. Postcardiopulmonary bypass pulmonary edema/hemorrhage after removal of totally occluding unilateral chronic pulmonary emboli

D. Severe hypoxemia related to unilateral lung disease

From Sheinbaum R, et al. Separation of the two lungs (double-lumen tubes, bronchial blockers, and endobronchial single-lumen tubes). In Hagberg CA, ed.: *Benumof's Airway Management*. 2nd ed., Philadelphia: Elsevier; 2007 PG 577.

Methods of Lung Separation

Several devices have been developed to enable isolation of one lung and ventilation of the other. The single-lumen endobronchial tube was developed in 1931 to isolate an infected lung.⁹⁰ Mimicking this simple approach by advancing a 7.5-mm wide, 32-cm long ETT over a fiberoptic scope into one bronchus may still be used in some circumstances. A disadvantage of using a single-lumen tube for OLV is that the ability to ventilate or suction the operative lung is lost. Another disadvantage is that use of a single-lumen tube in the right lung would probably occlude the right upper lobe orifice. However, in an emergent situation, use of a single-lumen tube advanced blindly down the right bronchus or placed into the left bronchus aided by a bronchoscope can be lifesaving. A summary of lung separation devices is presented in [Table 30.2](#). Given that each approach (DLT vs. bronchial blocker) has relative merits, neither can be recommended as a superior method of lung separation for thoracic surgery.

TABLE 30.2**Types of Lung Separation Devices**

Type	Examples	Notes
Endobronchial tube	Bronchocath, Carlens, Robertshaw, White	Left bronchus intubation preferable. Large size increases difficulty of transoral insertion, but facilitates emptying of surgical lung. Right-side more challenging to position, but may be preferable for descending aortic aneurism. Carlens and White: carinal hook aids placement when visualization is poor (hemorrhage/hemoptysis).
Bronchial blocker	Arndt, Cohen, Coopdech, Univent	Easier basic tube insertion, but requires a fiberoptic bronchoscope, thus takes longer to situate. Lung deflation may require suction. More often dislodged. Preferable if postoperative intubation planned. Cohen: flexible tip can be manipulated. Arndt, Coopdech: blocker is adapted to a regular endotracheal tube.

Double Lumen Endobronchial Tubes

DLTs consist of a single tube with two lumens. The bronchial lumen is identified by its blue cuff and is designed to be inserted into either the left or right mainstem bronchus. The bronchial lumen will be used to initially ventilate the corresponding lung. The tracheal lumen is positioned midtrachea, and the corresponding port will ventilate the opposite lung. The bronchial lumen does not necessarily have to be placed within the bronchus of the operative lung ([Fig. 30.9](#)).

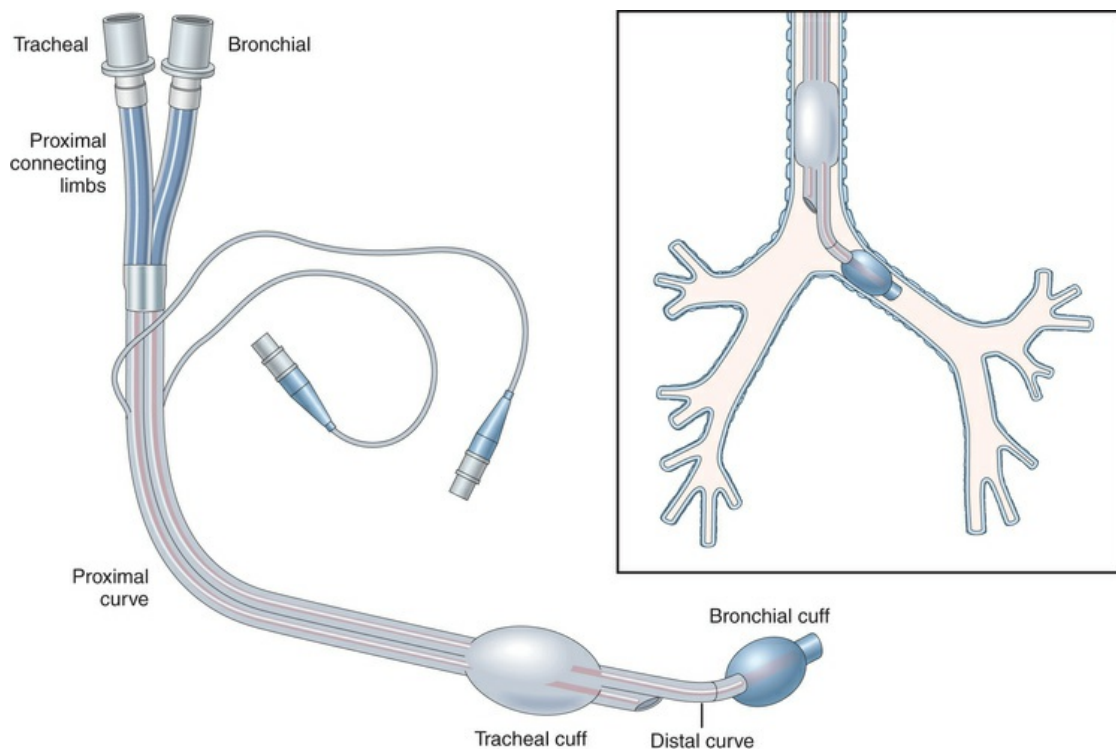

FIGURE 30.9 The double lumen endobronchial tube. *Inset* shows a left-sided tube correctly positioned in the bronchus. (From Miller RD, Pardo MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Churchill Livingstone; 2011. pg 429)

Features

Several types of DLTs are used in thoracic surgery. DLTs are designed for insertion either in the right or the left bronchus. Right-sided tubes include features to accommodate the proximity of the upper lobe bronchus. Disposable polyvinyl chloride tubes are available in French (F) sizes 26, 28, 35, 37, 39, and 41. The F scale refers to three times the external diameter of the ETT (in millimeters). The internal lumen diameters range from 3.4 mm to 6.6 mm,⁹¹ although there is wide size variation between manufacturers.^{92,93} It would be most important for the anesthetist to ascertain the appropriate size fiberscope that will fit through the intended tube lumens. Despite the perceived smaller size of the lumens, DLTs do not increase breathing resistance significantly in comparison to single lumen tubes.^{88,94}

Advantages and Disadvantages

Although the presence of two lumens limits the internal diameter of each, the external diameter of a DLT is large. The 37F DLT has an outer diameter equivalent to that of a standard 11-mm internal diameter (ID) ETT. For this reason, DLTs are not used for small children; the external diameter of the 26F DLT, which is the smallest version, is 7.5 mm.⁹⁵ Sizing of DLTs is determined by patient height, usually leading to the use of 35F to 37F tubes in females, and 39F to 41F tubes in males. More specifically, DLT use can include 35F for women up to 160 cm, 37F for women over 160 cm, 37/39F for men less than 175 cm, and 39/41F for men over 175 cm.⁹⁶

The distance from the carinal bifurcation to the right upper lobe is 1.5–2 cm, as compared with a 4–5 cm left mainstem bronchus. Modifications have been made in right-sided tubes to allow ventilation through a slot in the endobronchial cuff or to use two bronchial cuffs, but even slight movement of the right DLT can lead to malpositioning. Many practitioners have resolved to use left-sided DLTs for all right and left thoracotomies unless a left-sided tube is contraindicated by internal lesions of the airway, compression of the trachea or main bronchi by an external mass, or the presence of a descending thoracic aortic aneurysm, which can compress or erode the left main bronchus. This is due to the close proximity of the right upper bronchi to the carina. The bronchial cuff of a right-sided DLT is more likely to occlude the right upper lung lobe and further decrease ventilation. Intubation with the large DLT can pose a challenge, even in patients with a normal airway; insertion in those with poor airway anatomy may be particularly challenging.

Complications Associated With Double-Lumen Tubes

The most common complication associated with a DLT is malpositioning. [Fig. 30.10](#) demonstrates some variations of DLT positioning. Rupture of a thoracic aneurysm is possible with a left-sided DLT if the aneurysm compresses the left mainstem bronchus. Damage to the vocal cords or arytenoid cartilages is possible from a carinal hook. A carinal hook can also break off, requiring retrieval

with a bronchoscope. Bronchial rupture, which was thought to be caused by overinflation of the bronchial cuff, has been reported.^{97,98} Owing to the possibility of its being inserted too deeply, a DLT can also cause the entire V_T to be delivered to a single lung lobe, creating the potential for barotrauma. The larger size of the DLT is probably also responsible for the slightly increased incidence of hoarseness and vocal cord lesions observed in patients following DLT, versus using a bronchial blocker for lung separation.⁹⁹

Figure	Description	Ventilating through the bronchial lumen produces breath sounds:	Ventilating through the tracheal lumen produces breath sounds:
A	Correct position of left DLT	Left lung	Right lung
B	Correct position of right DLT	Right lung	Left lung
C	DLT insertion too shallow	Both lungs	Diminished or absent if bronchial cuff obstructs trachea; otherwise, both lungs
D	DLT too deep in right bronchus	Right middle and lower lobes	Left lung or right upper lobe (depending on depth of tracheal cuff)
E	DLT too deep in left bronchus	Left lung	Left lung

Additional variations are possible, such as if a left-sided DLT is inadvertently positioned in the right bronchus, or vice versa. Auscultation provides a quick check, but fiberoptic confirmation is preferable for definitive confirmation.

FIGURE 30.10 Positioning variations of the double-lumen endobronchial tube. *DLT*, Double lumen tube.

Insertion of Double-Lumen Endotracheal Tubes

The DLT has two curves along its length to aid in its placement. A stylet aids placement through the larynx. Some practitioners prefer the Macintosh blade for intubation because it offers greater clearance for the tube and may decrease the chance of balloon rupture from the teeth.¹⁰⁰ For laryngoscopy, the lubricated DLT is advanced with the distal curve concave anteriorly until the vocal cords are passed. The stylet is usually removed at this point to reduce the potential of the rigid tube causing mucosal damage. The tube is then rotated 90 degrees toward the bronchus that is to be intubated. The DLT is advanced to approximately a 27-cm depth in females or a 29-cm depth in males, or until resistance is met.¹⁰¹

The tracheal cuff requires 5 mL to 10 mL of air, and the bronchial cuff requires 1 mL to 2 mL of air. Overinflation of the bronchial cuff can cause its lumen to become narrowed or occluded, and increases the risk of bronchial damage. Unlike most tracheal high-volume, low-pressure cuffs, the bronchial cuff holds a small volume and can exert high pressure on the endobronchial mucosa. For that reason, unless unilateral lung contamination exists, the bronchial cuff should be deflated during the procedure once OLV is no longer needed. After the tube is situated in the bronchus, adapters are attached to the two lumens for interface with the anesthesia circuit. Auscultation of breath sounds is a simple, though not highly reliable, method of determining the position of a DLT (Box 30.4). When properly positioned, breath sounds should be auscultated in all fields of the lung corresponding to the bronchial lumen (depending on the use of a left- or right-sided tube) when that lumen alone is ventilated. Breath sounds should be heard only in the opposite lung, when the tracheal lumen is ventilated. Fig. 30.11 outlines some auscultation findings expected with various tube

Box 30.4

Auscultation of Breath Sounds After Placement of a Double Lumen Tube

1. Inflate the tracheal cuff.
2. Verify bilaterally equal breath sounds. If breath sounds are present on only one side, both lumens are in the same bronchus. Deflate the cuff and withdraw the tube 1–2 cm at a time until

breath sounds are equal bilaterally.

3. Inflate the endobronchial cuff.
4. Clamp Y-piece to the endobronchial lumen and open the lumen to atmosphere.
5. Verify breath sounds in the correct lung (tracheal side) and the absence of breath sounds in the opposite lung (bronchial side).
6. Verify the absence of air leakage through the bronchial lumen.*
7. Unclamp and reconnect the endobronchial lumen and verify bilateral breath sounds.
8. Clamp Y-piece to the tracheal lumen and open the lumen to atmosphere.
9. Verify breath sounds in the correct lung (bronchial side) and the absence of breath sounds in the opposite lung (tracheal side).

. Verify that breath sounds are equal at the apex of the lung and at the base. If the apex is diminished, withdraw the tube until upper lung sounds return.

. Verify the absence of air leakage through the tracheal lumen.*

*When absolute lung separation is needed, as in bronchopulmonary lavage, connecting tubing from the open, nonventilated lumen to an underwater drainage system will show air bubbles if a leak is present (see [Fig. 30.12](#)).

FIGURE 30.11 Verification of double lumen tube position with a fiberoptic bronchoscope. **A**, Correct position; bronchial cuff visualized just beyond the carina. **B**, Tube too shallow; bronchial cuff herniating across the carina. **C**, Tube too deep. See additional description in [Box 30.5](#).

Flexible fiberoptic bronchoscopy is essential to verify placement of the DLT (see [Fig. 30.11](#) and [Box 30.5](#)). Fiberoptic bronchoscopy has revealed a 38% to 83% incidence of malpositioning of DLTs that were judged by auscultation to be properly placed.^{91,102} Some particular advantages of fiberoptic inspection of the DLT over auscultation are guidance during initial placement, the ability to visualize the correct depth of the bronchial cuff, and visualization of proper positioning of the right upper lobe port (if present). Placement of the tube should again be verified by bronchoscopy after the patient is positioned laterally because the DLT will commonly withdraw from the bronchus by 1 cm.¹⁰³ When separation of the lungs is required to prevent cross-contamination, the integrity of the bronchial seal can be tested by connecting a tube from the bronchial port to a water seal and then providing ventilation through the tracheal lumen. Incompetence of the bronchial cuff will be evidenced by egress of bubbles in the water [Box 30.5](#) ([Fig. 30.12](#)).

Fiberoptic Bronchoscopy to Verify Placement of a Double Lumen Tube

1. Insert the scope through the tracheal lumen. Visualize the carina distally. (Confirm that the tracheal orifice is within the trachea and not a bronchus, or that the tube is not displaced proximally such that the bronchial cuff fills the trachea.)

2. Visualize the bronchial (blue) cuff 1–2 mm beyond the carina. Ensure that the cuff is not too proximal or overinflated such as to herniate across the carina and obstruct the contralateral bronchus.
3. Insert the scope through the bronchial lumen. Visually confirm that the tip of the bronchial lumen is unobstructed. For left-sided tubes, visualize the bronchial carina distal to the tube tip. For right-sided tubes with a right upper lobe (RUL) ventilation port, visualize that the RUL bronchus is aligned with the ventilation port.

FIGURE 30.12 Water seal setup to test for leaks around the bronchial cuff.

Bronchial Blockers

A bronchial blocker consists of a catheter with an inflatable balloon that blocks the bronchus of the operative lung. Blockers can be incorporated into a side channel of an ETT (e.g., Univent tube), or they can be separate devices that are inserted either through the regular ETT lumen or outside of it (more common in pediatrics) (Fig. 30.13). Common options for stand-alone bronchial blockers include the 8F Fogarty embolectomy catheter, the Cohen Flextip

blocker, the Coopdech blocker, the EZ blocker, and the Arndt Bronchial Blocker (formerly known as the *Wire-Guided Endobronchial blocker*).

FIGURE 30.13 The Univent (*bottom*) and Arndt (*top*) bronchial blockers. Inset shows detail of Univent double lumen tube design and Arndt wire guidance loop.

Features

Bronchial blockers are guided into the appropriate bronchus with the aid of a bronchoscope (Fig. 30.14). Wire-guided blockers have a loop on the end through which the fiberscope is passed, facilitating guidance of the blocker into the bronchus after the fiberscope. The Cohen blocker has a steerable tip to facilitate advancement into the appropriate bronchus. The Univent tube consists of an integrated ETT with a second lumen for a deployable bronchial blocker. The EZ blocker has a forked distal end that functions like the Carlens hook to rest on the carina, while one arm of the fork has the

inflatable balloon to occlude the bronchus it occupies.

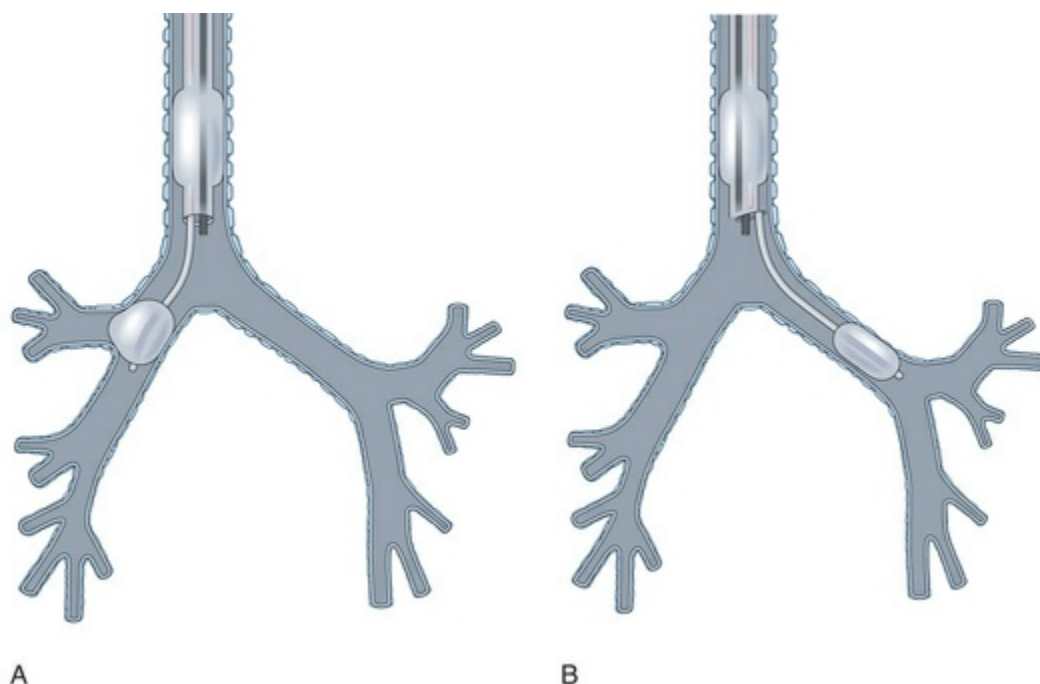

FIGURE 30.14 Positioning of the bronchial blocker in the right (**A**) and left (**B**) lung. The fiberoptic bronchoscope is used to establish and verify correct position. (From Stoelting RK, Miller RD. *Basics of Anesthesia*. 5th ed. Philadelphia: Churchill Livingstone; 2007.)

Advantages and Disadvantages

Because insertion of a DLT is more complicated, bronchial blockers are more useful in patients with a difficult airway or a tracheostomy. These devices are beneficial for patients who are already intubated, when changing to another tube would compromise ventilation. They can also be used for pediatric lung separation, even in children younger than 2 years of age, with a special small-sized blocker.^{104,105}

Positioning the bronchial blocker requires more time than the DLT, and placement is dependent on the use of a fiberscope. In comparison to DLT, blockers have a greater incidence of becoming malpositioned. Because a bronchial blocker affords little conduit for egress of gas, lung deflation is often less effective than with a DLT. This can be particularly troublesome in thoracoscopic surgery.

Suction of the blocker port can be helpful, but excessive negative pressure or duration can cause damage. Blockers also do not allow suctioning, particularly when separation is indicated by unilateral infection or bleeding. In that case, removal must follow special procedures to avoid contaminating the opposite lung.¹⁰⁶ The bronchial blocker is plagued with the same challenge as the DLT in blocking the right bronchus, but the DLT has the advantage of being able to exclude either lung with a left-sided device. Therefore, bronchial blockers are reserved by some exclusively for left-sided surgery.

Insertion of Bronchial Blockers

The method used for inserting the bronchial blocker depends on the device. Typically, it involves basic tracheal intubation and insertion of the blocker through the tube, followed by the fiberscope, which is used for final positioning. Variations include wire-guided catheters, which are already mounted on the fiberscope when it is inserted, and pediatric extraluminal blockers, which are inserted in the trachea, followed by intubation, followed by fiberoptic inspection and positioning of the blocker.

Physiology of One-Lung Ventilation

During two-lung ventilation, blood flow to the dependent lung averages approximately 60% (Fig. 30.15). When one lung is allowed to deflate and OLV is started, any blood flow to the deflated lung becomes shunt flow, causing the PaO₂ to decrease. Without autoregulation of pulmonary blood flow, a 40% shunt would be anticipated. The lungs have a compensatory mechanism of increasing vascular resistance in hypoxic areas of the lungs, and this diverts some blood flow to areas of better ventilation and oxygenation. This mechanism, which is present in most mammals, is termed *hypoxic pulmonary vasoconstriction* (HPV). HPV is a reflex intrapulmonary feedback mechanism in inhomogeneous lungs that improves gas exchange and arterial oxygenation. Whereas hypoxemia causes vasodilation in the general circulation, alveolar hypoxia has the opposite effect on pulmonary arteries. HPV is a unique compensatory mechanism, suited specifically to matching

pulmonary blood flow with well-oxygenated areas of lung.

FIGURE 30.15 When the left lung is the nondependent lung, the distribution of blood flow between the nondependent and dependent lungs is 35%:65%. When the right lung is the nondependent lung, blood flow distribution between the nondependent and dependent lungs is 45%:55%. Average one-lung ventilation blood flow distribution is a nondependent:dependent ratio of 40%:60%. (From Benumof JL. *Anesthesia for Thoracic Surgery*. 2nd ed. Philadelphia: Elsevier; 1995.)

The cellular mechanism for HPV involves a redox-based oxygen sensor in smooth muscle cells of the pulmonary arteries (probably focused on the electron transport chain of the mitochondria of these cells). Hypoxia reduces production of activated oxygen species (AOS) such as H_2O_2 . These AOS act as second messengers from the oxygen sensors, and reduction in their outflow leads to inhibition of voltage-dependent potassium channels. The result is an influx of extracellular calcium, which causes vasoconstriction.^{107,108} **Box 30.6**

Box 30.6 Characteristics of HPV.

Characteristics of Hypoxic Pulmonary Vasoconstriction

- A local reaction occurring in hypoxic areas of lung. May be very localized due to regional atelectasis (as in one-lung ventilation), or affect both lungs entirely in hypoxic situations (such as those leading to high altitude pulmonary edema).
- Opposite to systemic reaction to hypoxia, causes vasoconstriction in all but very proximal pulmonary arteries.

- Triggered by alveolar hypoxia, not arterial hypoxemia.
- Onset and resolution are within seconds following changes in partial pressure of oxygen (PO_2).
- Peak effect occurs within 15 minutes.
- May be inhibited by vasodilators and augmented by chemoreceptor agonists (almitrine).

HPV during OLV is effective in decreasing the cardiac output to the nonventilated lung by approximately 50% (Fig. 30.16).¹⁰⁹ HPV can increase the PVR by 50% to 300%, and the response can persist for long periods of time in the face of chronic hypoxia.¹⁰⁷ In fact, the chronic increase in PVR from COPD can be responsible for pulmonary vascular remodeling that leads to cor pulmonale.¹¹⁰ HPV occurs whether the lung is rendered hypoxic by atelectasis or by ventilation with a hypoxic mixture. It is initiated within seconds of hypoxia and reaches its maximum effect in approximately 15 minutes. HPV improves arterial oxygenation when the amount of hypoxic lung is between 20% and 80%, which occurs during OLV.¹¹¹ When less than 20% of the lung is hypoxic, the total amount of shunt is not significant. When more than 80% of the lung is hypoxic, HPV increases PVR, but the amount of well-perfused lung is not sufficient to accept enough diverted flow to maintain arterial oxygenation.

FIGURE 30.16 Two-lung ventilation nondependent:dependent lung blood flow ratio is

40%:60%. When two-lung ventilation is converted to one-lung ventilation (OLV), the hypoxic pulmonary vasoconstriction (HPV) response decreases the blood flow to the nondependent lung by 50%, and the nondependent:dependent lung blood flow ratio becomes 20%:80%. (From Benumof JL. *Anesthesia for Thoracic Surgery*. 2nd ed. Philadelphia: Saunders; 1995.)

HPV is effective in decreasing shunt flow, and attempting to avoid drugs or events that inhibit this mechanism is important (Box 30.7). Alveolar and intravascular volume derangements can inhibit the effects of HPV. Hypervolemia or high cardiac output may override HPV by recruiting constricted vessels.¹¹² Conversely, hypovolemia may trigger adrenergic vasoconstriction, reducing flow to well-ventilated portions of lung.¹¹³ Overdistention of alveoli may also reduce perfusion to well-ventilated lung areas by creating the “zone 1” ventilation-perfusion scenario. For these reasons, normal fluid volume should be maintained during OLV; moderate $V_{T,s}$ (6 mL/kg) should be used, and excessive PEEP should be

Box 30.7⁹⁹ Hypocapnia and alkalosis decrease HPV.

Factors That Reduce Effectiveness of Hypoxic Pulmonary Vasoconstriction

- Alkalosis
- Excessive tidal volume or PEEP
- Hemodilution
- Hypervolemia (LAP > 25 mm Hg), atrial natriuretic peptide
- Hypocapnia
- Hypothermia
- Prostacyclin
- Shunt fraction < 20% or > 80%
- Vasodilators, phosphodiesterase inhibitors, and calcium channel

blockers

- Volatile anesthetics > 1.5 MAC

LAP, Left atrial pressure; *MAC*, minimum alveolar concentration; *PEEP*, positive end-expiratory pressure.

Many vasodilatory drugs inhibit HPV, including nitroglycerin, nitroprusside, dobutamine, some calcium channel blockers (e.g., nifedipine, nicardipine, and verapamil), and some β_2 -agonists (such as isoproterenol).⁸⁹ Vasoconstrictive drugs, including dopamine, epinephrine, and phenylephrine, may preferentially constrict normally oxygenated pulmonary vessels and reestablish the shunt flow, opposing the effects of HPV.¹¹¹

Anesthetic Management During One-Lung Ventilation

Choice of Anesthetic

Side effects associated with general anesthesia stem from a variety of mechanisms and can negatively impact intraoperative and postoperative pulmonary function. They include impairment of HPV, disruption of V/Q matching, neural and pain-induced hypoventilation, postoperative residual muscle relaxation, and atelectasis. Few studies have been able to demonstrate clear differences in patient outcomes based on anesthetic technique alone. However, some factors have emerged as important in the pulmonary surgical patient.

Clinical doses of potent inhalation agents do not significantly alter the mechanism of HPV. Volatile agents offer several benefits in thoracic surgery. They allow the use of a high fraction of inspired oxygen (FiO_2) to help prevent hypoxemia during OLV. They produce bronchodilatory effects and decrease airway irritability in patients who will be subjected to direct manipulation of lung tissue. In some studies, volatile agents resulted in a decreased inflammatory response compared to IV agents.^{114,115} In contrast, the dose of narcotics required to obtund airway reflexes could depress ventilation and necessitate postoperative ventilation. Volatile agents are rapidly eliminated at the end of surgery, and allow for early extubation. For these reasons, volatile agents are usually chosen as the primary anesthetics during thoracic surgery.

IV anesthetics do not inhibit HPV, and, whereas all volatile agents theoretically do, the volatiles act as vasodilators in a dose-dependent manner.¹¹⁶ HPV can be expected to remain intact if volatile agents are administered at less than 1.5 of the minimum alveolar concentration.¹¹⁷⁻¹¹⁹ Most analyses fail to demonstrate a difference in gas exchange between IV and inhaled techniques.¹²⁰ Furthermore, there is no difference in perioperative morbidity and mortality whether inhalational anesthesia or total IV anesthesia is administered.¹²¹

To prevent hypoxia and any significant increase in PVR, N₂O is generally avoided in favor of an air-oxygen mixture. N₂O increases PVR in healthy patients, as well as in those with preexisting pulmonary hypertension.⁸⁷ This is cause for even greater concern with concurrent right ventricular dysfunction. Another indication to avoid N₂O includes patients with bullous or emphysematous lungs. Because N₂O is highly diffusible, increased air can be trapped within the lung. An air-oxygen mixture prolongs emptying of the operative lung, in contrast to pure oxygen or a N₂O mixture.¹²²

The choice of specific opioids or hypnotics will not influence pulmonary outcomes, but there is concern related to the choice of muscle relaxants used. Postoperative residual neuromuscular blockade can occur with both intermediate and long-acting relaxants and is present regardless of the use of neuromuscular monitoring.¹²³ However, the incidence of residual relaxation associated with the use of long-acting relaxants (e.g., pancuronium) is significantly higher, and complications from it are more frequent compared with the use of intermediate-acting relaxants.¹²⁴ Muscle weakness may follow long surgeries, even with adequate tests of neuromuscular recovery.¹²⁵ Therefore, the use of shorter-acting muscle relaxants and conservative monitoring, dosing, and reversal practices are indicated in the pulmonary surgical patient.

The Role of Regional Anesthesia

When compared with general anesthesia, regional anesthesia may be beneficial in reducing atelectasis, pneumonia, respiratory failure, and other pulmonary complications.¹²⁶ Unfortunately, regional anesthesia as the sole anesthetic technique is impractical for open-lung cases; however, regional anesthesia can offer postoperative analgesia without the respiratory depressant effects of systemic opioids, which confers great benefits. Epidural anesthesia was found to reduce complications both for patients with normal FEV₁ and those with airflow obstruction.¹²⁷ The sympathectomy that is associated with neuraxial blockade causes vasodilation. Some have questioned whether epidural anesthesia would inhibit HPV, but because HPV is a locally-mediated event, epidural anesthesia has

been found to be similar to IV or balanced techniques with regard to pulmonary gas exchange.¹²⁸

Analgesia for Thoracic Surgery

A thoracotomy is known as one of the most painful operations, and postoperative pain can be very protracted (as in postthoracotomy pain syndrome). Most of the pain is caused by resection of thoracic tissue and bone in order for the surgeon to enter the chest cavity. This can lead to complications such as pneumonia and atelectasis.⁸⁷ Pain immediately after thoracic surgery causes splinting, decreased respiratory effort, hypoxemia, and respiratory acidosis. Aggressive management of pain is aimed at seeking a balance between comfort and respiratory depression in patients with decreased lung function. Residual pain exists in half of thoracotomy patients after 1 year, and in one-third of patients after 4 years.⁸⁸

Several options can be considered in the management of postoperative pain. Patients can titrate IV patient-controlled analgesia to obtain a more constant level of analgesia than that provided by intermittent intramuscular injections, but the benefits of avoiding systemic opioids have made regional anesthesia emerge as a superior method of pain control.

Thoracic epidural analgesia is considered one of the most effective methods for treating postoperative pain.¹²⁹ An epidural catheter is placed at the level of T6 to T8 and infused with epidural opioids or dilute solutions of local anesthetics to provide analgesia. The efficacy of epidural analgesia may be improved with adjunctive interventions, such as IV administration of ketamine and nonsteroidal analgesics.¹³⁰

As an alternative regional anesthesia technique, paravertebral nerve blocks can be placed at the level of the incision plus one or two intercostal interspaces above and below. This technique provides good short-term pain relief and reduces opioid requirements. Paravertebral block provides quality pain control to rival epidural analgesia.^{131,132}

Management of One-Lung Ventilation

Ventilation Modes

The primary goal during OLV is to maintain adequate arterial oxygenation and protecting the lung, while providing a surgical field favorable for visualization and manipulation of the operative lung (Table 30.3). In the past, large V_T s of 10–15 mL/kg were recommended to prevent atelectasis in the dependent lung and maintain an adequate FRC. Contemporary understanding is that high volumes predispose to volutrauma, which is associated with increases in cytokine inflammatory mediators, alveolar fibrin deposition, and other markers of procoagulant effect that contribute to acute lung injury.^{133,134}

TABLE 30.3

Recommendations for Avoiding Hypoxemia and Acute Lung Injury During One-Lung Ventilation

Setting	Rationale	Problems
$FiO_2 < 1.0$	FiO_2 of 1.0 can facilitate atelectasis, so high FiO_2 can induce atelectotrauma and, paradoxically, hypoxaemia.	Is there any ‘cut-off’ point (e.g., SpO_2) to set the FiO_2 ?
Low TV (e.g., 6 mL/kg) (or low pressures)	High TV (or high pressures) can lead to volutrauma (or barotrauma).	What is the ideal TV for one lung?
Routine use of PEEP	PEEP is beneficial for oxygenation and also for lung protection.	Is there a general ‘best PEEP’? How can it be determined?
Recruitment maneuvers	RM improves oxygenation, and achieves a better distribution of aeration.	Should it be used routinely? How should it be applied?
Routine use of CPAP to nondependent lung	CPAP is beneficial for both oxygenation and lung protection.	The increasing frequency of VATS, where CPAP is contraindicated.
Permissive hypercapnia	High PCO_2 can be beneficial in avoiding ALI.	Is there any cut-off point for PCO_2 to avoid hemodynamic instability?
Inhalational anesthetics + TEA	They do not inhibit HPV relevantly; inhalational anesthetics avoid ALI.	What are the effects of TEA on ALI?

ALI, Acute lung injury; CPAP, continuous positive airway pressure; FiO_2 , fraction of inspired oxygen; HPV, hypoxic pulmonary vasoconstriction; PCO_2 , partial pressure of carbon dioxide; PEEP, positive end-expiratory pressure; RM, recruitment maneuvers; SpO_2 , blood oxygen saturation; TEA, thoracic epidural anesthesia; TV, tidal volume; VATS, video-assisted thoracoscopic surgery.

From Şentürk M, et al. Intraoperative mechanical ventilation strategies for one-lung ventilation. *Best Practice & Research Clinical Anaesthesiology*. 2015;29(3):357–369.

During OLV, patients frequently develop “auto-PEEP” and have

an increased FRC, such that large V_T s are unnecessary.

Understanding the detrimental effects of high V_T s has led to the more contemporary approach of using more physiologic volumes (e.g., 6 mL/kg on the left and 8 mL/kg on the right), adding PEEP to those patients without auto-PEEP, and limiting peak inspiratory pressures to less than 25 cm H₂O.^{128,133–135} With this approach, patients will maintain adequate or even improved oxygenation (as compared with using a higher V_T) and minimal elevations in PaCO₂.^{89,136} It is preferable to allow permissive hypercapnia, rather than aggressively attempting to maintain a normal PaCO₂, as hypercapnia supports HPV and directly reduces the cytokine response.^{137,138} The PaCO₂ should be maintained below 60–70 mm Hg to reduce the incidence of dysrhythmias, hypotension, and pulmonary hypertension. Although a high FiO₂ should induce vasodilation in the dependent lung and improve blood flow, hypocapnia causes vasoconstriction, and should be avoided. PEEP must be employed when using a low V_T , otherwise alveolar derecruitment and atelectasis will occur, reducing PaO₂.¹³⁹

Implementation of an alveolar recruitment maneuver prior to initiating OLV can help to support better PaO₂ throughout the OLV period.¹⁴⁰ Recruitment maneuvers are not universally accepted. Besides opening airways, they may also translocate cytokines into the circulation,¹⁴¹ impede hemodynamics, and provide only a transient effect.¹⁴²

An appropriate air-oxygen mixture, at times as high as an FiO₂ of 1, is necessary to maximize the PaO₂. However, considering the potential for oxygen toxicity (particularly in a setting of absorptive atelectasis or history of chemotherapeutic administration),¹⁴³ FiO₂ should be maintained at the lowest level that will support adequate SpO₂.¹¹⁶ This approach also leaves a “reserve” intervention in the case of hypoxemia. Increasing the FiO₂ in the face of declining oxygenation allows time to plan other interventions (such as checking tube placement). On 100% oxygen, by the time the SpO₂ falls, the insult will be more advanced, and the saturation will continue to decline during diagnosis and management of the issue.

Research validates the “protective ventilation” strategy,

including end-expiratory pressures above the lower inflection point on the pressure-volume curve, a V_T of less than 6 mL/kg, inspiratory pressures of less than 20 cm H₂O above the PEEP value, permissive hypercapnia, and preferential use of pressure-limited ventilatory modes.¹⁴⁴⁻¹⁴⁶ The superiority of pressure or volume modes of ventilation has not been definitively determined. It is compelling to consider that pressure-controlled ventilation limits maximal airway pressure, and that the square pressure waveform provides more widespread alveolar recruitment, but research has been equivocal about demonstrating consistently better outcomes based on the ventilation mode.¹⁴⁷⁻¹⁵⁰

Hypoxemia During One-Lung Ventilation

Hypoxemia occurs in 5% to 10% of patients under OLV.³ Although hypoxic pulmonary vasoconstriction attempts to normalize the relationship between ventilation and perfusion, it is not 100% effective at doing so. Certain characteristics predict the degree of hypoxemia that will be exhibited by a patient under OLV. Anatomically, the right lung is larger than the left lung, and thus, proportionally, there is a greater amount of perfusion to the right lung. This is the reason that there is an increased incidence of hypoxemia during right-sided surgery (see Fig. 30.15).¹⁵¹ The usual detrimental effect of lateral positioning on oxygenation paradoxically benefits the patient during OLV. Lateral positioning with mechanical ventilation normally imbalances V/Q matching by distributing more ventilation to the nondependent lung, while gravity encourages more perfusion to the dependent lung. During lateral-positioned OLV, direction of all ventilation to the dependent lung creates a more beneficial match of ventilation and perfusion. In fact, PaO₂ is found to be significantly worse in procedures (such as lung transplant) where OLV is performed in supine patients.¹¹⁶ Some patient data also predict the degree of hypoxemia that will be encountered during OLV. The reduction in FEV₁, paradoxically, is sometimes inverse to the degree of hypoxemia experienced. As a measure of disease progress, a lower FEV₁ indicates worse disease; but as a measure of air-trapping, patients with a lower FEV₁ sometimes develop intrinsic or auto-PEEP that helps keep their

airways patent and beneficially reduces hypoxemia during OLV.¹⁵¹ Ventilation-perfusion scanning, if completed preoperatively, can help the anesthetist to predict the potential for intraoperative shunt under OLV, because perfusion to the operative lung is inverse to the potential shunt.¹⁵² A last-minute predictor is the end-tidal CO₂ (ETCO₂). Being dependent on blood flow to the lung, ETCO₂ is a surrogate measure of perfusion.¹⁵³ The degree of decline in ETCO₂ when switching from two-lung ventilation to OLV indicates the degree of blood perfusing the nondependent lung, and therefore a greater initial decline predicts inferior oxygenation during OLV. Alveolar recruitment maneuvers and the use of subsequent PEEP at 8 cm H₂O improves arterial oxygenation during OLV.¹⁵⁴

Should hypoxemia occur during OLV, the anesthetist should assess for physiologic causes or tube malpositioning. Physiologic causes include bronchospasm, decreased cardiac output, hypoventilation, low FiO₂, or pneumothorax of the dependent lung. Tube malpositioning implies that movement of the DLT may have excluded a portion of dependent lung, usually the upper lobe. Assessing the position of the DLT should be the initial intervention, as a large proportion of hypoxemic episodes are remedied by tube repositioning.³ If physiologic causes have been ruled out, and adequate lung separation and ventilation have been determined, one or more of the following interventions will help improve PaO₂. First, continuous positive airway pressure (CPAP) to the nondependent, nonventilated lung is almost 100% efficacious in increasing PaO₂. This can be accomplished with a compact breathing system, such as a Mapleson C with a manometer for pressure determination, attached to the lumen of the deflated lung (Fig. 30.17), or with a calibrated, adjustable device made specifically for this purpose. Application of CPAP should help to oxygenate the persistent blood flow through the nondependent lung, but too much pressure will cause the lung to inflate, reducing surgical exposure. The lowest level of effective CPAP should be sought (start at 2 cm H₂O). The reservoir bag on the CPAP device can also be used to provide intermittent ventilation to the operative lung, should that intervention become necessary. Providing gentle ventilation with a separate system will minimize the diminution of

surgical exposure, as opposed to ventilating the lung with the same vigor as that required for the dependent lung. As an alternative to CPAP, a small catheter can be used to deliver low-flow oxygen insufflation to the nondependent lung without generating pressure. This approach may be adequate to reduce the shunt and reverse hypoxemia in mild cases.¹⁵⁵

FIGURE 30.17 Continuous positive airway pressure apparatus for improving oxygenation of the nonventilated lung.

Besides shunt flow through the operative lung, atelectasis and reduced FRC in the dependent lung may also degrade the PaO_2 . If CPAP to the nondependent lung does not improve oxygenation, PEEP applied (or titrated upward) to the dependent, ventilated lung acts to recruit collapsed airways, increasing lung compliance and FRC. Excessive PEEP may detrimentally reduce cardiac output. Combined with a fast respiratory rate and/or high inspiratory/expiratory ratio (I:E ratio), PEEP may impair adequate exhalation, leading to a net volume increase through auto-PEEP and the potential for volutrauma to the dependent lung. The actual end-expiratory pressure should be monitored during OLV to ensure that it does not significantly exceed the intended level of PEEP.

Other methods of improving oxygenation during OLV include combining PEEP and CPAP to the respective lungs, and intermittent reinflation of the nondependent lung. Innovative ventilatory approaches such as high-frequency jet ventilation to the operative lung and selective oxygenation to nonoperative lobes of the operative lung via a bronchial blocker or bronchoscope are also used.^{155–158} Jet ventilation is effective at reducing the shunt, but lung movement can be deleterious, which makes monitoring CO₂ levels and effecting CO₂ removal challenging.¹⁵⁹

If CPAP and PEEP fail, early ligation of the pulmonary artery in pneumonectomy patients may be used to improve oxygenation. If the pulmonary artery is planned to be ligated during the procedure, clamping it will immediately stop all significant flow through the lung contributing to the shunt. For the same reason, manual compression of the lung will also improve the PaO₂, but the expense of cardiac output and tissue trauma advises against this as a regular strategy.¹⁶⁰ If it becomes impossible to maintain adequate oxygenation with OLV in spite of CPAP and PEEP, manual two-lung ventilation can be used, with pauses in ventilation coordinated with the surgeon's activities to facilitate exposure, suturing of the lung, or other needs. Communication with the surgical team is vital throughout the procedure, especially during the evaluation and correction of hypoxia.

At the conclusion of the resection, the surgeon will commonly ask that the operative lung be reinflated using large V_Ts so that air leaks may be detected. At this time, the lung separator (DLT clamp or bronchial blocker) should be discontinued, and the lung inflated with slow breaths, achieving a peak inspiratory pressure of 30–40 cm H₂O.⁸⁹ Reexpansion of the lung can be observed while performing this maneuver, which also helps to reverse atelectasis in the lungs. Following lung reexpansion, the bronchial cuff should be deflated on the DLT to both reduce pressure on the bronchial mucosa and obviate any detrimental effects of slight tube malpositioning. Deflated, the cuff does not pose the threat of herniating over the carina or obstructing the lobar bronchi. [Box 30.8](#) outlines the management of one-lung anesthesia.

Management of One-Lung Anesthesia

- Ventilate:
- Tidal volume: 6–8 mL/kg
- Rate: 12–15 (permissive hypercapnia acceptable)
- FiO_2 : 0.4–0.8; maintain $SpO_2 > 90\%$
- PEEP: 5–10 cm H_2O (2.5–5 if COPD)
- I:E ratio: 1 : 2 (1 : 3 if COPD or intrinsic (auto) PEEP)
- Consider alveolar recruitment maneuver prior to OLV
- Assess ABG 15 minutes after OLV is initiated
- Volatile anesthetics < 1–1.5 MAC or IV agents
- Stepwise response to worsening hypoxemia:
- Increase FiO_2
- Confirm tube position with fiberoptic bronchoscope
- Ensure adequacy of cardiac output
- Remedy detrimental effects caused by anemia or vasodilators
- Perform alveolar recruitment maneuver to DL

- Titrate PEEP in DL
- CPAP 5–10 cm H₂O to NDL
- Intermittent or continuous two-lung ventilation
- Low- or no-pressure oxygen insufflation to NDL or selected lobe of NDL
- Reposition to lateral decubitus position if supine
- Alter perfusion with almitrine to NDL; nitric oxide to DL

ABG, Arterial blood gas; *COPD*, chronic obstructive pulmonary disease; *CPAP*, continuous positive airway pressure; *DL*, dependent lung; *FiO₂*, fraction of inspired oxygen; *I:E*, inspiratory/expiratory ratio; *IV*, intravenous; *MAC*, minimum alveolar concentration; *NDL*, nondependent lung; *PEEP*, positive end-expiratory pressure; *SpO₂*, blood oxygen saturation.

Emerging techniques of OLV focus attention away from manipulating ventilation of the operative lung to manipulation of perfusion of the nonoperative lung. V/Q matching can be supported by encouraging more perfusion to the ventilated lung or selectively diminishing perfusion to the nonventilated lung. Inhaled epoprostenol (prostacyclin) and N₂O are beneficial for increasing the perfusion of the dependent lung. The combination of inhaled epoprostenol and IV phenylephrine (for vasoconstriction of the operative lung) is an effective strategy.¹⁶¹ Another experimental approach is the use of almitrine, which enhances HPV of the nonventilated lung. Studies have shown a more than 100% increase in Pao₂ when almitrine and N₂O are used on their respective lungs^{162,163}; however, toxicity, cost, and challenges related to setting up and administering N₂O are deterrents to using these

interventions as part of a routine plan, except for the most critical cases.

Thoracic Surgical Concerns

Asthma Treatment

Asthma that is refractory to medical therapy may be treated with thermal ablation of the bronchial smooth muscle to reduce its responsiveness. Bronchial thermoplasty is performed through a fiberoptic bronchoscope. The procedure may be performed under general anesthesia or monitored anesthesia care (MAC). Either approach has positive and negative attributes. Monitored anesthesia care provides the advantage of not needing to instrument the airway; however, suppressing the cough and irritant reflexes while preserving spontaneous ventilation can pose a challenge. Agents which provide sedation while minimizing airway compromise and bronchial irritation (such as dexmedetomidine) are beneficial.¹⁶⁴ General anesthesia provides control of the airway and breathing and allows a deeper state of reflex attenuation; however, weaning and extubation may pose challenges. The procedure is completed in three stages, with a few weeks between procedures. Therefore, the patient is not “cured” upon completion of the procedure, and postoperative complications may include bronchospasm, hypoxemia, and respiratory distress.

Mediastinal Masses

Masses in the mediastinum can compress vital structures and cause changes in cardiac output, obstruct airflow, induce atelectasis, or produce central nervous system changes. Masses can include benign or cancerous tumors, thymomas, substernal thyroid masses, vascular aneurysms, lymphomas, teratomas, and neuromas (Box 30.9). Surgical procedures for diagnosis or treatment of these masses may include thoracotomy, thoracoscopy, and

Box 30.9 Thoracoscopy.

Common Tumors of the Anterior Mediastinum: “The 4 Ts”

- Thymoma

- Thyroid
- Teratoma
- “Terrible” lymphoma

Tumors within the anterior mediastinum can cause compression of the trachea or bronchi, increasing resistance to airflow. Changes in airway dynamics with supine positioning, induction of anesthesia, and positive-pressure ventilation can cause collapse of the airway with total obstruction to flow. General anesthesia can therefore be very dangerous in these patients. Total airway obstruction can occur at any phase of anesthesia and through the recovery phase. Positive-pressure ventilation may be impossible, even with a properly placed ETT, if the mass encroaches on the airway distal to the ETT. The airway can collapse, even when spontaneous respiration is maintained.¹⁶⁵ To anticipate this potential, anesthetic preparation should include the availability of a rigid bronchoscope and readiness to turn the patient lateral or prone in case of airway collapse. Cannulation for potential emergency femoral-femoral bypass should be considered if the tumor is large or if the patient becomes symptomatic.^{166,167} Localization of the mass by CT or bronchoscopy may facilitate placement of the ETT distal to the mass. A major anesthetic goal is to maintain spontaneous ventilation, which retains normal airway-distending pressure gradients and can maintain airway patency when positive-pressure ventilation will not.¹⁶⁸

Signs and symptoms associated with respiratory tract compression should be determined preoperatively. Many patients with mediastinal masses are asymptomatic or characterized by vague signs such as dyspnea, cough, hoarseness, or chest pain. Wheezing may represent airflow past a mechanical obstruction rather than bronchospasm. Symptoms may be positional, worsening in the supine position or other positions. A chest radiograph may show airway compression or deviation. CT, transesophageal echocardiography, and MRI may further delineate the size and effects of masses. Subclinical airway obstruction may be revealed by flow-volume loops, which demonstrate changes in

flow rates at different lung volumes. A decreased maximal inspiratory or expiratory flow rate alerts the anesthetist to an increased risk of obstruction perioperatively. Comparison of flow rates obtained with the patient in the upright and supine positions can reveal whether the supine position will exacerbate the obstruction intraoperatively (Fig. 30.18 and Box 30.10).¹⁶⁹

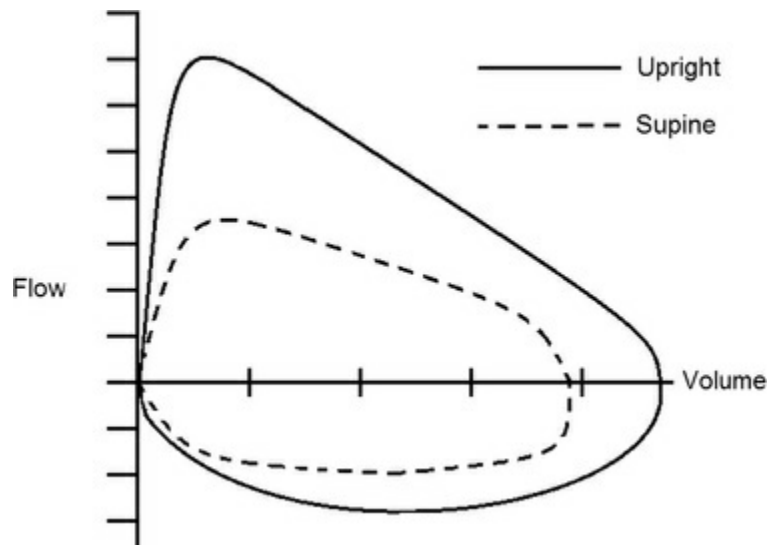

FIGURE 30.18 Upright and supine flow-volume curves representative of anterior mediastinal mass. Note that an abnormality appears in the supine position, when gravity causes the mass to impinge on the lower airway. The greatest decrement affects the expiratory limb of the loop, which is generally indicative of variable intrathoracic obstructions. Thoracic excursion during spontaneous inspiration relieves the pressure. This effect is lost when ventilation is changed to exclusively positive pressure input from above.

Box 30.10

Symptoms of Mediastinal Mass

- Sweats
- Stridor
- Syncope
- Cyanosis

- Orthopnea
- Hoarseness
- Inability to lie flat
- Chest pain or fullness
- Jugular vein distention
- Superior vena cava syndrome
- Cough (especially when supine)

Data from Slinger P, Karsli C. Management of the patient with a large anterior mediastinal mass: recurring myths. *Curr Opin Anaesthesiol.* 2007;20(1):1–3; Blank RS, de Souza DG. Anesthetic management of patients with an anterior mediastinal mass: continuing professional development. *Can J Anaesth.* 2011;58(9):853–859, 860–867.

Biopsy of masses should be performed with the patient under local anesthesia whenever possible. Bilevel positive airway pressure (BiPAP) has been used in this situation to support the airway and maintain spontaneous ventilation while still providing sedation.^{170,171} Radiation therapy may be helpful to decrease the mass of the tumor before major surgery is attempted. For airway management, awake fiberoptic bronchoscopy and intubation enables the anesthetist to evaluate the large airways for obstruction and place the ETT beyond the obstruction while maintaining spontaneous ventilation. The effect of positional changes can be assessed with the bronchoscope. Spontaneous ventilation should be maintained as long as possible or throughout the procedure if feasible. The ability to effectively provide positive-pressure ventilation should be guaranteed prior to administering muscle relaxants. The use of a helium-oxygen mixture can improve airflow during partial obstruction by decreasing turbulence past the stenotic area.¹⁷²

Mediastinal masses can cause compression of great vessels or cardiac chambers. Patients with any cardiac or great vessel involvement should receive only local anesthesia whenever possible, remain in the sitting position, and maintain spontaneous

respirations. Cardiopulmonary bypass must be able to be implemented within minutes in the case of sudden cardiopulmonary collapse.

Patients with mediastinal masses may develop superior vena cava (SVC) syndrome, which is venous engorgement of the upper body caused by compression of the SVC. The following signs and symptoms are associated with SVC syndrome: dilation of collateral veins of the upper part of the thorax and neck; edema and rubor of the face, neck, upper torso, and airway; edema of the conjunctiva with or without proptosis; shortness of breath, headache, visual distortion, or altered mentation.¹⁷³ Placement of IV lines in the lower extremities is preferred; insertion in sites above the SVC could delay the drug's effect as a result of slow distribution. Fluids should be administered with caution, because large volumes can worsen symptoms.

Mediastinoscopy

Mediastinoscopy involves insertion of a scope into the mediastinum via an incision made above the sternal notch. The scope is passed anterior to the trachea in close proximity to the left common carotid artery, the left subclavian artery, the innominate artery, the innominate veins, the vagus nerve, the left recurrent laryngeal nerve, the thoracic duct, the superior vena cava, and the aortic arch.

Complications associated with mediastinoscopy include hemorrhage resulting from disruption of major vessels; pneumothorax; dysrhythmias; bronchospasm; left recurrent laryngeal nerve palsy; laceration of the trachea or esophagus; and chylothorax secondary to laceration of the thoracic duct.¹⁷⁴ Large-bore IV access should be in place, and banked blood should be immediately available in the event of a tear in a major blood vessel. Air embolism is also a risk if a venous tear occurs. Dysrhythmias such as bradycardia are possible with manipulation of the aorta or trachea during blunt dissection.

The mediastinoscope can place pressure on the innominate (brachiocephalic) artery prior to its division into the right common carotid artery and right subclavian artery. This can cause decreased blood flow to the right common carotid artery and right vertebral artery, and decreased right subclavian blood flow to the right arm

(Fig. 30.19).¹¹⁷ The decrease in cerebral flow can cause an acute ischemic stroke, especially if the patient has a history of cerebrovascular disease. Monitoring perfusion to the *right arm* with a pulse oximeter or radial artery catheter can detect decreased flow to the right arm and signal concurrent loss of flow to the brain via innominate artery compression. Repositioning of the mediastinoscope is required to reestablish flow to the brain. A noninvasive blood pressure cuff placed on the left arm enables continued monitoring of systemic blood pressure during periods of innominate artery compression.

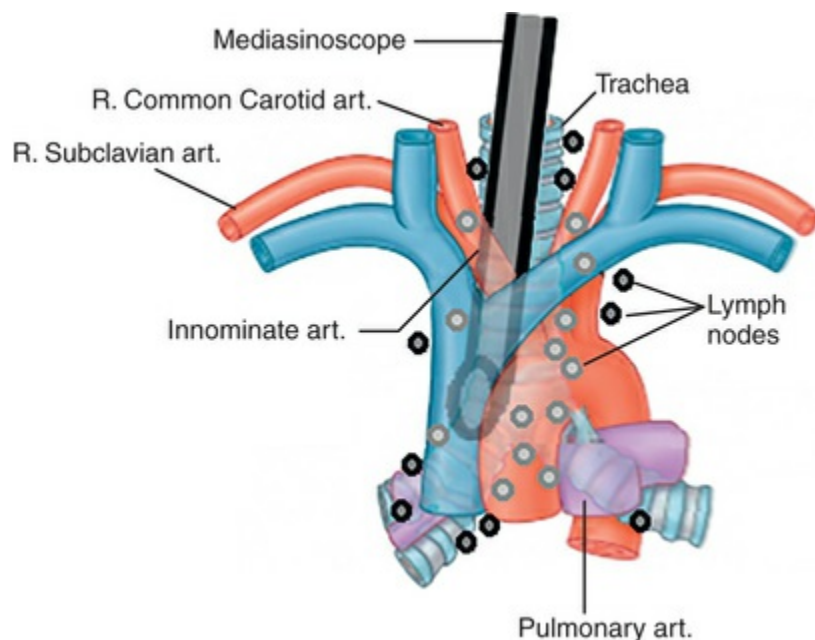

FIGURE 30.19 Placement of a mediastinoscope into the superior mediastinum. The mediastinoscope passes in front of the trachea but behind the thoracic aorta. The mediastinoscope can potentially compress or damage the aorta, innominate artery, trachea, superior vena cava, and left recurrent laryngeal nerve. Art., artery, R., right. Thoracoscopy

Advances in videoscopic technology have led to the increased use of thoracoscopy to replace open thoracotomy for a variety of

diagnostic and therapeutic intrathoracic interventions (Table 30.4). Video-assisted thoracoscopic surgery (VATS) most often requires general anesthesia, and frequently requires lung isolation during ventilation. A video camera and surgical instruments are inserted via a trocar (Thoracoport) into the chest, allowing for visualization and manipulation of thoracic structures (Fig. 30.20). The surgeon has less ability to manually compress the lung during this procedure as compared to during an open thoracotomy, and therefore, a DLT may be preferable to a bronchial blocker to facilitate lung isolation. An arterial line is frequently inserted for VATS procedures, except with minimally invasive procedures in selected healthy patients. However, the anesthetic plan should account for the potential need for rapidly obtaining arterial blood gas samples or for possible hemorrhage, which may be difficult to control during the endoscopic procedure. In addition to the potential for rapid massive hemorrhage, other complications associated with VATS include hypoxemia, cardiac/pulmonary artery/esophageal disruption, cardiac tamponade, left recurrent laryngeal nerve damage, and pulmonary edema. In cases of severe pulmonary compromise, VATS can be performed using epidural anesthesia in the spontaneously breathing patient who is sedated with a variety of techniques.¹⁷⁵ The degree of postoperative pain is less with VATS as compared to an open procedure. For this reason, an epidural used solely for postoperative pain management is rarely indicated. Patients who undergo VATS have an improved quality of life for the first year postoperatively as compared to those who undergo open thoracotomy, suggesting that VATS should be the preferred surgical approach for lobectomy in stage I non–small cell lung cancer.¹⁷⁶ VATS is associated with greater anti-angiogenic responsiveness in patients with non–small cell lung cancer as compared to open thoracotomy. The differences in anti-angiogenic responsiveness may have an important effect on cancer biology and recurrence after surgery.¹⁷⁷

TABLE 30.4

Indications for Video-Assisted Thoracoscopic Surgery

Diagnostic	Therapeutic

Pulmonary	
Identification of disease Biopsy and staging of cancer Evaluation of intrapleural infection	Lung volume reduction Resection of lung tumor(s) or metastasis Lobectomy, pneumonectomy Spontaneous pneumothorax Blebectomy Pleurodesis Decortication Drainage of empyema Lysis of adhesions
Mediastinum	
Biopsy of tumor(s) Biopsy of lymph node(s)	Excision of cysts: bronchogenic or pericardial Resection of mediastinal tumor(s) Thymectomy Ligation of thoracic duct
Esophagus	
Biopsy of tumor Staging of cancer	Esophageal resection: vagotomy, Heller myotomy, Nissen fundoplication, transhiatal esophagectomy Resection of primary esophageal tumor(s)
Cardiac	
Identification of pericardial distention	Drainage of pericardial effusion Pericardiectomy Ligation of patent ductus arteriosus Minimally invasive coronary artery bypass and valve procedures
Cardiac	
Identification of pericardial disease	Drainage of pericardial effusion Pericardiectomy Ligation of patent ductus arteriosus Minimally invasive coronary artery bypass and valve procedures
Spine	Sympathectomy Spinal surgery, discectomy, fusion Spinal abscess drainage
Other	Assessment of injury from trauma Stabilization of bleeding Clot evaluation

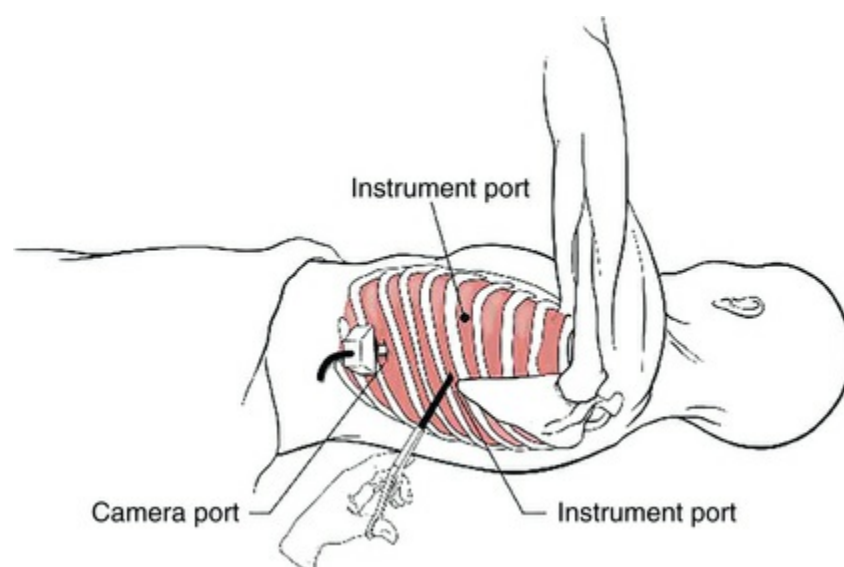

FIGURE 30.20 Surgical instrument placement during video-assisted thoracoscopic surgery. (From Kitabjian L, et al.

Thoracoscopic sympathectomy for hyperhidrosis is an outpatient procedure. A DLT is preferred over a bronchial blocker because the procedure is bilateral, and the DLT can more easily switch from ventilation of one lung to the other. The procedure is performed in the supine position, and no chest tubes are inserted.

Bullectomy

Patients with bullous COPD are often treated with VATS to prevent pneumothorax or tension pneumothorax, which may result from ruptured bullae. To reduce the risk of bulla rupture, spontaneous ventilation is desirable under anesthesia until the chest is opened. Patients with severe cardiopulmonary disease may not be able to ventilate adequately under general anesthesia, however, and positive-pressure ventilation may be required. Small V_T s, high respiratory rates, and high FiO_2 can be delivered by gentle manual ventilation to keep airway pressures below 10–20 cm H_2O .¹⁷⁸ An alternative to positive-pressure ventilation is high-frequency jet ventilation, which is used to decrease the chance of barotrauma.¹⁷⁹

The use of N_2O should be avoided in bullous disease because it rapidly enlarges the air-filled spaces. The anesthetic plan can involve general or epidural anesthesia, and is based on the patient's cardiopulmonary status and the anesthetist's desire to maintain spontaneous ventilation. The risk of bulla rupture persists even after surgery, so the same measures taken to avoid high airway pressure must be observed.

Complications After Thoracotomy

A number of complications may occur following thoracic surgery. Various factors have been correlated with an increased risk of complications. Admission to the intensive care unit or heightened surveillance should be considered for postoperative patients with the following characteristics: pulmonary fibrosis, age greater than 80 years, PPO FEV₁ or DLCO less than 40%, ASA status over 3, surgical time longer than 80 minutes, intraoperative hemorrhage, and others.¹⁸⁰⁻¹⁸³ The following frequent predictors of pulmonary complications are quantified in the FLAM score (named after two of its designers Francesco Leo and Marylene Anziani), which shows good predictive capacity for impending respiratory complications: dyspnea, chest X-ray changes, required oxygen administration, auscultated changes, cough, and bronchial secretions.¹⁸⁴ Among the most common postoperative complications are respiratory failure, cardiac dysrhythmia or failure, and acute lung injury (ALI).

Significant factors associated with ALI after pulmonary resections include right pneumonectomy, intraoperative overhydration with high vascular volume, high intraoperative airway pressure during OLV, and preoperative alcohol abuse. Other factors that have been suggested are female gender, poor postoperative predicted lung function, trauma, infection, chemotherapy, mediastinal lymphatic damage, transfusion and administration of fresh frozen plasma, oxygen toxicity, prolonged OLV (greater than 100 minutes), and an increased postoperative urine output.^{143,185}

OLV causes inflammatory changes in the ventilated and nonventilated lung, and some of the damage appears to occur upon reexpansion of the deflated lung.¹⁸⁶⁻¹⁹⁰ Protective ventilation strategies should always be employed to reduce the generation of inflammatory processes.^{136,191} There appears to be a lasting effect of OLV that is not reversed when reverting to two-lung ventilation. A small animal study demonstrated that after OLV has been discontinued, very low V/Q ratios in the range of 0.3–0.5 persist in the dependent lung.¹⁹² This, coupled with diffuse alveolar damage in comparison to controls, suggests that anesthetists should expect

hypoxemia from the resultant V/Q mismatch that may persist for an unknown period after OLV. Even in the absence of an inflammatory response, there is evidence of vascular injury to lung tissue that is collapsed during OLV, which suggests that CPAP may have both short- and long-term benefits.¹⁹³

Minimizing pulmonary intravascular pressures by intraoperative fluid restriction is advocated to decrease postoperative complications.¹⁹⁴ Surgical requirements for proper hydration and tissue perfusion must be balanced with the desire to prevent high postoperative intravascular pressures that can cause acute pulmonary edema.

Decreased cardiac output in the early postoperative period can be caused by several factors, including blood loss, herniation of the heart through a pericardial defect, right-sided heart failure, and dysrhythmias. Generally, blood entering the pleural space drains into chest tubes at a rate of less than 500 mL per day. Chest tube drainage greater than 200 mL per hour necessitates surgical exploration. An obstructed chest tube can conceal bleeding in a hemothorax. Hypotension, unexplained tachycardia, and decreasing hematocrit are other signs associated with hemorrhage.

Loss of pulmonary vasculature with lung resection can result in increased PVR and right-sided heart failure. The reduction in cardiac ejection fraction is greater following pneumonectomy than that following lobectomy. Conditions that increase the likelihood of right-sided heart failure include postoperative pneumonia, hypercarbia, and acidosis. Vasodilators are useful for decreasing the PVR. Amrinone or dobutamine can be administered for inotropic support, as needed.

Supraventricular dysrhythmias are common after thoracotomy and may herald other serious complications.¹⁹⁵ Morbidity and mortality rates in patients with supraventricular tachydysrhythmias are high, with 25% associated with death within 30 days postoperatively, despite institution of aggressive treatment. Administration of a β -blocking agent can help prevent atrial dysrhythmias. Metoprolol or esmolol provide rate control, and their cardioselectivity limits adverse effects on bronchial tone. Digitalis, adenosine, calcium channel blockers, and β -blockers are useful for treating supraventricular tachydysrhythmias.

Respiratory complications in the early postoperative period include atelectasis, pneumonia, respiratory failure, bronchopleural or bronchocutaneous fistula, pneumothorax, and pulmonary edema. Aggressive respiratory care to prevent deterioration and allow weaning from ventilation is vital.

Nerve injuries that may follow thoracic surgery include damage to the phrenic nerve as it passes through the mediastinum, and damage to the left recurrent laryngeal nerve, which is vulnerable during dissection of aortopulmonary lymph nodes and mediastinal procedures.¹⁹⁶ Spinal cord injury is a possibility if an intercostal artery supplying a major radicular artery is injured, or if an epidural hematoma is created by surgical dissection between the pleura and the epidural space. Nerve injuries related to surgical positioning are also possible complications.

Summary

Providing anesthesia for thoracic surgery requires a comprehensive knowledge of anatomy, physiology, pharmacology, and anesthetic considerations, as this is necessary for safe patient care. The patient may have cardiac or respiratory diseases, masses, bullae, and other problems that complicate anesthetic management. Knowledge of respiratory physiology, pathophysiology, and the physiology of OLV is vital to safe and effective practice. Special equipment such as double lumen endobronchial tubes, bronchial blockers, and fiberoptic bronchoscopes must be understood. A thorough understanding of the properties of anesthetic drugs is necessary so that the most beneficial combination of agents can be selected to manage the patient's anesthesia. Traditional ventilation concepts favoring high FiO_2 and large V_{T_s} have given way to protective ventilation strategies, considering the metabolic implications of oxygen toxicity and ALI. Protective lung strategies use lower V_{T_s} , PEEP, and modest FiO_2 levels. For pulmonary surgery, lung separation may be achieved by DLTs or bronchial blockers. Each has its own advantages, but neither is clearly preferable over the other in every case. Fiberoptic bronchoscopy should be used to ensure proper placement of airway devices for lung separation. For hypoxemia caused by shunting during OLV, intermittent expansion of one or both lungs, CPAP applied to the operative lung, or PEEP applied to the nondependent lung should be used. Judicious fluid management is an important component of reducing postoperative lung injury. Regional anesthesia is a useful adjunct for postoperative pain control. Future research and directions will include more practical methods of reducing the shunt during OLV, and a better understanding of the implications of hypoxemia. More critical monitoring (such as effect-site monitoring) of oxygenation will improve the management of thoracic anesthesia.

Neuroanatomy, Neurophysiology, and Neuroanesthesia

Lee J. Ranalli, Greg A. Taylor

This chapter reviews the organization of the central nervous system (CNS). Specific neurophysiologic concepts that are essential for the anesthetist are presented. These concepts include electrophysiology, cerebral blood supply, role of neurotransmitters, and the effects of anesthetic agents on cerebral physiology. This chapter also provides recommendations for the management of specific neurosurgical procedures.

Organization of the Central Nervous System

Cells of the Central and Peripheral Nervous Systems

The CNS includes the brain and spinal cord. The peripheral nervous system includes the cranial and spinal nerves and their receptors, and it is divided into the somatic and autonomic nervous systems. The somatic nervous system contains sensory neurons for the skin, muscles, and joints. The autonomic nervous system, which consists of the sympathetic, parasympathetic, and enteric subdivisions, is responsible for involuntary innervation of various organ systems.

The CNS is derived from two primary cell types: neurons and neuroglial (or glial) cells. The neuron is the basic functional cell of the CNS and it consists of a cell body (perikaryon) and specialized cytoplasmic processes, dendrites, and a single axon (Fig. 31.1). A single axon emerges from the cell body at the axon hillock. The axon may branch to form collateral nerves at a point distal to the neuron cell body. Axon diameters range from 0.2 to 20 μm . Most of the axons in the brain are only a few millimeters long, although the axons that run from the spinal cord may be as long as 1 meter. Stimulation of the dendrites produces anterograde impulse conduction (toward the neuron cell body) with subsequent conduction away from the neuron cell body by way of the axon.

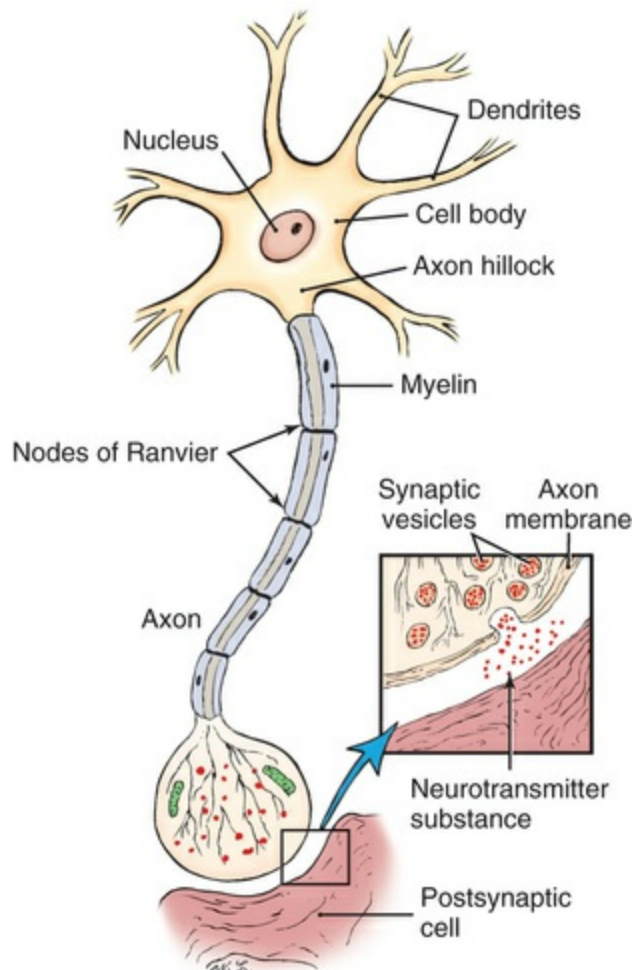

FIGURE 31.1 Neuron and chemical synapse.

Neuron cell bodies vary in size and shape and are classified as unipolar, bipolar, pseudounipolar, or multipolar. Unipolar neurons are found only in lower invertebrates. Bipolar neurons are found in the retina, ear, and olfactory mucosa. Pseudounipolar neurons have one cytoplasmic process that exits the cell and divides into two branches, one serving as the dendrite, the other as the axon. Pseudounipolar neurons are present in the dorsal root ganglia and cranial ganglion cells, enabling sensory impulses to travel from the dendrite directly to the axon without passing through the cell body. Multipolar neurons have multiple dendritic processes but only one axon, and constitute the majority of the CNS neurons.

The gray matter of the CNS is composed of neuron cell bodies in the CNS, and the white matter is composed of myelinated axons. Regions of concentrated cell bodies within the peripheral nervous system form the cranial, spinal, and autonomic ganglia.

Neurons may be classified according to their specific function:

motor neurons, sensory neurons, or interneurons. Motor neurons are multipolar and innervate and control effector tissues such as muscles and glands. Sensory neurons are pseudounipolar and receive exteroceptive, interoceptive, or proprioceptive input. Interneurons are pseudounipolar and connect adjacent neurons.

The neuron is bound by a bilaminar lipoprotein membrane derived from phospholipid molecules arranged with their fatty acid chains facing one another, producing an inner hydrophobic membrane. The membrane surface in contact with the extracellular fluid contains polar hydrophilic groups of phospholipid molecules. The neuronal membrane contains integral membrane proteins, which form ionic pumps, ion channels, enzymes (e.g., adenylate cyclase), receptor proteins, and structural proteins.

The neuron contains a number of common cellular organelles including a well-developed nucleus, mitochondria (distributed throughout the cell body), and cytoplasmic processes. Ribosomes, endoplasmic reticulum, lysosomes, and Golgi complexes are also found. Neurotubules and neurofilaments extend through the cytoplasm from the dendrites to the axon terminal; they provide structural support and a pathway for intracellular transport of neurotransmitters.

The second major cell type found within the CNS is the neuroglial, or glial cell ([Table 31.1](#)). Four types of glial cells are found within the CNS: astrocytes, oligodendrocytes, microglial cells, and ependymal cells. Most neoplasms of the CNS arise from glial cells (astrocytes). Glial cells are smaller, outnumber neuronal cells, and lack dendritic and axonal processes. Although they do not participate in neuronal signaling, glial cells are essential for neuronal function. The role of neuroglia includes the maintenance of a proper ionic environment, the modulation of nerve cell electrical conduction, control of reuptake of neurotransmitters, and repair after neuronal injury.

TABLE 31.1

Glial Cells

Type	Major Functions
Astrocytes	Support (for neurons)
	Metabolic and nutritive functions

Ependymal cells	Probable role in cerebrospinal fluid production
Microglia	Phagocytosis
Oligodendrocytes	Insulation (form myelin sheath in the brain and spinal cord)
Schwann cells	Insulation (form myelin sheath in the peripheral nerves)

The astrocyte is the predominant glial cell. Astrocytes provide structural neuronal support, group and pair neurons and nerve terminals, regulate the metabolic environment, and are active in repair after neuronal injury.

Two distinct types of astrocytes exist: fibrous astrocytes, which are found in the white matter, and protoplasmic astrocytes, which are concentrated in the gray matter. Astrocytes have multiple processes that radiate from the cell, producing a star-shaped appearance. Some of these processes (astrocytic feet) terminate on the surfaces of blood vessels within the CNS (perivascular feet). The contact of the cerebral endothelium by astrocytes has been proposed to be essential in the development of the blood-brain barrier (BBB).¹

Oligodendrocytes have fewer branches than astrocytes (*oligo* meaning “few”; *dendro* meaning “branches”). Oligodendrocytes form the myelin sheath of axons in the brain and spinal cord and are capable of myelinating more than one axon. However, oligodendrocytes are incapable of division and fail to regenerate after injury.

The velocity of nerve impulse conduction in an unmyelinated axon increases with the square root of the diameter of the axon. Accordingly, a doubling of impulse conduction requires that the axon be doubled in size. One could only imagine the size of the peripheral nervous system without the presence of myelin. Myelin is essential to increase the velocity of impulse conduction and minimize the size of the axon.

Myelin is formed in the vertebral peripheral nervous system by modified glial cells termed *Schwann cells*.² Unlike the oligodendrocyte, the Schwann cell myelinates only one axon, surrounding the axon and forming successive layers of plasma membrane. The resultant thickness is variable in different axons. The junction between adjacent Schwann cells is devoid of myelin at 1-mm intervals along the length of the axon. This nonmyelinated portion of the axon, the node of Ranvier, is the site of electrical impulse propagation. Impulses in myelinated axons travel from one

node of Ranvier to another (saltatory conduction), bypassing the area between the nodes and increasing the velocity of conduction (see Fig. 31.1). Wallerian degeneration results in the distal degeneration of the axon after peripheral nerve injury. Proximal axon degeneration also may occur. Within 1 week of the initial injury, Schwann cells proliferate to form a tube into the area of degeneration, forming a scaffold to direct axon regeneration. Myelin regeneration precedes axon regeneration, with the myelin eventually reaching its previous thickness.

Microglial cells are the smallest neuroglial cells and are scattered throughout the CNS. They are transported throughout the CNS to sites of neuronal injury or degeneration, where they proliferate and develop into large macrophages that phagocytize neuronal debris.

Ependymal cells line the roof of the third and fourth ventricles of the brain and the central spinal canal. Ependymal cells form the cuboidal epithelium (choroid plexus), which secretes cerebrospinal fluid (CSF).

Blood-Brain Barrier

The injection of an intravenous dye causes most of the body tissues and internal organs to be stained; yet the brain and spinal cord remain unblemished. This finding led to the discovery of the BBB, which effectively isolates the brain and spinal cord extracellular compartment from the intravascular compartment.³

The BBB is essential for maintaining homeostasis within the CNS, and it is vital for proper neuronal function. The BBB is localized to microvascular endothelial cells that strictly control the passage of substances into and out of the CNS. Complex and continuous tight junctions and lack of fenestrae, combined with low pinocytotic activity, make the BBB endothelium a tight barrier for water soluble molecules. In combination with its expression of specific enzymes and transport molecules, the BBB endothelium is unique and distinguishable from all other endothelial cells in the body. A number of midline brain structures receive neurosecretory products from the blood and therefore lack a BBB. These structures, the circumventricular organs, include the area postrema, pituitary gland, pineal gland, choroid plexus, and portions of the hypothalamus.⁴

The BBB is incompletely developed in the newborn. The high vascular content of bile pigments in jaundiced newborns may enter the basal ganglia, producing kernicterus. BBB disruption can be caused by traumatic head injury, subarachnoid or intracerebral hemorrhage, or cerebral ischemia. The BBB can be disrupted in several disease processes such as multiple sclerosis, stroke, and brain tumors. Osmotically active substances may penetrate the brain or spinal cord after BBB disruption. Intentional intracarotid injection of a hyperosmolar solution crenates or shrinks the endothelial cells, opens tight junctions, and disrupts the BBB. This technique allows the delivery of chemotherapeutic drugs through the BBB for the treatment of neural malignancy.^{5,6}

Anatomy of the Central Nervous System

Cerebral Structures

The cerebral hemispheres are the most intricately developed and largest regions of the brain (Fig. 31.2). They contain the cerebral cortex, hippocampal formation, amygdala, and basal ganglia. The cerebral cortex consists of the outer 3-mm layer of the cerebral hemispheres. The surface of the cerebral cortex is convoluted, increasing the surface area of the cerebral hemispheres. Elevated convolutions called *gyri* are separated by shallow grooves called *sulci* and by deeper grooves called *fissures*.

FIGURE 31.2 Functional areas of the cerebral cortex.
(From Patton KT, Thibodeau GA. *Anatomy and Physiology*. 9th ed. St. Louis: Elsevier; 2016:458.)

The medial longitudinal fissure divides the cerebral hemispheres into right and left halves. The lateral fissure of Sylvius and the central sulcus of Rolando divide each hemisphere into four lobes, which are named for the cranial bones that overlie each area. The frontal lobe, essential for motor control, and the parietal lobe, essential for the senses of pain and touch, are separated by the

central sulcus. The cerebral cortex is divided into nearly 50 structurally distinct areas called *Brodmann areas* (Fig. 31.3). Voluntary muscle activity is controlled by the motor cortex located in the precentral gyrus, or Brodmann area 4. Brodmann areas 1, 2, and 3 make up primary somatosensory area 1, also referred to as the *somatosensory cortex*. This area contains a high degree of localization for various body parts, whereas areas 5 and 7 function as the somatosensory association area (Fig. 31.4). The sensations of touch, pain, and limb position, as well as the sensory perception of grasped objects, are controlled by the somatic sensory cortex located in the postcentral gyrus of the parietal lobe. The temporal lobe, which contains the auditory cortex, is separated from the frontal and parietal lobes by the Sylvian fissure. The occipital lobe lies posterior to the parieto-occipital sulcus. Here the visual cortex lies within the walls of the calcarine fissure on the medial brain surface.

FIGURE 31.3 Structurally distinct areas, called *Brodmann areas*, of the human cerebral cortex. Note specifically areas 1, 2, and 3, which constitute primary somatosensory area I, and areas 5 and 7, which constitute the somatosensory association area. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:611.)

FIGURE 31.4 Two somatosensory cortical areas, somatosensory areas I and II. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:611.)

The corpus callosum lies deep in the longitudinal fissure and contains commissural fibers that interconnect the cerebral hemispheres. These fibers arise from neurons in one hemisphere and synapse with neurons in the corresponding area of the adjacent hemisphere. The remaining major structures of the cerebral hemispheres include the basal ganglia, the amygdala, and the hippocampal formation. The basal ganglia are involved in the control of movement. The amygdala functions in the regulation of emotional behavior, response to pain, and appetite, and is essential in forming the response to stressors. The hippocampal formation is essential for memory formation and learning.

The diencephalon is located in the midline between the two cerebral hemispheres and contains the thalamus, hypothalamus, epithalamus, and the subthalamus. The oval-shaped thalamus integrates and transmits sensory information to various cortical areas of the cerebral hemispheres via separate thalamic nuclei. The hypothalamus is composed of several nuclei, including the mammillary bodies. The hypothalamus is the master neurohumoral organ.

The midbrain, pons, and medulla form the brainstem. The brainstem contains the reticular activating system, which functions to maintain consciousness, arousal, and alertness. The pons is anterior to the cerebellum, separated by the fourth ventricle,

connecting the medulla oblongata and the midbrain (Fig. 31.5). The pons contains ascending and descending fiber tracts and the nuclei of the trigeminal nerve (cranial nerve V) and the facial nerve (cranial nerve VII). The medulla extends from the pons to the foramen magnum, where it becomes continuous with the spinal cord (see Fig. 31.5). In addition to ascending and descending fiber tracts, the medulla contains respiratory and cardiovascular control centers and the vestibulocochlear nerve (cranial nerve VIII), the glossopharyngeal nerve (cranial nerve IX), the vagus nerve (cranial nerve X), the spinal accessory nerve (cranial nerve XI), and the hypoglossal nerve (cranial nerve XII) nuclei.⁷

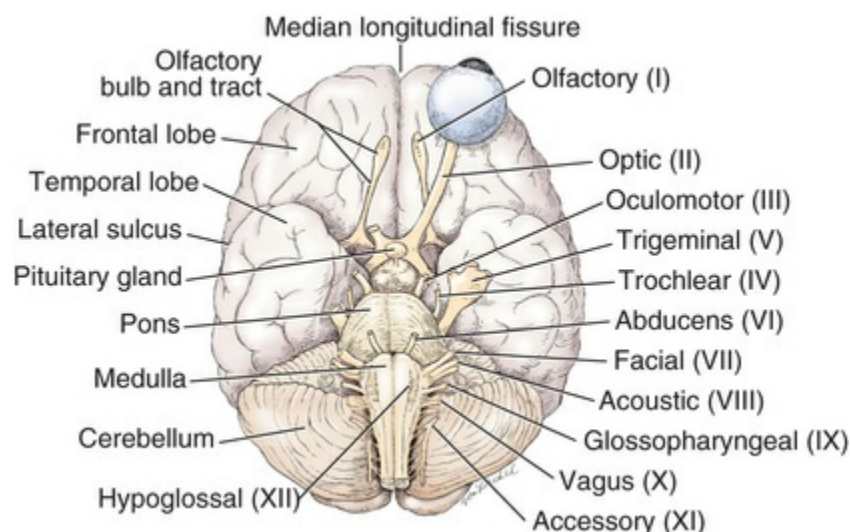

FIGURE 31.5 The pons and medulla and the origin of the cranial nerves.

The cerebellum appears convoluted and lies below the occipital lobe of the cerebral cortex and posterior to the pons and medulla. Structurally it resembles the cerebral cortex, containing an outer layer of gray matter and an inner core of white matter with several nuclei embedded within. The cerebellum can be divided into three functional areas. The flocculonodular lobe (archeocerebellum) actively maintains the equilibrium, and the paleocerebellum (anterior lobe and part of vermis) regulates muscle tone. The neocerebellum (posterior lobe plus most of the vermis) is the largest subdivision of the cerebellum and is essential in coordinating voluntary muscle activity. The cerebellum integrates information

received from other areas of the CNS and the peripheral nervous system. Information from the cerebellum is transmitted to the cerebral cortex and to lower motor neurons involved in the maintenance of muscle tone, equilibrium, and voluntary muscle activity.⁷

Meninges

The brain and spinal cord are enveloped by three meningeal layers: the dura mater, the arachnoid mater, and the pia mater (Fig. 31.6). The dura mater, the thickest of the meningeal layers, overlies the cerebral hemispheres and brainstem and is functionally separated into an outer periosteal layer (adherent to the inner cranium) and an inner meningeal layer. The dura mater forms a fold, the falx cerebri that functionally separates the cerebral hemispheres. A similar fold, the tentorium cerebelli, separates the occipital lobe and the cerebellum. The dura mater of the spinal cord is continuous with the meningeal layer of the cranial dura mater and the perineurium of the peripheral nerves. The first three cervical roots and the trigeminal nerve provide innervation of the dura mater. During awake craniotomy, the patient may complain of pain “behind the eye” when traction is applied to the dura.

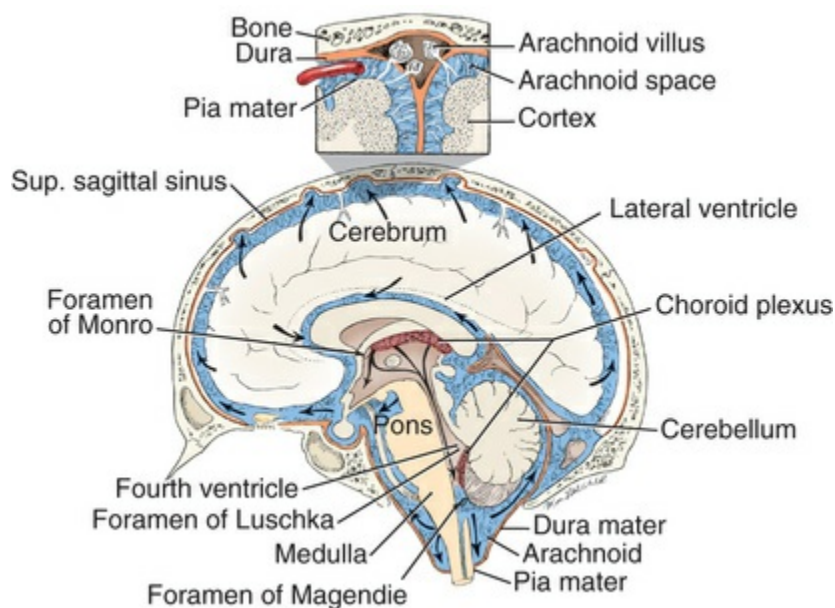

FIGURE 31.6 Meninges and the flow of cerebrospinal fluid through the ventricular system.

The arachnoid mater is a thin, avascular membrane joining the dura mater. The subdural space, a potential space between the dura mater and the arachnoid mater, is of clinical importance. The unintentional injection of a local anesthetic during spinal anesthesia into the subdural space produces patchy, asymmetric block. In addition, injury to a blood vessel in the subdural space can create bleeding (subdural hematoma), requiring surgical intervention.

The pia mater is a thin avascular membrane adherent to the brain and spinal cord. The subarachnoid space lies between the arachnoid mater and the pia mater. In the spinal cord, the subarachnoid space extends to the S2 to S3 level and is filled with CSF. In addition, the vasculature that overlies the CNS is located within the subarachnoid space. Injury to the vascular structures may produce subarachnoid hemorrhage and hematoma.

The epidural space is located above the dura but inside the spinal canal. The epidural space contains a venous plexus and epidural fat that provides protection of the neural structures. The distance from the skin to the epidural space may be as little as 3 cm or as large as 8 cm.

Cerebrospinal Fluid

Cerebrospinal fluid is contained within the ventricles of the brain, the cisterns surrounding the brain, and the subarachnoid space of the brain and spinal cord (see [Fig. 31.6](#)). The total volume of cranial and spinal CSF in the adult is approximately 150 mL. The specific gravity varies from 1.002 to 1.009, and the pH is 7.32. CSF bathes the brain and spinal cord, cushioning these delicate structures, and controls and maintains the extracellular milieu for neurons and glial cells.

FIGURE 31.16 The intracranial pressure-volume relationship. *CPP*, Cerebral perfusion pressure; *CSF*, cerebrospinal fluid. (From Miller RD, et al., eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015:2160.)

Cerebrospinal fluid is secreted by the ependymal cells of the choroid plexus within the ventricular system at a rate of approximately 30 mL/hr. Although CSF is isotonic with plasma, it is not a plasma filtrate. CSF concentrations of potassium, calcium, bicarbonate, and glucose are lower than their respective plasma concentrations, and concentrations of sodium, chloride, and magnesium are higher. The entire CSF volume is replaced every 3 to 4 hours. Normal CSF pressure is between 5 and 15 mm Hg. CSF flows from the lateral ventricles of the cerebral hemispheres through the foramen of Monro into the third ventricle, through the aqueduct of Sylvius in the midbrain, into the fourth ventricle. CSF enters the subarachnoid space through the medial foramen of Magendie and the paired lateral foramina of Luschka, openings posterior to the pons and anterior to the cerebellum.

The cisterna magna, located between the medulla and the cerebellum, is formed from the separation of the arachnoid mater from the pia mater and is filled with CSF. Two additional cisterns exist, the cisterna pontis and the cisterna basalis. CSF drains into the venous blood via the superior sagittal sinus and is absorbed by arachnoid granulations.

Spinal Cord

The spinal cord extends from the medulla at the foramen magnum to the filum terminale, a threadlike connective tissue structure that attaches to the first segment of the coccyx. Thirty-one pairs of spinal nerves carry motor and sensory information: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The first pair of cervical nerves exits the spinal cord between the base of the skull and the first cervical vertebra (atlas), and the remaining 30 pairs exit between adjacent vertebrae. All the exiting spinal nerves are covered with pia mater. Because the spinal cord is approximately 25 cm shorter than the vertebral canal in adults, the lumbar and sacral nerves have relatively long roots (the cauda equina). The spinal cord fills the canal in utero, but the canal elongates at a greater rate than does the neural tissue as the child ages, forming the cauda equina.

The spinal cord is divided into dorsal, lateral, and ventral regions by the entering dorsal sensory root fibers and the outgoing ventral motor root fibers. Neuron cell bodies and unmyelinated fibers lie in the H-shaped central gray region of the cord, surrounded by fiber tracts that form the white matter. Although it does not have a uniform appearance, this general arrangement continues throughout the entire spinal cord.

The spinal gray matter is divided into the ventral and dorsal gray commissures. The ventral projections of gray matter are called the *gray horns* or *columns*; the posterior projections are called the *posterior gray horns* or *columns*. Intermediolateral gray horns or columns are found between T1 and L2. The gray matter has been subdivided into 10 (I through X) laminae of Rexed. Rexed laminae I through VI are located in the dorsal (posterior) horn and contain cell bodies that receive sensory information from the periphery. Projections from the laminae form afferent tracts. A large number of interneurons are found in laminae V, VI, and X. Laminae VII, VIII, and IX make up the ventral (anterior) horn and contain motor neurons and interneurons involved in motor functions. The gray matter is enlarged in two areas of the spinal cord, C5 to C7 and L3 to S2. The cervical enlargement contains neuron cell bodies that innervate the upper extremities; the lumbosacral enlargement contains neuron cell bodies that innervate the lower extremities.

The tracts or fascicles that comprise the white matter are highly organized, similar to the organization of the cerebral cortex and

other areas of the brain. The dorsal white matter is composed almost exclusively of ascending sensory fiber tracts. The lateral and ventral white matter contain descending motor tracts. Commonly, fiber tracts at various levels within the spinal cord or brain decussate or cross over to the other side. As in the brain, spinal cord fiber tracts can be projection tracts connecting the spinal cord and brain, or they can be association (intersegmental, fasciculi proprii) tracts that originate and terminate entirely within the spinal cord. The association tracts play an important role in spinal reflexes.⁷⁻¹⁰

Shortly after emerging from the spinal cord, the meningeal coverings of the peripheral nerves merge with the connective tissue layers that cover the peripheral nerve. The outermost covering of the peripheral nerve is called the *epineurium*. The bundles or fascicles of axons in each nerve are covered by the perineurium, and each axon in a fascicle is surrounded by the endoneurium.

Peripheral nerves may be classified according to their diameter. Generally, the larger the diameter, the faster the conduction velocity; therefore A alpha fibers, the fibers with the largest diameters, have the fastest conduction velocity, and C fibers, which have the smallest diameter, have the slowest conduction velocity. Between the two extremes lie A beta, A gamma, A delta, and B fibers, in decreasing order of size and conduction velocity. The degree of myelination affects the conduction velocity of the nerves.

Peripheral Nervous System

The peripheral nervous system is divided into the somatic and autonomic nervous systems (Fig. 31.7). The somatic system contains sensory neurons for the skin, muscles, and joints. Somatic motor fibers arise from motor neurons in the ventral horn, their axons exiting the spinal cord via the ventral root. A few centimeters after emerging from the spinal cord, the somatic motor fibers join with incoming sensory fibers carrying information from afferent receptors (muscles, skin, tendons, and joints) to form a mixed nerve. As a mixed nerve approaches its site of innervation, the motor and sensory fibers separate.

FIGURE 31.7 Both divisions of the autonomic nervous system. *gang.*, Ganglion; *n.*, nerve.

Cranial nerves emerge from the cranium. Cranial nerves provide sensory and motor innervation for the head and neck. The sensory cranial nerves include the olfactory nerve (cranial nerve I), optic nerve (cranial nerve II), and vestibulocochlear nerve (cranial nerve

VIII); the motor cranial nerves include the oculomotor, trochlear, abducens, spinal accessory, and hypoglossal nerves; and the four mixed cranial nerves with both sensory and motor function are the trigeminal nerve (cranial nerve V), facial nerve (cranial nerve VII), glossopharyngeal nerve (cranial nerve IX), and vagus nerve (cranial nerve X). [Table 31.2](#) lists cranial and peripheral nerve fiber types, locations, and functions.

TABLE 31.2
Cranial and Peripheral Nerves

Fiber Type	Location	Information Conveyed
General somatic afferent	CN V, CN VII, CN IX, CN X, all spinal nerves	Pain, touch, temperature, pressure, and proprioception from muscles, tendons, and joint capsules
General visceral afferent	CN V, CN VII, CN IX, CN X, all spinal nerves	Conscious pain sensations
Special somatic afferent	CN II, CN VIII	Sight, hearing
Special visceral afferent	CN I, CN IX, CN X, CN VII (intermediate branch)	Olfaction, taste
Special visceral efferent	CN V, CN VII, CN IX, CN X, CN XI	Mastication, facial expressions
General somatic efferent	CN III, CN IV, CN VI, CN VII, all spinal nerves	Voluntary muscles (trunk and extremities), extrinsic muscles of eye, muscles of the tongue
General visceral efferent	CN III, CN VII, CN IX, CN X, spinal nerves T1 through L2 or L3, S2, S3, S4	Smooth muscle, cardiac muscle, some glands

CN, Cranial nerve.

The autonomic nervous system controls involuntary visceral functions and is composed of three subdivisions: the sympathetic, parasympathetic, and enteric nervous systems. The sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS) are functionally antagonistic.^{8,11} The SNS and PNS originate within the CNS and require two efferent neurons: a preganglionic neuron originating within the CNS and a postganglionic neuron terminating within the effector organ (smooth muscle, cardiac muscle, or sweat gland). Autonomic fibers originating in the brain arise from cell bodies located in the brainstem. PNS fibers supplying the lower gastrointestinal tract and genitourinary

systems arise from the sacral portion of the spinal cord.

Sympathetic Nervous System

Preganglionic neurons of the SNS originate in the intermediolateral gray horn of the spinal cord between the first thoracic (T1) and second or third lumbar vertebra (L2 or L3). The myelinated preganglionic axons (i.e., preganglionic fibers of the preganglionic neurons) exit the spinal cord via the anterior (ventral) nerve root. These processes leave the spinal cord by way of a small trunk, the white rami communicantes. A series of paired paravertebral ganglia is ranged bilaterally along the spinal cord (Fig. 31.8). All the paired segmental paravertebral ganglia are connected, forming the sympathetic trunks. These ganglia may contain the cell body of the second efferent neuron (postganglionic neuron). The preganglionic fibers of the preganglionic neuron enter the white rami communicantes and may synapse with the second efferent neuron located within the ganglion. The postganglionic fiber of the postganglionic neuron may either exit the gray ramus to enter a spinal nerve or may extend through a connection between the paravertebral ganglion and one of the three (celiac, superior, or inferior) mesenteric ganglia. The postganglionic fibers then synapse with the smooth muscle of the digestive tract and other abdominal organs. SNS preganglionic axons secrete acetylcholine at their ganglionic synapses, and postganglionic fibers secrete catecholamines.^{1,7,9}

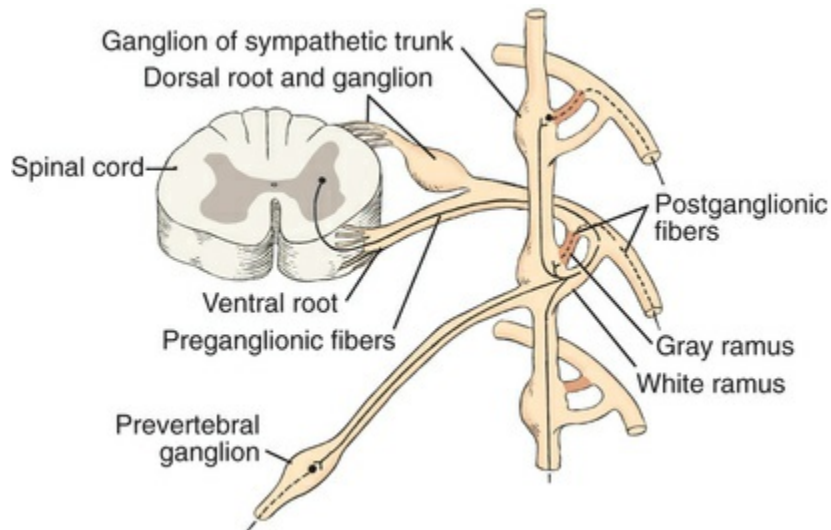

FIGURE 31.8 Sympathetic ganglia.

Usually one paravertebral ganglion is present for each spinal nerve, except in the cervical area, where they fuse to form two or three ganglia. On entering the sympathetic chain, the preganglionic fiber may synapse at the entry level or travel up or down the ganglionic chain before forming a synapse. Some preganglionic axons pass through the sympathetic chain without synapsing and, after leaving the chain, form a distinct nerve (e.g., splanchnic nerve) before synapsing in prevertebral ganglia, such as the superior or inferior mesenteric ganglia. Some preganglionic axons in the sympathetic trunk synapse with several postganglionic neurons located in several chain ganglia. This arrangement explains the manner in which a central SNS discharge spreads over several segments. After synapsing in the sympathetic chain, the postganglionic axons, which are unmyelinated, enter the spinal nerve through the gray ramus communicans and travel to the periphery.

The cervical ganglia are divided into superior, medial, and inferior cervical ganglia. The inferior cervical ganglion fuses with the first thoracic ganglion to form the stellate ganglion. Stimulation of SNS fibers from the superior cervical ganglion produces contraction of the radial muscle of the iris (mydriasis), relaxation of the ciliary muscle of the eye, and constriction of the blood vessels of the head. Destruction of the superior cervical ganglion, central SNS damage, or injury to other cervical paravertebral ganglia produces Horner syndrome, clinically distinguished by miosis, anhidrosis

(absence of sweating), and ptosis on the affected side. Ptosis is incomplete because the primary innervation to the levator palpebrae superioris muscle of the eyelid is through the oculomotor nerve, and only a few SNS fibers innervate this muscle.^{1,7,9}

Postganglionic fibers from the upper thoracic chain ganglia (stellate to T4 to T5) innervate the heart and lungs. β -Receptor stimulation produces an increased heart rate (positive chronotropic effect), an increase in conduction (positive dromotropic effect), and an increase in myocardial contractility (positive inotropic effect). Myocardial α -receptor stimulation produces coronary vasoconstriction. The resultant pulmonary effects also depend on the receptor type that is stimulated; bronchial dilation follows β_2 -receptor stimulation, and mild bronchoconstriction follows α -receptor stimulation.

The SNS fibers supplying abdominal and pelvic viscera (T5 through L3) pass through the chain ganglia forming the greater and lesser splanchnic nerves, which subsequently terminate in preterminal ganglia. Postganglionic fibers from the prevertebral ganglia, such as the superior and inferior mesenteric ganglia, travel to the abdominal and pelvic viscera. Stimulation of these SNS fibers activates liver glycogenolysis and gluconeogenesis, decreases secretions from pancreatic acinar cells and β -cells, initiates lipolysis, decreases the tone and motility of the gastrointestinal tract, contracts gastrointestinal sphincters, relaxes urinary smooth muscle, and increases renin secretion from the kidney.^{1,7,9}

Parasympathetic Nervous System

The efferent neurons of the parasympathetic subdivision are located in the gray matter of the midbrain and medulla. The preganglionic fibers exit the brain via cranial nerves II, VII, IX, and X. The remainder of the cell bodies of the first efferent neurons arise from the lateral horn of the sacral portion of the spinal cord (S2 through S5). Acetylcholine is secreted by both parasympathetic preganglionic and postganglionic fibers (see Fig. 31.8).

The second efferent neuron (postganglionic neuron) of the parasympathetic subdivision may be located in a small ganglion adjacent to the innervated organ or within the organ itself.

Preganglionic axons travel with the vagus to ganglia located near the organ they innervate. The postganglionic axons innervate the bronchioles, heart, coronary arteries, stomach, and large intestine up to the left colic flexure. PNS postganglionic fibers to the descending colon and the genitourinary systems are supplied by parasympathetic fibers from sacral segments of the spinal cord. Most of the parasympathetic preganglionic fibers originate at the S3 and S4 segments. Shortly after exiting the spinal cord with the spinal nerves, the preganglionic fibers form the pelvic nerves (nervi erigentes), which synapse in ganglia in close proximity to the innervated organ.^{1,7,9}

Vasculature of the Central Nervous System

The brain and spinal cord are dependent on an uninterrupted blood supply to deliver essential fuels, oxygen, and glucose (Fig. 31.9). The brain receives 15% of the cardiac output, or approximately 50 mL/100 g per min. The brain's blood supply originates from two arterial circulations that receive blood from two distinct systemic arteries: the anterior circulation receives blood from the internal carotid arteries, and the posterior circulation receives blood from the vertebral arteries. These arterial systems communicate through arterial anastomoses that form the circle of Willis. The paired anterior, middle, and posterior cerebral arteries originate from the circle of Willis. Although these arterial communications exist, under normal conditions, little mixing of blood flow occurs. Intraarterial contrast studies demonstrate that the carotid artery supplies the ipsilateral cerebral hemisphere, and the vertebrobasilar system supplies the structures of the posterior fossa.

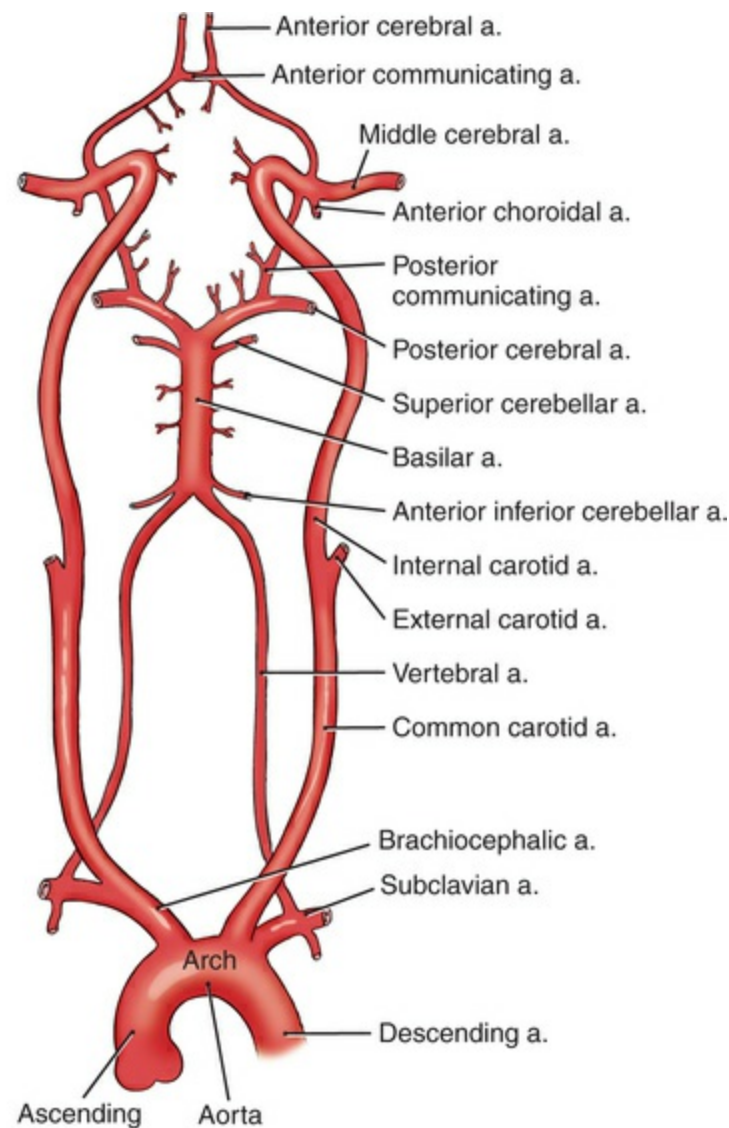

FIGURE 31.9 Cerebral vasculature. a, Artery.

The internal carotid arteries enter the skull through the foramen lacerum and bifurcate near the lateral border of the optic chiasm, forming the anterior and middle cerebral arteries. The anterior cerebral arteries supply the medial surface of the cerebral hemispheres, and the middle cerebral arteries supply the lateral surface of the hemispheres. The striate arteries, which are branches of the middle cerebral arteries, supply the internal capsule and its motor tracts. Cerebrovascular accidents commonly involve the striate arteries. Communicating arteries provide connections between the two anterior cerebral arteries of each hemisphere (anterior communicating arteries) and between the middle and posterior cerebral arteries (posterior communicating arteries).^{1,7,9}

The vertebral arteries, branches of the subclavian artery, enter the

cranium through the foramen magnum and join to form the basilar artery in the vicinity of the pons. Branches of the vertebral and basilar arteries supply a wide area, including the cervical region of the spinal cord, the brainstem, the cerebellum, the vestibular apparatus and cochlea of the inner ear, parts of the diencephalon, and the occipital and temporal lobes of the cerebral hemispheres.

Venous blood exits the brain via two separate systems. The blood from the cerebral and cerebellar cortex flows through veins on the surface and empties into overlying dural venous sinuses. Venous blood from the basal portions of the brain empties into the great vein of Galen and the straight sinus. These sinuses empty into the internal jugular veins. The superficial veins of the scalp are linked to the dural sinuses by the emissary veins.^{7,8}

Like the brain, the spinal cord receives blood from two arterial sources: the anterior and posterior spinal arteries, which are branches of the vertebral artery, and the radicular arteries, which are branches of segmental vessels (cervical, intercostal, and lumbar). The spinal cord blood supply is not continuous along its length, and although each spinal cord segment is perfused, blood is delivered preferentially by one of the supply sources. The cervical cord is supplied by the vertebral and radicular arteries, and the thoracic and lumbar cord is supplied by the radicular arteries arising from this respective region (intercostal and lumbar). Of particular importance is the radicular artery, the artery of Adamkiewicz, which enters the cord at approximately T7 and supplies the lumbosacral segment. Spinal cord segments that receive blood from one source are particularly prone to ischemic injury if this blood supply is interrupted. Interruption of the blood flow from the artery of Adamkiewicz results in paraplegia.^{1,7,9}

Electrophysiology

The physiologic basis for the propagation of a nerve impulse lies in the structural nature of the axolemma, the differential concentration of electrolytes within the axolemma and extracellular space, and the semipermeability of the axolemma to these specific ions. The resting nerve cell has a potential difference, or voltage, created by the asymmetric distribution of sodium and potassium ions. Sodium ions are tenfold richer in the extracellular medium, and potassium ions are tenfold richer in the intracellular medium. The resting membrane potential is created through the excess positive charges on the extracellular surface and excess negative charges on the interior of the cell membrane. The nerve cell is said to be *polarized* in the resting state.

In the resting state, the cell membrane permeability to sodium ions is low, so little movement of extracellular sodium ions to the cell interior occurs. Although larger than sodium ions, potassium ions are freely permeable through the axolemma, and their movement creates a net deficit of positive ions within the interior of the axolemma. This ionic asymmetry is maintained by the sodium-potassium adenosine triphosphate (ATP) pump. The distribution of ions outside the cell produces a negative resting membrane potential of approximately -60 to -90 mV.

Nerve impulses are transmitted through action potentials that are generated with membrane alterations in permeability of the axolemma to sodium and potassium ions. Depolarization occurs when a stimulus of sufficient intensity (threshold potential) increases membrane permeability to sodium ions, facilitating the passage of a greater number of sodium ions into the cell interior than potassium ions to the cell exterior. The lowering of the voltage difference of the axolemma occurs as a result of "gating," or the opening or closing of integral membrane proteins. Gating occurs in response to voltage differences across the axolemma (voltage-gated channel) or after the binding of a specific molecule to a receptor or channel protein (chemically gated channel, e.g., the binding of acetylcholine to the neuromuscular junction).^{1,7,9}

Sodium channels open when the threshold potential is reached,

facilitating a rapid influx of sodium into the axolemma interior and producing depolarization (Fig. 31.10). The initial flow of sodium ions results in the opening of additional sodium channels. The action potential develops as the cell interior undergoes a transition from negative to positive. At the peak of depolarization, the electrical potential is 30 to 40 mV higher than the cell exterior, and sodium channels close. The action potential develops because of the change from the resting potential of -60 to -90 mV to a peak of 30 to 50 mV at the completion of depolarization. The action potential cannot occur without the delivery of a stimulus, or critical threshold potential.

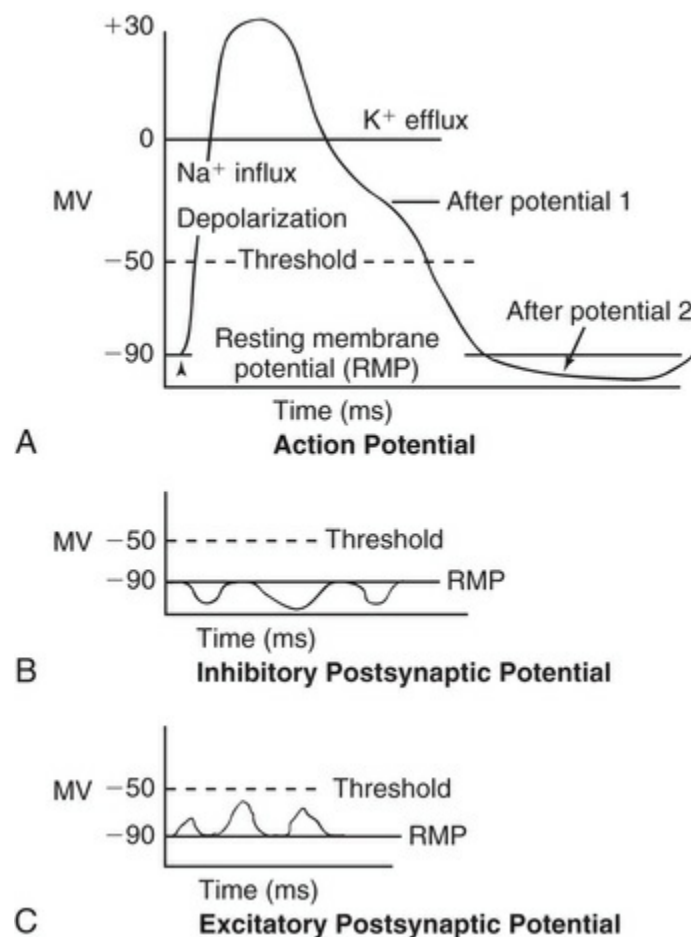

FIGURE 31.10 **A**, Phases of the action potential (AP) and major ionic movements during the AP. **B** and **C**, Subthreshold changes in the resting membrane potential.

For myelinated mammalian nerves, the threshold potential is 20 to 30 mV less than the resting potential. This threshold potential can

be modified by a variety of factors, including pH, partial pressure of oxygen (PO_2), and partial pressure of carbon dioxide (PCO_2). Alkalosis increases neuronal excitability, and hypoxemia and acidosis depress neuronal excitability.

After depolarization, cell repolarization is initiated with the closing of sodium channels and the opening of potassium channels, allowing the flow of potassium ions to the exterior of the axolemma to return the axon to the resting potential of -60 to -90 mV. The sodium pump is active in reestablishing this ionic asymmetry. During repolarization, the axon is refractory, or unable to respond to an additional stimulus, no matter how strong (it will not respond to an action potential). In the later phases of repolarization, the axolemma is in a state of ready refractoriness, that is, depolarization can be initiated only by a stimulus with an intensity greater than that which produced the original depolarization.

Chemical, mechanical, and electrical stimulation may elicit an action potential. Mechanical stimulation via pinching or crushing increases the membrane's permeability to sodium ions. The resulting change in ion permeability determines whether the postsynaptic neuron is either excited or inhibited.

Tissues whose sodium channels are not completely closed at rest (cardiac and smooth muscle) have a constant leak of sodium inside the cell, and excitation occurs by electrical stimulation to produce an action potential. Because these tissues repetitively discharge, they are described as having *rhythmicity*. The usual resting membrane potential of cells displaying rhythmicity is -60 to -70 mV. After stimulation, a wave of depolarization is transmitted to the axon terminal. At electrical synapses, the wave of depolarization crosses the 2-nm synaptic space and spreads to the postsynaptic cell (neuron or muscle cell).^{1,7,9}

Synaptic Transmission

After depolarization, the flow of information is transmitted to adjacent neurons at specialized membrane sites called *synapses* (see Fig. 31.1). Synapses are present on dendrites and axons. Synapses may be present on axon terminals of specific neurons in contact with endocrine glands (e.g., salivary glands) or skeletal muscle. The

neuron sending the information is the presynaptic neuron, and the receiving neuron is the postsynaptic neuron. Separating the presynaptic and postsynaptic neurons is a small intracellular space (the synaptic cleft). Most synaptic transmission occurs in the direction from the presynaptic to the postsynaptic neuron, but retrograde nerve impulse conduction is known to occur and modulates the strength of synaptic connections.

Synaptic transmission may be electrically or chemically mediated. Electrically mediated synapses are large compared with chemically mediated synapses. Electrical synapses have direct cytoplasmic continuity and no synaptic delay. Electrical synapses are excitatory in nature and are located in the CNS, peripherally in smooth muscle, and in cardiac muscle. Synaptic delays (delayed synaptic transmission) occur in chemically mediated transmission because of the transit time of the chemical mediator (specific neurotransmitter) from the presynaptic terminal to the postsynaptic membrane.

The majority of neurons in the CNS have chemically mediated synapses. The presynaptic neuron releases a neurotransmitter, a low-molecular-weight compound that diffuses across the synaptic cleft and binds to specific receptors on the postsynaptic membrane. Depolarization stimulates the uptake of calcium by the nerve terminal, fusing intracellular vesicles that contain the neurotransmitter to the presynaptic membrane. The neurotransmitters are subsequently released into the synaptic cleft. The neurotransmitter diffuses across the synaptic cleft, interacting with a specific postsynaptic receptor. Neurotransmitters that increase the permeability of the axolemma to sodium ions are excitatory (e.g., acetylcholine, glutamate); neuroinhibitory neurotransmitters (e.g., γ -aminobutyric acid [GABA], glycine) hyperpolarize the membrane by increasing the permeability to chloride ions. The neurotransmitter serotonin excites some neurons and inhibits others. The attachment of the neurotransmitter to the postsynaptic receptor can produce either an immediate (fraction of millisecond) or a delayed (from a few milliseconds up to seconds) effect on the postsynaptic membrane. The delayed transmission involves second messengers, such as cyclic adenosine monophosphate and cyclic guanosine monophosphate, which are

activated when the neurotransmitter attaches to the postsynaptic membrane.^{1,7,9}

Neurotransmitters

Neurotransmitters are molecules contained within the presynaptic neuron that are discharged in a calcium-dependent manner after presynaptic depolarization and that interact with specific receptors on the postsynaptic membrane. More than 100 molecules are deposited within the synapse via this mechanism. Acetylcholine is an excitatory neurotransmitter that interacts with both nicotinic and muscarinic receptors. Additional neurotransmitters include biogenic amines (e.g., epinephrine, norepinephrine, dopamine, serotonin, histamine), amino acids (e.g., aspartate, glycine, GABA, glutamate), neuropeptides (e.g., substance P, the opioids, several hormones), and the second messenger nitric oxide ([Table 31.3](#)).

TABLE 31.3

Common Neurotransmitters

Class	Neurotransmitter
Monoamines	Epinephrine
	Norepinephrine
	Dopamine
	5-Hydroxytryptamine (serotonin)
	Histamine
Amino acids	γ -Aminobutyric acid
	Glycine
	Glutamate
Neuropeptides	Calcitonin family
	Calcitonin
	Calcitonin gene-related peptide
	Hypothalamic hormones
	Oxytocin
	Vasopressin
	Hypothalamic releasing and inhibitory hormones
	Corticotropin-releasing factor (CRF or CRH)
	Gonadotropin-releasing hormone (GnRH)
	Growth hormone-releasing hormone (GHRH)
	Somatostatin
	Thyrotropin-releasing hormone (TRH)
	Neuropeptide Y family
	Neuropeptide Y (NPY)
	Neuropeptide YY (PYY)
	Pancreatic polypeptide (PP)
	Opioid peptides
	β -Endorphin (also a pituitary hormone)
	Dynorphin peptides
	Leu-enkephalin
Met-enkephalin	
Pituitary hormones	

	Adrenocorticotrophic hormone (ACTH) α -Melanocyte-stimulating hormone (α -MSH) Growth hormone (GH) Follicle-stimulating hormone (FSH) Luteinizing hormone (LH) Tachykinins Neurokinin A (substance K) Neurokinin B Neuropeptide K Substance P VIP-Glucagon family Glucagon Glucagon-like peptide (ARP) Bradykinin Cholecystokinin (CKK; multiple forms) Cocaine- and amphetamine-regulated transcript (CART) Galanin Chrelin Melanin-concentrating hormone (MCH) Neurotensin Orexins (or Hypocretins) Orphanin FQ (or Nociceptin) (also grouped with opioids)
Other	Acetylcholine Nitric oxide

VIP, Vasoactive intestinal peptide.

The synthesis of neurotransmitters occurs within the presynaptic neuron terminal. The neuron regulates the synthesis, packaging, release, and degradation of the synthesized neurotransmitter. The enzymes essential for the synthesis of neurotransmitters are obtained by axonal transport and taken into the nerve terminal by transport proteins. The synthesized neurotransmitter is then packaged into synaptic vesicles by membrane transport proteins.

Acetylcholine

Acetylcholine is an excitatory neurotransmitter that is released in many areas within the body. It is the predominant neurotransmitter within the CNS, at the neuromuscular junction, within all autonomic nervous system preganglionic fibers and postganglionic parasympathetic fibers, and within postganglionic sympathetic fibers innervating sweat glands. Acetylcholine is synthesized in the presynaptic nerve terminal from acetic acid, coenzyme A, and choline in the presence of the enzymes acetyl kinase and choline acetylase. This enzyme is also referred to as *choline acetyl transferase*. Acetylcholine is packaged in vesicles and stored in the presynaptic terminal. Calcium uptake into the presynaptic terminal is required

for acetylcholine release, and magnesium (Mg^{2+}) and manganese (Mn^{2+}) block the uptake of calcium (Ca^{2+}) and the subsequent release of acetylcholine. Acetylcholine interacts with the postsynaptic receptor for a few milliseconds before being hydrolyzed by acetylcholinesterase to acetic acid and choline. Both the acetic acid and the choline are taken up by the presynaptic nerve terminal and recycled.^{1,7,9}

Cholinergic receptors are classified as either nicotinic or muscarinic. Nicotinic receptors are found in autonomic ganglia and at the neuromuscular junction. Muscarinic receptors are found on smooth muscle, cardiac muscle, and sweat glands. Acetylcholine is the neurotransmitter at cranial nerve nuclei and ventral horn motor neurons of the spinal cord, including various collateral nerves to Renshaw cells (interneurons). Acetylcholine may be interactive in neuronal circuits involved with pain reception. Acetylcholine may also act as a sensory transmitter in thermal receptors and taste bud endings.

Biogenic Amines

The biogenic amines include epinephrine, norepinephrine, dopamine, serotonin, and histamine. The catecholamines epinephrine, norepinephrine, and dopamine are synthesized in a series of hydroxylation, decarboxylation, and methylation reactions from the amino acid phenylalanine, a precursor to tyrosine. The adrenal medulla secretes both epinephrine (75%) and norepinephrine (25%). Postganglionic adrenergic neurons secrete norepinephrine; norepinephrine and dopamine are probably neurotransmitters within the CNS. Amacrine cells of the retina and some neurons of the intrinsic nervous system of the intestine secrete dopamine. As with acetylcholine, the release of norepinephrine, epinephrine, and dopamine is calcium dependent. One notable difference from acetylcholine is that norepinephrine and dopamine act by means of second messengers (slow synaptic transmission), whereas most of the actions of acetylcholine are directly on ion channels (fast synaptic transmission). The duration of effect of catecholamines is regulated by presynaptic reuptake. Enzymatic breakdown of catecholamines by monoamine oxidase and catechol-O-methyltransferase within the liver is primarily responsible for

terminating their effects.

Dopamine is an inhibitory neurotransmitter and the predominant biogenic amine within the CNS. Dopamine is concentrated within the basal ganglia. Dopamine's inhibitory effects occur through action on adenylate cyclase.

Norepinephrine is concentrated in the reticular activating system and the hypothalamus. Norepinephrine acts as an inhibitory neurotransmitter, inhibiting impulses to the cerebral cortex.

Serotonin is an inhibitory neurotransmitter that influences behavior and mood. Histamine is also an inhibitory neurotransmitter concentrated within the hypothalamus and the reticular activating system. Histamine requires the second messenger cyclic adenosine monophosphate to mediate its inhibitory effects.^{1,7,9}

Amino Acids

Glutamate is the primary excitatory transmitter found within the cerebral cortex, the hippocampus, and the substantia gelatinosa of the spinal cord.¹² Glutamate plays a significant role in learning and memory (perhaps interactive in memory formation during awareness that occurs during anesthesia) and the appreciation of pain. Glutamate has also been implicated in excitotoxic neuronal injury after ischemic or traumatic brain injury.

Glutamate is formed from the deamination of glutamine supplied by the Krebs cycle. Glutamate may activate either an inotropic or a metabotropic amino acid receptor. *N*-methyl-D-aspartate (NMDA) receptors are ligand-gated inotropic receptors that produce a conformational change in the receptor, opening a sodium channel, which results in the depolarization of the postsynaptic membrane. The metabotropic receptor is an integral transmembrane receptor that regulates intracellular second messenger systems.¹³

GABA is the major inhibitory neurotransmitter found in the CNS. It is concentrated in the basal ganglia, cerebral cortex, cerebellum, and spinal cord. Activation of the GABA receptor opens neuronal membrane chloride channels, producing hyperpolarization (the hyperpolarized neuron is resistant to excitation). GABA is important in antagonizing the excitatory effects of amino acid neurotransmitters.¹⁴

Glycine is the primary inhibitory neurotransmitter in the spinal cord. In the past, glycine irrigation was employed during transurethral resection of the prostate. Postoperative visual impairment after the intravascular absorption of glycine suggests that glycine may act as an inhibitory neurotransmitter within the retina.

Neuropeptides

Neuropeptides have either excitatory or inhibitory physiological effects. Common neuropeptides include the opioids, substance P, and many pituitary and pancreatic islet hormones.

Substance P is an excitatory neurotransmitter found in the striatum and substantia nigra of the basal ganglia, hypothalamus, brainstem (raphe nuclei), and dorsal root ganglia of the spinal cord. Pain-fiber terminals that synapse with the substantia gelatinosa of the spinal cord release substance P.

The opioid neuropeptides include β -endorphin, enkephalins, dynorphins, and endomorphins. They act at opiate receptors distributed throughout the brain and spinal cord. Three classes of opiate receptors have been identified: delta, kappa, and mu. Dynorphin is a potent agonist at kappa receptors, and the enkephalins are agonists at delta and mu receptors. Opiate alkaloids like morphine interact with mu receptors. Morphine-like agents block slow pain pathways, raise the pain threshold, and modify the response to pain. Other effects, such as miosis and respiratory depression, result from the actions of these agents on opiate receptors located in the parts of the brain that control these functions.^{2,10,15}

Sensory Pathways

Sensory or afferent pathways transmit pain, temperature, pressure, touch, vibratory sense, and proprioceptive information to the CNS. Sensory pathways also include the special senses of vision, taste, hearing, smell, and equilibrium.

Receptors for pain and temperature are located in the epidermis and the dermis; those for pressure, touch, vibratory sense, and proprioception are located in the dermis. Receptors can be classified as (1) exteroceptors, which are located near the surface of skin and oral mucosa, and (2) proprioceptors, which are located in deeper skin layers, joint capsules, ligaments, tendons, muscles, and periosteum. Several types of receptors exist. Pacinian corpuscles are receptors for vibration and pressure. Free nerve endings, Ruffini corpuscles, muscle spindles, and Golgi tendon organs are involved in movement sense. The receptors for light (or crude) touch sensations include Merkel disks, Meissner corpuscles, and the nerve plexuses surrounding some hair roots. Fibers travel from these receptors to a ganglion, where they synapse with first-order neurons, the fibers of which continue to the CNS. Fibers from receptors in the trunk and extremities travel to the dorsal root ganglion, where they synapse with first-order neurons. Most of the sensory fibers from the head, excluding those from the special sense organs (hearing, equilibrium, vision, taste, and smell), synapse in first-order neurons located in the semilunar or trigeminal ganglion.^{10,11}

Pain and Temperature Pathways

Pain and temperature fibers from the head synapse in the trigeminal ganglion and enter the pons, forming the trigeminal nerve (cranial nerve V). These fibers subsequently synapse with second-order neurons in the nucleus of the descending tract of cranial nerve V. The second-order axons cross to the ventrolateral side and ascend as the ventral trigeminal tract to the ventral posteromedial nucleus of the thalamus, where they synapse with third-order neurons. From the ventral posteromedial thalamic

nucleus, third-order axons ascend in the internal capsule and end in the postcentral gyrus of the cerebral cortex, which is the primary somatic sensory area of the brain.

Pain and temperature receptors in the skin of the trunk and extremities send signals to the spinal cord via the dorsal roots of the spinal nerves. The majority of these dorsal root sensory nerve fibers terminate in the dorsal horn on laminae I, IV, V, and VI (Fig. 31.11). This is the origination site of the anterolateral pathway for signal transmission up the spinal cord to the brain.¹⁶ From this point in the dorsal horn, the anterolateral fibers decussate (cross) in the ventral commissure to the opposite anterior and lateral white columns (Fig. 31.12). The fibers then ascend cephalad via the anterior spinothalamic and lateral spinothalamic tracts to the ventral posterolateral thalamic nucleus, where they synapse with third-order neurons. Axons from the third-order neurons travel in the posterior limb of the internal capsule and ultimately synapse in the postcentral gyrus, where sensations of pain, temperature, touch, and pressure are interpreted, and responses to the sensations are initiated.

FIGURE 31.11 Cross-section of spinal cord, showing the anatomy of the cord gray matter and of ascending sensory

tracts in the white columns of the spinal cord. (From Hall JE,
Guyton and Hall Textbook of Medical Physiology. 13th ed. Philadelphia:
Elsevier; 2016:609.)

FIGURE 31.12 Pain, temperature, and crude sensations travel via the anterior spinothalamic and lateral spinothalamic tracts. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:610.)

Some pain and temperature fibers in the dorsal horn bifurcate into branches that synapse with internuncial (messenger) neurons. The internuncial neurons have axons that synapse with motor neurons in the ventral horn, which are not necessarily at the same level of the spinal cord. The axons can cross over and travel up or down the spinal cord before synapsing. These circuits are part of the reflex response to pain, which results in a rapid, automatic response to nociceptive stimuli.

The afferent fibers from each dorsal root ganglion come from a relatively limited area of the skin termed a *cutaneous dermatome*. Some overlap exists, so if a spinal nerve that supplies a certain dermatome is severed, pain and temperature sensations from that dermatome are supplied by adjacent dermatome fibers. For example, if T6 is severed, T5 and T7 sensory neurons carry pain and temperature sensations from the skin area supplied by T6. Axons entering the dorsal horn from the dorsal root ganglion send branches to one spinal segment above and one segment below in the dorsolateral column of Lissauer.^{2,9,11,17}

Pressure and Crude Touch

Nerve fibers that mediate pressure and light touch from the head synapse with first-order neurons in the trigeminal ganglion. From the trigeminal ganglion, first-order axons travel to the pons, where they synapse with second-order neurons in the sensory nucleus of cranial nerve V. From the sensory nucleus of cranial nerve V, second-order axons form the dorsal trigeminal tract, which has both crossed and uncrossed fibers. The second-order fibers terminate in the ventral posteromedial nucleus of the thalamus. Third-order axons from the ventral posteromedial nucleus subsequently terminate in the postcentral gyrus of the cerebral cortex.

After leaving the dorsal root ganglion, light touch and pressure fibers from the extremities and trunk enter the dorsal white column on the ipsilateral side and bifurcate (see [Fig. 31.12](#)). One branch

immediately enters the dorsal gray horn and synapses with second-order neurons. The other branch ascends for up to 10 spinal segments before synapsing with the second-order neurons in the dorsal horn. Second-order axons from both branches cross over and enter the ventral white column, forming the ventral spinothalamic tract, which ascends to the thalamus and synapses with third-order neurons in the ventral posterolateral nucleus. Tertiary axons travel through the internal capsule to the postcentral gyrus.

Owing to the branching arrangement of the first-order fibers from the trunk and extremities, injuries to the spinal cord rarely result in the total loss of these two sensations. Each cerebral cortex receives both crossed and uncrossed pressure and light-touch fibers from the face; as a result, damage to the postcentral gyrus on one side does not result in loss of pressure and light touch sensations to the face, even though these sensations are lost on the trunk and extremities of the contralateral side.^{2,10,11,17}

Vibratory Sense, Proprioception, and Discriminatory Touch

Proprioceptive fibers from muscles of the face involved in facial expression and mastication synapse in cell bodies located in the mesencephalic nucleus of the midbrain. Little is known about the complete functioning of the pathway.

Fibers from the trunk and extremities carrying proprioceptive, vibratory, and discriminatory (fine) touch sensations synapse with neuron cell bodies in the dorsal root ganglion. From the dorsal root ganglion, first-order axons enter the dorsal white column and immediately ascend to the medulla (Fig. 31.13). The fibers are somatotopically organized in the white columns. Axons from the lumbar and sacral parts of the spinal cord travel medially in the fasciculus gracilis, and fibers from the cervical and thoracic areas of the cord are located laterally in the fasciculus cuneatus of the dorsal white column of the spinal cord. Each fasciculus terminates in its respective medullary nucleus; for example, the fasciculus gracilis terminates in the nucleus gracilis. Second-order axons decussate after leaving their medullary nucleus and form a bundle termed the *medial lemniscus*, which terminates in the ventral posterolateral

thalamic nucleus. Third-order fibers from the ventral posterolateral nucleus terminate in the postcentral gyrus.^{2,10,11,17}

FIGURE 31.13 Vibration, proprioception, and fine tactile sensations travel via the dorsal column[en dash]medial lemniscal system. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:610.)

There are important distinctions to be made between the *dorsal column medial lemniscal system* and the *anterolateral system*. The differences actually determine the types of sensory information that can be transmitted by the two systems. The dorsal column medial lemniscal system is composed of large myelinated fibers with a high degree of spatial orientation that is maintained from their origin in the dorsal root to their termination in the thalamus. Therefore sensations that must be transmitted rapidly with a high degree of localization to the stimulus travel via the dorsal column. The anterolateral system, on the other hand, is composed of smaller myelinated nerve fibers with less spatial orientation. Hence, the anterolateral system transmits a wider variety of sensations, at a slower velocity, and with less specificity than the dorsal column system.¹⁶ A summary of the different sensations transmitted between the two systems is shown in [Box 31.1](#).

Sensations Transmitted Through the Dorsal Column–Medial Lemniscal System and Anterolateral System

Dorsal Column–Medial Lemniscal System

- Touch sensations requiring high degree of localization of the stimulus
- Touch sensations requiring transmission of fine gradations of intensity
- Phasic sensations, such as vibratory sensations
- Sensations that signal movement against the skin
- Position sensations from the joints

- Pressure sensations related to fine degrees of judgment of pressure intensity

Anterolateral System

- Pain
- Thermal sensations, including both warmth and cold sensations
- Crude touch and pressure sensations capable only of crude localizing ability on the surface of the body
- Tickle and itch sensations
- Sexual sensations

From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:573.

Pupillary light and accommodation reflexes are mediated through the Edinger-Westphal nucleus and cranial nerve III. Pupillary dilation is produced by postganglionic sympathetic fibers from the superior cervical ganglion that travel with branches of the internal carotid artery to the radial muscle of the iris.^{2,10,11,17}

Motor Pathways

Motor, or efferent, pathways transmit information from the brain to the voluntary muscles of the body, to smooth and cardiac muscles, and to some glands. The corticospinal tracts supply the voluntary muscles of the trunk and extremities; nine cranial nerves supply the voluntary muscles of the head and neck. Autonomic preganglionic fibers arise in the brain and spinal cord and transmit efferent signals to smooth muscle, cardiac muscle, and some glands (lacrima, bronchial).¹⁰

Corticospinal Tract

The corticospinal tract originates in large, upper motor neurons located in the precentral gyrus of the frontal lobe (Fig. 31.14). These neurons are arranged in a specific manner. Neurons supplying voluntary muscles of the head are found in the precentral gyrus near the lateral fissure of Sylvius, and those innervating the legs and feet are found in an area of the gyrus near the median longitudinal fissure. All parts of the body are represented in the gyrus. However, areas that perform complex movements (such as the hands when writing, typing, or playing the piano) have a larger area in the gyrus than other parts of the body not involved in intricate movements. Many of the upper motor neurons are shaped in the form of a pyramid.

FIGURE 31.14 Corticospinal tracts. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:709.)

Axons travel from the pyramidal cells through the internal capsule, the major pathway for ascending and descending fibers between the cortex and other sites in the CNS. The internal capsule has three parts: the anterior limb, the posterior limb, and the genu, which lies between the anterior and posterior limbs. Fibers in the internal capsule are highly organized. Motor fibers to all parts of the body except the face are located in the anterior limb and part of the posterior limb. Fibers supplying the face are located in the genu. From the internal capsule, the axons travel through the midbrain (basis pedunculi) to the medulla, where approximately 90% of the fibers decussate, forming the pyramids of the medulla. The corticospinal tract is frequently called the *pyramidal tract*, either because of the shape of the upper motor neurons or because of the site at which the fibers decussate in the medulla. The fibers that cross over form the lateral corticospinal tract. Axons from the

lateral corticospinal tract continue their descent to the spinal cord. At each level of the cord, some fibers leave the lateral corticospinal tract and enter the ventral horn gray matter, where they synapse with lower motor neurons. The fibers that do not decussate (approximately 10%) in the medulla continue to the spinal cord as the ventral corticospinal tract. The ventral corticospinal tracts cross over before synapsing with lower motor neurons in the gray matter. Axons from the lower motor neurons travel in the spinal nerves to innervate voluntary muscle.

A few corticospinal tract neurons are located anterior to the precentral gyrus. Axons from these neurons have an inhibitory effect on the lower motor neurons because they prevent them from discharging excessively. Damage to these suppressor fibers can stimulate the lower motor neurons either to overfire, resulting in hyperreflexia, or to discharge simultaneously, causing spasticity. Damage to the corticospinal tract anywhere along its route to the spinal cord can cause upper motor neuron paralysis. If the injury occurs above the decussation in the medulla, the paralysis is on the opposite side of the body. Paralysis occurs on the same side of the body if the damage occurs below the medulla. With upper motor neuron paralysis, reflexes are intact, but suppressor-fiber activity is impeded. As a result, hyperreflexia is present, and the upper motor neuron paralysis is spastic. Damage to lower motor neuron cell bodies in the ventral horn or ventral root fibers produces lower motor neuron paralysis, a flaccid type of paralysis. Cerebral palsy and amyotrophic lateral sclerosis are diseases that affect the corticospinal tracts.^{2,7,9,10}

Motor Innervation to the Head

Upper motor neurons whose axons supply the voluntary muscles of the head are found in the precentral gyrus next to the lateral fissure of Sylvius. The cell bodies, whose axons supply the extrinsic muscles of the eye, are located in the middle frontal gyrus. Axons from both areas form the corticobulbar tracts, which travel through the genu of the internal capsule to the brainstem, where they synapse with neurons located in nuclei spread throughout the brainstem. Axons from these neurons form many of the cranial nerves.

Axons originating from neurons located in the midbrain form the oculomotor and trochlear nerves (Fig. 31.15). The oculomotor nerve innervates most of the external muscles of the eye (inferior oblique and the inferior, medial, and superior rectus muscles), along with the levator palpebrae superioris muscle, which raises the upper eyelid. The trochlear nerve innervates the external oblique muscle of the eye. Three other groups of nuclei have neurons whose axons form the trigeminal, abducens, and facial nerves. The trigeminal nerve innervates part of the soft palate and all the muscles of mastication. The abducens innervates the lateral rectus muscle of the eye, and the facial nerves supply all the muscles involved in facial expression.

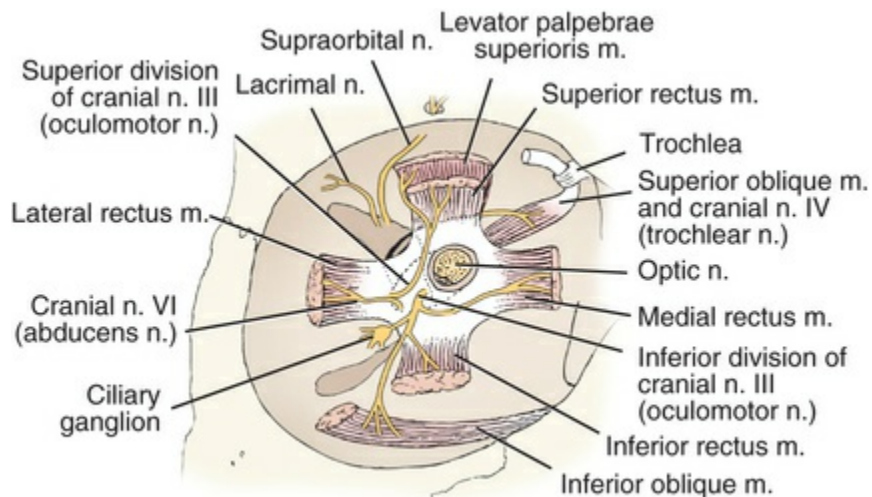

FIGURE 31.15 Frontal view of the posterior orbit with its motor nerves and the extraocular muscles. *n.*, Nerve; *m.*, muscle.

Axons from neurons located in medullary nuclei form the glossopharyngeal, vagal, accessory, and hypoglossal nerves. Both the glossopharyngeal and vagal nerves arise from the ambiguous nucleus. The glossopharyngeal nerve supplies the stylopharyngeal muscle of the pharynx, and the vagal nerve innervates the muscles of the throat involved in swallowing and phonation. All the tongue muscles are supplied by the hypoglossal nerve. The accessory nerve innervates the trapezius and sternocleidomastoid muscles of the neck. With the exception of the facial and hypoglossal nerves, the remaining nerves receive information from both the right and the

left corticobulbar tracts. The nuclei of facial nerve fibers to the upper part of the face receive axons from the left and right corticobulbar tracts; the facial nerve nuclei whose fibers supply the lower part of the face receive fibers only from the contralateral corticobulbar tract. The nuclei from the origin of the hypoglossal nerves receive innervation from only the contralateral corticobulbar tract.^{2,10,11,17}

Subcortical Motor Areas

Several motor areas in the brain are outside the cerebral cortex. For the most part, these are relatively primitive motor areas that have a modulating influence on motor function. Included in the subcortical motor areas are the basal ganglia, the nucleus of Luys, the red nucleus (nucleus ruber), the substantia nigra, and the reticular formation.

The basal ganglia lie deep within the cerebral hemispheres at the level of the internal capsule. They are composed of three nuclei: the globus pallidus, the putamen, and the caudate, which are collectively termed the *corpus striata*. The globus pallidus and the putamen are sometimes termed the *lentiform nucleus*. The globus pallidus makes up the paleostriatum, and the other two nuclei are part of the neostriatum.

The globus pallidus receives input from the motor cortex and from the other basal ganglia; it sends fibers to the subcortical motor areas. The globus pallidus is connected to the thalamus by two tracts, the ansa lenticularis and the lenticular fasciculus, which merge as they enter the thalamus to form the thalamic fasciculus. The thalamus forms a feedback process by sending fibers to the caudate nucleus and motor cortex. In this way, the motor activity of the basal ganglia can be influenced by the motor cortex without the presence of direct connections between the two structures. Dopamine, an important neurotransmitter in the basal ganglia, is produced in the substantia nigra of the midbrain and then travels by axonal transport to the caudate nucleus and the putamen.

The subthalamic nucleus of Luys is located in the diencephalon and is connected to other subcortical motor areas. Lesions in this nucleus result in a suppression of motor activity.

Three motor areas are located in the midbrain: the red nucleus,

the substantia nigra, and the reticular formation. The red nucleus is located at the level of the corpora quadrigemina and gives rise to the crossed rubrospinal tract. When stimulated, this tract excites alpha and gamma flexor motor neurons and inhibits extensor motor neurons. The reticular formation consists of a diffuse collection of neurons found throughout the brainstem and into the diencephalon. Two major tracts arise from the reticular formation. One tract is the uncrossed medial reticulospinal tract, which excites alpha and gamma extensor motor neurons and inhibits flexor motor neurons when stimulated. The second tract is the lateral reticulospinal tract, which contains crossed and uncrossed fibers and activates alpha and gamma flexor motor neurons and inhibits extensor motor neurons when stimulated.

Lesions contained within the subcortical motor areas produce diseases characterized by disturbed muscle tone and dyskinesia (abnormal involuntary movements). In Parkinson disease, the globus pallidus and substantia nigra are affected. Huntington chorea involves atrophy of the caudate nucleus and putamen, as well as degeneration of cortical neurons. Other diseases that involve subcortical motor nuclei include athetosis, dystonia, ballismus, and Sydenham chorea.^{2,10,11,17}

Neuroanesthesia

Creating a comprehensive plan to care for patients having neurosurgical procedures should include comorbid disease states, positioning and surgical approach. An overview of the effects of anesthetic agents on cerebral blood flow (CBF), cerebral metabolic rate of oxygen consumption (CMRO₂), and intracranial pressure (ICP) is discussed below. The remainder of this chapter provides a general discussion of the preoperative, intraoperative, and immediate postoperative care associated with common intracranial surgical procedures.

Effects of Anesthetic Agents on Cerebral Physiology

CBF, cerebral blood volume (CBV), ICP, CMRO₂, and cerebral compliance all must be considered in concert with pharmacologic principles in the design of a neurosurgical anesthetic regimen (Table 31.4). These factors have a dramatic effect of cerebrovascular tone, blood flow and oxygen delivery.

TABLE 31.4
Effects of Anesthetics on Cerebral Dynamics

Drug	Cerebral Blood Flow	CMRO ₂	Intracranial Pressure	Cerebral Perfusion Pressure

From Zaglaniczny KL, Aker J, eds. *Clinical Guide to Pediatric Anesthesia*. Philadelphia: Elsevier; 1999:176; Matsumoto M, Sakabe T. Effects of anesthetic agents and other drugs on cerebral blood flow, metabolism, and intracranial pressure. In Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*: 6th ed. Edinburgh: Elsevier; 2017:74–91.

Inhalation Agents

The majority of anesthetic agents influence ICP by decreasing cerebrovascular resistance through cerebrovascular dilation and by dose-dependent impairment of autoregulation, producing increases in ICP and CBV and a decrease in $CMRO_2$. The changes in ICP are frequently greater in patients who have an underlying increase in ICP.^{18,19} Inhalation agents decrease mean arterial pressure (MAP) and increase ICP, reducing cerebral perfusion pressure (CPP).^{20–22} Isoflurane produces the greatest increases in CBF and ICP, followed by sevoflurane and desflurane.^{18,23–25}

Cerebral blood flow in humans is unaltered with isoflurane-inspired concentrations of 0.6 to 1.1 minimum alveolar concentration (MAC); however, 1.6 MAC isoflurane doubles CBF. Animal studies have shown that isoflurane may enhance the carbon dioxide (CO_2) reactivity of the cerebral vessels. Cerebral autoregulation is impaired with concentrations exceeding 1 MAC.^{26,27} $CMRO_2$ is depressed with isoflurane, as with all potent inhalation anesthetics, and progressive metabolic depression occurs with concentrations of isoflurane greater than 1 MAC until the electroencephalograph (EEG) becomes isoelectric at approximately 2.5 MAC.^{28,29} These properties suggest that clinically relevant doses may provide a neuroprotective effect against ischemic insults, as demonstrated in human studies of critical regional CBF during carotid clamping.³⁰ Although strong experimental data support a neuroprotective potential of several anesthetic agents, consistent long-term protection by either agent has not been demonstrated. Unfortunately, there is a lack of clinical studies to support the use of any one anesthetic agent over the others. Proposed mechanisms related to the neuroprotective effect of inhalation anesthetic agents include activation of ATP-dependent potassium channels, up-

regulation of nitric oxide synthase, reduction of excitotoxic stressors and cerebral metabolic rate, augmentation of peri-ischemic cerebral blood flow and up-regulation of antiapoptotic factors including mitogen-activated protein kinases.³¹ Activation of intracellular signaling cascades that lead to altered expression of protective genes may also be involved.³² The high concentrations of isoflurane necessary for abolishing cortical activity have no toxic effect on cerebral metabolic pathways.^{29,33} The majority of human studies show that inspired concentrations of isoflurane of less than 1% have minimal effect on ICP and that any increase in ICP is attenuated by mild hyperventilation. An exception to this generalization is that some patients with malignant brain tumors may show increases in ICP despite hyperventilation, particularly if computed tomography (CT) shows a midline shift.³⁴⁻³⁶

Desflurane is unique among the potent inhalation agents in that its low blood/gas solubility facilitates a rapid emergence, which may be useful for immediate postoperative neurologic evaluation. Desflurane has effects on EEG, CBF, and CMRO₂ similar to those of isoflurane. Young³⁷ and Ornstein et al.³⁸ compared the effects of desflurane and isoflurane on CBF at two concentrations, 1 MAC and 1.5 MAC, in an air-oxygen mixture during hypocapnia and reported no difference between isoflurane and desflurane at the two different MAC levels. Holmström and Akeson³⁹ reported that desflurane was associated with more CBF than isoflurane at the same depth of anesthesia. However, the results of ICP studies are not as definitive. Muzzi et al.⁴⁰ reported that desflurane 1 MAC in an air-oxygen mixture with an arterial CO₂ tension (PaCO₂) of 26 mm Hg resulted in sustained increases in ICP until the dura was incised. The physiologic effects of sevoflurane are similar to those of other inhalation anesthetics, but some consider sevoflurane less vasoactive than isoflurane or desflurane.⁴¹ In summary, all inhalational agents are known to increase CBF, CBV, and ICP. Mild hyperventilation attenuates these dose-dependent increases in ICP. Isoflurane, desflurane and sevoflurane all preserve cerebrovascular carbon dioxide reactivity. They are all concentration-dependent cerebral vasodilators and decrease CMRO₂. Sevoflurane induces the smallest cerebral vasodilatation and preserves cerebral autoregulation up to 1.5 MAC, compared to isoflurane and

desflurane which impair it upon 1 MAC. In intracranial surgery, inhaled agents can be used as a maintenance anesthetic with a preference for sevoflurane.²⁴

The use of nitrous oxide (N₂O) in intracranial procedures continues to be a controversial area for clinical practice. N₂O can produce increases in CBF, CMRO₂, and ICP. The effect of N₂O on cerebral dynamics varies widely and is influenced by what drugs are coadministered, the doses of each, and body temperature. Concomitant hyperventilation or the administration of one of several intravenous anesthetics (barbiturates, propofol, benzodiazepines, opioids) can reduce the increases in CBF and CMRO₂ during N₂O administration. However, the combination of N₂O and volatile anesthetics behaves much differently.

Administering a volatile anesthetic in low doses (below 1 MAC) may decrease CBF and CMRO₂. The addition of 50% N₂O with less than 1 MAC of the volatile anesthetic produces increases in both CBF and CMRO₂. The cerebral vasodilation produced by N₂O is greater when increasing doses (greater than 1 MAC) of the volatile anesthetic are administered. N₂O may increase CBF by 100% or more at approximately 0.5 MAC. N₂O appears to produce nonuniform changes in CBF, increasing flow in anterior regions and decreasing flow in posterior brain regions. N₂O is not thought to affect CBV or CSF dynamics.⁴²⁻⁴⁶

Many clinicians have advocated that N₂O should no longer be administered in neurosurgical patients. However, there is little scientific evidence that N₂O produces significant neurotoxicity during limited periods of exposure. Typically, only very small amounts of N₂O are broken down in the body, but when used on long cases (over 12 hours), substantial accumulation of metabolic breakdown products may occur. These metabolites have been associated with megaloblastic anemia, leukopenia, impaired fetal development, and a depressed immune system. Circumstances in which the practitioner should consider eliminating the use of N₂O

Box 31.2 in Box 31.2.

Neurosurgical Considerations for Omitting the Use of Nitrous Oxide

- In the presence of intracranial air (recent craniotomy, craniofacial trauma)
- When signal quality during intraoperative evoked potential monitoring is inadequate
- When the patient has clinical evidence of moderate to severe increases in ICP
- When a “tight-brain” is clinically appreciated during the intraoperative period
- When the duration of the case is greater than 8 hours

ICP, Intracranial pressure.

N₂O is more soluble than nitrogen and expands closed-gas spaces. Its use should be restricted in patients with an intracranial or intravascular air compartment such as pneumocephalus.⁴⁷ Some practitioners discontinue N₂O before closure of the dura to attenuate the development of iatrogenic pneumocephalus.

Intravenous Agents

Propofol is a popular induction and maintenance agent for neurosurgical patients. It is very useful in patients with intracranial pathologic conditions, provided that hypotension is prevented. The cerebral effects are a dose-dependent reduction in CBF and CMRO₂. The reductions are usually in the 40% to 50% range. CPP may decrease because of reductions in blood pressure after bolus induction doses; however, the reduction in CBF appears to be independent of systemic hemodynamic changes.^{48,49} They are most likely due to the metabolic depressant effect and cerebral vasoconstriction.^{50,51} Reductions in systemic blood pressure produce corresponding reductions in CPP.

Etomidate, like other CNS depressants, reduces CMRO₂ and CBF. Etomidate produces cerebral vasoconstriction, which results in the reduction of ICP without reducing CPP.⁵²⁻⁵⁴ Major disadvantages include a high incidence of myoclonia, thrombophlebitis, nausea,

vomiting, and suppression of the adrenocortical response to stress.^{54,55} Many clinicians feel that etomidate should be avoided in brain-injured patients. Although it is considered as an induction drug of choice in situations of hemodynamic compromise, prolonged adrenal insufficiency is a major concern. Adrenal insufficiency is of special concern in critically ill patients, with sepsis and traumatic brain injury. Etomidate should be replaced by an amnestic dose of a benzodiazepine in combination with an opioid or ketamine to facilitate endotracheal intubation. If etomidate is used, empirical adrenal replacement therapy for 24 hours should be considered.⁵²

Dexmedetomidine is gaining popularity in neuroanesthesia and neurocritical care practice. This presynaptic α_2 -adrenergic receptor agonist offers a unique “cooperative sedation,” anxiolysis, and analgesia with no respiratory depression.⁵⁶ Dexmedetomidine produces a dose-dependent sedation that resembles natural sleep. Sleep patterns differ from the classic GABA receptor agonists such as propofol. Patients do not experience respiratory depression and are readily arousable.⁵⁷ An advantage of this type of sedation is that procedures requiring “wake-up” tests can be more readily accomplished compared with usual anesthetic regimens.⁵⁸ Dexmedetomidine does not interfere with electrophysiologic monitoring, thereby allowing brain mapping during awake craniotomy and microelectrode recording during implantation of deep-brain stimulators. Motor and somatosensory evoked potentials are maintained when added to a desflurane and remifentanyl technique. Dose-dependent decreases in the amplitude of motor evoked potentials (MEPs) may occur.^{59,60} Bispectral index (BIS) values are also decreased in a dose-dependent manner, to a greater extent than with propofol.⁶¹

Dexmedetomidine does not alter cerebral metabolism ($CMRO_2$). CBF is decreased due to cerebral vasoconstriction. This suggests uncoupling between cerebral metabolism and flow because of decreases in central catecholamine degradation. Effects on ICP are not clinically significant.^{62,63}

The central sympatholytic effects also result in an antishivering action, hypothermia, and a reduction in the neuroendocrine stress response to surgery. A reduction in postoperative agitation and

emergence delirium in children and adults is an increasingly used clinical action. A neuroprotective effect has been proposed, but benefits in head-injured patients remain to be clarified.⁶² Analgesic- and anesthetic-sparing effects are well documented and are produced at both the brain and spinal cord level. The greatest utilization of dexmedetomidine outside the neurosurgical intensive care environment is for awake craniotomy.

Opioid-based anesthetic techniques are popular for neurosurgical procedures because they provide a steady hemodynamic course and predictable emergence. The synthetic opioids produce dose-related reductions in CBF (decrease to 25 mL/100 g per min) and CMRO₂ (40% to 50%).⁶⁴⁻⁶⁷ Later investigations in patients after acute head injury or in those undergoing supratentorial craniotomy noted increases in ICP and decreases in CPP after administration of induction doses of fentanyl, sufentanil, and alfentanil.⁶⁸ These opioid-induced changes in ICP have been suggested to occur secondarily to an autoregulatory response to decreases in MAP.⁶⁹

Fentanyl decreases the resistance to CSF absorption and results in a 10% reduction in CBV.^{55,64} Sufentanil is 5 to 10 times more potent than fentanyl and has the highest therapeutic index of the clinically used opiates. Of the synthetic opiates, alfentanil produces the greatest decreases in MAP and CPP.^{55,64} Remifentanyl is a 4-anilidopiperidine derivatives. It is characterized by an ultrashort duration of action and a metabolism independent of both hepatic and renal functions. The main drawback is a lack of residual analgesia and the risk of postoperative hyperalgesia.⁷⁰ Meperidine should be avoided in the neurosurgical patient, because its metabolite, normeperidine, is a well-known convulsant.

Judiciously titrated doses of naloxone reverse opioid-induced respiratory depression and normalize both CBF and CMRO₂. The abrupt reversal of opioid-induced respiratory depression should be avoided in neurosurgical patients. Naloxone administered is associated with hypertension, cardiac dysrhythmias, pulmonary edema, and intracranial hemorrhage.^{71,72}

The benzodiazepines are useful for their anxiolytic, anticonvulsant, and amnestic effects. Benzodiazepines produce a dose-dependent decrease in CMRO₂ and reductions in CBF; however, their effects on ICP are minimal.

Flumazenil, the benzodiazepine-specific antagonist, has no effect on cerebral dynamics when administered alone. High-dose midazolam anesthetic in the canine was associated with rebound increases in CBF and ICP to values greater than baseline when abrupt reversal was accomplished with flumazenil.⁷³ Flumazenil may produce seizures when large doses are administered.

Ketamine has had limited popularity in neuroanesthesia. The dissociative mechanism of action and resultant stormy emergence from anesthesia are undesirable after neurosurgical procedures. The primary advantage associated with ketamine is the stable hemodynamic course in the face of hypovolemia that may occur in the head-injured patient with multisystem trauma. Ketamine is known to produce untoward alterations in cerebral physiology, increasing CBF by 60% to 80% and elevating ICP. Ketamine also increases the resistance to CSF reabsorption, which over time may increase ICP beyond that produced by increases in CBF alone. Cerebral metabolic rate is unchanged, but regional differences may exist.

A renewed interest in ketamine has been prompted because of its noncompetitive antagonism of the glutamine NMDA receptor. Similar compounds have been demonstrated to afford some degree of neuroprotection. Ketamine is a profound analgesic that has a preference for skin, bones, and joint pain. Analgesia occurs with subanesthetic doses, and it is widely used for sedation in combination with low doses of benzodiazepines, propofol, and other analgesics.⁷⁴ The effect on glucose utilization varies by brain region. The response of cerebral vessels to carbon dioxide is left intact. For these reasons, ketamine has traditionally been considered to be contraindicated in patients with a head injury or an increased ICP.

However, it has been noted that ketamine can be used safely in neurologically impaired patients under conditions of controlled ventilation, coadministration of a GABA receptor agonist such as midazolam or propofol, and avoidance of N₂O.⁷⁵ Trauma patients with multiple injuries may benefit from the favorable cardiovascular effects while avoiding untoward neurologic adverse actions. Ketamine produces atypical anesthesia; thus EEG patterns also differ from standard anesthetics. On loss of consciousness and

onset of analgesia, ketamine induces a transition from alpha to theta waves (slow waves with moderate to high amplitude) on the EEG. Alpha waves do not reappear until after consciousness returns and analgesia is lost. Ketamine alone does not decrease the BIS even when patients are unconscious.⁷⁶ Several researchers have, in fact, noted an increase in BIS levels when ketamine is added to a propofol, fentanyl, or sevoflurane anesthetic. Ketamine does not alter auditory evoked potentials (AEPs), mid-latency auditory evoked potential (MLAEP), or A-line autoregressive index monitors based on MLAEPs.

Nondepolarizing neuromuscular relaxants do not appear to have clinically significant direct effects on CBF or CMRO₂, provided MAP is not altered after administration.⁷⁷ The depolarizing agent succinylcholine in select circumstances may produce transient elevations in ICP, CBF, and CMRO₂.

Upper motor neuron disease may alter the peripheral nerve–stimulating response of nondepolarizing neuromuscular relaxants. Generally, the twitch response shows relative resistance to muscle relaxants on the hemiparetic or hemiplegic side, compared with the unaffected side or respiratory muscles.^{78,79} Decreased sensitivity to nondepolarizing muscle relaxants is most exaggerated in the first 3 weeks of upper motor neuron disease. Therefore monitoring neuromuscular blockade is preferentially performed on the unaffected side. Patients on chronic anticonvulsant therapy may be more resistant to long-acting nondepolarizing muscle relaxants.⁸⁰ Phenytoin causes cytochrome P450 enzyme induction, and therefore increased doses and decreased duration of action for aminosteroid neuromuscular blockers is possible.

Succinylcholine induced fasciculations can cause transient increases in ICP, and therefore this drug must be used with caution for neurosurgical patients. Research conducted in animals shows a small and transient rise of 10 to 15 mm Hg for 5 to 8 minutes after administration.⁸¹ The rise is associated with an increased cerebral blood flow, muscle spindle afferent activity, and electroencephalogram arousal. Fasciculation of the neck muscles causing jugular vein stasis appears to be a factor. The effects on ICP are inhibited by pretreatment with a small dose of nondepolarizing relaxant. In clinical practice, the administration of succinylcholine is

preceded by an anesthetic induction agent that lowers ICP. Nevertheless, the routine use of succinylcholine in neurosurgery has declined. It remains widely used, with nondepolarizing relaxant and lidocaine pretreatment, for emergency procedures requiring rapid airway control via rapid sequence induction. As mentioned previously, succinylcholine is contraindicated in patients with neurologic or denervated muscle because of the potential for life-threatening hyperkalemia. Succinylcholine should be avoided in patients with cerebrovascular accident, upper and lower motor neuron lesions, coma, encephalitis, closed head injury, and after severe burns and prolonged bedrest.⁸²

The availability of suitable nondepolarizing alternatives such as rocuronium (1 mg/kg intubating dose) facilitates endotracheal intubation within 60 to 90 seconds and avoids the known complications attendant on the administration of succinylcholine. Sugammadex is also available for rapid reversal if necessary.

Antihypertensives

β -Adrenergic antagonists have great utility for the control of the inotropic and chronotropic effects of sympathetic stimulation that attend laryngoscopy, endotracheal intubation, and endotracheal extubation. Esmolol is a rapid-onset, short-acting selective β_1 -adrenergic receptor antagonist. Administration of 0.5 to 1 mg/kg 2 minutes before laryngoscopy and endotracheal intubation attenuates the predictable increases in heart rate and blood pressure. Its effects on ICP are thought to be negligible. Labetalol is a selective α_1 -adrenergic antagonist and nonselective β_1 - and β_2 -adrenergic antagonist (ratio of β -blockade to α -blockade is 7 : 1 for intravenous preparation). Labetalol spares presynaptic α_2 -receptors; consequently, released norepinephrine produces further inhibition of catecholamine release via a negative feedback from the stimulation of β_2 -receptors. Labetalol and esmolol may be preferred for the control of emergence hypertension after intracranial procedures. In one study, patients treated with labetalol as compared with esmolol experienced a higher incidence of bradycardia in the immediate postoperative period.^{83,84}

Sodium nitroprusside and nitroglycerin produce increases in

CBV and ICP. Sodium nitroprusside is a direct-acting cerebrovasodilator, increasing CBV after dilation of cerebral capacitance vessels.^{77,85} Deliberate hyperventilation and administration of propofol may attenuate cerebrovasodilation. Most contemporary neuroanesthetists consider nitroglycerin and sodium nitroprusside to be potent dilators of capacitance vessels and unsafe in patients with abnormal elastance. Cerebrovascular dilation increases ICP by increasing CBV. These effects can result in intracranial hypertension and potentially herniation if increased ICP already exists.⁸⁶

Intracranial Pressure

Intracranial pressure refers to the supratentorial CSF pressure. The supratentorial pressure may be measured within the lateral ventricle or within the subarachnoid space over the convexity of the cerebral cortex. CSF pressure may vary markedly in different areas within the cranium, and similarly, CSF pressure in the cranial subarachnoid space may differ from that in the spinal subarachnoid space. In individuals free of neurologic pathology who are in a recumbent position, the CSF pressure measured at the lumbar cistern accurately reflects ICP. However, many factors, including the assumption of the upright position, can alter the relationship between cranial and spinal CSF pressures. In addition, in the presence of intracranial mass lesions, infratentorial CSF pressure (as measured in the cisterna magna or lumbar cistern) often decreases, whereas supratentorial pressure increases. Therefore the measurement of supratentorial CSF pressure is a useful clinical concept.^{21,87}

Determinants of Intracranial Pressure

The brain is enclosed within the cranium and because the brain is not compressible, any increase in total intracranial volume produces an accompanying increase in ICP (Monro-Kelly doctrine). Increased ICP may have a detrimental effect on neurologic function. The intracranial space is occupied by four constituent compartments: the brain (accounting for 80% to 90% of the intracranial volume), the blood, intracellular water, and CSF. The intracranial contents combined have a volume of approximately 1200 to 1500 mL.⁸⁸ Under normal conditions, local CNS pressure gradients are equilibrated if the CSF circulation is patent. Because the skull is rigid, any expansion of one of these compartments must be compensated by a reduction in size of the others if ICP is to remain constant. If these compensatory mechanisms are insufficient, ICP rises. Small increases in intracranial volume can be initially accommodated with little or no effect on the ICP, but as more volume is added, intracranial compliance falls until it reaches

a critical point beyond which a minimal increase in volume causes an exponential rise in ICP.⁸⁹ Intracranial hypertension may lead to global reductions in CPP ($CPP = MAP - ICP$) from compression-induced ischemia, or may produce shifting of intracranial contents, resulting in compression of the brain against the falx, the tentorium, or the foramen magnum.

Normal ICP is approximately 5 to 15 mm Hg in adults; lower values are recorded in children and infants. This pressure is determined by the relationship between the volume allowed by the structures that limit intracranial volume and the actual volume of the intracranial space. Because of the normal elastance of the intracranial contents, individuals without intracranial pathology maintain normal ICP despite transient increases that develop with coughing or during a Valsalva maneuver. Small increases in the intracranial volume do not produce abrupt increases in ICP. This normal elastance exists because the limits of the intracranial contents have not been reached. Pressures exceeding 20 to 25 mm Hg are indicative of intracranial hypertension and monitoring and treatment are necessary.

Once intracranial volume begins to increase ICP, dramatic increases in ICP may occur.⁹⁰ This relationship is depicted in [Fig. 31.16](#). Although this ICP-volume curve is commonly used to explain these relationships, some researchers suggest that the x-axis be relabeled as the “volume of the growing mass,” because this axis does not really represent total intracranial volume.⁹¹ The initial portion of the ICP curve is relatively flat because the total intracranial volume does not change with early periods of bleeding or tumor growth. This portion of the curve reflects the phenomenon of spatial compensation. As the mass (blood or tumor) increases, the volume of the intracranial compartments must decrease to maintain normal ICP. In most cases, the CSF compartment decreases; that is, CSF is absorbed by the arachnoid granulations or shunted to the spinal subarachnoid space to compensate for the increasing intracranial volume. Compensation is exhausted when the CSF compartment cannot decrease further in size and total intracranial volume increases, accounting for the increase in ICP. Once volume compensation has reached exhaustion, the subsequent increasing ICP has a direct relationship with a

reduction in cerebral perfusion and an increased herniation risk (see Fig. 31.16).⁹²

Measurement of Intracranial Pressure

Intracranial pressure may be monitored using intraparenchymal, intraventricular, epidural, or subdural devices. The current gold standard for ICP monitoring is the intraventricular catheter because of its precision. Although it is highly invasive, it allows for drainage of CSF to lower ICP. As with any indwelling catheter, there can be insertion problems and strict sterile technique must be maintained. Infection is the most frequent complication of ICP monitoring. Ventriculostomy carries an infection risk of up to 22% in contrast with fiber-optic intraparenchymal monitors (1.8%). Risk factors include drainage duration greater than 5 days, CSF leak, concurrent systemic infection, craniotomy, and intraventricular hemorrhage. Neither prophylactic antibiotics nor routine catheter exchange has been shown to decrease the incidence of infection. Tract hematoma along the catheter trajectory and subdural hematoma due to ruptured bridging veins from over drainage can also occur.

Intraparenchymal probes are a popular method of measuring ICP. They are easy to use and transport and are zeroed when inserted. Infection problems are minimal. The microsensor transducer and the fiber optic transducer are the most widely available. ICP should be monitored in patients with severe traumatic brain injury (TBI) and a Glasgow coma scale (GCS) sum score below 9 and an abnormal CT scan, or a normal CT scan with two or more of the following criteria: age older than 40, unilateral or bilateral motor posturing, and systolic blood pressure (SBP) less than 90 mm Hg.⁹³⁻⁹⁶

ICP is pulsatile and the pressure waveforms provide useful information beyond numbers measured. The ICP waveforms are made of three distinct components: heart pulse waves, respiratory waves, and slow vasogenic waves (Lundberg B waves), each with a characteristic frequency. The normal ICP waveform consists of a 3-peaked wave (Fig. 31.17). P1, the first and generally the tallest peak, is also known as the *percussion wave* and corresponds to the transmitted SBP; P2 (the tidal wave) and P3 (the dicrotic wave) are normally smaller peaks, and the notch between them corresponds

to the dicrotic notch of the arterial waveform. As ICP increases, P2 and P3 rise and eventually surpass P1. Ultimately, with continued elevation of ICP, the waveform loses distinct peaks and assumes a triangular morphology. Intracranial pathology leading to sustained elevations of ICP may produce plateau waves, also known as *A-waves of Lundberg*. These waves reflect a sudden dramatic rise in ICP to levels of 40 to 100 mm Hg, often lasting 5 to 20 minutes. Plateau waves indicate critically low intracranial compliance leading to marked changes in ICP, even with very small variations in intracranial volume. Although their pathophysiology is not fully elucidated, plateau waves are thought to be generated by brief episodes of decreased CPP (often caused by systemic hypotension), leading to exaggerated cerebral vasodilation, increased blood volume, and increased ICP. This further decreases CPP potentially resulting in cerebral ischemia. Cushing's triad (systemic hypertension, tachycardia and irregular respiratory pattern) are signs of severely increased ICP.⁹⁵

FIGURE 31.17 Intracranial pressure tracings in the setting of normal and reduced compliance. Plateau wave (A wave of Lundberg) is seen in the center of the figure. (From Daroff RB, et al., eds. *Bradley's Neurology in Clinical Practice*. 7th ed. London: Elsevier; 2016:745.)

Intracranial Hypertension

Intracranial hypertension occurs with a sustained increase in ICP above 20 to 25 mm Hg.⁹⁷ Intracranial hypertension develops with expanding tissue or fluid mass, interference with normal CSF absorption, excessive CBF, or systemic disturbances promoting brain edema. Often, multiple factors are responsible for the development of intracranial hypertension. For example, tumors in the posterior fossa usually produce some degree of brain edema and readily obstruct CSF flow by compressing the fourth ventricle.⁹⁸

Although many patients with intracranial hypertension are initially asymptomatic, all eventually develop characteristic signs and symptoms, including headache, nausea, vomiting, papilledema, focal neurologic deficits, altered ventilatory function, decreased consciousness, seizures, and coma. When ICP exceeds 30 mm Hg, CBF progressively decreases, and a vicious cycle is established: ischemia produces brain edema, which in turn increases ICP, and further precipitates ischemia. If this cycle remains unchecked, progressive neurologic damage or catastrophic herniation may result.^{21,98,99} A consistent increase in intracranial pressure above 20 mm Hg requires treatment.

When intracranial hypertension is caused by hematoma, contusion, tumor, hygroma, hydrocephalus, or pneumatocephalus, surgical treatment is indicated. In the absence of a surgically treatable condition, ICP may be controlled by correcting the patient's position, temperature, ventilation, hemodynamics, and drainage of CSF. Other first-tier options include controlled hypocapnia (hyperventilation; PaCO₂ 35–40 mm Hg). On average, CBF decreases by 4% for every 1 mm Hg decrease in PaCO₂. The effect of hyperventilation is temporary, however, as tolerance develops within hours. Hyperosmolar therapy (mannitol, hypertonic saline) and induced arterial hypertension (CPP concept) are also used. When autoregulation of CBF is compromised, hyperoncotic treatment aimed at reducing vasogenic edema and intracranial blood volume may be applied. When intracranial hypertension persists, second-tier treatments may be indicated. These include forced hyperventilation (PaCO₂ less than 25 mm Hg), barbiturate coma, or experimental protocols such as induced

hypothermia. Lastly, emergent bilateral decompressive craniectomy can be performed.⁹³

Intracranial Pressure Reduction

The major interventions for treating elevated ICP are listed in [Box 31.3](#). Selective application of these methods often results in ICP reduction accompanied by clinical improvement. A patent airway, adequate oxygenation, and controlled ventilation provide the foundation for neuroresuscitative care in acute intracranial hypertensive states. Frequently, overlap occurs among causes of increased ICP, and this may necessitate simultaneous application of [Box 31.3](#) of different therapeutic modalities.⁶⁸

Methods for the Treatment of Elevated Intracranial Pressure

- Insertion intracranial pressure monitor such as a ventricular catheter or parenchymal probe; tissue oxygen partial pressure, AVDO₂, and CBF monitoring recommended
- Optimize sedation and analgesia to allow for ventilatory control. Administer propofol and/or fentanyl
- Open external ventricular drain if present for ICP > 20 mm Hg for 10 minutes; repeat as needed
- Hyperosmolar therapy:
 - 3% hypertonic saline bolus of 250 mL
 - Before administering 3% hypertonic saline bolus, check if Na < 130 mEq/L.
- Mannitol 0.25 to 1 mg/kg bolus once in emergency.

- Start 3% hypertonic saline drip at 30 mL/h if \geq three 3% hypertonic saline boluses within 6 hours
- Check sodium and serum osmolality
- Hyperventilation:
 - Do not hyperventilate in the first 24 hours (goal PaCO_2 of 35-40 mm Hg).
 - Elevate patient's head 15–30 degrees if the surgery allows; position to improve cerebral venous return; avoid neck-vein compression; loosen cervical collar if in place
 - Avoid overhydration; target normovolemia
 - Optimize hemodynamics: mean arterial pressure, central venous pressure, pulmonary capillary wedge pressure, heart rate, and cerebral perfusion pressure; consider antihypertensive therapy as needed
 - Surgical decompression; consider decompressive craniectomy if hematoma is present
 - Consider mild hypothermia
 - Avoid corticosteroids with traumatic brain injuries

AVDO₂, Arteriovenous difference in oxygen content; *CBF*, cerebral blood flow; *ICP*, intracranial pressure; *IV*, intravenous; *PaCO₂*, partial pressure of arterial carbon dioxide.

Hyperventilation

Hyperventilation has the potential to reduce ICP via reflex

vasoconstriction in the presence of hypocapnia. The vasoconstriction leads to decreases in CBF, overall cerebral fluid volume, and therefore ICP. The potential dangers associated with inducing hypocapnia are related to the vasoconstriction and possible cerebral hypoxia that occurs, and thus this intervention is not used initially to treat increased ICP. Excessive hypocapnia may lead to ischemia secondary to insufficient CBF. Therefore it is not recommended in the first 24 hours after TBI or prophylactically. The reactivity of cerebral vessels to changes in PaCO₂ is an important physiologic control system. When the physiologic control is intact, hyperventilation lowers PaCO₂, resulting in respiratory alkalosis and subsequent vasoconstriction. When vasoconstriction is pronounced, intracranial blood volume will decrease and lower ICP. This is particularly important in known low-CBF conditions, such as severe TBI or vasospasm. To avoid cerebral ischemia, PaCO₂ should be lowered to approximately 30–35 mm Hg. The vasoconstrictive effect on cerebral arterioles lasts only 11 to 20 hours because the pH of the CSF rapidly equilibrates to the new PaCO₂ level. When hypocapnia is monitored by end-tidal capnometry, the PaCO₂ is approximately 2 to 5 mm Hg higher than end-tidal carbon dioxide (ETCO₂) readings, although many conditions can affect this gradient. Compared with autoregulation of CBF, CO₂ vascular reactivity is usually maintained even in the traumatized brain. When CO₂ vascular reactivity is lost, a poor prognosis is probable.^{95,100}

Cerebrospinal Fluid Drainage

Intracranial hypertension may be reduced by a surgical CSF diversion. The long-term effectiveness of this therapeutic alternative depends on the cause of the increased ICP. Cerebral spinal fluid drainage can be cycled in 10 minute intervals when an external ventricular drain is present.¹⁰⁰ When brain edema produces elevation of ICP, CSF drainage may provide only transient abatement of intracranial hypertension. If external drainage is continued in this circumstance, ventricular collapse can occur and prevent further venting of CSF. Successful chronic control of increased ICP caused by hydrocephalus can be achieved with

ventriculoperitoneal shunts.^{68,93,100}

Surgical Decompression

Surgical decompression may be used for uncontrollable increases in ICP. Internal decompression involves the excision of brain tissue, reduction in ICP, and reduction of the potential for brainstem displacement or herniation. External decompression involves excision of the skull overlying the site of either an epidural or a subdural hematoma. Decompressive surgery is generally considered to be a last resort in patients with persistent, intractable increases in ICP.⁵⁴

Hypothermia

Hypothermia may help to decrease ICP by decreasing CMRO₂ by 7% for each degree centigrade decrease in core body temperature. Temperature is lowered by convective cooling to a bladder temperature of 35°C to 36°C for 48 hours after trauma or hemorrhage. There has been considerable interest in the use of hypothermia in the management of severe TBI. However, despite promising experimental evidence, results from clinical studies have failed to demonstrate benefit. There would still appear to be a role for hypothermia in the management of intractable intracranial hypertension. However, optimizing therapeutic time frames and better management of strategies for complications will be required if experimental evidence for neuroprotection is to be translated into clinical benefit.¹⁰¹

Pharmacologic Manipulation of Intracranial Pressure

Diuretics

Loop diuretics (furosemide, bumetanide, ethacrynic acid) produce a general diuresis, decrease the rate of CSF production, and decrease cerebral edema. Osmotic diuretics are effective to decrease the water content of the brain. Mannitol is the most widely used osmotic diuretic for acute control of intracranial hypertension.

Rapid administration of mannitol may produce vasodilation, increases in CBF, a transient rise in ICP, and a transient increase in circulating blood volume. Increases in circulating blood volume may prove to be detrimental to patients with underlying cardiac dysfunction. Prior administration of intravenous furosemide may minimize these potential complications. Decreases in ICP begin shortly after mannitol administration and may continue for up to 6 hours. The typically prescribed dose of mannitol is 0.25 to 1 g/kg. Continued use of mannitol may produce hyperosmolality and electrolyte imbalance, which may be attenuated with concurrent administration of a loop diuretic.¹⁰²

Hypertonic saline has an osmotic effect on the brain because of its high tonicity and ability to effectively remain outside the BBB. Like mannitol, hypertonic saline produces an osmolar gradient causing shrinkage of brain tissue and reduction in ICP. It also increases circulating blood volume, MAP, and CPP. The ICP reduction is seen for approximately 2 hours and may be maintained for longer periods by using a continuous infusion of hypertonic saline. The ICP reduction is thought to be caused by a decrease in water content in areas of the brain with intact BBB, such as the nonlesioned hemisphere and cerebellum. Most comparisons with mannitol suggest almost equal efficacy in reducing ICP, but there is a suggestion that mannitol may have a longer duration of action. Results from studies directly comparing hypertonic saline with standard treatment in regard to safety and efficacy are inconclusive. However, the low frequency of side effects and a definite reduction of ICP observed with use of hypertonic saline in these studies are very promising. Systemic effects include transient volume expansion, natriuresis, hemodilution, immunomodulation, and improved pulmonary gas exchange. Adverse effects include electrolyte abnormalities, cardiac failure, bleeding diathesis, and phlebitis.¹⁰³ Caution must be exhibited when administering hypertonic saline, as a rapid rise in serum sodium concentration (> 9 mEq/L in 24 hours) can lead to an osmotic demyelination syndrome, also known as *central pontine myelinolysis*.¹⁰⁴

Corticosteroids

Glucocorticoids penetrate the BBB and decrease edema associated

with mass lesions. Steroids have been in use for neurosurgical patients for decades. They are commonly used for primary and metastatic brain tumors to decrease vasogenic cerebral edema.

Increased ICP decreases over 2 to 5 days with treatment. The most commonly used regimen is intravenous dexamethasone, 4 mg every 6 hours. Despite many years of use, the Corticosteroid Randomization After Significant Head injury (CRASH) trial results showed that steroids were harmful in TBI. They may be given in spinal cord trauma. There is no indication for steroids with intracranial hypertension after TBI. Classical indications, such as perifocal edema surrounding intracranial tumors or edema associated with cerebral abscess, remain valid.¹⁰⁵

Barbiturates

Barbiturate coma, hypothermia, or decompressive craniectomy should be considered for intracranial hypertension refractory to initial medical management. Barbiturate coma is used to reduce refractory ICP by decreasing CMRO₂, scavenging free radicals, preventing convulsions, and reducing the hyperthermic response to ischemia. Barbiturates induce hypotension, which at times may be very difficult to treat.¹⁰⁶ Volume expansion should be the first-line treatment to maintain SBP, although intravenous vasopressors may be used. The cerebral metabolic rate cannot be lowered further after burst suppression is achieved by barbiturates; theoretically, ICP will be at its lowest barbiturate-induced level when burst suppression is achieved.¹⁰⁷ Patients may be kept in burst suppression–induced barbiturate coma for hours to days. Although routine use of barbiturates has not been effective in reducing morbidity or mortality after severe head injury, beneficial reductions in ICP are produced. A disadvantage is the inability to perform neurologic assessments during the coma.¹⁰⁸

Neurophysiologic Monitoring

Neurophysiologic monitoring is discussed in detail in [Chapter 19](#). It is important to confer with the surgeon to determine which neurophysiologic monitoring is to be used. Then, a comprehensive plan of care that accounts for the anesthetic considerations related to various neuromonitoring techniques can be employed.

Intraoperative monitoring (IOM) is used routinely to assess the nervous system during procedures that present significant risk of brain, spinal cord, or nerve injury. Intraoperative testing is used to identify nerves and to define brain regions and structures for resection. There is significant improvement in patient outcomes associated with neuromonitoring. The Therapeutics and Technology Subcommittee of the American Academy of Neurology concluded that the following are useful and noninvestigational: (1) EEG, compressed spectral array, and somatosensory evoked potentials (SSEPs) in carotid endarterectomies and brain surgeries that potentially compromise CBF; (2) brainstem auditory evoked response and cranial-nerve monitoring in surgeries performed in the region of the brainstem or inner ear; and (3) somatosensory evoked monitoring performed for surgical procedures potentially involving ischemia or mechanical trauma of the spinal cord.¹⁰⁹ MEP monitoring is commonly used during spine surgery and has a good correlation to postoperative motor outcome. The novel technique of motor evoked potential monitoring using transcranial electrical stimulation allows reliable assessment of the functional integrity of the corticospinal and corticobulbar tracts while the patient is under general anesthesia.¹¹⁰

Surgical procedures that commonly use intraoperative monitoring are shown in [Box 31.4](#). Intracranial posterior fossa cases commonly use brain auditory evoked potentials (BAEPs), SSEPs, and cranial nerve electromyography (EMG) monitoring. Typical applications are cerebellopontine angle and skull base tumor resection, brainstem vascular malformation and tumor resection, and microvascular decompressions. Intracranial supratentorial procedures include resections for epilepsy, tumors, and vascular malformations, as well as for aneurysm clipping. These use

multimodality monitoring with a combination of EEG and SSEP monitoring together with functional cortical localization with direct cortical stimulation and electrocorticography (ECoG). Surgery of the carotid, aorta, or heart may use EEG to monitor hemispheric function or assess the need for shunting or adequacy of protective hypothermia. SSEPs are also used for these vascular cases.

Clinical Conditions Monitored During Surgery

- Epilepsy surgery
- Cerebral tumor and vascular malformation resection
- Intracranial aneurysm clipping
- Movement disorders electrode placement
- Mapping nerves, tracts, and nuclei during brainstem and cranial base surgery
- Ear and parotid surgery near facial nerve
- Thyroid and aortic arch surgery near laryngeal nerve
- Carotid endarterectomy
- Carotid balloon occlusion
- Endovascular spinal and cerebral procedures
- Spinal deformity correction
- Spinal fracture stabilization
- Spinal tumor resection
- Cervical myelopathy decompression and fusion
- Cervical radiculopathy decompression and fusion

- Lumbar stenosis decompression and fusion
- Tethered cord and cauda equina procedures
- Dorsal root entry zone surgery
- Brachial and lumbosacral plexus surgery
- Peripheral nerve surgery
- Cardiac and aortic procedures

Adapted from Nuwer MR. Clinical neurophysiology: intraoperative monitoring. In Daroff et al., eds. *Bradley's Neurology in Clinical Practice*. 7th ed. London: Elsevier; 2016:410.

Spinal surgery is the most common setting for IOM. Procedures include cervical discectomy and fusion for myelopathy, stabilization for deformities such as scoliosis, resection of spinal column or cord tumors, and stabilization of fractures. Both sensory evoked potentials (SEP) and MEP are often used to assess the posterior columns and corticospinal tract functions. The use of MEP depends on the case, because it usually requires total intravenous anesthetic and incurs some movements during surgery. As a result, some spinal cases are still carried out with SEP alone. In cases involving pedicle screw placement, EMG is monitored to detect screw misplacement. Spinal cord monitoring is also used for cardiothoracic procedures of the aorta that jeopardize spinal perfusion. Peripheral nerve monitoring is carried out for cases risking injury to the nerves, plexus, or roots. Testing can also determine which segments of a nerve are damaged when performing a nerve graft.

When SSEP monitoring is used for spinal cord surgery, the risk of paraplegia was 60% less among the monitored cases when compared with historical and contemporaneous controls. This information translates to 1 out of every 200 patients that did not have paraplegia when monitoring was used. Multimodal monitoring combining SSEPs with MEPs and others is now standard for many spinal procedures. The expectation is that the rate of postoperative neurologic deficits will be reduced even further.¹¹¹

Electroencephalography

The EEG recorded from the scalp is a summation of the excitatory and inhibitory postsynaptic potentials produced in the pyramidal layer of the cerebral cortex. EEG activity requires approximately 50% of the total oxygen consumed by the brain; the remaining 50% is needed to maintain cellular integrity. When oxygen delivery is compromised, slowing of EEG activity ensues.

Changes in EEG frequency and amplitude may be caused by administration of anesthetic drugs and changes in anesthetic depth. Low doses of potent inhalation agents with N₂O produce an active EEG. Steady-state anesthesia, regardless of the agent used, usually produces a stable EEG pattern. It is worth noting that deep levels of anesthesia and cerebral ischemia produce similar EEG changes. In both cases, fast activity is replaced by slower, larger EEG waveforms. Boluses of anesthetic drugs may produce large EEG changes indistinguishable from those seen during ischemia. The EEG provides information about the overall electrical functioning of the cerebral cortex but not much about the subcortical brain, spinal cord, or cranial and peripheral nerves.¹¹¹

Somatosensory Evoked Potentials

An evoked potential differs from the EEG mainly in two ways: (1) the EEG is a random, continuous signal that arises from the ongoing activity of the outer layers of the cortex, and an evoked potential is the brain's response to a repetitive stimulus along a specific nerve pathway, and (2) EEG signals range from 10 to 200 millivolts (mV). Evoked potentials are smaller in amplitude (1, 5, 20 microvolts), requiring precise electrode positioning and special techniques (signal averaging) to extract the specific response from the underlying EEG "noise." The technique of signal averaging has been further developed in computer processing. The technique now used applies a stimulus repeatedly—preferably at randomized intervals—and records the evoked response over the corresponding area of the brain, averaging out mathematically the change over the number of stimuli.¹¹² SSEP can be used for detecting localized injury to specific areas of the neural axis by assessing cortically generated waves, or it can serve as a nonspecific indicator of the adequacy of

cerebral oxygen delivery.¹¹¹

Although volatile anesthetics alter the generation and transmission of SSEP, suppression of muscle artifact by neuromuscular blocking drugs and the ability to use much higher stimulus intensity in the anesthetized patient allow rapid production of waves that are reproducible, although they differ from those found in the awake patient. Early components of SSEP are generally resistant to anesthetic depression. Etomidate and ketamine both increase the amplitude of scalp-recorded waves by 200% to 600%. Volatile anesthetics and N₂O depress the SSEP waveform in a dose-dependent manner. Avoiding changes in inhaled gas concentration and bolus injection of hypnotic drugs during periods of risk minimizes difficulties in determining whether waveform changes are due to surgical manipulation.¹¹³ The effects of anesthetics on somatosensory and motor evoked potentials are shown in [Chapter 8, Table 8.4](#).

Hypothermia increases SSEP latency. Latency increases approximately 3 milliseconds with every decrease in temperature of 2°C to 3°C. This amount of change is suggestive of neural injury. Hyperthermia suppresses SSEP amplitude, with the amplitude being only 15% of that at normothermia.¹¹³⁻¹¹⁶

Reproducible, very-short-latency waves of the trigeminal system are produced by stimulation of the lip at 2 to 4 Hz (512 stimuli). This modality of evoked potential is abnormal in patients with posterior fossa masses in the region of cranial nerve V or in symptomatic hydrocephalus.¹¹⁷ This modality of evoked potential monitoring may be useful in patients with large posterior fossa tumors that cause severe cranial nerve VIII dysfunction and make brainstem auditory evoked response (BAER) monitoring impossible.¹¹³

BAER assesses only brainstem function, although long-latency cortical waves can be assessed to evaluate cortical function. BAER has been used extensively in patients at risk of brain injury during intracranial surgery, despite the extremely small amount of neural tissue assessed and the resistance of BAER to oxygen deprivation when compared with other neural monitors such as the EEG or SSEP waves.^{113,118}

Compared with SSEPs, intraoperative factors other than surgical

brain damage are relatively unlikely to alter the BAER. BAER waveforms are resistant to both intravenous and inhalational drugs.¹¹³ Fentanyl in large doses does not alter BAER.^{113,119} Propofol (2 mg/kg, followed by an infusion) increases the latency of waves I, III, and V without a change in the amplitudes, but it completely suppresses middle-latency auditory waves.^{113,120} N₂O produces a linear decrease in BAER amplitude from 10% to 40%^{113,121}; N₂O at doses of 33% reduces the wave amplitude without altering latency.^{113,122,123}

BAER waves are easily identifiable at more frequently used levels of hypothermia (29°C), although latencies are delayed by approximately 33%.¹²⁴ BAER latency is inversely related to temperature over the range of 36°C to 42°C, with a decrease in amplitude as temperature increases.^{113,125}

BAER appears to be a sensitive monitor to the auditory apparatus in response to direct injury.¹¹³ The auditory apparatus includes the cochlear hair cells, spiral ganglion, eighth cranial nerve, cochlear nuclei, superior olivary complex, lateral lemnisci, inferior colliculus, and medial geniculate thalamic nuclei.¹¹¹ Some have recommended BAER monitoring be undertaken in all patients at risk of brainstem injury, even if the primary disease causes hearing loss on the affected side.¹¹³ Some also consider BAER clinically useful and probably approaching standard of care for microvascular decompression procedures and acoustic tumor surgery.¹¹¹

Aggressive intraoperative monitoring does not guarantee prevention of neurologic injury, because all parts of the brain are not assessed using currently available monitoring.¹¹³ Except when the entire brainstem is at risk, there will likely be a high incidence of cases in which BAERs are unaffected intraoperatively, yet significant impairment in motor function or consciousness occurs postoperatively.¹¹¹

EMG monitoring is frequently used for facial nerve monitoring. Generally, two types of EMG activity are monitored. The first involves active stimulation of the nerve for localization and the second, spontaneous EMG activity initiated by irritation or manipulation of the nerve. It has been noted that in the presence of light anesthesia, spontaneous EMG activity caused by slight movements may become apparent and mimic neuronal irritation.¹¹¹

The effects of muscle relaxants on EMG monitoring have not been adequately studied.^{111,113} Chronically injured facial nerves may show greater sensitivity to the effects of neuromuscular blockade, suggesting lower levels of neuromuscular blockade should be used.¹²⁶ Some anesthesiologists do not paralyze patients during the time EMG monitoring is used. Facial nerve monitoring is considered the standard of care for acoustic tumor surgery and during other surgery that risks facial nerve function.¹¹¹

The motor component of cranial nerves III, IV, X, XI, and XII also can be monitored using EMG.^{111,127,128} Whereas some consider the use of EMG monitoring of cranial nerves other than VII not widespread or universally accepted,¹¹¹ recent interest in skull-base surgery has spurred EMG monitoring for lower cranial nerve preservation. Some evidence suggests EMG monitoring proved to be a safe tool for the intraoperative identification and localization of the lower cranial nerves, contributing to their anatomic and functional preservation. The predictive value of standard neurophysiologic parameters for functional outcome, however, is limited.¹²⁹

There is great interest in intraoperative use of MEPs because of the theoretic limitations of SSEPs in monitoring motor function.¹¹¹ MEPs assess function of the motor cortex and descending tracts. The peripheral response of the MEP is recorded by measuring the compound muscle action potential.¹¹³ The motor cortex is stimulated by electrical or magnetic stimulation. Both volatile anesthetics and neuromuscular blocking drugs suppress these responses.^{113,130,131}

Evoked potentials may be affected by various anesthetics. Neuromuscular blockade resulting in a 70% or less reduction in the height of the response to ulnar nerve stimulation is compatible with MEP monitoring.^{111,132} A combination of N₂O-narcotic anesthetic and a stable level of neuromuscular blockade, such as that provided by an infusion of neuromuscular blocking agent, has been advocated to provide a stable response.¹¹³ Some authors recommend that N₂O be kept to less than 50% or not used if monitoring of MEPs is used.^{133,134} Total intravenous anesthesia using infusions of propofol in combination with a narcotic allow stable MEP recordings. Total intravenous anesthesia with ketamine has

also been recognized as being compatible with stable MEP readings.^{111,135}

MEP responses produced by electrical stimulation of the spinal cord are resistant to the effects of anesthesia and require no special anesthetic considerations other than the need for muscle relaxants to prevent gross movements.¹¹¹ Recommended monitoring modalities and anesthetic techniques for various surgical procedures are shown in [Table 31.5](#).

TABLE 31.5
Recommended Monitoring Modalities and Anesthetic Regimens for Surgical Procedures

Anesthesiol Clin. 2006;24:777.

Anesthetic Considerations for Specific Procedures

Supratentorial Surgery

Intracranial masses may be congenital, neoplastic (benign, malignant, or metastatic), infectious (abscess or cyst), or vascular (hematoma or malformation). Most, but not all, anesthetics can be used safely in patients with cerebral lesions. Important considerations are the effects of the anesthetic agents on ICP, CPP, CBF, CMRO₂, promptness of return of consciousness, drug-related protection from cerebral ischemia or edema, blood pressure control, and compatibility with neurophysiologic monitoring techniques.¹³⁶

Most craniotomies performed within the United States today include the use of propofol for induction of anesthesia with intubation of the trachea after administration of a nondepolarizing relaxant. Maintaining anesthesia is commonly accomplished with a volatile agent and a narcotic, such as fentanyl, sufentanil, alfentanil or remifentanil.¹³⁶

Preoperative Evaluation

The clinical signs of a supratentorial mass include seizures, hemiplegia, and aphasia. The clinical signs of infratentorial masses include cerebellar dysfunction (ataxia, nystagmus, dysarthria) and brainstem compression (cranial nerve palsies, altered consciousness, abnormal respiration). When ICP increases, frank signs of intracranial hypertension also can develop.⁹⁸

Preanesthetic evaluation should attempt to establish the presence or absence of intracranial hypertension. CT or magnetic resonance imaging (MRI) data should be reviewed for evidence of brain edema, midline shift greater than 0.5 cm, and ventricular size. A neurologic assessment should evaluate the current mental status and any existing deficits. Anticonvulsant therapy and medications prescribed for control of ICP (corticosteroids, diuretics) should be reviewed. Laboratory evaluation should rule out corticosteroid-induced hyperglycemia and electrolyte disturbances that may

develop secondary to diuretic therapy. For anticonvulsants, amount, time of last dose, and blood levels should be noted.

The decision regarding the amount and timing of the premedication should be made only after a thorough patient evaluation. Benzodiazepines produce respiratory depression and hypercapnia. Premedication should be omitted in patients with a large mass lesion, a midline shift, and abnormal ventricular size. If premedication is desired in those patients deemed appropriate, careful titration of intravenous midazolam may begin once the patient has been delivered to the preoperative holding area. In an attempt to help control ICP in patients with mass lesions, the head of the bed should be elevated 15 to 30 degrees during transport to the preoperative holding area and the operating room. The anesthetist must be aware of existing hospital recommendations for prophylactic antibiotics to ensure proper timing and dosage.

Intraoperative Monitoring

Routine monitors for supratentorial procedures include continuous electrocardiography, cuff measurement of blood pressure, precordial stethoscope, monitoring of the fraction of inspired oxygen, pulse oximetry, temperature, peripheral nerve stimulation, ETCO₂ monitoring, and indwelling urinary catheterization. For patients with ischemic heart disease, use of a modified V₅ ECG lead is recommended. An arterial line placed either before or immediately after anesthetic induction provides for uninterrupted blood pressure monitoring and easy access for blood sampling for laboratory analysis. SSEPs may be assessed. Methods for cerebral oxygenation monitoring are listed in [Table 31.6](#)¹³⁷⁻¹³⁹

TABLE 31.6
Cerebral Oxygenation Monitoring

Monitor	Abbreviations	Comments
Jugular bulb oximetry	SjvO ₂	Invasive; monitors global not focal ischemia and hypoxia; < 50% desaturation suggests inadequate delivery or excessive consumption; > 75% suggests hyperemia or stroke
Transcranial Doppler monitoring	rsO ₂	Noninvasive; monitors flow within the Circle of Willis; temporal bone thickness may prevent monitoring; ratio > 3 may be indicative of vasospasm; ratio < 3 suggests hyperemia
Brain tissue	PbO ₂	Invasive; reserved for global head injuries; simultaneously estimates

oxygen tension		tissue oxygen tension and ICP; normal values 20–45 mm Hg; pathologic reading < 15 mm Hg
Near-infrared spectroscopy	NIRS	Noninvasive; estimates brain tissue saturation; concerns with reliability and specificity; may be best used as a trend monitor for flow

ICP, Intracranial pressure.

Fluid Management

Tissues within the CNS are subject to water movement governed by the BBB. The pore size in the BBB is only one-tenth that of the periphery, at 0.7 to 0.9 nm.¹⁴⁰ There is a fundamental difference between capillaries within the CNS and the peripheral capillaries. The BBB remains impermeable to both ions and proteins. The number of ions represents a greater magnitude in determining the net movement of water than the number of plasma proteins. There can be little doubt that osmolarity is the primary determinant of water movement across the intact BBB.^{141,142}

Normovolemia is the goal during intracranial surgery. Preoperative fluid deficits and intraoperative blood and fluid losses must be adequately replaced during neurosurgical procedures. Judicious fluid administration minimizes the occurrence of cerebral edema and increased ICP, reduced CPP, and worsened cerebral ischemia. In most neurosurgical patients, fluids that contain sodium in a concentration similar to that of serum (e.g., lactated Ringer's solution or 0.9% saline) are administered in a volume sufficient for maintaining peripheral perfusion but avoiding hypervolemia (0.5 to 1 mL/kg per hr). Traditionally, less fluid was given than would be administered for nonneurologic surgery, although current recommendations indicate that patients should be kept isovolemic, isotonic, and isoncotic.^{143–146} Glucose-containing or hypoosmolar solutions such as lactated Ringer's solution should be avoided. The use of isoosmolar crystalloids is widely accepted and can be justified on a scientific basis.^{142,147,148}

Hyperglycemia induces marked detrimental cerebrovascular changes during both ischemia and reperfusion.¹⁴⁹ An essential component in the overall management of acute brain injury, especially during the acute phase, is maintaining adequate and

appropriate control of serum glucose. Intensive insulin therapy is associated with unacceptable rates of hypoglycemia and metabolic crisis, and does not necessarily provide benefit. Hyperglycemia is harmful to the injured brain as it compromises microcirculatory blood flow, increases BBB permeability, and promotes inflammation. In addition, it triggers osmotic diuresis, hypovolemia, and immunosuppression.¹⁵⁰

Multiple studies have demonstrated that hyperglycemia before and during an episode of global cerebral ischemia will exacerbate the neurologic injury. Hyperglycemia-enhanced ischemic injury is due to several factors, including a rise in lactate production and concomitant tissue acidosis.¹⁵¹⁻¹⁵³ Another theory suggests that hyperglycemia enhances ischemic injury by attenuating an increase in adenosine.^{151,154,155} Yet another theory suggests that hyperglycemia significantly worsens the degree of acute BBB disruption that occurs during ischemia.^{151,156} It is also thought that hyperglycemia is associated with a significantly reduced CBF and increased heterogeneity of regional CBF during the postischemic period.^{151,157-160}

Fluid therapy is most challenging during prolonged surgical procedures or in the surgical management of multiple traumas. If tissue trauma is severe or if hemorrhage has been prolonged, patients develop a marked reduction in functional extracellular volume as a result of the internal redistribution of fluids (third-space losses). Although the extent of tissue manipulation in most routine neurosurgical procedures is small, third-space fluid losses during prolonged surgery and in patients with severe associated systemic trauma can be sufficient to decrease intravascular volume, reduce peripheral perfusion, and impair renal function. The sequestered extracellular fluid can be cautiously replaced with 0.9% saline. In the absence of diuretic therapy, a urinary output of 0.5 to 1 mL/kg per hr suggests adequate replacement, as do hemodynamic stability and cardiac filling pressures within the normal range. Hematocrit should be kept above 28%.¹³⁶

Anesthetic Induction and Maintenance

Although induction of anesthesia for patients undergoing craniotomy can be performed with various agents, a smooth and

gentle induction of general anesthesia is more important than the drug combination used. No evidence indicates that one technique or set of drugs is better than another. A reasonable induction sequence would combine preoxygenation, propofol (1 to 2 mg/kg), and a nondepolarizing muscle relaxant. No evidence suggests that any of the induction agents is superior. The hemodynamic response to intubation may be blunted with the administration of fentanyl (10 to 15 mcg/kg total dose) or lidocaine (1.5 mg/kg) administered 3 minutes before laryngoscopy. Whatever agents are selected, the induction should be accomplished without the development of sudden and profound hypertension or hypotension.

The head is typically elevated from 15 to 30 degrees to facilitate venous and CSF drainage. The head may also be turned to the side to facilitate exposure. Excessive neck flexion may impede jugular venous drainage and increase ICP. Because of the flexion-extension-rotation of the head in combination with head fixation in a pinion headrest, the use of an armored or reinforced endotracheal tube (ETT) is recommended to avoid kinking of the tube once positioning is accomplished. The ETT follows the position of the chin. With extension of the neck, the chin and ETT move cephalad; with neck flexion, the chin and ETT move caudad. The anesthesia circuit connections must be firmly secured by simultaneously pushing and twisting to seat the plastic connectors. The risk of unrecognized disconnections may be increased because the operating table is usually turned 90 to 180 degrees away from the anesthetist, and both the patient and the breathing circuit are almost completely covered by surgical drapes.⁹⁸

Maintenance of anesthesia may be accomplished with an oxygen-air-opioid technique, a selected potent inhalation agent, or oxygen-air and a continuous infusion of propofol. After endotracheal intubation, mechanical hyperventilation is begun, decreasing $ETCO_2$ to 30 to 35 mm Hg, confirmed through arterial blood gas analysis. The patient should be covered with blankets or a forced-air warming blanket to maintain core body temperature.

An opioid-based anesthetic technique with air in oxygen with low-dose (less than 1%) isoflurane is a popular choice. Incremental administration of fentanyl, sufentanil, alfentanil, or an infusion of remifentanil is acceptable. Sufentanil as a 0.5 to 1 mcg/kg loading

dose, followed by either incremental boluses (not to exceed 0.5 mcg/kg per hr) or an intravenous infusion of 0.25 to 0.5 mcg/kg per hr in combination with less than 1% isoflurane in oxygen may be used. Sufentanil administration should be discontinued approximately 45 minutes before the end of surgery to ensure that the patient awakens promptly. The primary advantage of remifentanyl is rapid awakening. If the patient experiences hypertension or tachycardia near the end of surgery, the practitioner should consider giving either labetalol or esmolol, not additional opioids.¹⁶¹

A volatile agent (isoflurane, desflurane, or sevoflurane) can also be used for maintenance of anesthesia. If isoflurane is used, the concentration should remain less than 0.1%.¹⁶¹ A 2016 study suggests that a Canadian Cardiovascular Society (CCS) Score = 10, Mini Mental Status Exam = 30, and GCS = 15 may be more quickly achieved postoperatively after providing a sevoflurane based anesthetic versus propofol for maintenance during supratentorial tumor resection.¹⁶²

N₂O may be used in an anesthetic regimen if it is deemed desirable. However, if the patient is suspected to have a pneumocephalus or the potential for air embolism exists, N₂O use is contraindicated. N₂O expands both the pneumocephalus and the air embolus. A tension pneumocephalus acts as an expanding mass lesion. A large air embolus can cause cardiovascular collapse.¹⁶¹

Very mild hyperventilation is an important adjunct to any neuroanesthetic technique. Hypocapnia decreases ICP before opening of the dura and attenuates the vasodilation produced by the volatile anesthetic agents. Optimal hyperventilation during surgery would yield a PaCO₂ of 35 to 40 mm Hg. Diuretics, when indicated, may be timed just before or after the cranial vault is opened to facilitate surgical exposure.

Skeletal muscle relaxation prevents patient movement at inappropriate times. It may decrease ICP by relaxing the chest wall, decreasing intrathoracic pressure, and facilitating venous drainage. In choosing an agent for muscle relaxation, the length of the procedure and the effect of the drug on ICP should be considered.¹⁶¹

Emergence

Arguably, in no other anesthetic situation is careful attention to appropriate planning for the emergence from anesthesia as important as in neurosurgical brain tumor surgery. Sudden emergence from anesthesia can result in uncontrolled hypertension. Delirium with coughing and straining on the ETT should be avoided. In a patient with a compromised BBB, this stormy emergence can produce devastating consequences. Late emergence from anesthesia can result in a confusing diagnostic picture with possible intracranial hematoma, acute hydrocephalus, or other diagnoses masked by the residual anesthesia.⁹²

A controlled emergence focuses on regulation of blood pressure, ICP, and CBF. Controlled emergence also accounts for the preexisting pathophysiology, the surgical trauma, the length of the procedure, and appropriate management of the airway.⁹²

Emergence from anesthesia begins when the surgical pathology has been addressed. Collaboration with the surgeon is essential. Prior to closing the dura, the appropriate levels of postoperative blood pressure can be determined. The PaCO₂ should be allowed to return to a normal level. Blood pressure can then be raised to 20% above baseline prior to closing of the dura. Hypertension is considered a frequent occurrence of the postoperative period.^{135,163,164} Tachycardia associated with hypertension frequently results from emergence excitement.¹⁶⁵ By raising the blood pressure and the PaCO₂ prior to dural closure, the ability of the brain to withstand systemic hypertension can be directly assessed by the surgeon.⁹² Once the dura has been closed, the blood pressure is maintained at baseline levels throughout the remainder of the closure.

There is strong support for the notion that sympatholytic drugs should be used to decrease blood pressure during emergence.¹⁶⁶ Studies have shown that during the first hour after craniotomy for supratentorial lesions, the arteriovenous oxygen content difference is low, suggesting a state of cerebral luxury perfusion.^{167,168} This event coincides with a high level of mean arterial blood pressure. Accordingly, it is supposed that this correlation is caused by changes in the mean blood pressure and impaired autoregulation.

This may be deleterious, because it enhances BBB leakage, provoking edema and hemorrhage.

A relationship between hypertension and postoperative hematoma formation exists.¹⁶⁹ The parameters for these events for each individual patient are unknown. Normal autoregulation of CBF maintains adequate perfusion at mean blood pressures ranging from 50 to 150 torr,¹⁷⁰ but the effects on autoregulation of combinations of anesthetic agents over a prolonged case and under varying temperatures are unknown.¹⁵⁰ Labile hypertension and unstable blood pressure during the perisurgical period may contribute to intracerebral hemorrhage remote from the site of the initial neurosurgical procedure.¹⁷¹ Given the evidence, and without the need to volume expand and maintain the patient in a hyperdynamic manner, it would seem prudent to institute some form of blood pressure control to provide the most controlled emergence possible.

Judicious titration of short-acting antihypertensives (esmolol, labetalol) has great clinical utility in controlling blood pressure during emergence. When access to the patient is regained, the use of anesthetic gases is discontinued, and the muscle relaxant is reversed. Intravenous lidocaine (1.5 mg/kg) can be given just before suctioning for cough suppression before extubation. Rapid awakening facilitates immediate neurologic assessment and can generally be expected after a pure opioid-N₂O technique. Delayed awakening may result from residual opioid or remaining end-tidal concentrations of potent inhalation agent. After extubation, the patient is transported to the intensive care unit postoperatively for continued monitoring of neurologic function.¹⁶⁶

Awake Craniotomy

In a small percentage of patients—those in whom a seizure focus may be suppressed during general anesthesia or may be adjacent to an area of eloquent cortical function—awake craniotomy may be necessary.¹⁷² Sources feel awake craniotomy is the most reliable method to ensure neurologic integrity in the presence of cerebral gliomas that infiltrate or come close to the especially sensitive areas of the brain. Awake craniotomy allows for localization of eloquent

cortical areas by electrical stimulation and of epileptic foci through cortical recordings. Continuous monitoring of the functional integrity of the brain in awake patients is inherently protective while surgical removal of the gliomatous tissue is performed.¹⁷³ Anesthetic techniques may vary, depending on whether the procedure is for tumor removal or seizure treatment.

Patient Selection

To minimize the risk of intraoperative complications, contraindications for awake craniotomy include developmental delay, lack of maturity, an exaggerated or unacceptable response to pain, a significant communication barrier, and a failure to obtain patient consent. Only those patients with the ability to clearly understand risks and benefits and who, in the opinion of the neurosurgeon and the anesthesia team, will cooperate during surgery should be considered as candidates for an awake craniotomy.¹⁷² Seizure management should be optimized with acceptable blood levels of antiepileptic medications.

Patient Teaching

The single most important element in the successful awake craniotomy is a highly motivated, well-informed patient. Each step of the procedure is discussed with the patient and family. Special emphasis is paid to prolonged surgical procedure, positioning, head immobility, pain anxiety, monitoring, noise, seizure management, and any individual considerations.

Induction and Maintenance of Anesthesia

Upon arrival to the holding area, an intravenous line is established. Preanesthesia medications are administered; they may include antibiotics, steroids, antiemetic prophylaxis, and anticonvulsants as indicated.

In the operating room suite, application of noninvasive monitoring is completed. Last minute questions are addressed, and the patient is induced with propofol. Some sources use either dexmedetomidine singly or in combination with propofol.¹⁷⁴ After

satisfactory general anesthesia is established, a laryngeal mask airway (LMA) is placed, with patient ventilation controlled using a continuous propofol infusion. Invasive monitoring is established (arterial line, central line, urinary catheter). The scalp is anesthetized with 0.5% bupivacaine and the head placed in a pinion head holder. The patient is carefully positioned with all bony surfaces padded and the patient carefully secured to the table to minimize a sense of falling when the table is moved during the awake phase of the surgery. Frameless stereotaxis registration is accomplished. Depending on the preoperative radiographic edema findings, hypertonic saline or mannitol is given. During draping, an area is constructed around the patient's face such that the face may be clearly seen and accessed. A light is introduced under the drapes to keep the patient from darkness. During the scalp opening, spontaneous ventilation is established. Prior to the bone flap removal, the LMA is removed and verbal contact established.

Awake Phase

All sedation must be discontinued. All issues regarding patient comfort and concerns are addressed prior to the incision of the dura. Conversation with the patient is confined to the surgeon and one member of the anesthesia team. Stimulation of eloquent areas is carried out with results noted. Any seizures are controlled with propofol, or cold saline is available if needed.¹⁷⁵ Following the stimulation and mapping, volumetric surgical removal of the tumor or seizure focus is accomplished with interval monitoring. Upon completion of the surgical removal and requisite monitoring, propofol sedation may be restarted and titrated to patient preference. Sedation is discontinued upon conclusion of surgery. The most common complications associated with awake craniotomy are pain, seizures, nausea, and confusion.^{176,177}

Posterior Fossa Surgery

Neuropathology within the posterior fossa may impair control of the airway, respiratory function, cardiovascular function, autonomic function, and consciousness. The major motor and sensory pathways, the primary cardiovascular and respiratory

centers, the reticular activating system, and the nuclei of the lower cranial nerves are all concentrated in the brainstem. All these structures are contained in a tight space with little room for edema, tumor, or blood.

Venous Air Embolus

In addition to the previously mentioned monitoring modalities, monitoring during posterior fossa surgery requires consideration of patient position and the potential for venous air embolus (VAE). Clinical situations that contribute to the occurrence of VAE are listed in [Box 31.5](#). Air may also be entrained from the cranial pin sites of the Mayfield head holder and from improperly connected vascular lines (arterial, central, and intravenous).

Clinical Situations Contributing to the Occurrence of Venous Air Embolism

- Patient positioning (seated, prone, steep Trendelenburg)
- Transfusion therapy
- Intravenous therapy
- Central venous catheterization
- Hepatic surgical procedures
- Urologic surgical procedures
- Posterior spinal procedures
- Epidural or caudal catheter insertion
- Bone marrow harvesting
- Laparoscopy
- Radical pelvic surgery
- Obstetric gynecologic procedures

- Thoracic procedures
- Orthopedic procedures
- Cardiac surgery
- Head and neck surgery

The occurrence of VAE depends on the development of a negative pressure gradient between the operative site and the right side of the heart. As the gradient between the cerebral veins and the right atrium increases, the potential for air entry increases. The estimated incidence of VAE during neurosurgical procedures ranges from 5% to 50%, with an increased incidence in the sitting position.^{178,179} A 2009 systematic review of 4806 patients undergoing sitting position neurosurgery noted a 39% rate of VAE for posterior fossa surgery and 12% for cervical procedures.¹⁸⁰

As the venous pressure at wound level is usually negative, air can be entrained. This air may follow any of four pathways. Most commonly it passes through the right heart into the pulmonary circulation, diffuses through the alveolar-capillary membrane, and appears in expelled gas. It may also pass through a pulmonary-systemic shunt such as in a patient with a patent foramen ovale (paradoxical air embolism). It may collect at the superior vena cava–right atrial junction. Lastly, rarely, it may traverse through lung capillaries into the systemic circulation.^{181,182}

The physiologic consequences associated with VAE depend on both the volume and the rate of air entrainment. In the canine model, large cumulative doses of air produce sudden cardiac arrest and death; smaller cumulative doses produce less profound physiologic consequences, including increased pulmonary artery and central venous pressure, decreased cardiac output with accompanying hypotension, progressive hypotension, and dysrhythmias.¹⁸³ Despite the potentially devastating effects of VAE, a retrospective review of neurosurgery patients who had appropriate monitoring for the detection of VAE found that VAE contributed to patient morbidity or mortality in only six instances (0.4%).^{184–186}

Paradoxical Air Embolism

Paradoxical air embolism (PAE) develops with the entry of air into the systemic circulation. Individuals with an existing anatomic connection between the right and left sides of the heart (atrial or ventricular septal defect, probe-patent foramen ovale) are at risk. A patent foramen ovale may exist in 30% to 35% of the population.¹⁸⁷ If right-sided heart pressures exceed left-sided pressures (a situation that may occur in fluid-restricted neurosurgical patients), systemic air may embolize and enter the arterial circulation through a probe-patent foramen ovale.

Patients who are placed in the sitting position should be carefully evaluated with echocardiograms if the history suggests the presence of an intracardiac defect (presence of heart murmur) or probe-patent foramen ovale. The presence of a probe-patent foramen ovale may be elicited with the injection of contrast material before, during, and after the patient produces a Valsalva maneuver. If the condition is identified, the surgical procedure should be accomplished in an alternative position.¹⁸⁸

Detection of Venous Air Embolus

The entrainment of air into the vascular system is usually of little consequence, because the lungs serve as effective blood filters.¹⁸⁹ Small amounts of air are absorbed into the blood or enter the alveoli, where they are eliminated. However, the efficient filtering capacity of the lung may be breached by a large bolus of air. Air enters the venous circulation as small bubbles that pass through the right side of the heart, entering the pulmonary arterioles. A reflexive sympathetic pulmonary vasoconstriction is produced after the release of endothelial mediators, which are ultimately responsible for the clinical manifestations (pulmonary hypertension, hypoxemia, CO₂ retention, increased dead-space ventilation, and decreased ET_{CO}₂). The continued entry of air produces an airlock within the right ventricle, producing right ventricular failure and decreased cardiac output. Altered ventilation-perfusion relationships parallel the hemodynamic changes. Obstructed pulmonary blood flow increases dead-space ventilation, resulting in decreased ET_{CO}₂. The entry of a large

volume of air in the alveoli may be detected by the sudden appearance of end-tidal nitrogen (ETN₂). Studies indicate that entrainment of small amounts of air less than 0.5 mL/kg will manifest as a decreased ETCO₂, increased ETN₂, oxygen desaturation, altered mental status, and wheezing. Moderate amounts of entrapped air, approximately 0.5 to 2.0 mL/kg, will produce difficulty breathing, wheezing, hypotension, ST changes, peaked P waves, jugular venous distention, myocardial and cerebral ischemia, bronchoconstriction, and pulmonary vasoconstriction. Large quantities of air entrainment (greater than 2.0 mL/kg) result in chest pain, right-sided heart failure, and cardiovascular collapse.¹⁹⁰

The selection of appropriate monitoring for the detection of VAE is based on the various sensitivities of the available monitoring modalities (Table 31.7).¹⁸⁹ The order of sensitivity of the monitoring methods from most sensitive to least is: transesophageal echocardiography (TEE) > precordial Doppler > pulmonary artery and ETCO₂ changes > cardiac output and central venous pressure changes > blood pressure, EKG and precordial stethoscope detection.

TABLE 31.7
Monitors for Detection of Venous Air Embolism

Monitor	Advantages	Disadvantages
Precordial Doppler	Most sensitive noninvasive monitor Earliest detector (before air enters pulmonary circulation)	Not quantitative May be difficult to place in obese patients, patients with chest wall deformity, or patients in the prone/lateral positions False-negative result if air does not pass beneath ultrasonic beam (approximately 10% of cases) Useless during electrocautery IV mannitol may mimic intravascular air
Pulmonary artery (PA) catheter	Quantitative, slightly more sensitive than ETCO ₂ Widely available Placed with minimum difficulty in experienced hands Can detect right-atrial pressure greater than pulmonary capillary wedge pressure	Small lumen, less air aspirated than with right-atrial catheter Placement for optimal air aspiration may not allow pulmonary capillary wedge pressure measurement Nonspecific for air
Capnography (ETCO ₂)	Noninvasive Sensitive Quantitative Widely available	Nonspecific for air Less sensitive than Doppler ultrasound, PA catheter Accuracy affected by tachypnea, low cardiac

		output, chronic obstructive pulmonary disease
Transesophageal echocardiography (TEE)	Most sensitive detector of air Can detect air in left side of heart, aorta	Invasive, cumbersome Expensive Must be observed continuously Not quantitative May interfere with Doppler ultrasonography

ETCO₂, End tidal carbon dioxide; *IV*, intravenous.

From Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*; 6th ed. Edinburgh: Elsevier; 2017:215.

TEE is the most sensitive method of air embolism detection but may not be practical, especially in longer procedures. Precordial Doppler monitoring can detect air entrainment at rates as small as 0.0021 mL/kg per min.¹⁹¹ The Doppler probe is affixed over the right side of the heart along the right sternal border between the third and sixth intercostal spaces. Proper positioning over the right atrium is confirmed if a change in Doppler signal is elicited when a 10-mL bolus of saline is injected rapidly into a previously placed right central venous catheter.¹⁹¹⁻¹⁹³ Placement of a right atrial catheter affords the means for diagnosis and recovery of intravenous air and also reflects cardiac preload. When a right atrial catheter is placed, it is recommended that either radiographic confirmation or ECG confirmation of proper placement of the catheter tip be obtained.¹⁹³ Advantages and disadvantages of selected monitors for detection of VAE are noted in [Table 31.7](#).

Capnography complements the capabilities of the Doppler device, because small, hemodynamically insignificant air emboli detected with the Doppler device can be differentiated from emboli that may produce arterial hypotension. The detection of a “mill-wheel” murmur via precordial or esophageal stethoscope is a late sign of air entrainment. As noted already, TEE is the most sensitive method of air embolism detection, but it is also the most expensive. With TEE, it is possible to observe both cardiac contractility and air bubbles as they pass through the heart.¹⁹⁴ TEE is also capable of detecting PAE in the heart.

Treatment of Venous Air Embolus

Detection of VAE should be rapidly treated ([Box 31.6](#)). The surgeon should be notified, and N₂O should be immediately discontinued, 100% oxygen delivered, and the right atrial catheter aspirated.¹⁹⁵

The surgeon should flood the surgical field with irrigation or pack the area with saline-soaked sponges. A Valsalva maneuver or bilateral compression of the jugular veins for 5 to 10 seconds increases the cerebral venous pressure and induces bleeding. The addition of positive end-expiratory pressure also slows air entry. However, 10 to 15 cm H₂O may be required to effectively elevate venous pressure when the head is elevated. The head should be lowered to decrease air entrainment. This may be accomplished by placing the operating table in Trendelenburg position. If air entrainment continues, the anesthetist should ask for an assistant. A second pair of hands allows simultaneous jugular vein compression and atrial catheter aspiration.^{196,197}

Therapy for Venous Air Embolism

- Notify surgeon on detection (flood surgical field with saline and wax bone edges).
- Discontinue nitrous oxide administration; administer 100% oxygen.
- Perform a Valsalva maneuver or compression of jugular veins.
- Aspirate air from atrial catheter.
- Support blood pressure with volume and vasopressors.
- Reposition patient in left lateral decubitus position with a 15-degree head-down tilt if blood pressure continues to decrease.
- Modify the anesthetic as needed to optimize hemodynamics.
- Postoperative follow-up should include ECG, chest x-ray, and arterial blood gases with oxygen as needed.

ECG, Electrocardiogram.

Supportive therapy is required for hemodynamic compromise. Administration of ephedrine, 10 to 20 mg intravenously, and an intravenous fluid bolus improves the blood pressure. If these

measures do not restore blood pressure, additional vasopressors (epinephrine) may be required.

Anesthetic agents and techniques may influence the rate of air entrainment and the resulting physiologic consequences. Munson and Merrick¹⁹⁵ demonstrated that the expansion of an intravascular air bubble is proportional to the delivered concentration of N₂O. A 50% concentration doubles the initial air-bubble volume, and a 70% concentration quadruples the air-bubble volume. General endotracheal anesthesia with controlled ventilation is thought to be protective in patients experiencing VAE.

Surgical Positioning

Although many posterior fossa explorations may be performed with the patient in either the lateral or prone position, the sitting position (Fig. 31.18) is occasionally preferred because the enhanced CSF and venous drainage facilitates surgical exposure. The use of this position, however, has declined due to the potential for serious complications.^{198,199} The patient is semirecumbent in the standard sitting position with the back elevated to 60 degrees and the legs elevated (with the knees flexed) to the level of the heart. The latter is important for preventing venous pooling and reducing the risk of venous thrombosis. The head is fixed in a three-point head holder with the neck in flexion, and the arms remain at the sides with the hands resting on the lap.⁹⁸

FIGURE 31.18 Neurosurgical sitting position for posterior

approach. Frame of head holder is attached to side rails of back section of operating room bed. Note that legs are flexed at thighs and are approximately at level of heart. Feet are padded at right angles to legs. Subgluteal padding protects sciatic nerves. (From Phillips N. *Berry and Kohn's Operating Room Technique*. 13th ed. St. Louis: Elsevier; 2017:764.)

Careful positioning is essential to prevent iatrogenic injury. Pressure points such as the elbows, ischial spines, and forehead must be protected with foam padding. Excessive neck flexion has been associated with swelling of the upper airway (venous obstruction) and, rarely, quadriplegia. This results from compression of the cervical spinal cord and decreased cervical cord perfusion when the neck is elevated above the heart. Preexisting cervical spinal stenosis probably predisposes the patient to the latter injury.⁹⁸

Anesthetic Induction, Maintenance, and Emergence

Increased ICP, although common in patients with supratentorial lesions, is less common in patients with posterior fossa lesions. Obstructive hydrocephalus is more typical because CSF outflow is occluded at the level of the aqueduct of Sylvius or fourth ventricle. This can be readily identified preoperatively by MRI or CT and may be corrected before definitive surgical intervention with the placement of a ventricular catheter. Premedication is contraindicated in patients with obstructive hydrocephalus.

Induction should be slow and deliberate to avoid changes in cerebral perfusion and increased ICP. Because the head is generally flexed and fixed in this position, a wire-reinforced ETT may prevent intraoperative kinking. These ETT may become kinked if the patient is lightly anesthetized and bites the tube. Intravenous fluid administration during posterior fossa surgery should be limited to the infusion of deficit and maintenance quantities of a balanced salt solution. Major volume resuscitation can be accomplished with the infusion of blood, colloid, or crystalloid solutions.

Emergence from anesthesia should be as smooth and gentle as possible. The intraoperative use of opioids facilitates a smooth

emergence without significant coughing and bucking. The administration of lidocaine, 1.5 mg/kg intravenously, decreases the airway irritation of the ETT.¹⁹⁶

The decision to remove the ETT should be made after the anesthetic course and surgical procedure are reviewed. Intraoperative air embolism may be followed by the development of pulmonary edema. Although this condition is self-limiting, continued mechanical ventilation is the treatment of choice. Consideration must also be given to the possibility of cranial nerve damage during the operative procedure. Provided the patient is safely extubated, continued vigilant observation is essential because airway compromise may develop after injury to cranial nerves IX, X, and XI (Box 31.7).

Postoperative Considerations With Posterior Fossa Surgery

- Cranial nerve dysfunction
- Central apnea
- Loss of upper airway control and patency
- Altered level of consciousness
- Altered cardiomotor function
- Cardiac dysrhythmias

Adapted from Miller RD, et al., eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier Saunders; 2015:2187.

Pituitary Surgery

Approximately 10% of intracranial neoplasms are found in the pituitary gland and come to clinical attention because of their mass effects or the hypersecretion of pituitary hormones. These tumors are rarely metastatic and produce local symptoms via bone invasion, hydrocephalus, and compression of a cranial nerve (most often the optic nerve). Frontotemporal headache and bitemporal

hemianopsia are the most common nonendocrine symptoms of enlarging pituitary lesions. Nonsecreting pituitary tumors account for approximately 20% to 50% of lesions in this area and are classified as *chromophobe adenomas*.^{199,200}

Tumors that secrete excess growth hormone produce acromegaly. Increased growth hormone increases the size of the skeleton, particularly the bones and soft tissues of the hands, feet, and face. The enlarged facial structures may increase the likelihood of difficult intubation. Excess growth hormone may also contribute to the development of coronary artery disease, hypertension, and cardiomyopathy. Hyperglycemia is also a common finding, reflecting a growth hormone–induced glucose intolerance.²⁰¹

Surgical Approach

Medical and surgical therapies exist for both functional and nonfunctional pituitary tumors. Transsphenoidal surgery (Fig. 31.19) offers several advantages over the intracranial approach. Statistically, morbidity and mortality rates are reduced because of a decrease in blood loss and less manipulation of brain tissue. In addition, the risk of inducing panhypopituitarism and the incidence of permanent diabetes insipidus are both reduced. For patients with large tumors (greater than 10 mm), tumors of uncertain type, and tumors that have substantial extrasellar (beyond the sella turcica) extension, the transsphenoidal approach is inadequate, and a bifrontal intracranial approach is required for successful removal.²⁰¹ Current trends support the use of endoscopic approaches to pituitary tumor excision. Less invasive approaches, such as the transnasal approach combined with endoscopic resection of tumor, have been performed. The endoscopic technique is associated with less morbidity and a shorter hospital stay than the traditional approach.²⁰²

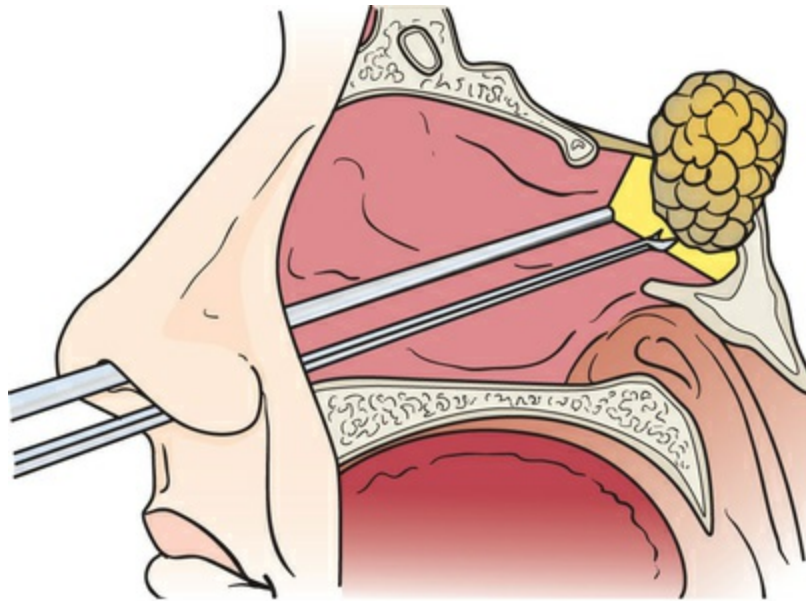

FIGURE 31.19 Transnasal hypophysectomy. (From Phillips N. Berry and Kohn's *Operating Room Technique*. 13th ed. St. Louis: Elsevier; 2017:772.)

Preoperative Evaluation

Patients undergo transsphenoidal operations for the treatment of hypersecreting pituitary tumors. Clinical symptoms of pituitary tumors include amenorrhea, galactorrhea, Cushing disease, and acromegaly.

Each preoperative condition has its own constellation of systemic disorders and accompanying effects on intracranial dynamics that must be considered when an anesthetic technique is selected. Pituitary tumors can damage decussating optic fibers, producing blindness in the temporal half of the visual field of both eyes (bitemporal heteronymous hemianopsia). Occasionally, an aneurysm of one of the internal carotid arteries may produce nasal hemianopsia on the affected side. Patients who have Cushing disease may also be affected by hypertension, diabetes, osteoporosis, obesity, and friability of skin and connective tissue. Patients who have acromegaly may have hypertension, cardiomyopathy, diabetes, and osteoporosis, as well as cartilaginous and soft-tissue hypertrophy of the larynx and enlargement of the tongue, complicating intubation of the trachea.

Patients who have panhypopituitarism may exhibit hypothyroidism, requiring preoperative thyroid supplementation.

The transsphenoidal approach usually necessitates the head and back be elevated 10 to 20 degrees. The patient's head is supported by a three-point pin head holder and centered within a C-arm fluoroscopy unit for radiographic control during surgery. The patient's arms are placed at the sides and padded so that injury to the ulnar nerves is avoided. The patient's airway is shared with the surgeon; therefore great attention must be directed to securing of the ETT and anesthesia circuit to prevent unintended extubation and anesthesia-circuit disconnect. Hyperventilation is avoided after anesthetic induction, because reductions in ICP result in retraction of the pituitary into the sella, making surgical access difficult. The anesthetist should also consider the potential for massive hemorrhage, because the carotid arteries lie adjacent to the suprasellar area and may be inadvertently injured.

When the resection involves the suprasellar area, postoperative endocrine dysfunction may occur, namely, diabetes insipidus. Diabetes insipidus that occurs after most transsphenoidal procedures is usually self-limited and resolves within a week to 10 days.²⁰⁰ Although the onset is usually on the first or second postoperative day, diabetes insipidus may develop during the perioperative period or in the immediate recovery period. Intraoperative diagnosis is made with the sudden onset of diuresis. The diagnosis may be confirmed with concurrent urine and serum osmolalities. If diabetes insipidus persists or if it becomes difficult to match urinary losses then DDAVP (desmopressin), given as a nasal solution or as an oral or sublingual tablet, is the treatment of choice. Intravenous DDAVP is longer acting and is not associated with the coronary vasoconstriction that follows administration of aqueous vasopressin.²⁰³

Anesthetic Induction, Maintenance, and Emergence

After anesthetic induction and intubation, the ETT is typically moved to the left corner of the patient's mouth and secured to the chin with adhesive and tape. A right-angled ETT may be effective

because such tubes are prebent and curve along the mandible when exiting the mouth. The esophageal stethoscope and temperature probe are inserted and secured on the lower left as well, leaving the upper lip totally exposed. An orogastric tube is placed, aspirated, and then put to gravity drainage during the procedure. The oropharynx is then packed with moist cotton gauze. The eyes are first taped closed and then covered with cotton-padded adhesive patches to prevent corneal abrasion and seepage of cleansing solution and blood into the eyes.

Propofol, an opioid (fentanyl, sufentanil, alfentanil, or remifentanyl), and a neuromuscular relaxant (either succinylcholine or a nondepolarizing neuromuscular relaxant for intubation, followed by a selected nondepolarizing agent), with a combination of air and oxygen is a commonly used anesthetic combination for this procedure. Isoflurane, desflurane, or sevoflurane may be added in low concentrations for blood pressure control; alternatively, it may be used as the primary anesthetic drug.

The topical use of vasoconstrictors and the oral and nasal submucosal injection of local anesthetic solutions containing epinephrine help constrict gingival and mucosal vessels and dissect the nasal mucosa away from the cartilaginous septum. Epinephrine use may produce hypertension or dysrhythmias or both. The use of epinephrine is relatively safe if (1) ventilation is adequate, (2) epinephrine is given in combination with lidocaine instead of saline, (3) epinephrine concentrations of 1 : 100,000 to 1 : 200,000 are used, and (4) total dose does not exceed 10 mL of 1 : 100,000 solution in 10 minutes for a 70-kg adult. Persistent dysrhythmias may require treatment with an antiarrhythmic drug. Hypertension may be controlled with an increased concentration of the selected inhalation agent or with labetalol or esmolol.²⁰⁴

In some cases, it may be necessary to insert a catheter into the lumbar subarachnoid space to facilitate the injection of preservative-free saline to delineate the suprasellar margins or for prevention of CSF leak postoperatively. If air is injected, N₂O must be discontinued from the anesthetic mixture because of rapid diffusion into the air present in the closed cranial vault.²⁰⁴

Emergence from anesthesia should be conducted as described for the previously discussed procedures. Intravenous lidocaine, 1.5

mg/kg given approximately 3 minutes before suctioning and extubation, decreases coughing, straining, and hypertension. Postoperatively, patients should be responsive to commands in the recovery room.

Cerebrovascular Surgery

Cerebral Aneurysms

Interventional neuroradiology is now the recommended as the initial treatment for the management of intracranial aneurysms. Aneurysm coiling or occlusion of the proximal arteries and obliteration of the aneurysm sac is the preferred therapy for many lesions.²⁰⁵ The International Subarachnoid Aneurysm Trial and subsequent studies have shown this approach to have several advantages over craniotomy with clipping although recurrence may be higher. Endovascular treatment of ruptured aneurysms results in quicker recovery and better functional outcomes at 1 year at the expense of lower rates of complete aneurysm obliteration frequently requiring retreatment.²⁰⁶

Cerebral aneurysms are abnormal, localized dilations of the intracranial arteries. They are classified as berry (or saccular), mycotic, traumatic, fusiform, neoplastic, or atherosclerotic. Rupture of a saccular aneurysm is a leading cause of subarachnoid hemorrhage (SAH).²⁰⁷

An estimated 6 million people in the United States have an unruptured brain aneurysm, or 1 in 50 people. The annual rate of rupture is approximately 8 to 10 per 100,000 people; approximately 30,000 people in the United States suffer a brain aneurysm rupture each year. Ruptured brain aneurysms are fatal in approximately 40% of cases. Of those who survive, approximately 66% suffer some permanent neurological deficit. Brain aneurysms are most prevalent in people ages 35 to 60, but can occur in children as well. The median age when aneurysmal hemorrhagic stroke occurs is 50 years old and there are typically no warning signs. Most aneurysms develop after the age of 40. Most aneurysms are small, approximately one-eighth inch to nearly one inch, and an estimated 50% to 80% of all aneurysms do not rupture during the course of a person's lifetime. Aneurysms larger than one inch are referred to as

giant aneurysms and can pose a particularly high risk and can be difficult to treat. Women, more than men, suffer from brain aneurysms at a ratio of 3 : 2.²⁰⁸

More than four out of seven patients with SAH die or develop significant and lasting neurologic disabilities before they receive any treatment. A small bleed occurs in approximately 50% of patients and is often tragically ignored or misdiagnosed. Even in patients who receive prompt care, only half remain functional survivors; the remainders die or develop serious neurologic deficits.²⁰⁹

Aneurysms may arise at any point in the circle of Willis. Most aneurysms are broad based and located in the middle cerebral system. Traumatic aneurysms develop as a result of direct trauma to an artery, with injury to the wall.

Mirror aneurysms of the internal carotid system are common, and other combinations of locations occur. The site of the bleeding aneurysm is best located by CT studies, evidence of vasospasm in the immediate vicinity, and lobulation of the aneurysm wall on angiographic studies.²⁰⁷

Diagnosis of Subarachnoid Hemorrhage

SAH produces an abrupt, intense headache in 85% of patients, and transient loss of consciousness may be seen in up to 45% of patients. Nausea and vomiting, photophobia, fever, meningismus, and focal neurologic deficits are not uncommon. The severity of an SAH can be graded clinically with the use of classifications such as Hunt and Hess or the World Federation of Neurological Surgeons Scale ([Table 31.8](#)). Although surgical mortality rates vary somewhat among institutions, patients with a neurologic grade I SAH generally undergo surgical clipping with a low mortality rate (less than 5%), whereas grade V patients generally do not survive.²⁰⁹ Unruptured cerebral aneurysms are commonly detected on brain imaging performed for reasons unrelated to the aneurysms.²¹⁰ The data on 1-year aneurysm- and procedure-related morbidity and mortality appear to support treatment over watchful waiting, as long as one avoids treating large aneurysms in those greater than 65 years of age with microsurgery.²¹¹

TABLE 31.8**Most Commonly Used Clinical Grading Scales for Subarachnoid Hemorrhage**

Hunt and Hess Scale		
Grade 0: Asymptomatic		
Grade 1: Mild headache and mild nuchal rigidity, no neurological deficit		
Grade 2: Moderate to severe headache but no neurological deficit other than cranial nerve palsy		
Grade 3: Drowsy, confused, or mild focal deficit		
Grade 4: Stupor, moderate to severe hemiparesis, and early decerebrate posturing		
Grade 5: Deep comatose, decerebrate posturing		
World Federation of Neurological Surgeons (WFNS) Scale		
	Glasgow Coma Scale	Motor Deficit
Grade 0	15	Absent
Grade 1	15	Absent
Grade 2	13–14	Absent
Grade 3	13–14	Present
Grade 4	7–12	Present or absent
Grade 5	3–6	Present or absent

From Daroff RB, et al., eds. *Bradley's Neurology in Clinical Practice*. 7th ed. London: Elsevier; 2016:990.

General Considerations

Hypertension often accompanies acute SAH and is postulated to develop secondary to autonomic hyperactivity, which may increase transmural pressure in the aneurysmal sac. *Transmural pressure* is defined as the differential pressure between MAP and ICP and represents the stress applied to the aneurysm's wall (Figs. 31.20 and 31.21).²⁰⁹

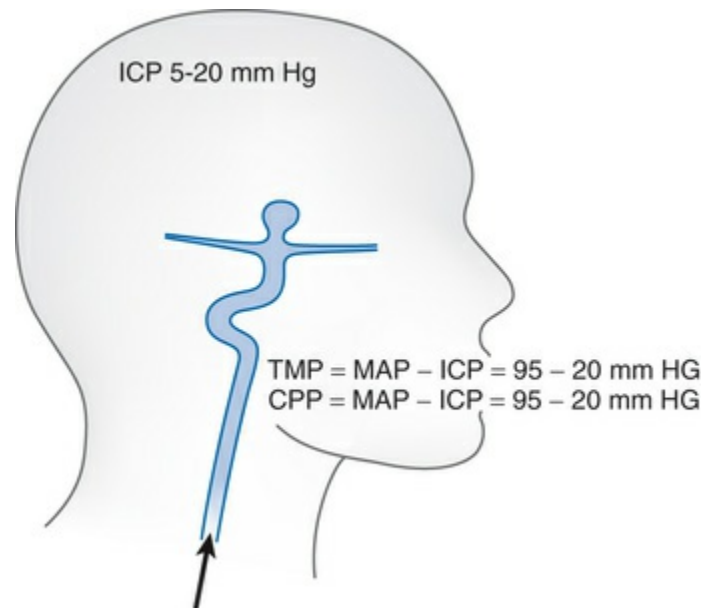

FIGURE 31.20 Determinants of transmural pressure (TMP) and cerebral perfusion pressure (CPP). Both are determined by the difference between mean arterial pressure (MAP) and intracranial pressure (ICP) and are therefore numerically identical. (From Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*, 6th ed. Edinburgh: Elsevier; 2017:229.)

FIGURE 31.21 Aneurysm wall stress.

Increases in blood pressure directly increase the transmural pressure and the likelihood of bleeding; conversely, reductions in blood pressure reduce transmural pressure and may compromise perfusion. Caution should be exercised when purposefully reducing transmural pressure because cerebral autoregulation may be impaired after SAH, and a reduction in blood pressure may induce or aggravate cerebral ischemia, particularly if vasospasm is

present. To balance these opposing factors, many neurosurgeons attempt to maintain systolic blood pressure between 120 and 150 mm Hg before clipping the aneurysm.^{205,209}

ECG changes are common after SAH and they have been reported to occur in 50% to 80% of patients. The most common changes involve the T wave or the ST segment, but other changes, such as the presence of a U wave, QTc interval (interval corrected for heart rate) prolongation, and dysrhythmias may be present. Whether such changes in the ECG represent myocardial injury has long been debated. In the majority of patients, these changes do not appear to be associated with adverse neurologic or cardiac outcomes.^{209,211}

Rebleeding from a previously ruptured aneurysm is a life-threatening complication. The incidence of rebleeding is approximately 50% in the first days after SAH, and rebleeding is associated with an 80% mortality rate.²¹² The chance of rebleeding from an unsecured aneurysm declines over time; by 6 months, the risk stabilizes at approximately 3% per year. Approaches used to decrease the risk of rebleeding include early surgical clipping, the use of antifibrinolytic agents, and blood pressure control.^{209,213}

Vasospasm

Cerebral vasospasm, a delayed and sustained contraction of cerebral arteries, continues to be a leading cause of morbidity and mortality in patients with SAH after aneurysm rupture.²⁰⁷

Vasospasm is reactive narrowing of cerebral arteries after SAH. Approximately one in four patients who have an SAH will develop vasospasm. Although arterial narrowing may be detected with angiography in 60% of patients, only half of these patients develop clinical symptoms. The accompanying neurologic deterioration, arising from impaired cerebral perfusion, ischemia, and secondary infarction of the brain, peaks between the third and fourteenth day after SAH and resolves over the next 2 to 3 weeks.²¹³ Vasospasm causes a decrease in blood flow and a resultant lowering of cerebral perfusion pressure. Medical treatments include oral nimodipine and hypertensive therapy to enhance cerebral oxygenation in the setting of vasoconstriction. Despite maximal medical measures, 15% of patients who initially survive an SAH experience stroke or death

secondary to vasospasm. For vasospasm that is refractory to medical management endovascular therapy has emerged as an alternative or supplementary therapeutic modality. Both balloon angioplasty and intraarterial vasodilator infusion have established roles in the management of medically intractable vasospasm. The optimal method and timing of endovascular treatment, however, remains controversial. Angioplasty is ideally accomplished in patients who have already had the symptomatic aneurysm surgically clipped and for patients in the early course of symptomatic ischemia to prevent hemorrhagic transformation of an ischemia region. A balloon catheter is guided under fluoroscopy into the vasospastic segment and inflated to distend the constricted area mechanically. It is also possible to perform a “pharmacologic” angioplasty by direct intraarterial infusion. Papaverine is an opium alkaloid and nonspecific smooth muscle relaxant. Papaverine causes vasodilation through cyclic adenosine and guanosine monophosphate phosphodiesterase inhibition and has a half-life of nearly 2 hours. Although papaverine produced clinical improvement in 43% of treated patients, the effect was temporary, and individuals often needed multiple treatment sessions. Concerns regarding the toxicity profile and short effect of papaverine have prompted the off-label use of calcium channel antagonists such as verapamil, nimodipine, and nicardipine in the treatment of cerebral vasospasm.^{205,213}

Vasospasm and the ensuing delayed ischemic deficit are thought to result from several factors. Vasospasm is initiated by the release of oxyhemoglobin, one of the blood breakdown products. However, the exact mechanism of cerebral vasospasm after SAH is not completely understood. The mechanism involves multifactorial processes and chemicals such as free radicals, lipid peroxidation, and the release of endothelin-1. Past studies on vasospasm have demonstrated prolonged smooth-muscle contraction in affected arteries. Hypertrophy, fibrosis, wall degeneration, and inflammatory changes were also observed.^{207,214,215}

Successful treatment of vasospasm depends on maintaining adequate CPP. This is accomplished by expanding intravascular volume (which augments blood pressure and cardiac output), avoiding hyponatremia, and preserving relative hemodilution

(hematocrit approximately 32%).²¹⁵ Because of the risk of rebleeding, careful blood pressure control is necessary.

Nimodipine is commonly used to prevent vasospasm after neurologic trauma or hemorrhage. Nimodipine is the only calcium channel blocker shown to reduce morbidity and mortality from vasospasm. Various agents are being tested as means to prevent or ameliorate vasospasm, including magnesium sulfate, statins, and an endothelin antagonist.²¹⁶ Cerebral vasospasm is frequently the cause of poor outcomes after successful surgical or endovascular treatment.

Currently, the most consistently effective regimen to prevent and treat ischemic neurologic deficits due to cerebral vasospasm uses hypervolemia, hypertension, and hemodilution. It is referred to as *triple-H therapy*. The use of nicardipine, labetalol, and esmolol to avoid hypertension that may cause aneurysm rupture, and avoiding hypotension that may decrease cerebral perfusion pressure is vital. Nimodipine is recommended for vasospasm prophylaxis in all patients with an SAH. Erythropoietin has shown to lower the incidence of vasospasm and delayed cerebral ischemia. Albumin is the preferred colloid. The rationale behind induced hypervolemia and hypertension is that in SAH the ischemic areas of the brain have impaired autoregulation and thus CBF is dependent of CPP. CBF depends on the intravascular volume and mean arterial blood pressure. Sufficient intravenous fluids are given to raise the CVP to 10 mm Hg. Hypervolemia is generally achieved with infusions of colloids (e.g., 5% albumin), as well as crystalloids. Hemodilution, should be induced to keep the hematocrit between 27% and 30%. Hypertension often results from the fluid loading; however, vasopressors may be required. Hypertensive, hypervolemic therapy may induce a vagal response and profound diuresis, requiring administration of large amounts of intravenous fluids. Atropine (1 mg intramuscularly every 3 to 4 hours) may be given to maintain the heart rate between 80 and 120 beats/min, and aqueous vasopressin (Pitressin), 5 units intramuscularly, may be administered to maintain the urine output at less than 200 mL/hr.

With this regimen, often only small amounts of vasopressor drugs are required. The blood pressure should be manipulated to a level necessary to reverse the signs and symptoms of vasospasm or

to a maximum of 160 to 200 mm Hg systolic postclipping. In the postclipping or postcoiling period, patients frequently autoregulate with SBP in the range of 200 mm Hg. If the aneurysm has not been clipped, the SBP is increased to only 120 to 150 mm Hg. The elevated blood pressure must be maintained until the vasospasm resolves, usually in 3 to 7 days. Response to therapy can be monitored noninvasively with transcranial Doppler. Improvement in vasospasm may be associated with a decrease in flow velocity, and thus angiography may be necessary.^{215,217}

Timing of Surgery

Early surgery has been shown to carry higher procedural morbidity and mortality. The presence or absence of vasospasm on angiographic studies has often been a major determinant. Nevertheless, early surgery prevents devastating rebleeding and enables aggressive hypervolemia/hypertension/hemodilution (triple-H) therapy for cerebral vasospasm. Current evidence supports that conventional open surgery or endovascular treatment should be performed as soon as possible after the onset of SAH unless contraindicated. A good outcome may be achieved with early operation (within 24 to 48 hours) in patients who are neurologically intact (grades I or II), regardless of whether vasospasm has been demonstrated. Such emergency intervention decreases the likelihood of rebleeding. Only 53% of grade III patients achieve a good outcome after early surgery; this indicates that the gross neurologic condition preoperatively is the best prognostic indicator of intact survival.²⁰⁷ In the first few days after hemorrhage, the brain is swollen, soft, hyperemic, and prone to contusion and laceration. The International Cooperative Study on the Timing of Aneurysm Surgery guided practice for many years. This multicenter study demonstrated that SAH patients who underwent surgery on posthemorrhage days 4 to 10 had worse outcomes than patients treated on days 0 to 3 and days 11 to 14. It was concluded that patients who present with SAH on days 4 to 10 should have aneurysm surgery delayed until after day 10. Since the introduction of interventional neuroradiology techniques, practitioners have come to believe that coiling of ruptured aneurysms can be performed safely on patients who arrive on

posthemorrhage days 4 to 10, and treatment need not be delayed until after day 10, as the results of the Timing of Aneurysm Surgery Study initially suggested.^{212,218}

Impaired autoregulation may decrease cerebral tolerance to brain retraction. Although removal of a subarachnoid clot probably decreases the incidence and severity of delayed arterial narrowing, clearly, operative management may be hazardous. In more severely brain injured patients (grades III through V), surgery is often delayed in anticipation of resolution of vasospasm and improvement in neurologic status.^{207,212,218} Data from 2011 suggest that early surgery, in good-grade patients within 48 hours of an SAH, is associated with better outcomes than surgery performed in the 3- to 6-day posthemorrhage interval. Surgical treatment for aneurysmal SAH may be more hazardous during the 3- to 6-day interval, but this should be weighed against the risk of rebleeding.^{219,220}

As mentioned earlier, endovascular clipping or coiling is increasingly used for treating SAH secondary to aneurysm rupture.^{206,221-223}

Preoperative Evaluation

The patients baseline neurologic status must be ascertained. The level of consciousness may vary from perfect alertness to deep coma and is an important prognostic factor for the postoperative state. Evidence of increased ICP should be elicited preoperatively so it can be managed appropriately. Focal motor and sensory signs may indicate intracerebral extension of SAH, vasospasm, or cerebral edema.²⁰⁹

Pulmonary complications, such as pneumonia, neurogenic pulmonary edema, and atelectasis, are not uncommon. Patients often have an increased risk of aspiration because of their depressed level of consciousness, and measures should be taken to reduce gastric acidity and volume preoperatively. The use of prophylactic hypervolemia also increases the likelihood of pulmonary edema.²⁰⁹

The hemodynamic status of the patient should be assessed, with particular attention paid to the relationship between neurologic deterioration and blood pressure changes. Continuous arterial blood pressure monitoring is essential. Serious dysrhythmias or

evidence of ventricular dysfunction should be diagnosed preoperatively so appropriate monitoring and management can be instituted.²²⁴ The syndrome of inappropriate antidiuretic hormone and diabetes insipidus can occur in patients with SAH.

The presence of blood in the subarachnoid space may produce a 1°C to 2°C elevation of body temperature. Hyperthermia increases cerebral oxygen requirements and therefore should be treated to prevent an increase of cerebral ischemia.^{209,213,225}

Preoperative sedation is rarely necessary in these patients. Depression of ventilation associated with opioids and benzodiazepines may result in hypercapnia, with resultant increases in CBF and ICP. Additionally, the reduced level of consciousness preoperatively and postoperatively may make clinical assessment difficult. Preoperative anxiety is not a problem in patients with a depressed level of consciousness (grades III through V), so sedation is not required. In awake patients, a reassuring preoperative visit helps to allay anxiety. If preoperative sedation is considered necessary, a benzodiazepine (midazolam) is appropriate, and continued observation after its administration is warranted.^{226–228}

Anesthetic Induction, Maintenance, and Emergence

Maintaining adequate intravascular volume requires two large-bore intravenous cannulas. Intraoperative monitoring includes continuous ECG (V₅), arterial pressure monitoring, peripheral nerve stimulator, central venous pressure monitoring, EEG, ETCO₂ monitoring, pulse oximetry, and monitoring of temperature and fluid balance.²²⁹

Intraoperative neurophysiologic monitoring during intracranial aneurysm surgery is standard practice. It is an important adjunct to surgical inspection and intraoperative angiography to detect cerebral ischemia. SSEPs, particularly median and posterior tibial nerve SSEPs, are commonly monitored during anterior circulation procedures. Dural monitoring with SSEPs and BAERs are preferred for posterior circulation and aneurysm surgeries. There is a significant correlation between alterations in electrical signals and

regional cerebral blood flow (rCBF), with transient electrophysiologic changes generally corresponding to good outcomes and permanent changes corresponding to postoperative deficits. EEG is also commonly used. Prior to temporary clip application, the neuroanesthesia team titrates brain protective anesthetics to achieve burst suppression on EEG. Burst suppression helps decrease metabolic demand so that the cerebral tissue can better tolerate induced ischemia such as during temporary clipping.²⁵

The anesthetic induction should be slow and deliberate. The anesthetic depth should be sufficient to avoid the hypertensive responses that accompany laryngoscopy and endotracheal intubation. Anesthesia is induced with titrated doses of propofol. The addition of an opioid (5 to 10 mcg/kg of fentanyl or 1 to 2 mcg/kg of sufentanil) and intravenous lidocaine (1.5 mg/kg) further blunts the patient's response to the sympathetic stimulation of laryngoscopy and intubation. An additional dose of opioid or propofol is required for the placement of the three-point pin head holder. Prior injection of local anesthetic minimizes the associated sympathetic stimulation. Epinephrine should not be included with the local anesthetic because delayed absorption (up to 30 minutes after injection) may produce significant increases in blood pressure. Ventilation is controlled with administration of 100% oxygen to achieve a PaCO₂ of 35 to 40 mm Hg with normal intracranial compliance. Mild hyperventilation (PaCO₂ of 30 to 35 mm Hg) is instituted when intracranial compliance is impaired.²⁰⁹

Succinylcholine produces moderate increases in ICP; however, as noted earlier, it is commonly used as this is not clinically relevant.²³⁰⁻²³² Alternatively, intubation can be accomplished with rocuronium 1 mg/kg.

The patient is placed in one of several positions, depending on the site of the aneurysm. Aneurysms that arise from the anterior part of the circle of Willis require that the patient be supine for a frontotemporal approach. The lateral position for a temporal approach is required for aneurysms that arise from the posterior aspect of the basilar artery. Aneurysms that arise from the vertebral artery or from the lower basilar artery require a sitting or prone position for a suboccipital approach. Aneurysms that arise from the

anterior communicating artery are usually approached from the right and those from the middle cerebral and posterior communicating arteries are approached from the side on which the aneurysm is located.²³³

Anesthesia is maintained with air and oxygen or N₂O in oxygen, with incremental titrated dosages of an opioid (fentanyl, alfentanil, or sufentanil), or an infusion of remifentanyl and a muscle relaxant. Isoflurane may also be added in inspired concentrations not to exceed 1%. Patients who have intracranial aneurysms may require induced hypertension or hypotension to rebleeding and counteract vasospasm.²³⁴ In addition, controlled hypotension is commonly used intraoperatively to make aneurysms softer and more pliable at the time of clipping, as well as to minimize blood loss if aneurysmal rupture occurs at this time.²¹¹ Sodium nitroprusside and an inhalation anesthetic agent are the drugs most widely used for induction or hypotension.^{203,234}

The safe limit of controlled hypotension has not been definitively established. Since the lower limit of cerebral vascular autoregulation is 60 mm/Hg and intact arterial reactivity may be compromised in brain tissue surrounding an aneurysm, tight hemodynamic control is vital. This autoregulatory curve is shifted to higher pressures in patients with preexisting hypertension, so decreases in MAP should probably be limited to no more than 40% of preoperative values.²⁰⁹

Rather than induce hypotension to facilitate clip ligation of the neck of the aneurysm, many neurosurgeons now routinely use temporary proximal occlusion of the parent vessel.²³⁵

The use of mild intraoperative hypothermia has been advocated for cerebral protection during periods of temporary occlusion.²³⁶ Deliberate mild hypothermia was first used in 1955 as an intraoperative technique to ameliorate new neurologic deficits after cerebral aneurysm clipping. Subsequently, it was also used after neonatal asphyxia, head trauma, and cardiac arrest. The Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST II) was a randomized, control trial designed to evaluate the effectiveness of mild hypothermia in decreasing neurologic deficits after aneurysm surgery. Intraoperative hypothermia did not improve the neurologic outcome after craniotomy among good-

grade patients with aneurysmal subarachnoid hemorrhage.²³⁷

At the conclusion of the anesthetic procedure, patients with good-grade aneurysms may be extubated in the operating room, although care must be exercised so that coughing, straining, hypercarbia, and hypertension are avoided. Propofol, lidocaine, or fentanyl may be used for short-term anesthesia as the procedure is being finished and for reducing the hemodynamic responses to extubation. Although the residual depressant effects of opioids may be reversed with judicious titrated dosages of naloxone, larger doses of naloxone can be hazardous in that they may cause sudden, violent awakening of the patient and marked increases in systemic blood pressure. ETTs should be retained in patients with poor-grade aneurysms and in those who have had intraoperative complications.²¹³

Postoperative Care

Postoperative care is directed at the prevention of vasospasm via the maintenance of intravascular volume expansion and moderate hypertension (MAP of 80 to 120 mm Hg). Changes in the level of consciousness and development of focal neurologic deficits are usually early signs of vasospasm. These clinical signs should be aggressively managed with hypertension, hypervolemia, and hemodilution. Vasopressors may be used for blood pressure support. CT should be used for ruling out other causes of neurologic deterioration, including rebleeding, infarction, and hydrocephalus.²¹³

Aneurysmal Rupture

Intraoperative aneurysmal rupture can be catastrophic. An abrupt increase in blood pressure during or after induction of anesthesia may indicate that an aneurysm has bled. The use of propofol 1 to 2 mg/kg or sodium nitroprusside 0.5 to 1 mcg/kg decreases the transmural pressure of the aneurysm. Intraoperative aneurysmal rupture necessitates maintaining the MAP between 40 and 50 mm Hg or lower to facilitate surgical control of the neck of the aneurysm or the parent vessel. Alternatively, one or both carotid arteries may be compressed for up to 3 minutes to produce a

bloodless field. Blood that is lost should be continuously replaced with blood, blood products, or colloid solution so that intravascular volume is maintained.²¹³

Although barbiturates have been used for protection against focal cerebral ischemia, their efficacy has not been demonstrated in this clinical situation.²³⁸

Interventional Neuroradiology

Treatment of aneurysms by an interventional neuroradiology procedure presents some special anesthetic considerations. These include maintaining immobility during procedures to facilitate imaging, rapid recovery from anesthesia at the end of procedures to facilitate neurologic examination and monitoring, or to provide for intermittent evaluation of neurologic function during procedures, managing anticoagulation, treating and managing sudden hemorrhage or vascular occlusion, manipulating systemic or regional blood pressures, and guiding the management of the patients during transport to and from the radiology suites. Both general and intravenous sedation are used; however, general anesthesia is preferred because the procedures can be long and manipulation of blood pressure and respiration may be necessary. The patient is prepared in a manner similar to that for open intracranial aneurysm clipping. Anesthesia considerations and management are also the same; however, if an intracranial emergency occurs during the procedure, several steps should be taken. [Box 31.8](#) outlines the management of intracranial emergencies.²⁰⁵ Anesthetic considerations for select interventional neuroradiology procedures are noted in [Table 31.9](#), and in [Chapter](#)

[Box 31.8](#)

Management of Intracranial Catastrophes*

Initial Resuscitation

- Communicate with endovascular therapy team
- Assess need for assistance; call for assistance

- Secure the airway; ventilate with 100% O₂
- Determine whether problem is hemorrhagic or occlusive (see text)
- *Hemorrhagic*: Immediate heparin reversal (1 mg protamine for each 100 units of heparin given) and low normal mean arterial pressure
- *Occlusive*: Deliberate hypertension, titrated to neurologic examination, angiography, or physiologic imaging studies; or to clinical context

Further Resuscitation

- Head up 15 degrees in neutral position, if possible
- PaCO₂ manipulation consistent with clinical setting, otherwise normocapnia
- Mannitol 0.5 g/kg, rapid IV infusion
- Titrate IV agent to electroencephalogram burst suppression
- Passive cooling to 33°C–34°C
- Consider ventriculostomy for treatment or monitoring of increased ICP
- Consider anticonvulsants (e.g., phenytoin or phenobarbital)

ICP, Intracranial pressure; *PaCO₂*, partial pressure of arterial carbon dioxide.

*These are only general recommendations and drug doses that must be adapted to specific clinical situations and in accordance with a patient's preexisting medical condition. In some cases of asymptomatic or minor vessel puncture or occlusion, less aggressive management may be appropriate.

TABLE 31.9**Interventional Neuroradiologic Procedures and Primary Anesthetic Considerations**

Procedure	Possible Anesthetic Considerations
Therapeutic embolization of vascular malformation	
Intracranial AVMs	Deliberate hypotension, postprocedure NPPB
Dural AVM	Existence of venous hypertension; deliberate hypercapnia
Extracranial AVMs	Deliberate hypercapnia
Carotid cavernous fistula	Deliberate hypercapnia, postprocedure NPPB
Cerebral aneurysms	Aneurysmal rupture, blood pressure control*
Ethanol sclerotherapy of AVMs or venous malformations	Brain swelling, airway swelling, hypoxemia, hypoglycemia, intoxication from ethanol, cardiorespiratory arrest
Balloon A&S of occlusive cerebrovascular disease	Cerebral ischemia, deliberate hypertension, concomitant coronary artery disease, bradycardia, hypotension
Balloon angioplasty of cerebral vasospasm secondary to aneurysmal SAH	Cerebral ischemia, blood pressure control*
Therapeutic carotid occlusion for giant aneurysms and skull base tumors	Cerebral ischemia, blood pressure control*
Thrombolysis of acute thromboembolic stroke	Postprocedure ICH (NPPB), concomitant coronary artery disease, blood pressure control*
Intraarterial chemotherapy of head and neck tumors	Airway swelling, intracranial hypertension
Embolization for epistaxis	Airway control

*Blood pressure control refers to deliberate hypo- or hypertension.

A&S, Angioplasty and stenting; AVM, arteriovenous malformation; ICH, intracerebral hemorrhage; NPPB, normal perfusion pressure breakthrough; SAH, subarachnoid hemorrhage.

Arteriovenous Malformation

Arteriovenous malformations are congenital intracerebral networks in which arteries flow directly into veins. Patients with these malformations generally are younger than those with aneurysms. They may have bleeding or seizures or, less commonly, ischemia resulting from “steal” from normal areas or occurring with high-output congestive heart failure. The anesthetic concerns parallel those associated with patients undergoing aneurysm surgery. Notably, arteriovenous malformations lack the ability to autoregulate blood flow at the site of the malformation. Surgery may be preceded by an attempt at embolization of the

arteriovenous malformation. The neurologic examination should be repeated after embolization to document new deficits that otherwise might be attributed to anesthesia and surgery.

Head Trauma and Traumatic Brain Injury

TBI is a contributory factor in up to 50% of deaths resulting from trauma. Most patients with head trauma are young, and many (10% to 40%) have associated intraabdominal injuries, long-bone fractures, or both. The significance of a head injury is dependent not only on the extent of the irreversible neuronal damage at the time of injury but also on the potential for secondary injuries. Additional insults include systemic factors such as hypoxemia, hypercapnia, and hypotension; the formation and expansion of an epidural, subdural, or intracerebral hematoma; and sustained intracranial hypertension ([Box 31.9](#)). Studies suggest that sustained increases in ICP of approximately 60 mm Hg result in irreversible brain edema. Surgical and anesthetic management is directed at preventing secondary insults.⁹⁸ Types of cerebral hematomas and mechanisms of head injuries are illustrated in [Fig. 31.22](#).

Peripheral Sequelae of Head Trauma

- Hemodynamic instability
- Abnormal breathing patterns
- Bone fractures
- Pneumothorax
- Airway obstruction
- Aspiration
- Hypoxia
- Adult respiratory distress syndrome
- Neurogenic pulmonary edema

- Electrocardiographic changes
- Hematologic
- Disseminated intravascular coagulation
- Endocrinologic
- Cervical spine injury
- Maxillofacial injuries

St. Louis: Saunders; 2009:1934–1936.)

Preoperative Management

Emergency therapy for head injury should begin before hospital admission, because a large proportion of deaths occur in the prehospital phase. Therapy is based on prevention of secondary brain injury resulting from hypoxia, hypercapnia, hypotension, and expanding intracranial masses.

Airway Management

Measures to ensure airway patency, adequacy of ventilation and oxygenation, and the correction of systemic hypotension should be instituted simultaneously with neurologic evaluation. Airway obstruction and hypoventilation are common. Up to 70% of head-injured patients have concurrent hypoxemia, which may be complicated by pulmonary contusion, fat emboli, or neurogenic pulmonary edema. All patients must be assumed to have a cervical spine injury (10% incidence) until disproved by radiography. Axial traction to maintain the head in a neutral position should be used during airway instrumentation. Fiberoptic intubation may be preferred for airway management in some cases. Patients who are hypoventilating, do not have a gag reflex, or a persistent total score below 7 on the GCS (see [Table 31.8](#)) require emergent tracheal intubation and hyperventilation. A modified coma scale for infants is given in [Table 31.10](#) and outlines response patterns seen after neurologic injuries. All other patients should be carefully observed for deterioration. [Table 31.11](#) summarizes respiratory patterns seen with various neurologic injuries. The GCS score correlates to the severity of injury and outcome.⁹⁸

TABLE 31.10

Modified Coma Scale for Infants

Response	Score
Eye Opening	
Spontaneous	4
To speech	3
To pain	2

TABLE 31.11
Respiratory Patterns With Head Trauma

Pattern	Description	Location of Injury and Other Causes
Cheyne-Stokes respiration	Regular increase in the rate and depth of breathing that peaks and is followed by a decreasing rate and depth of breathing, which progresses to apnea; then the cycle repeats itself	Bilateral dysfunction of cerebral hemispheres Midbrain and upper pons
Central neurogenic hyperventilation	Deep, rapid, and regular pattern of breathing	Low midbrain and upper pons Increased intracranial pressure with head trauma
Apneusis breathing	A pause at full inspiration occurs; may see prolonged inspiratory pause alternating with prolonged expiratory pause	Mid and low pons Hypoglycemia, anoxia, and meningitis
Cluster breathing	Periodic breathing with frequent apneic episodes	Low pons and high medulla
Ataxic breathing	Irregular breathing with shallow, deep respirations and irregular apneic episodes; usually slow	Medulla

From Drain CB, Odom-Forren J, eds. *Perianesthesia Nursing: A Critical Care Approach*. 5th ed. St. Louis: Elsevier; 2009:574.

When intubation is indicated, the oral route provides the most efficient means of safely securing the airway. Whenever possible, a modified, rapid-sequence endotracheal intubation should be performed.²³⁹⁻²⁴¹ Nasal intubation should be avoided in the presence of suspected basilar skull fracture, bleeding diathesis, suspected upper-airway foreign body, or severe facial fractures.²³⁹ If a difficult intubation is anticipated, awake intubation, fiberoptic techniques, or tracheostomy may be necessary.

Cardiovascular Assessment

Multisystem trauma often accompanies head injury. Hypotension results from intravascular loss from associated injuries. These injuries must be identified and treated early in the resuscitative period. Fluid resuscitation is facilitated by the administration of isotonic fluid, either normal saline or lactated Ringer's solution, or colloids if blood is not readily available. Glucose in water should not be used because it decreases serum osmolarity and can exacerbate cerebral edema. The ideal replacement fluid, of course, is blood. Because the cerebral vessels are already dilated from hypotension, rapid restoration of the normal arterial pressure precipitates brain swelling. It is extremely valuable to insert an ICP monitor during resuscitation for the monitoring of both systemic arterial pressure and ICP.²³⁸ Dysrhythmias and ECG abnormalities in the T wave, U wave, ST segment, and QT interval are common after head injuries but are not necessarily associated with cardiac injury.⁹⁸ Guidelines for blood pressure management in select neurosurgical emergencies are noted in [Table 31.12](#).

TABLE 31.12

Guidelines for Blood Pressure Management in Common Neurologic Conditions

Diagnosis	Recommendation
Acute ischemic stroke	Keep < 180/110 mm Hg if thrombolysis
	Treat only BP > 220/120 if no thrombolysis
Intracerebral hemorrhage	Keep SBP < 180 and MAP < 130 mm Hg
	(ideal SBP < 160 and MAP < 110 mm Hg)
Subarachnoid hemorrhage	Keep SBP < 160 mm Hg before aneurysm treated
	Do not lower BP after aneurysm treated
Traumatic brain injury	Keep MAP to maintain CPP > 60 mm Hg

BP, Blood pressure; *CPP*, cerebral perfusion pressure; *MAP*, mean arterial pressure; *SBP*, systolic blood pressure.

Coagulopathies

Chronic Subdural Hematoma.

Bridging veins run between the dura and the surface of the brain. A subdural hematoma develops when these veins tear and leak blood, usually as the result of a head injury. A collection of blood then forms over the surface of the brain. In a chronic subdural collection, the problem is not discovered immediately, and blood leaks from the veins slowly over time. A subdural hematoma is more common in the elderly because normal brain shrinkage occurs with aging that stretches and weakens the bridging veins. Rarely, a subdural hematoma can occur spontaneously. Risks include head injury, old age, chronic use of aspirin or antiinflammatory drugs such as ibuprofen, anticoagulant medication, chronic heavy alcohol use, or diseases that are associated with blood-clotting problems.²⁴²

A 2006 study of 713 emergency referrals documented over 90 days evaluated the effect of antithrombotic therapy on neurosurgical emergency referral. Of the 713 patients, 174 (24.4%) were discovered to have intracranial or spinal hemorrhage, and 75 (43.1%) of these were on antithrombotic therapy. Seventeen of these seventy-five patients (22.6%) had no documented indication for antithrombotic therapy (all were on aspirin therapy), and 9 of the 29 on warfarin (31%) had an INR (international normalized ratio [prothrombin time]) in excess of 3.5 on presentation.²⁴³

The key elements when managing coagulation abnormalities in patients presenting for emergent/urgent neurosurgery are (1) identifying the coagulopathy, (2) implementing a plan that allows for optimum coagulation status given the comorbidities of the patient, and (3) timing the period of optimum coagulation to coincide with the conclusion of surgery and the immediate postoperative period.

The relationship between coagulopathy and chronic subdural hematoma requires correction of coagulation to facilitate surgery.²⁴⁴ Forty-two percent of 114 patients presenting for drainage of chronic subdural hematoma were found to have coagulation disorders before surgery. Addressing coagulopathies in the geriatric population is a situation best addressed by a multidisciplinary approach. This patient population has limited vascular space that may not be able to accommodate the volume of blood products necessary for treatment in an urgent/emergent fashion. For

example, studies suggest that 10 to 17 mL/kg of fresh frozen plasma is necessary to reverse Coumadin toxicity.²⁴⁵

The general principles for emergency bleeding management include discontinuing the anticoagulant; hemodynamic and hemostatic resuscitation; and obtaining coagulation tests, including platelets, fibrinogen levels, and renal function studies. In warfarin-associated bleeding, prothrombin complex concentrate (PCC) or fresh frozen plasma (FFP) in combination with vitamin K can be administered to replace the missing functional clotting factors. Some hospitals use FFP; however, PCC is often preferred because it lowers the INR more rapidly, more completely, and without the added risks of transfusion reactions and excess volume. When reversing warfarin, concomitant vitamin K should be administered because of warfarin's long half-life. Without the use of PCC, vitamin K and FFP can take at least 12 to 24 hours to lower the INR into the reference range.^{245,246}

The direct oral anticoagulants dabigatran (Pradaxa), apixaban (Eliquis), edoxaban (Savaysa), and rivaroxaban (Xarelto) are frequently being used in lieu of warfarin and idarucizumab (Praxbind) is available for the urgent reversal of the anticoagulant effect of dabigatran.²⁴⁷

Reversal of clopidogrel, aspirin, or aspirin plus clopidogrel may be addressed by platelet administration. Alternatively, recombinant factor VIIa has been shown to reverse the inhibitory effects of aspirin or aspirin plus clopidogrel and could be useful for bleeding complications or when acute surgery is needed during treatment with these antiplatelet drugs.²⁴⁸

Severe brain injury initiates the outpouring of tissue thromboplastin and activation of the complement system, causing disseminated intravascular coagulopathy and fibrinolysis, as well as precipitating the development of adult respiratory distress syndrome. Early recognition of abnormal prothrombin and partial thromboplastin times is crucial. Prompt therapy with FFP, cryoprecipitate, whole blood, and, if necessary, platelets, may decrease the likelihood of disseminated intravascular coagulopathy.^{241,242}

Increased Intracranial Pressure

The initial therapy is directed toward lowering or preventing further increases in ICP. Simple maneuvers such as using a head-up tilt of 15 to 30 degrees to keep the head in the midline position and not rotated to either side (to ensure jugular vein patency), avoiding overhydration, maintaining normovolemia, and maintaining normal (rather than increased) arterial pressure all help control ICP.²⁴⁰

In patients in whom intracranial hypertension is suspected, whether from an epidural or subdural hematoma or from diffuse brain swelling, emergency treatment directed at reducing ICP is the rational course. Treatment of an increased ICP has been described previously. Corticosteroids (dexamethasone or methylprednisolone) are of little benefit, are likely detrimental in TBI, and should be avoided.²⁴⁹

Although mannitol effectively lowers the ICP minutes after administration, its use remains controversial. The drug is indicated, however, when either elevated ICP or a mass and herniation are responsible for the patient's deteriorating state. The risk of increasing the size of a hematoma is negligible compared with the disastrous effects of untreated progressive uncal herniation. If decompression of transtentorial herniation is delayed, secondary hemorrhage into the brainstem can occur and cause irreversible neurologic deficit. Once mannitol is given and the ICP is reduced, the specific intracranial disorder must be identified as soon as possible if a recurrence of the patient's deterioration is to be prevented.²⁴⁹

Animal and human studies have demonstrated that hypertonic saline has clinically desirable physiologic effects on CBF, ICP, and inflammatory responses in models of neurotrauma.²⁵⁰ Some studies suggest that 23.4% hypertonic saline is a safe and effective treatment for elevated ICP in patients after traumatic brain injury.^{251,252}

Mannitol therapy administered for increased ICP may have a beneficial effect on mortality when compared with pentobarbital treatment, but a detrimental effect on mortality when compared with hypertonic saline in treating increased ICP in head-injury patients.²⁵³

Neurodiagnostic Evaluation

The choice between operative and medical management of head trauma is based on radiographic and clinical findings. Patients should be stabilized before any CT or angiographic studies are performed. Critically ill patients should be closely monitored during such studies. Restless or uncooperative patients may require general anesthesia or sedation if these diagnostic examinations are to be accomplished. Sedation without control of the airway should be avoided because of the risk of further increases in ICP from hypercapnia or hypoxemia. Diagnostic imaging plays an important role in the management of patients with TBI. CT is the first-line imaging technique allowing rapid detection of primary structural brain lesions that require surgical intervention. CT also detects various deleterious secondary insults, allowing for early medical and surgical management. Serial imaging is critical to identifying secondary injuries. MRI is indicated for patients with acute TBI when CT results are inconsistent with neurologic findings. However, MRI is superior in patients with subacute and chronic TBI and is also predictive of neurocognitive outcome.²⁵⁴

Intraoperative Management

Operative treatment is reserved for depressed skull fracture, depressed fractures associated with underlying brain injury, and evacuation of epidural, subdural, and some intracerebral hematomas.²⁵⁵

Monitoring during anesthesia is generally similar to that for other mass lesions associated with intracranial hypertension. Intraarterial and central venous (or pulmonary artery) pressure monitoring should be established if it is not already present, but it should not delay surgical decompression in a rapidly deteriorating patient.^{98,242}

Anesthetic Induction, Maintenance, and Emergence

Intubation must be accomplished as expeditiously as possible with the use of incremental doses of propofol, rocuronium (assuming the airway can be instrumented), lidocaine, and labetalol (as needed for

the treatment of systemic hypertension), with concurrent cricoid pressure. Hyperkalemia may be induced with succinylcholine in a patient with closed-head injury without paresis; therefore use of this drug should be avoided.²⁵⁶ Intracranial damage is usually associated with hypertension.

If the patient is unconscious in the absence of a drug overdose, the ICP may be elevated. In this case, propofol and an opioid in combination with oxygen (or air in oxygen) and a muscle relaxant are appropriate. A similar technique is indicated in the patient who has a CT scan that demonstrates obliteration of basal cisterns, dilation of the fourth or lateral ventricles, or a midline shift of 10 mm.²⁵⁵

Although hyperventilation attenuates the increase in ICP when inhalation anesthetics are used, in patients with head injury, cerebral vasoconstriction in response to hypocapnia is not recommended. The administration of inhalation anesthetics in concentrations less than 1 MAC may have a role in the treatment of intraoperative hypertension.²⁵⁵

Patients who have chronic subdural hematoma and are alert and responsive may have burr holes placed for evacuation of accumulated blood under local anesthesia with sedation. Depressed skull fractures also may be elevated while the patient is awake and under local anesthesia with sedation. This technique must be used cautiously when the patient placed in the three-point pin head holder has a full stomach.²⁵⁵

Fluid replacement should be accomplished with glucose-free solutions. Hypovolemia results in systemic hypotension, an unstable anesthetic course, and (by decreasing cerebral oxygen delivery) increased cerebral vasodilation. Rheologic conditions are optimal at hematocrit levels of 30% to 32%.²⁴¹

The decision of whether to extubate the trachea at the conclusion of the surgical procedure depends on the severity of the injury, the presence of concomitant abdominal or thoracic injuries, preexisting illnesses, and the preoperative level of consciousness. A 2007 study noted that up to 54.5% of patients had an adverse event after surgery.²⁵⁵ Occurrence of nausea, vomiting, and respiratory and cardiac problems was significantly more likely than in patients undergoing routine surgical procedures. Young patients who are

conscious preoperatively may be extubated after the removal of a localized lesion, whereas patients with diffuse brain injury should remain intubated. Moreover, persistent intracranial hypertension requires continued paralysis, sedation, hyperventilation, and possibly a pentobarbital infusion postoperatively.⁹⁸

Summary

Advances in surgical approaches to tumors, vascular lesions, and TBIs necessitate constant reappraisal of the important role of anesthesia care in improving a patient's long-term outcome. Intraoperative monitoring modalities new to neurosurgical procedures remain to be definitively evaluated. Interventional radiologic approaches are now a primary therapy for several neurologic disorders, and anesthesia management presents many new challenges in caring for these patients.

Renal Anatomy, Physiology, Pathophysiology, and Anesthesia Management

Catherine Y. Morse

The kidneys are paired solid organs lying retroperitoneally on either side of the vertebral column. The main function of these organs is excreting end products of metabolism and controlling the concentration of constituents of body fluids. A rich blood supply to these vital organs, coupled with the physiologic processes of filtration, reabsorption, secretion, and excretion, maintains homeostasis of the fluid within cells. For management of anesthetized patients to be optimal, clinicians must be familiar with physiologic mechanisms utilized by the renal system to control intracellular and extracellular environments to maintain homeostasis.

This chapter addresses the effects of anesthesia and surgery on both the normal and the diseased kidney. After a discussion of the anatomic structure and physiologic mechanisms of the kidney, the effects of anesthesia on normal renal function are addressed. Pathophysiologic mechanisms associated with acute and chronic kidney injury follow. Preoperative renal assessment and anesthetic considerations for patients with impaired renal function are emphasized, and pertinent anesthetic considerations for common urologic procedures are discussed.

Structure of the Kidney

The kidneys are bean-shaped, reddish-brown organs located in the posterior part of the abdomen on both sides of the vertebral column (Fig. 32.1). These organs extend from the 12th thoracic vertebra to the 3rd lumbar vertebra; each weighs approximately 125 to 170 g in men and 115 to 155 g in women. Each kidney is approximately 11.25 cm long, 5 to 7.5 cm wide, and 2.5 cm thick. Due to hepatic displacement, the right kidney's position is slightly lower than the left kidney. The kidneys and renal vessels are embedded in fatty tissue known as *perirenal fat* and enclosed in renal fascia. Renal fascia and large vessels hold the kidneys in anatomical position (see Fig. 32.1).

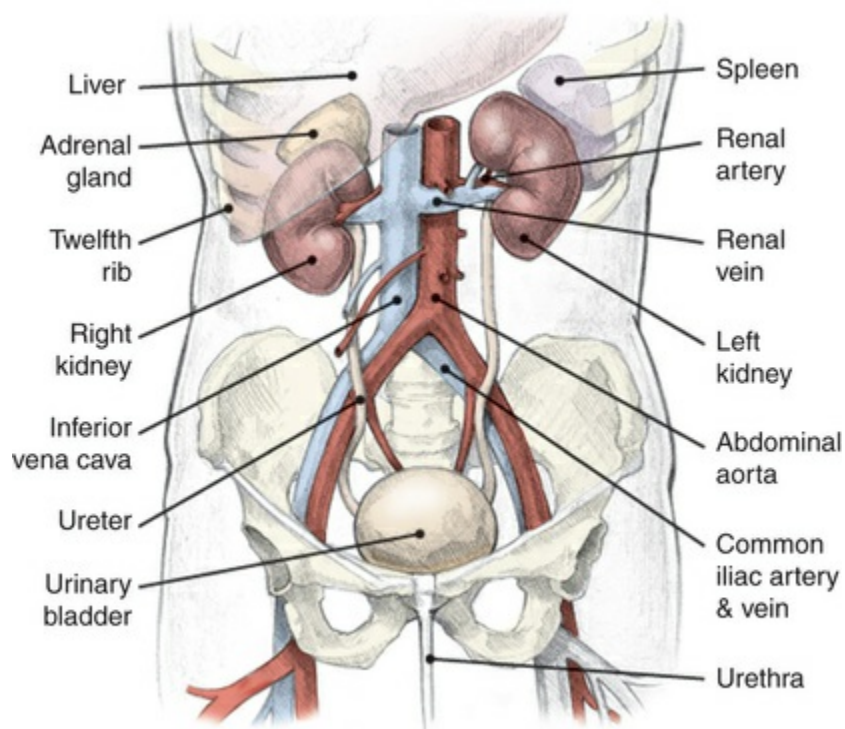

FIGURE 32.1 Kidney position.

The anterior and posterior surfaces, upper and lower poles, and lateral margin of the kidney have convex contours. The medial margin is concave because of the presence of a recessed fissure known as the *hilus*. Structures entering or exiting the kidney

through the hilus include the renal artery and vein, nerves, lymphatics, and ureters.

A longitudinal section of the kidney reveals two distinct regions, the outer cortex and the inner medulla (Fig. 32.2). The medulla is divided into 8 to 18 triangular wedges called *pyramids*. The base of each pyramid is directed toward the renal cortex, and the apexes converge toward the renal pelvis. Pyramids have a striated appearance due to the presence of the loop of Henle and collecting ducts of the nephron. The apex of each pyramid, called the *papilla*, is composed of many collecting ducts, and those papillary ducts empty into a cup-shaped structure known as the *minor calyx*. Several minor calyces join to form major calyces, which come together as the renal pelvis. The renal pelvis is the major reservoir for urine. Ureters connect the renal pelvis to the bladder.¹

FIGURE 32.2 Longitudinal section of the kidney.

Nephron

The functional unit of the kidney is the nephron (Fig. 32.3), and approximately 1,250,000 of these units reside in each kidney. The

shape of the nephron is unique, unmistakable, and admirably suited for its function. Each area of the nephron is selective with regard to its performance. Filtered blood flows through the nephrons, which, in turn, hold the filtered fluid known as *filtrate*. Through this process end products of metabolism are excreted, and metabolically important substances such as water are reabsorbed as needed.

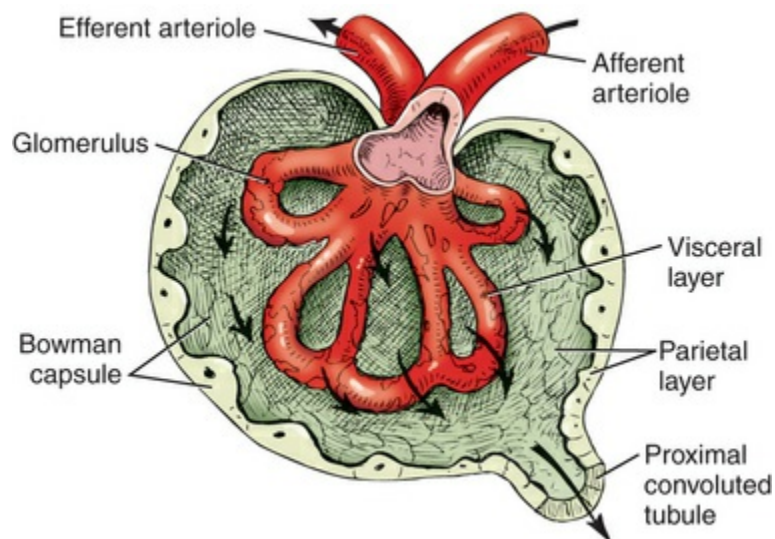

FIGURE 32.3 The nephron.

The formation of urine begins with the nephron. The nephron begins in the cortex at the glomerulus and ends where the tubule joins the collecting duct at the papilla. The glomerulus is a tuft of capillaries derived from the afferent arteriole. Blood is transported to the glomerulus by the afferent arteriole; blood that is not filtered, in the nephron, returns to the systemic circulation via the efferent arteriole. The filtrate from the glomeruli enters the Bowman capsule, or capsula glomeruli, then flows through a tortuous tube, or proximal convoluted tubule, to the loop of Henle, distal convoluted tubule, and, finally, the collecting duct.

The nephron, which changes in shape and direction as it follows its course, is contained partly in the renal cortex and partly in the medulla (Fig. 32.4). The cortex contains the Bowman capsule, glomerulus, and proximal and distal tubules. The thin, descending loop of Henle comes from the proximal tubule and extends toward the pyramid. The descending loop of Henle eventually bends on

itself and forms an enlarged, ascending loop of Henle. The ascending limb joins the distal convoluted tubule.¹

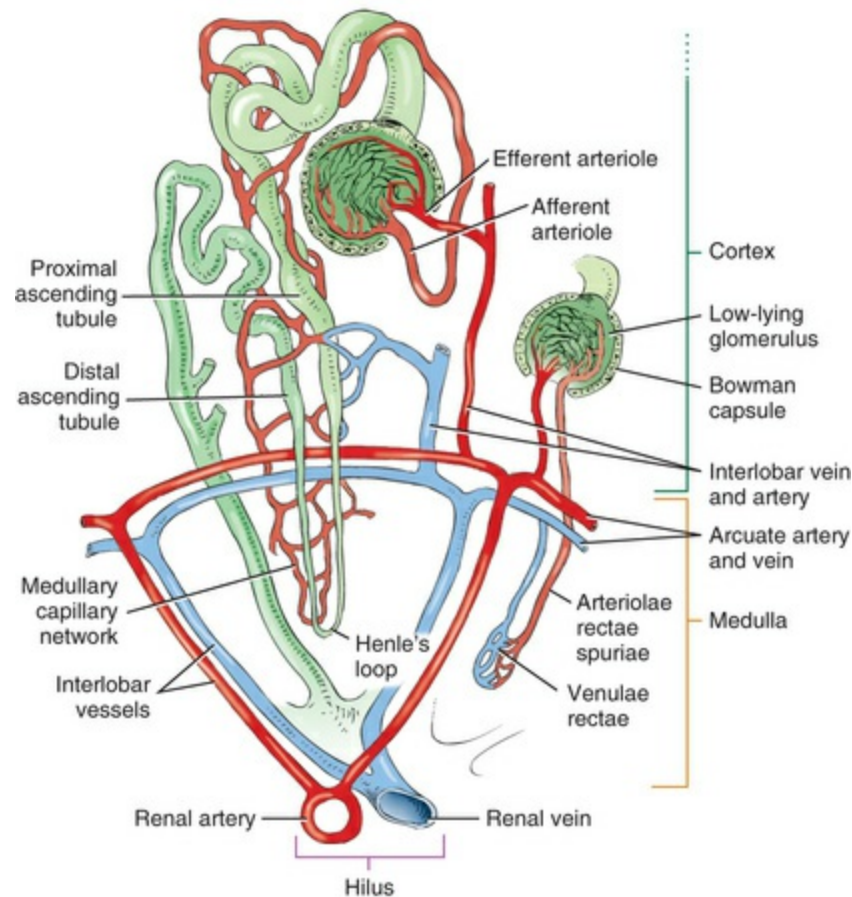

FIGURE 32.4 Renal filtration.

The kidneys have two types of nephrons: cortical nephrons, which extend only partially into the medulla, and juxtamedullary nephrons, which lie deep in the cortex and extend deep into the medulla. Juxtamedullary nephrons comprise one-fifth to one-third of total nephrons and play an important role in concentration of urine.²

Renal Blood Supply

To understand how the kidneys function, it is essential to understand their blood supply. The kidneys are highly vascular, receiving 1100 to 1200 mL of blood per minute, or 20% to 25% of the cardiac output, although they represent only 0.5% of body weight. Blood reaches these organs through the renal arteries. At the hilus

of the kidney, the renal artery divides into several lobar arteries and then subdivides again into interlobar arteries, which run between the pyramids. When these vessels reach the corticomedullary zone, they make well-defined arches over the bases of the pyramids. These vessels, known as *arcuate arteries*, divide into a series of arteries known as *interlobular arteries* (see Fig. 32.2). An interlobular artery may terminate as an afferent arteriole or as a nutrient artery to the tubule.

The afferent arterioles form the high-pressure capillary bed within the Bowman capsule that is called the *glomerulus*. Because little or no oxygen is removed in the glomerulus, blood that is not filtered begins its passage to the venous system via the efferent arteriole. The efferent arteriole is smaller than the afferent arteriole, thereby affording some resistance to blood flow. The efferent vessel soon becomes a plexus of capillaries again, and this low-pressure bed is known as the *peritubular capillary bed* which winds and twists around the proximal and distal tubule. A few hairpin loops, called *vasa recta*, dip down among the loops of Henle. Anatomic arrangements of these capillary beds and the renal tubules set the stage for filtration, reabsorption, and concentration of urine.

After leaving the peritubular capillary, blood returns to the central circulation via the renal veins. Renal veins are named in reverse order of the arteries, and therefore are the interlobular, arcuate, interlobar, lobar, and renal veins. The renal vein leaves the kidney at the hilus and empties into the inferior vena cava.

The cardiac output portion that passes through the kidney is called the *renal fraction*. Because cardiac output in a 70-kg man is approximately 5600 mL/min, and blood flow through both kidneys is 1200 mL/min, the normal renal fraction is 21%. This flow may vary from 12% to 30%. Distribution of renal blood flow is to the renal cortex and the medulla, with the cortex receiving the larger amount. Values obtained from dogs indicate that 3 to 5 mL/g per min are distributed to the cortex, 1 to 2 mL/g per min to the outer medulla, and 0.3 to 0.6 mL/g per min to the inner medulla. Only a small portion of blood (1% to 2%) flows through the vasa recta in the medulla.¹

Regulation of Renal Blood Flow

Blood flow to any organ is determined by the arteriovenous pressure difference across the vascular bed and is given by the following relationship:

$$\text{Renal blood flow} = (\text{MAP} - \text{VP}) \times \text{VR}$$

where MAP is the mean arterial pressure, VP is the venous pressure, and VR is the vascular resistance. Renal blood flow is regulated by intrinsic autoregulation and neural regulation.

Autoregulation of renal blood flow implies that blood flow remains normal despite a considerable change in pressure. With a MAP between 50 and 180 mm Hg, renal blood flow to both kidneys remains 1200 mL/min. If mean systemic blood pressure falls below 50 mm Hg, filtration ceases. Afferent arteriole vasodilation and myogenic mechanisms are responsible for autoregulation.¹

There is a direct relationship between renal blood flow and glomerular filtration. When renal blood flow decreases, glomerular filtration is reduced. A reduction in glomerular filtration leads to dilation of the afferent arteriole. An increase in blood flow to the glomerulus returns glomerular filtration to normal.

Myogenic mechanisms also play a role in renal autoregulation. When arterial pressure rises, the arterial wall is stretched, the vessel constricts, and blood flow remains normal. When arterial pressure decreases, the opposite effect occurs. Therefore, renal blood flow remains constant over a wide range of pressure changes.

Renal blood flow is also influenced by neural regulation. The sympathetic nervous system innervates the afferent and efferent arterioles. Autoregulation will override the adrenergic system with mild stimulation; acute sympathetic stimulation and associated vasoconstriction can decrease renal blood flow substantially. The parasympathetic nervous system is not physiologically significant in relationship to renal blood flow.¹

Renal Physiology

The kidneys maintain a steady state, which promotes homeostasis and is essential to life. This is accomplished through three major mechanisms: filtration, reabsorption, and tubular secretion. Plasma filtrate may be reabsorbed or excreted as urine depending on the physiological needs.²

Filtration

Filtration, which results from pressures forcing fluids and solutes through the glomerulus, is the first step in the formation of urine. The quantity of glomerular filtrate formed each minute in all nephrons is called the *glomerular filtration rate (GFR)*. The filtration fraction is the quantity of renal plasma flow that becomes filtrate and is defined as GFR divided by the flow to one kidney. Because the GFR is approximately 125 mL/min, and the flow to one kidney is 650 mL/min, the filtration fraction is 125/650, or 19% (approximately one-fifth) of plasma flow. Of the 125 mL/min (or 180 L/day) of this protein-free filtrate made, 99% is reabsorbed from the renal tubules, and the remaining small portion is excreted as urine.¹

Regulation of Glomerular Filtration Rate

Glomerular filtration is also dependent on several physiologic factors:

- The pressure inside the glomerular capillaries
- The pressure in the Bowman capsule
- The colloid osmotic pressure of the plasma proteins

The pressure inside the high-pressure glomerulus (60 mm Hg) is an outward force, whereas the colloid osmotic pressure created by proteins in the glomerulus (28 mm Hg) is an inward force that tends to hold fluid within the glomerulus. Pressure in the Bowman capsule (18 mm Hg) opposes filtration. Filtration pressure is the pressure that forces fluid through the glomerular membrane and is equal to the glomerular pressure minus the sum of the glomerular

colloid osmotic pressure and the capsular pressure. With the values given, the normal filtration pressure is 10 mm Hg. Several factors can alter GFR. Increased renal blood flow, dilation of the afferent arteriole, and increased resistance in the efferent arteriole increase GFR. Afferent arteriole constriction and efferent arteriole dilation tend to decrease GFR.

A special structure called the *juxtaglomerular complex* regulates GFR. At the juxtaglomerular complex, the distal convoluted tubule lies between the afferent and efferent arterioles. Cells of the distal tubule coming into contact with the arterioles are dense and therefore are referred to as the *macula densa*. Smooth muscle cells of both the afferent and efferent arterioles consist of juxtaglomerular cells, which contain renin. Anatomically, this structure is arranged to allow fluid in the distal tubule to alter afferent or efferent arteriolar tone and thus regulate GFR.

Decreased glomerular filtration causes overabsorption of sodium ions (Na^+) and chloride ions (Cl^-) in the ascending limb of the loop of Henle resulting in a reduction in the delivery of these ions to the macula densa, which are specialized cells designed to detect small changes in osmolality. Decreases in sodium and chloride concentrations cause afferent arterioles to dilate, thus increasing renal blood flow and GFR. Sympathetic stimulation and decreased delivery of both sodium and chloride to the macula densa stimulates the juxtaglomerular cells to release renin. Renin clears angiotensinogen from the liver to form angiotensin I. In the lung, angiotensin I is changed into angiotensin II under the influence of a converting enzyme, known as *angiotensin converting enzyme* (ACE). In addition to having a generalized vasoconstricting effect, angiotensin II causes efferent arteriole constriction. This causes the pressure in the glomerulus to increase and the GFR to return to normal. In this manner, the renal system autoregulates blood flow and GFR remains relatively unchanged despite changes in systemic blood pressure.¹

Filtrate Composition

Although permeability at the glomerulus is 100- to 500-times greater than most capillaries, glomerulus filtration is a selective process and it is only partially understood why some substances

are filtered and others are not. It is postulated that the glomerular capillary contains negatively charged pores, which are 70 to 100 nm in size, and are freely permeable to water and small molecules, as well as to some ions. Molecules with diameters up to 80 nm that do not have a negative charge are easily filtered. The glomerulus is almost impermeable to all plasma proteins but highly permeable to most other dissolved substances. Glomerular filtrate is therefore similar to plasma, except that it lacks significant amounts of proteins.²

Tubular Reabsorption and Secretion

Conversion of glomerular filtrate to urine is the result of filtration at the glomerulus, tubular reabsorption or transport from the tubular lumen to the renal cell, and secretion or transport from the renal cell to the filtrate. Approximately 99% of plasma filtrate is reabsorbed in the nephron.

Tubular reabsorption permits conservation of essential substances such as water, glucose, amino acids, and electrolytes. Some substances, such as water and sodium, are reabsorbed throughout the nephron, whereas others, such as glucose, are completely reabsorbed when plasma concentrations are low. Certain substances have a reabsorption maximum value, and after that value is reached, excess filtered material is excreted, regardless of plasma concentration. This maximum value is termed *maximum transport*. Maximum transport occurs because of saturation of a carrier for a particular substance.

By the time the blood has reached the peritubular capillary, one-fifth of the plasma has been filtered into the Bowman capsule. The hydrostatic pressure in this low-pressure capillary bed has dropped to 13 mm Hg, whereas the osmotic pressure has increased to 30 to 32 mm Hg. The peritubular capillaries are extremely porous compared with those in other body tissues, and the proximity to the proximal and distal tubule allows movement of water and solutes from the tubule to the peritubular capillary bed. The anatomical location and colloid osmotic pressure of plasma proteins account for the rapid absorption requirements.¹

Transport Mechanisms

Basic mechanisms of transport through the tubular membrane can be divided into active transport and passive transport. Active transport is the net movement of particles across a membrane against an electrochemical gradient, generally at the cost of metabolic energy. Passive transport involves the movement of substances across membranes and relies on either concentration gradients or chemical gradients. Active transport can be further divided into primary active transport, which requires energy, and secondary active transport, which does not require energy. Most primary active transport is for sodium. Secondary active transport is a result of the movement of sodium from the tubular lumen to the interior of the cell. For example, the active transport of sodium pulls glucose and amino acids with it. Because a carrier protein in the membrane combines with sodium and glucose, the process is termed *cotransport*. In addition to glucose and amino acids, chloride, phosphate, calcium, magnesium, and hydrogen ions are cotransported.

Some substances are actively secreted into the renal tubule in exchange for other molecules. Hydrogen, potassium, and urate ions are secreted in this manner. Hydrogen and potassium are generally secreted in exchange for sodium in a process termed *countertransport*.

When substances are actively transported from the tubule to the peritubular capillary bed, a concentration gradient that causes passive absorption of water by osmosis is established. When positive ions are actively transported, negative ions follow to maintain electrical neutrality. Chloride ions and urea are examples of substances that are passively absorbed.¹

Proximal Tubule

Each portion of the renal nephron is selective with regard to what is reabsorbed or secreted. Active transport of sodium is the primary function of the proximal tubule. Water, most electrolytes, and organic substances are cotransported with sodium. The osmotic force generated by active sodium transport promotes passive diffusion of water out of the tubules into the peritubular capillaries.

Passive transport of water is further enhanced by the elevated osmotic pressure of the blood in the peritubular capillaries. Reabsorption of water leaves an increased concentration of urea within the tubular lumen, thereby creating a gradient for its passive diffusion into the peritubular plasma. As positively charged sodium ions leave the tubular lumen, negatively charged chloride ions passively follow to maintain electroneutrality. Hydrogen ions are actively secreted in exchange for sodium. Secretory transport of sodium also occurs in the proximal tubule.

As the filtrate passes along the proximal tubule, 60% to 70% of filtered sodium and water, 50% of urea, as well as potassium, calcium, phosphate, uric acid, and the bicarbonate (HCO_3) form of carbon dioxide (CO_2) have been reabsorbed. Glucose, proteins, amino acids, acetoacetate ions, and vitamins are completely or almost completely reabsorbed by active processes. Because protein molecules are too large to be reabsorbed by normal mechanisms, a special mechanism called *pinocytosis* is used to save proteins. In this process, the tubular membrane engulfs the protein and internalizes it. Once inside the cell, the protein is digested into amino acids that can then be absorbed into the interstitial fluid.²

Loop of Henle

The primary function of the loop of Henle is to establish a hyperosmotic state within the medullary area of the kidney, a vital function vital to conserve salt and water. Water conservation and the production of concentrated urine involves a countercurrent exchange system. The counter current exchange system uses a concentration gradient causing fluid to be exchanged across parallel pathways. The fluid moves up and down the parallel sides of the hairpin loop of Henle in the medulla and the longer the loop, the greater the concentration gradient. As the gradient increases from the cortex to the medulla, movement of water is enhanced. Sluggish blood flow in the vasa recta assists in maintaining the gradient. The countercurrent mechanism is described in detail below in the section on “Concentration and Dilution of Urine—Countercurrent Multiplication.”

Late Distal Tubule

In the late distal tubule, sodium, under the influence of aldosterone, is reabsorbed. In this area, potassium is secreted into the lumen in exchange for sodium. It is mainly by this means that the potassium concentration is controlled in the extracellular fluids of the body.

The late distal tubule also secretes hydrogen against a concentration gradient. This function has a role in acid-base balance and determines the final degree of urine acidification. The late distal tubule reabsorbs 10% of filtered water. This area is permeable to water only in the presence of antidiuretic hormone (ADH).^{1,2}

Collecting Duct

Collecting duct permeability to water is controlled by ADH, which determines urine concentration. When this neurohypophyseal hormone is present, water is reabsorbed into the medullary interstitium, and the urine volume is reduced and concentrated. The collecting duct can also secrete hydrogen and therefore has a role in acid-base balance. [Fig. 32.5](#) illustrates renal blood flow, filtration, reabsorption, and secretion.¹

Renal Secretion

In addition to renin, hydrogen, and potassium, the kidneys release erythropoietin, a glycoprotein stimulating red blood cell production in the bone marrow. Any condition that causes the quantity of oxygen transported to the tissues to decrease stimulates the release of erythropoietin, production of red blood cells, and correction of hypoxia. A clinical diagnosis of anemia emerges when both kidneys are destroyed by renal disease.^{1,2}

Renal Hormones

Aldosterone

A number of hormones affect renal function. Aldosterone, the chief mineralocorticoid produced by the adrenal cortex, affects the distal segment of the nephron, causing the reabsorption of sodium and

water. Several physiologic control systems regulate aldosterone release: potassium concentration in extracellular fluid; the renin-angiotensin system; and sodium concentration in extracellular fluid. Of these, potassium is the strongest trigger, followed by renin and then sodium, respectively.²

Antidiuretic Hormone

ADH, a hormone synthesized in the hypothalamus but released from the neurohypophysis, also has the distal nephron as its target tissue. Because the distal tubule and collecting ducts are almost totally impermeable to water in the absence of ADH, water is not reabsorbed and is lost in the urine. In the presence of ADH, tubular permeability is increased, and water is reabsorbed. The release of ADH is controlled by the osmotic concentration of the extracellular fluids (Fig. 32.6). Osmoreceptors located near the hypothalamus sense extracellular fluid concentration and release ADH accordingly. ADH is inhibited by a stretch of atrial baroreceptors.^{1,2}

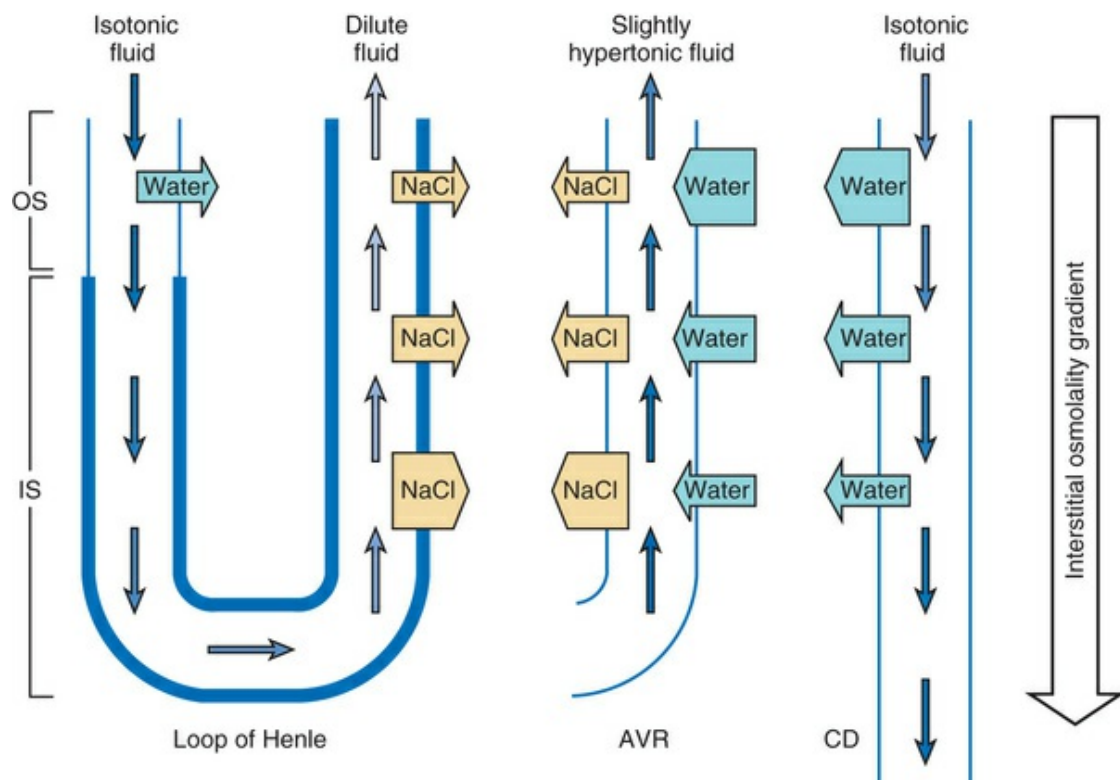

FIGURE 32.6 Outer medullary concentrating mechanism based on NaCl addition to the interstitium but without water absorption from descending limbs of short loops. *Arrows*

indicate water (*cyan*) and NaCl (*yellow*) transepithelial transport; *arrow widths* suggest relative transport magnitudes. Isotonic fluid is considered to have the same osmolality as blood plasma. Flow entering the ascending vas rectum (AVR) is assumed to arise from a descending vas rectum that is in, or near, a vascular bundle. Outflow from collecting duct (CD) enters the inner medullary CD.

Tubule fluid flow direction is indicated by *blue arrows*; increasing osmolality is indicated by *darkening shades of blue*. *Thick blue lines* indicate that a tubule is impermeable to water; *thin lines* indicate high permeability to water. *IS*, Inner stripe; *OS*, outer stripe. (From Skorecki K, et al. *Brenner and Rector's the Kidney*. 10th ed. St. Louis: Elsevier; 2016:268.)

Angiotensin

Angiotensin is a hormone that has a direct renal effect, as well as a general systemic effect. As previously discussed, renin is a small protein enzyme released by the kidneys. Stimuli for the release of renin include β -adrenergic stimulation, decreased perfusion to the afferent arterioles, and reduction in sodium delivery to the distal convoluted tubule. Once released, renin acts on hepatic angiotensinogen to form angiotensin I. ACE converts angiotensin I to angiotensin II in the lung. In addition to causing powerful vasoconstriction, angiotensin II stimulates aldosterone release from the adrenal cortex. Aldosterone increases salt and water retention by the kidneys. Both these actions increase arterial pressure.^{1,3}

Atrial Natriuretic Factor

Atrial natriuretic factor (ANF) is a peptide hormone synthesized, stored, and secreted by the cardiac atria.⁴ It acts on the kidney to increase urine flow and sodium excretion, and it may enhance renal blood flow and GFR. In addition, ANF antagonizes both the release and end-organ effects of renin, aldosterone, and ADH. The stimulus for ANF release is atrial distention, stretch, or pressure. ANF is one of the most potent diuretics known. Inhibition of plasma renin, angiotensin, and aldosterone can produce a dose-dependent decrease in blood pressure.^{1,2}

Vitamin D

Vitamin D, along with parathyroid hormone and calcitonin, has a vital role in calcium metabolism. Vitamin D, or cholecalciferol, is obtained in the diet or synthesized by the action of ultraviolet radiation on cholesterol in the skin. To become active, cholecalciferol is first hydroxylated in the kidney to 25-hydroxycholecalciferol, then in the liver to 1,25-dihydroxycholecalciferol. Patients with advanced renal disease often have abnormal serum calcium levels.²

Prostaglandins

Prostaglandins (PGs) such as PGE₂ and thromboxane A₂ modulate the renal effects of other hormones. PGE₂ is a vasodilator, and thromboxane A₂ produces contraction of vascular smooth muscle. Renal PGs influence renal excretion.^{1,2}

Renal Regulation of Acid-Base Balance

The kidneys, along with protein buffers and respiratory system, play a major role in regulating acid-base balance. Epithelial cells of the proximal tubules, the thick portion of the loop of Henle, distal tubules, and collecting ducts secrete hydrogen into the tubular fluid. This secretory process actually begins with CO₂ in the epithelial cells, where, under the influence of carbonic anhydrase, CO₂ combines with water to form carbonic acid (H₂CO₃). H₂CO₃ dissociates into HCO₃⁻ and hydrogen ions, and hydrogen ions are actively secreted into tubular fluid in exchange for sodium ions. This exchange maintains appropriate electrical balance between anions and cations in the tubular fluid.

An increase in HCO₃⁻ in alkalosis means that the filtered amount of HCO₃⁻ exceeds the amount of hydrogen secreted. Because excess HCO₃⁻ must react with hydrogen (HCO₃⁻ + H⁺ → H₂CO₃ → CO₂ + H₂O) and be absorbed as CO₂, excess HCO₃⁻ ions are lost in the urine along with sodium. In this way, sodium and excess HCO₃⁻ are removed from the extracellular fluid.

In acidosis, the concentration of hydrogen ions increases to a

level far greater than that of HCO_3^- in the tubules. Excess hydrogen ions are lost in the urine through the phosphate or ammonia (NH_3) buffer system.

The phosphate buffer is composed of hydrogen phosphate (HPO_4^{2-}) and dihydrogen phosphate (H_2PO_4^-). Both these ions become concentrated in the tubular fluid because of poor reabsorption. The quantity of HPO_4^{2-} is normally fourfold that of H_2PO_4^- . Excess hydrogen ions entering the tubules combine with monohydrogen phosphate to form H_2PO_4^- , which is lost in the urine. A sodium ion is absorbed into the extracellular fluid in exchange for hydrogen. It combines with HCO_3^- , which was formed in the process of secretion of the hydrogen, and sodium bicarbonate is added to the extracellular fluid.

NH_3 , which is synthesized by all epithelial cells except those in the thin segment of the loop of Henle, is also secreted into the tubules. NH_3 reacts with hydrogen to form the ammonium ion (NH_4^+). Ammonium ions are lost in the urine with chloride and other tubular anions.

The kidneys control extracellular fluid hydrogen concentration by excreting an acidic or basic urine. Excretion of acidic urine removes excess acid from the extracellular fluid, whereas loss of basic urine removes base from the extracellular fluid.^{1,2}

Concentration and Dilution of Urine— Countercurrent Multiplication

Doubts have arisen about whether the classic countercurrent multiplication process, as conceptualized, provides an accurate representation of the means by which the gradient is generated in the outer medulla. Newer theories state that the outer medullary osmolality gradient arises principally from vigorous active transport of NaCl , without accompanying water, from the thick ascending limbs of short- and long-looped nephrons. The tubule fluid of the thick limbs that enters the cortex is diluted well below plasma osmolality, and thus, the requirement of mass balance is met. This osmolality imbalance will facilitate water withdrawal from the descending limbs of long loops and from collecting ducts.

Descending vasa recta are thought to be found only in the vascular bundles. Thus the ascending vasa recta will act as the collectors of any NaCl that is absorbed from loops of Henle and water that is absorbed from the descending limbs of long loops and from collecting ducts.

The countercurrent configuration of the ascending vasa recta, relative to the descending limbs and collecting ducts, is likely to participate in sustaining the axial gradient: as ascending vasa recta fluid ascends toward the cortex, its osmolality will exceed that in the descending limbs of long loops and in the collecting ducts. Thus ascending vasa recta fluid will be progressively diluted as that fluid contributes to the concentrating of fluid in descending limbs of long loops and in collecting ducts, by giving up NaCl to, and absorbing water from, the interstitium ([Fig. 32.6](#)).⁵

Effects of Anesthesia on Normal Renal Function

Before considering anesthetic implications for patients with renal disease, it is important to review the effects of anesthesia and surgery on normal renal function. As you would expect, anesthesia tends to depress normal renal function. Some differences exist among anesthetics and are discussed in the next section.

Anesthetic Effects

General anesthesia is associated with a temporary depression of renal blood flow, GFR, urinary flow, and electrolyte excretion. Although similar changes occur after spinal and epidural anesthesia, the magnitude of change tends to parallel the degree of sympathetic block and blood pressure depression. This consistent and generalized depression of renal function has been attributed to a number of factors, including type and duration of surgical procedure, physical status of the patient, volume and electrolyte status, depth of anesthesia, and choice of agent.⁵

Anesthesia may alter renal function by direct or indirect effects. Indirect effects are mediated through changes in the circulatory, endocrine, or sympathetic nervous system. Anesthetic drugs alter the circulatory system by decreasing renal perfusion, increasing renal vascular resistance, or a combination of both. Drugs associated with catecholamine lead to vasoconstriction, an increase in renal vascular resistance, a decrease in renal blood flow, and a decrease in renal function. Volatile agents such as isoflurane, desflurane, and sevoflurane cause a mild to moderate increase in renal vascular resistance as a compensatory response to decreased perfusion pressure secondary to alterations in cardiac output or systemic vascular resistance.⁶⁻⁸ Desflurane has been shown to produce hemodynamic effects comparable to those produced by isoflurane.⁵ It increases heart rate and decreases both MAP and systemic vascular resistance while maintaining cardiac output. In some studies, but not all, desflurane maintains arterial pressure and systemic vascular resistance to a greater degree than equianesthetic

concentrations of isoflurane. Otherwise, desflurane and isoflurane have similar effects on most vascular beds, including the renal circulation.⁶

Issues regarding the renal effects of the release of free fluoride ion associated with sevoflurane metabolism have been debated. Historically, after methoxyflurane metabolism, high fluoride ion concentrations in the range of 60 to 90 $\mu\text{mol/L}$ have led to nephrotoxicity characterized by polyuria. This methoxyflurane polyuria was commonly referred to as *high-output renal failure*. Sevoflurane has not produced the expected toxicity in the same way as methoxyflurane even though significant fluoride ion levels may result from prolonged administration. A few reasons have been theorized for the lack of nephrotoxicity of sevoflurane, even though levels of metabolically released fluoride ions can approach those of methoxyflurane. They include the fact that sevoflurane metabolism is largely hepatic rather than renal. Intrarenal production of inorganic fluoride may be a more important factor than hepatic metabolism for the nephrotoxicity produced by increased serum fluoride concentration. Sevoflurane also has very low blood solubility and undergoes rapid elimination. Sevoflurane has not been associated with nephrotoxicity.⁹⁻¹¹

Changes in renal function during opiate, and nitrous oxide anesthesia are similar to those observed during the administration of low-dose volatile anesthesia. Preoperative hydration, lower concentrations of volatile anesthetics, and maintenance of normal blood pressure attenuate reductions in renal blood flow and GFR.^{12,13}

High levels of spinal or epidural anesthesia can impair venous return, diminish cardiac output, and reduce renal perfusion.¹⁴⁻¹⁶ Epidural blocks at thoracic levels with epinephrine-containing local anesthetics cause moderate reductions in renal blood flow and GFR that parallel the decrease in mean blood pressure. Epidural blocks performed with epinephrine-free solutions generate little change in systemic hemodynamics; however, absorption of local anesthetics is enhanced in uremic patients.¹⁷

In summary, virtually all anesthetics have the potential to alter the physiologic state, usually depressing the cardiovascular system and affecting renal blood flow, GFR, and urinary output. Although

systolic arterial blood pressure may not fall below 80 to 90 mm Hg, renal blood flow may be decreased by 30% to 40% after the administration of various anesthetics. This suggests impairment of autoregulation. In most cases, changes in renal function are transient and reversible. If they persist into the postoperative period, the cause is often a combination of factors such as preexisting renal or cardiovascular disease, or severe fluid imbalance, and the importance of the anesthetic effects is decreased.⁵

Physiologic Responses

The renal vasculature is richly innervated by the sympathetic nervous system. Drugs or perioperative events that stimulate this system cause an increase in renal vascular resistance and a decrease in renal blood flow and glomerular filtration. Surgical stress may also alter autonomic and neuroendocrine responses.

Norepinephrine from sympathetic postganglionic nerve fibers and epinephrine and norepinephrine from the adrenal medulla shift blood away from the cortical nephrons resulting in decreases in renal blood flow, GFR, electrolyte excretion, and urinary output. Catecholamines also stimulate the release of renin, which ultimately leads to the production of angiotensin II, a potent vasoconstrictor.

Neuroendocrine changes associated with anesthesia and surgical stress involves ADH, aldosterone, and the renin-angiotensin-aldosterone system. Although the perioperative period is associated with high circulating levels of ADH and aldosterone, it is not clear whether anesthetics stimulate the release or the release is secondary to the surgical stress response. General anesthetics and narcotics may cause a minor stimulus to release ADH. Laparoscopic surgical procedures have been shown to increase ADH levels. Clinical studies have specifically identified that pneumoperitoneum during laparoscopic surgery increases the level of ADH. Other studies indicate patients undergoing anesthetics lasting long durations had significant increases in ADH, with the greatest increase occurring at emergence.¹⁸ Additional investigations have shown that ADH levels increase after the induction of anesthesia and are higher in subjects receiving lower concentrations of remifentanil-propofol anesthesia.¹⁹

It is clear that ADH release is modulated by blood volume changes sensed by atrial wall stretch receptors. Hemorrhage, positive pressure ventilation, and upright positions increase ADH release.^{20,21} A decrease in arterial pressure stimulates ADH release. Distention of a balloon in the atrium, negative pressure ventilation, and immersion in water up to the neck decrease ADH release.

Renin-angiotensin levels may be elevated during the perioperative period, but the role of anesthetics and stress is not clear. Some studies have reported large increases in plasma renin levels associated with the use of anesthetics, whereas others report variances dependent on type of anesthesia delivered as well as surgical procedure. Balanced anesthesia has been found to result in higher levels of epinephrine, norepinephrine, and adrenocorticotrophic hormones than total intravenous anesthesia.²² Renin levels have been shown to increase during laparoscopic surgery, as well as levels of vasopressin, epinephrine, norepinephrine, and cortisol.²³ Hydration status prior to the start of surgery may play an important role in the intraoperative release of renin.²

Aldosterone, a hormone released from the adrenal gland, is responsible for the precise control of sodium excretion. It is not known whether anesthetic agents act directly on the adrenal gland to cause aldosterone release. Most likely, there is indirect influence through the neuroendocrine system and the renin-angiotensin-aldosterone system. Stimulation of the sympathetic nervous system causes renal vasoconstriction, which is a trigger for the renin-angiotensin-aldosterone system. Aldosterone leads to sodium and water reabsorption and can be associated with decreased urinary output.²

Nephrotoxicity of Anesthetic Agents

The kidneys are extremely vulnerable to toxicity because of their rich blood supply and the increase in concentration of excreted compounds occurring in the renal tubules during the process of reabsorption. Medullary hyperosmolality encourages concentration of all substances, including toxins. The amount of renal damage associated with nephrotoxic agents depends on (1) the concentration of the toxins, (2) the degree of toxin binding to

plasma proteins and nonrenal versus renal tissue, and (3) the length of exposure of the kidneys to the toxin. Evidence indicates the release of the inorganic fluoride ions (F⁻) in the metabolism of the fluorinated anesthetic methoxyflurane was the causative agent in nephrotoxicity. Fortunately, none of the modern inhalation anesthetics are nephrotoxic.⁵

Fluoride Ion Toxicity

Fluoride alters renal concentration mechanisms by interfering with active transport of sodium and chloride in the loop of Henle medullary portions. It also acts as a potent vasodilator, resulting in increased vasa recta blood flow and washout of medullary solute. Fluoride is a potent inhibitor of many enzyme systems, including those involving ADH, which is necessary for distal nephron reabsorption of water. Proximal tubular swelling and necrosis associated with fluoride ions also contribute to nephrotoxicity. Signs and symptoms of fluoride nephrotoxicity include polyuria, hypernatremia, serum hyperosmolality, elevations in blood urea nitrogen (BUN) and serum creatinine levels, and decreased creatinine clearance. The extent of nephrotoxicity in general surgical patients has been correlated with dosage or maximum allowable concentration hours (MAC-hours), duration, and peak fluoride concentrations.²⁴

Methoxyflurane

Methoxyflurane, an anesthetic no longer used, was the first anesthetic associated with serious nephrotoxicity. The serum fluoride concentration after methoxyflurane anesthesia showed positive correlation with the degree of renal dysfunction.¹ In the postoperative period, usually 2–5 days, patients exhibited a tremendous increase in nonconcentrated urine output. This toxicity was referred to as *high output renal failure* or *Penthrane polyuria*. The acute kidney injury with resulting fluid and electrolyte imbalances often led to death.¹¹

Isoflurane

Isoflurane is metabolized only slightly and defluorinated much less than other halogenated agents. In one report of nine surgical patients, mean peak serum fluoride concentration measured 6 hours after anesthesia was only 4.4 μmol .²⁵ Clinical experience has indicated that renal toxicity does not occur after the administration of isoflurane.

Desflurane

The metabolism of desflurane has been assessed in both animals and humans with the appearance of fluoride metabolites (fluoride ion, nonvolatile organic fluoride, trifluoroacetic acid) in blood and urine. Administration of desflurane to rats that were either pretreated or not pretreated with phenobarbital or ethanol for 3.2 MAC-hours, as well as to swine for 5.5 MAC-hours, produced fluoride levels in blood that were almost indistinguishable from values measured in control animals.²⁶ In human studies, desflurane administered to patients for 3.1 MAC-hours and volunteers for 7.3 MAC-hours resulted in postanesthesia serum fluoride concentrations that did not differ from background fluoride concentrations. Similarly, postanesthesia urinary excretion rates of fluoride and organic fluoride in volunteers were comparable with preanesthetic excretion rates.²⁷ Small but statistically significant increases in the levels of trifluoroacetic acid were found in both the serum and urine of volunteers after exposure to desflurane. Although these increases in trifluoroacetic acid were statistically significant, they were approximately one-tenth the levels seen after exposure to isoflurane. Desflurane strongly resists biodegradation, and only a small amount is metabolized in animals and humans. Desflurane does not produce nephrotoxicity.

Sevoflurane

Sevoflurane undergoes approximately 5% to 8% metabolism, and the primary metabolites are fluoride and hexafluoro-2-propranolol (HFIP). The oxidative defluorination of sevoflurane in the liver with the liberation of free fluoride ions raised concerns that sevoflurane, like methoxyflurane, might impair the ability of the kidneys to concentrate urine. Earlier research indicated that with

methoxyflurane, renal dysfunction was likely to occur when plasma fluoride levels exceeded 50 μmol . The same does not appear to be true with sevoflurane.

Numerous published reports indicate the absence of renal toxicity after sevoflurane anesthesia. As mentioned previously, an explanation for the absence of fluoride-induced nephrotoxicity may be a lower intrarenal production of fluoride ions, which is important in the pathogenesis of this complication. The intrarenal metabolism of methoxyflurane is four times greater than that of sevoflurane.

Studies of surgical patients receiving intermediate-duration sevoflurane with high and low fresh gas flow and long-duration sevoflurane with high fresh gas flow included sensitive measures of renal function or injury. These studies also indicate the absence of renal toxicity after sevoflurane anesthesia.

In addition to the release of inorganic fluoride ions resulting from biotransformation, CO_2 absorbents degrade sevoflurane, causing the production of a type of vinyl ether called *compound A*. This reaction occurs in the anesthesia machine, and the resulting toxin, compound A, is then delivered to the patient via the machine breathing system. Factors associated with the generation of higher levels of compound A during administration of sevoflurane to patients include (1) higher concentration of the agent, (2) increased temperature in CO_2 absorbent, (3) low fresh gas flow rates, (4) increased states of CO_2 production, and (5) absorbents containing strong base activators such as sodium or potassium hydroxide. The potential for compound A nephrotoxicity theoretically exists although no reports of problems in clinical practice have been reported.²⁴

Because the potential for renal injury exists with sevoflurane, studies in volunteers have raised the question of whether it is important to apply more sensitive measures of renal function in evaluation of this drug. Such tests have included urine concentrations or excretion of enzymes, albumin, protein, and glucose and creatinine clearance. Two studies of volunteers receiving prolonged sevoflurane anesthesia with fresh gas flow no greater than 2 L/min concluded that the potential for adverse renal effects of sevoflurane might exist. However, other studies of

volunteers did not find the same results. The only proven direct toxic effect of any anesthetic agent is the fluoride-related toxicity of methoxyflurane.

Currently, the US Food and Drug Administration recommends the use of sevoflurane for a minimum of 1 L/min of fresh gas flow and advise 2 MAC-hours at this flow rate should not be exceeded. The use of newer carbon dioxide absorbents such as Litholyme and others, which do not react with sevoflurane, to replace soda lime-type absorbents in modern anesthesia practice, have virtually eliminated any concern regarding compound A toxicity.^{5,9}

Acute Kidney Injury

Acute kidney injury (AKI) describes the clinical syndrome formerly called *acute renal failure* (ARF). AKI is defined as a renal functional or structural abnormality manifesting within 48 hours as determined by blood, urine, or tissue tests or by imaging studies. Diagnostically, the reduction in kidney function is associated with either an absolute increase in serum creatinine of 0.3 mg/dL or a percentage increase in serum creatinine of 50%. In addition, a reduction in urine output with oliguria (< 0.5 mL/kg per hr) for more than 6 hours also fulfills the diagnostic criteria. Patients are frequently classified based on urine flow rates as nonoliguric (urine output > 400 mL/day), oliguric (urine output < 400 mL/day), or anuric (urine output < 100 mL/day).

Most episodes of AKI occur in the hospital, with an incidence ranging from 5% to 7% among all hospitalized patients and 15% to 40% among patients in intensive care units (ICUs). Approximately 36% of ICU patients will develop AKI after major surgical procedures.²⁸ By contrast, the incidence of community-acquired AKI is less than 1%.

AKI is usually divided into three broad pathophysiologic categories based on cause:

1. Prerenal AKI: diseases characterized by effective hypoperfusion of the kidneys in which there is no parenchymal damage to the kidney
2. Intrinsic AKI: diseases involving the renal parenchyma
3. Postrenal (obstructive) AKI: diseases associated with acute obstruction of the urinary tract

Each of the categories represents a unique pathophysiologic process with distinctive diagnostic parameters and prognosis. Causes of prerenal ([Box 32.1](#)), intrinsic ([Table 32.1](#)), and postrenal ([Box 32.1](#)) AKI are summarized in the boxes noted.

Causes of Prerenal Acute Kidney Injury

Intravascular Volume Depletion

- Hemorrhage—trauma, surgery, postpartum, gastrointestinal
- Gastrointestinal losses—diarrhea, vomiting, nasogastric tube loss
- Renal losses—diuretic use, osmotic diuresis, diabetes insipidus
- Skin and mucous membrane losses—burns, hyperthermia
- Nephrotic syndrome
- Cirrhosis
- Capillary leak

Reduced Cardiac Output

- Cardiogenic shock
- Pericardial diseases—restrictive, constrictive, tamponade
- Congestive heart failure
- Valvular diseases
- Pulmonary diseases—pulmonary hypertension, pulmonary embolism
- Sepsis

Systemic Vasodilation

- Sepsis
- Cirrhosis
- Anaphylaxis
- Drugs

Renal Vasoconstriction

- Early sepsis
- Hepatorenal syndrome
- Acute hypercalcemia
- Drugs—norepinephrine, vasopressin, nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, calcineurin inhibitors
- Iodinated contrast agents

Increased Intraabdominal Pressure

- Abdominal compartment syndrome

From Sharfuddin AA, et al. Acute kidney injury. In Skorecki K et al., eds. *Brenner & Rector's The Kidney*. 10th ed. Philadelphia: Elsevier; 2016:959.

TABLE 32.1

Major Causes of Intrinsic Acute Kidney Injury

Tubular Injury	
Ischemia due to hypoperfusion	Hypovolemia, sepsis, hemorrhage, cirrhosis, congestive heart failure
Endogenous toxins	Myoglobin, hemoglobin, paraproteinemia, uric acid
Exogenous toxins	Antibiotics, chemotherapy agents, radiocontrast, media, phosphate preparations
Tubulointerstitial Injury	
Acute allergic interstitial nephritis	Nonsteroidal antiinflammatory drugs, antibiotics
Infections	Viral, bacterial, and fungal infections
Infiltration Allograft rejection	Lymphoma, leukemia, sarcoid
Glomerular Injury	
Inflammation	Anti-glomerular basement membrane disease, antineutrophil cytoplasmic autoantibody disease, infection, cryoglobulinemia, membranoproliferative glomerulonephritis, immunoglobulin A nephropathy, systemic lupus erythematosus, Henoch-Schönlein purpura, polyarteritis nodosa
Hematologic disorders	Hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, drugs

Renal Microvasculature	
	Malignant hypertension, toxemia of pregnancy, hypercalcemia, radiocontrast media, scleroderma, drugs
Large Vessels	
Arteries	Thrombosis, vasculitis, dissection, thromboembolism, atheroembolism, trauma
Veins	Thrombosis, compression, trauma

From Sharfuddin AA, et al. Acute kidney injury. In Skorecki K et al, eds. *Brenner & Rector's The Kidney*. 10th ed. Philadelphia: Elsevier; 2016:960.

Box 32.2

Causes of Postrenal Acute Kidney Injury

Upper Urinary Tract Extrinsic Causes

- Retroperitoneal space—lymph nodes, tumors
- Pelvic or intraabdominal tumors—cervix, uterus, ovary, prostate
- Fibrosis—radiation, drugs, inflammatory conditions
- Ureteral ligation or surgical trauma
- Granulomatous diseases
- Hematoma

Lower Urinary Tract Causes

- Prostate—benign prostatic hypertrophy, carcinoma, infection
- Bladder—neck obstruction, calculi, carcinoma, infection (schistosomiasis)
- Functional—neurogenic bladder secondary to spinal cord injury, diabetes, multiple sclerosis, stroke, pharmacologic side effects of drugs (anticholinergics, antidepressants)
- Urethral—posterior urethral valves, strictures, trauma, infections, tuberculosis, tumors

Upper Urinary Tract Intrinsic Causes

- Nephrolithiasis

- Strictures
- Edema
- Debris, blood clots, sloughed papillae, fungal ball
- Malignancy

From Sharfuddin AA, et al. Acute kidney injury. In Skorecki K et al., eds. *Brenner & Rector's The Kidney*. 10th ed. Philadelphia: Elsevier; 2016:960.

Classification

Historically, acute kidney injury was classified according to urine output: oliguric, nonoliguric, or polyuric, or by its predominant cause: prerenal, renal, or postrenal. Oliguria is defined as a urinary flow rate less than 0.5 mL/kg per hr. Polyuric failure is associated with elevations of BUN and serum creatinine levels and is characterized by urine flow rates that exceed 2.5 L/day.²⁹ Prerenal AKI results from hemodynamic or endocrine factors impairing renal perfusion, intrinsic AKI results from tissue damage, and postrenal AKI results from urinary tract obstruction.

Current classification focuses on serum creatinine clearance and urinary output as markers for severity of injury: Acute Dialysis Quality Initiative's RIFLE (*Risk of renal dysfunction, Injury to the kidney, Failure of kidney function, Loss of kidney function, and ESRD* [end-stage kidney disease]) or the Acute Kidney Injury Network's (AKIN) stages 1 through 3. Both classifications demonstrate that serum creatinine clearance is a sensitive marker for AKI, as opposed to urine output. The classifications delineate kidney injury progression from an at-risk standpoint to complete ESRD.³⁰⁻³² [Table 32.2](#) shows the RIFLE and AKIN classification systems. Additional markers, such as urine creatinine levels, angiotensinogen, or presence of proteinuria can be used in conjunction with RIFLE or AKIN classifications to aid in diagnosing the severity of AKI. However, use of diuretics must be factored in before using these additional biomarkers.^{29,33,34}

TABLE 32.2

RIFLE, Acute Kidney Injury Network, and Kidney Disease: Improving Global Outcomes Definitions and Staging of Acute Kidney Injury

Definitions			
	RIFLE	AKIN	KDIGO
Serum creatinine level	An increase of > 50% developing over < 7 days	An increase of ≥ 0.3 mg/dL or of > 50% developing over < 48 hr	An increase of ≥ 0.3 mg/dL developing over < 48 hr; or an increase of > 50% developing over < 7 days
Urine output*	< 0.5 mL/kg per hr for > 6 hr	< 0.5 mL/kg per hr for > 6 hr	< 0.5 mL/kg per hr for > 6 hr

Staging Criteria						
RIFLE	Increase in Serum Creatinine Level	AKIN	Increase in Serum Creatinine Level	KDIGO	Increase in Serum Creatinine Level	Urine Output*
Risk	$\geq 50\%$	Stage 1	≥ 0.3 mg/dL; or $\geq 50\%$	Stage 1	≥ 0.3 mg/dL; or $\geq 50\%$	< 0.5 mL/kg per hr for > 6 hr
Injury	$\geq 100\%$	Stage 2	$\geq 100\%$	Stage 2	$\geq 100\%$	< 0.5 mL/kg per hr for > 12 hr
Failure	$\geq 200\%$	Stage 3	$\geq 200\%$	Stage 3	$\geq 200\%$	< 0.5 mL/kg per hr for > 24 hr or anuria for > 12 hr
Loss	Need for renal replacement therapy for > 4 wk					
End-stage	Need for renal replacement therapy for > 3 mo					

*The urine output criteria for both definition and staging of acute kidney injury are the same for the RIFLE, AKIN, and KDIGO criteria.

AKIN, Acute Kidney Injury Network; *KDIGO*, Kidney Disease: Improving Global Outcomes; *RIFLE*, Risk, Injury, Failure, Loss, and End-stage kidney disease.

From Sharfuddin AA, et al. Acute kidney injury. In Skorecki K, et al, eds. *Brenner & Rector's The Kidney*. 10th ed. Philadelphia: Elsevier; 2016:961.

Prerenal conditions leading to urine output reductions include acute reductions in GFR, excessive reabsorption of salt or water, or both. Increases in circulating levels of catecholamines, ADH, or aldosterone are physiologic factors which can decrease urinary output.³² If not reversed, initial stages of AKI may progress to injury, tissue loss, or ESRD with progressively increasing mortality rates.^{34,35}

Acute tubular necrosis may be produced by a variety of factors interfering with glomerular filtration or tubular reabsorption. Reabsorption of urea, sodium, and water are all impaired, in contrast to AKI, in which these functions are maintained.³²

Renal hypoperfusion or a nephrotoxic insult may initiate renal failure. Surgical patients with external and internal fluid losses or sepsis may have renal hypoperfusion. The renal medulla, with its slow blood supply and active transport mechanisms, is especially susceptible to even moderate renal ischemia.

The initiating insult culminates in the development of one or more maintenance factors, such as (1) decreased tubular function, (2) tubular obstruction, (3) sustained reductions in renal blood flow, and (4) glomerular filtration. Urine flow and solute excretion are reduced. Once the maintenance period has begun, pharmacologic interventions to improve renal blood flow do not reverse the failure.

Hemodynamic optimization is crucial in preventing postoperative AKI. Decreasing the need for renal replacement therapy (RRT) decreases AKIN classification and the incidence of progression. Administering fluids and inotropes, to maintain adequate perfusion, in the pre-, intra-, and postoperative periods, is associated with significantly decreased mortality and less risk of developing AKI.^{5,36}

Patients with parenchymal disease have trouble concentrating urine, therefore urine sodium levels are high, and osmolality is low. Renal damage is also associated with a progressive rise in serum urea, creatinine, uric acid, and polypeptide levels. Serum potassium levels increase, and a decrease, or dilution, occurs in the serum levels of sodium, calcium, and proteins such as albumin. Exogenous factors may alter BUN level, and subtle changes in serum creatinine concentration are easily ignored.^{5,32}

Risk Factors

A number of conditions may place patients at high risk for acute renal injury. Renal reserve decreases progressively with age. Older patients are less able to cope with fluid and electrolyte imbalance and are more prone to renal damage. In the geriatric population, overall mortality rates associated with AKI increase.¹²

Patients with preexisting renal dysfunction are also at high risk. Cardiac and hepatic failure are associated with abnormal renal hemodynamics. Reduced GFR is associated with cortical redistribution of blood flow and salt and water retention. All these

aberrations are increased by anesthetics, stress, and hypovolemia. Furthermore, these alterations correlate with greater incidences of postoperative AKI and mortality.³⁷ Elevated bilirubin is related to hepatitis and other liver diseases and is an independent risk factor of AKI.

Certain surgical procedures involving such as nonrenal solid organ transplants, prolonged cardiac bypass or aortic cross clamp time are associated with a higher risk of AKI. The risk increases with (1) patients with preoperative ventricular dysfunction or bacterial endocarditis, (2) patients undergoing emergency or high-risk procedures, and (3) patients who are anemic or receive perioperative blood products. Postoperative bleeding with reexploration and low cardiac output requiring use of the intraaortic balloon pump also carry a higher incidence of injury.^{30,38,39} Some major risk factors for the development of perioperative acute kidney injury are noted in [Table 32.3](#).⁴⁰

TABLE 32.3

Major Risk Factors for the Development of Perioperative Acute Kidney Injury

Patient	Surgery	Other
Chronic diseases	Emergency	Acute illness
Kidney	Nonrenal solid organ transplant	Sepsis
Heart failure	Cardiac bypass time	Multiorgan dysfunction
Hypertension	Aortic cross clamp	
Peripheral arterial	Intraperitoneal surgery	Nephrotoxic drugs
Obstructive pulmonary	Emergency surgery	ACEi
Diabetes mellitus		ARB
Alcoholism Ascites		Diuretics
Male		Radio-opaque intravenous contrast
Obesity		

ACEi, Angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker.

Adapted from Golden D et. al. Peri-operative renal dysfunction: prevention and management. *Anaesthesia*. 2016;71(Suppl 1):51–7; Wanderer JP, Rathmell JP. Postoperative Acute Kidney Injury: Risk Factors and Possible Interventions. *Anesthesiology*. 2016;124(5):A21.

A ruptured abdominal aortic aneurysm commonly results in hypovolemia, shock, and the need for high aortic cross-clamping. Of these patients, 40% have renal damage, and 11% develop AKI

with an associated mortality rate of 80%. Renal dysfunction after elective surgery is less profound if attention is given to adequate hydration and if a brisk diuresis is established before, and maintained during, aortic cross-clamping. The aortic clamp proximity to the renal arteries is critical. Aortic clamp placement above the renal arteries increases the risk of AKI. Aortic arteriography performed just before surgery also increases risk. Predisposing factors include preexisting renal disease with serum creatinine levels greater than 3 mg/dL; proteinuria; diabetes; and hypovolemia. Risk is reduced by (1) minimizing the amount of dye given, (2) maintaining hydration, and (3) using diuretics such as mannitol to promote diuresis. Postoperative AKI is a common complication of thoracic aorta, thoracoabdominal aorta, and aortic arch surgeries. It is observed in 6% to 18% of such surgical procedures. Predisposing factors for this complication include (1) age older than 50, (2) preoperative renal dysfunction, (3) duration of renal ischemia, and (4) amount of blood transfused.

Mechanical obstruction by calculi or prostatic disease is the most common cause of obstructive uropathy. Risk is increased by the frequent presence of hypovolemia and electrolyte imbalance and by preoperative diagnostic studies that involve the use of dye.

Hypovolemia, decreased pulmonary function, and acidosis are key factors in the development of AKI in septic patients. The use of vasoconstricting adrenergic agonists and antibiotics with nephrotoxic potential compounds the problem.^{34,41,42} The type of replacement fluid (crystalloids vs. colloids) is important in patients at risk for developing AKI. There are several studies demonstrating colloid replacement therapy is not superior to crystalloid infusion and may actually increase the incidence of perioperative AKI. In patients with RIFLE or AKIN scores indicating the presence of AKI, the need for replacing fluids is based on the hemodynamic parameters. Patients at low risk undergoing minor surgery should receive liberal perioperative fluid replacement (10–30 mL/kg) to reduce postoperative adverse outcomes (i.e., postoperative nausea and vomiting [PONV], pain), whereas patients at high risk undergoing major surgery will likely benefit from more stringent fluid replacement strategies or goal-directed therapy with fluid replaced to maintain urine output between 0.5 and 1.0 mL/kg per

hr.^{36,43}

Complications of pregnancy such as hemorrhage, amniotic fluid embolus, and toxemia carry a high risk of renal failure, although mortality in this group is reduced because patients are usually young and healthy. Proteinuria, related to or independent of pregnancy, also serves as a major risk factor for the development of AKI.⁴⁴

In the first trimester of pregnancy, hyperemesis gravidum or septic abortion poses a risk for renal injury. Risks in the third trimester include preeclampsia, HELLP (*hemolysis, elevated liver enzymes, and low platelet count*) syndrome, acute fatty liver of pregnancy, or thrombosis. Diagnosis is by serum creatinine because GFR calculations are complicated due to the altered volume status of pregnant women.^{5,9}

Prevention and Management

Prevention of AKI is far more successful than management after its development. Prevention can be based on the following generalizations:

- The most common cause of AKI is prolonged renal hypoperfusion.
- Prophylaxis reduces mortality more effectively than dialytic therapy.
- The duration and magnitude of the initiating renal insult are critical in determining the severity of AKI.

A key strategy in reducing the incidence of AKI is limiting the magnitude and duration of renal ischemia. Prevention begins in the preoperative period.^{45,46}

Preoperative Strategies

High-risk patients and procedures should be identified. Reversible renal dysfunction should be addressed; fluid deficits and hypovolemia should be corrected by the use of intravenous fluids and inotropes. Perioperative ADH and renin-angiotensin-aldosterone secretion can be minimized with adequate hydration before anesthetic induction and perioperative attenuation of

surgical stress. Administration of saline, such as a balanced salt solution rather than solutions low in sodium, is helpful in prevention of aldosterone secretion, hyponatremia, and oliguria.^{5,46}

Oliguria often signals inadequate systemic perfusion, and prevention of AKI requires its rapid recognition through appropriate monitoring and early intervention. In addition to standard monitors and a urinary catheter, monitors for patients with questionable cardiac and pulmonary function should include (1) a direct arterial line for blood pressure monitoring and (2) central venous pressure (CVP), pulmonary artery catheter, or transesophageal echocardiography as applicable, for assessment of cardiac function and volume status. The hemodynamic end-point should be adequate cardiac output and renal perfusion.⁴³

Perioperative Strategies

Use of a urinary catheter is the standard means of monitoring renal function in the operating room. A fluid challenge of 500 to 1000 mL may be necessary if hourly urinary output decreases to below acceptable levels. For patients with renal compromise, 250 mL bolus is a safe alternative.

Diuretics increase urine output, but do not decrease chronic renal dysfunction or mortality. The use of diuretics in the face of inadequate urinary output is common; however, it is controversial. Data suggests diuretic use to prevent AKI is not useful. Diuretic use in established AKI offers little benefit in changing outcome of mortality or need for renal replacement therapy, particularly in the presence of oliguria. Given the current literature, use of diuretics for volume management when necessary in patients with AKI can be considered. However, diuretic use to prevent oliguria in the AKI setting is not indicated.^{29,36,47}

High-dose diuretics have been effective in decreasing 60-day mortality rates associated with AKI. Diuretic therapy must be balanced with fluid administration to prevent hypotension and hypoperfusion. The best outcomes have been reported with furosemide and fluid balance to avoid a fluid excess or deficit. Mechanisms for protection include inhibition of sodium reabsorption and prevention of tubular obstruction through the maintenance of high renal tubule flow and pressure and reversal of

intrinsic renal vasoconstriction. Prophylactic use of diuretics may be of benefit in the case of jaundice in surgical patients, excessive exposure to contrast media, hyperuricemia, or the presence of pigment in the urine.^{29,45}

Fenoldopam (Corlopam) is a selective dopamine-1 (DA₁) receptor agonist. It causes both systemic and renal arteriolar vasodilation and has no effect on dopamine-2 (DA₂), α -adrenergic, or β -adrenergic receptors. Unlike dopamine, which causes renal vasoconstriction and systemic cardiovascular changes at higher doses, fenoldopam at high doses produces renal vasodilation with little systemic effects. Despite theoretically promising pharmacology, clinical benefit with fenoldopam has been limited. Attempts at developing a clinical protocol for the use of fenoldopam in AKI has proven unsuccessful. Currently, it is not recommended for use in AKI.^{36,48} No benefit in survival or the need for RRT has been noted as compared with placebo. Other therapies under investigation include atrial natriuretic peptide (ANP), urodilatin, and nesiritide. Survival rates may be higher in patients with oliguria, who have not begun dialysis, receiving ANP for treatment of fluid overload.³⁶

Treatment of Acute Kidney Injury

Therapy for AKI involves rapid recognition and correction of reversible causes, avoidance of any further renal injury, and correction and maintenance of a normal electrolyte and fluid volumes. Preventive therapy or medical interventions performed early provide the greatest chance for minimizing injury. Hyperkalemia, hyperuremia, metabolic acidosis, and fluid overload are indications for renal replacement therapy, but it is uncertain what values should precipitate treatment.⁴²

Key approaches include (1) administering volume (e.g., normal saline) to achieve euolemia, (2) improving cardiac output by afterload reduction, and (3) normalizing systemic vascular resistance. Postrenal AKI secondary to prostatic hypertrophy can frequently be corrected by placement of a bladder catheter or nephrostomy tube. Intrarenal AKI can be the most complex and difficult to treat. AKI caused by glomerulonephritis or vasculitis

frequently requires immunosuppressive therapy. For suspected acute interstitial nephritis, the offending medication must be determined and discontinued; a 2-week tapering course of glucocorticoids, beginning with 1 mg/kg of prednisone for 3 days, is commonly recommended despite the absence of definitive data. Serum electrolytes, creatinine, and BUN should be monitored at least daily, more frequently if the patient's renal function appears to be tenuous. Patients with AKI should also receive a low sodium, potassium, and protein diet. Early nephrology consultation will ensure that the patient receives optimal care. Some patients will require urgent hemodialysis because of marked metabolic acidosis unresponsive to sodium bicarbonate infusions; electrolyte abnormalities, such as hyperkalemia unresponsive to medical management; pulmonary edema not responding to diuretic therapy; and uremic symptoms of encephalopathy, seizures, and pericarditis. Intermittent hemodialysis and continuous renal replacement therapy may be necessary.^{42,43,48,49}

Prognosis.

Typically, AKI secondary to prerenal causes, if diagnosed and treated early, has the best prognosis for renal recovery. Patients with prerenal AKI commonly return to baseline level of renal function and have a mortality rate of less than 10%. Similarly, patients with postrenal AKI also have a good prognosis for renal recovery if the outlet obstruction is promptly diagnosed and definitively treated.⁴⁶

In contrast, patients with intrarenal AKI have a less predictable renal outcome, and mortality in this group varies between 30% and 80%, depending on the severity of injury. Patients who have a severe episode of AKI requiring hemodialysis may not recover renal function and may need hemodialysis indefinitely. AKI hastens progression of chronic kidney disease (CKD) to end-stage kidney disease and is often the major factor causing such

Box 32.3 Progression.⁵⁰ Clinical management of oliguria is found in **Box 32.3**.

Clinical Management of Perioperative Oliguria

- Oliguria is a urine output less than 0.5 mL/kg but may be 1 to 2 mL/kg in a patient who has received mannitol.
- Assume oliguria is prerenal until proven otherwise. Signs of prerenal include the following:

Oliguria

High urine osmolality

Low urine sodium

- A common cause of postoperative oliguria is impaired perfusion and outflow obstruction. A bladder ultrasound or examination for abdominal compression may be helpful
- Begin treatment with serial fluid boluses if assessment does not indicate overload.
- Do *not* give a diuretic to “make urine” in the face of intravascular hypovolemia or hypotension because this may result in exacerbation of renal injury.
- Do give diuretics if there are signs of fluid overload or if oliguria persists despite fluid challenges and stabilized hemodynamics.
- If improvement is not noted with fluid challenge or diuretics, institute invasive hemodynamic monitoring (central venous pressure and arterial pressure monitoring when large fluid shifts are expected).
- Maximize renal blood flow by enhancing cardiac function: normalize preload, heart rate, and rhythm; institute afterload reduction with vasodilators or inodilator agents.
- Maintain renal perfusion pressure.
- Prophylactic pharmacologic agents may be used when renal risk

is high, but there is little evidence to suggest they are better at maintaining glomerular filtration rate than volume.

- Diuretic resistance may be related to the following:

Acute tolerance induced by hypovolemia

Chronic tolerance

Refractory states

Chronic Kidney Disease

CKD, or chronic renal failure, is a slow, progressive, irreversible condition characterized by diminished functioning of nephrons and a decrease in renal blood flow, GFR, tubular function, and reabsorptive capacity. By definition, CKD exists when GFR is less than 60 mL/min per 1.73 m² for 3 months or more.^{43,50} Although many conditions may lead to renal failure, primary causes include glomerulonephritis, pyelonephritis, diabetes mellitus, hyperlipidemia, autoimmune disease, obesity, vascular or hypertensive insults, and congenital defects. A definitive link between AKI and the development of CKD is not yet established.³⁵ Table 32.4 outlines the systemic effects of chronic renal failure. Normal aging processes reduce nephron function by 10% for each decade of life. Therefore renal insufficiency is common in the geriatric population.

TABLE 32.4

Systemic Effects of Chronic Renal Disease

System	Effects
Cardiovascular	Hypertension
	Congestive heart failure
	Peripheral and pulmonary edema
	Pericarditis
	Coronary artery disease
Hematologic	Normochromic, normocystic anemia
	Platelet dysfunction
	Leukocyte, immunologic dysfunction
Neurologic	Encephalopathy
	Peripheral and autonomic neuropathy
Endocrine	Hyperparathyroidism
	Adrenal insufficiency
Respiratory	Pneumonitis
	Pulmonary edema
Gastrointestinal	Bleeding
	Nausea, vomiting
	Delayed gastric emptying
Metabolic	Acidosis
	Electrolyte imbalance

The general course of progressive CKD may be divided into five stages.^{51,52}

Stage 1: Kidney damage with normal or increased GFR

Stage 2: GFR 60 to 89 mL/min per 1.73 m² with evidence of kidney damage

Stage 3: GFR 30 to 59 mL/min per 1.73 m²

Stage 4: GFR 15 to 29 mL/min per 1.73 m²

Stage 5: End-stage renal failure with GFR less than 15 mL/min per 1.73 m²

Initial nephron injury causes adaptation in remaining nephrons, including increased glomerular size and pressure, which results in progression of renal disease. As the number of functioning nephrons declines, the signs, symptoms, and biochemical abnormalities become more severe.

Clinical signs or laboratory evidence of renal disease are absent until less than 40% of normal-functioning nephrons remain. Loss of nephron function without symptoms is known as a *decrease in renal reserve*. Renal insufficiency occurs when only 10% to 40% of nephrons are functioning adequately. Nocturia occurs secondary to a decrease in concentrating ability. Elimination of a large protein load or excretion of certain drugs is impaired. Preservation of remaining nephron function is a major goal in renal insufficiency.

Toxic substances such as aminoglycosides, nonsteroidal antiinflammatory drugs, and piperacillin have been implicated in causing interstitial nephritis and renal insufficiency. The administration of radiographic contrast media in at-risk patients results in renal insufficiency at the same rate as in 1979. Patients at greatest risk for developing contrast-induced renal insufficiency include those with preexisting renal insufficiency (creatinine greater than 1.2 mg/dL) and diabetes. Strategies including the administration of *N*-acetylcysteine, sodium bicarbonate, and ascorbic acid have been studied.⁵

As renal function deteriorates further, end-stage renal disease develops. In this stage, concentrating and diluting properties of the kidney are severely compromised, and electrolyte, hematologic, and acid-base disturbances are common. The loss of 95% of

functioning nephrons culminates in uremia, which is associated with volume overload and congestive heart failure. Uremia, which can be viewed as urine in the blood, adversely affects almost every organ system. Mortality is inevitable unless dialysis is performed for end-stage renal disease.⁴⁷

Renal Failure and Dialysis

Approximately 350,000 people in the United States today require chronic dialysis, and the end-stage renal failure population is projected to grow approximately 8% per year. Three hundred thirty-nine patients per 1 million receive renal replacement therapy for end-stage renal disease per year, and almost half of these patients require treatment early in the postoperative period.^{5,47,52}

Box 32.4 Indications for renal replacement therapy are shown in **Box 32.4**.

Indications for Renal Replacement Therapy

Absolute Indications

- Volume overload unresponsive to diuretic therapy
- Persistent hyperkalemia despite medical treatment
- Severe metabolic acidosis
- Overt uremic symptoms

Encephalopathy

Pericarditis

Uremic bleeding diathesis

Relative Indications

- Progressive azotemia without uremic manifestations

- Persistent oliguria

Dialysis Techniques

Dialysis is a general term used to describe therapy designed to move solute from plasma through a semipermeable membrane into a chemically prescribed solution. The movement of solute, or *diffusive transport*, depends on differences in molecular concentration between the blood compartment and the dialysate. Ultrafiltration is a technique in which a hydraulic pressure difference across a semipermeable membrane causes bulk fluid removal and solute by convective transport.

Major types of dialysis include hemodialysis and peritoneal dialysis. In hemodialysis, blood moves through a device exposing it to an individually prescribed dialysate solution across a semipermeable membrane. Hemodialysis requires systemic or regional anticoagulation. Concerns about hemodynamic stability during hemodialysis, nephron injury, and inability to adequately remove excess water and solutes have led to the development of a slower, less aggressive renal replacement therapy: continuous renal replacement therapy (CRRT).

CRRT is an extracorporeal process in which blood is removed from the arterial lumen of a catheter by a peristaltic blood pump and pushed through a semipermeable membrane before being pumped back into patients via the venous lumen of the catheter. CRRT includes several treatment modalities. Pump-driven, veno-venous CRRT is currently the most common technique. The modalities of veno-venous CRRT vary primarily by mechanism of solute removal: in continuous veno-venous hemofiltration, solute transport occurs by convection; in continuous veno-venous hemodialysis, it occurs by diffusion; and continuous veno-venous hemodiafiltration is a combination of the two. The hybrid modalities of RRT with conventional hemodialysis equipment modified to provide extended-duration dialysis provides enhanced hemodynamic tolerability.⁵³

Peritoneal Dialysis.

The use of peritoneal dialysis in the management of AKI has diminished as the use of continuous and hybrid therapies have increased. Peritoneal dialysis has the unique advantage of requiring minimal technology and can be performed easily at home. Access for short-term peritoneal dialysis can be obtained either by percutaneous placement of an uncuffed temporary peritoneal catheter or through surgical placement of a tunneled cuffed catheter. Peritoneal dialysis has the distinct advantage of avoiding the need for vascular access or anticoagulation. Solute clearance and control of metabolic parameters may be inferior to other modalities of RRT. Although systemic hypotension is less of an issue than with other modalities of RRT, ultrafiltration cannot be as tightly controlled. Other limitations include (1) relative contraindication in patients with acute abdominal processes or recent abdominal surgery, (2) risk of visceral organ injury during catheter placement, (3) risk of peritoneal dialysis-associated peritonitis, and (4) increased tendency toward hyperglycemia, which is associated with adverse outcomes in acute illness, due to the high glucose concentrations in peritoneal dialysate.⁵⁴

Physiologic Effects

Dialysis and ultrafiltration are associated with a number of physiologic effects and complications. Major systems involved include the nervous system, cardiovascular system, and respiratory system. The disequilibrium syndrome is the most severe central nervous system (CNS) effect of dialysis. This syndrome is associated with a rapid increase in brain intracellular volume because serum sodium and BUN levels are reduced. Predisposing factors include a BUN concentration greater than 150 mg/dL, hypernatremia, severe acidemia, and preexisting brain disease. The syndrome may be mild or may progress to seizures, stupor, and coma. The incidence is reduced by the avoidance of high rates of hemodialysis therapy in high-risk patients.

Hemodialysis is associated with a 30% incidence of hypotension. Contributing factors include reduced plasma volume and blunted sympathetic nervous system response associated with uremia.

Acetate from the dialysate moves into the blood contributing to the hypotension by causing vasodilation and cardiac depression.

The incidence of hypotension with dialysis is less in patients who have fasted than in those who have not. Fasting prevents the contribution to systemic hypovolemia due to increased gastrointestinal blood flow and secretion of isotonic intestinal juices. Anemia should be corrected if the hematocrit is less than 20% to increase vascular resistance. Leg elevation, a decrease in dialyzer transmembrane pressure, or the use of volume expanders or vasoconstrictors usually corrects hypotension. Substitution of HCO_3 for acetate in the dialysate also decreases the incidence of hypotension.

Hypoxemia is a common side effect of hemodialysis and may be seen during peritoneal dialysis. During hemodialysis, arterial oxygen tension often decreases by 5 to 20 mm Hg. Pulmonary leukostasis and extracorporeal loss of CO_2 with a reduction in minute ventilation have been implicated. Hypoxemia is managed by increasing the inspired oxygen concentration during dialysis. The use of HCO_3 in place of acetate limits extracorporeal losses of CO_2 and reduces the incidence of hypoxemia.

Muscle cramping is the most common neuromuscular complication of dialysis. It is seen almost exclusively with hemodialysis and results from the rapid reduction of intravascular volume and serum sodium level. Intravenous administration of hypertonic saline relieves muscle cramping.

The nutritional depletion common in dialysis-dependent patients may be caused by the primary disease, dietary restrictions, or the loss of protein associated with peritoneal dialysis. Protein depletion may produce hypoalbuminemia and immune system suppression. The large quantities of hypertonic glucose solutions absorbed with peritoneal dialysis contribute to obesity, hyperglycemia, and hyperlipidemia. Administration of insulin controls hyperglycemia, and diet and exercise limit hyperlipidemia.^{53,54}

Preoperative Renal Assessment

Preoperative assessment of the patient with suspected or known renal dysfunction must include a thorough history and physical examination, which includes appropriate laboratory evaluation (Box 32.5). The medical history is the single most important source of information in establishing the presence or absence of renal disease. Poorly controlled hypertension, trauma to the urinary system, prior renal surgery, or systemic disease (e.g., diabetes) may be associated with renal impairment. A history arousing suspicion **Box 32.5** should lead to a more thorough evaluation of renal function.

Preoperative Assessment and Preparation of the Patient With End-Stage Renal Disease

I. Clinical History

- A. Evaluate renal function.
- B. Document central nervous system deficits.
- C. Review cardiovascular history; look for significant hypertension, accelerated atherosclerosis, pericarditis, tamponade; assess extent, stability, and management of coronary artery disease.
- D. Look for history of excessive bleeding; if present consider use of desmopressin.
- E. Assess intravascular volume; correlate body weight changes with changes in blood pressure

and heart rate before and after dialysis.

F. Review pulmonary history.

G. Dialyze 24 hours or less before surgery; ideal weight preoperatively is 1 to 2 kg above “dry” weight.

II. Physical Examination

A. Locate and check patency of arteriovenous fistula or shunt.

B. Evaluate vessels for venous or arterial access.

C. Look for signs of congestive heart failure, pericarditis, or cardiac tamponade.

D. Look for evidence of noncardiogenic pulmonary edema or aspiration.

III. Laboratory Tests

A. Electrocardiography, chest radiography

B. Glomerular filtration rate or creatinine clearance

C. Blood urea nitrogen, creatinine

D. Complete blood count with platelet count

E. Bleeding time; prothrombin time; partial

thromboplastin time

F. Hematocrit; red-blood-cell index

G. Electrolytes (especially potassium)

H. Acid-base status

I. Hepatitis antigen status

Although abnormalities are commonly identified by urinalysis, the quality of urinalysis results obtained by dipstick technique varies. Abnormal urinalysis results usually fail to lead to a change in management, so the test is generally omitted. If the test is available, attention should be directed to the following:

1. *Specific gravity.* Specific gravity, a measurement of solutes in the urine, indicates the renal capability to excrete concentrated or dilute urine. It is a reflection of tubular function and normally varies from 1.003 to 1.030, depending on fluid intake and the presence or absence of high-molecular-weight substances such as glucose or mannitol. In the absence of such substances, a specific gravity of 1.018 or greater after overnight dehydration indicates reasonable function. A low specific gravity is meaningless if the condition under which the sample was collected is not known.

2. *Urine osmolality.* Osmolality, or the number of moles of solute (measured in osmoles) per kilogram of solvent, is more unambiguous than specific gravity. Excretion of concentrated urine (specific gravity 1.030; 1400 mOsm/kg) indicates excellent tubular function, whereas urinary osmolality fixed to that of plasma (serum gravity 1.010; 290 mOsm/kg) suggests tubular concentrating defects. Urinary diluting mechanisms are dominant after concentrating ability is lost.

3. *Proteinuria.* Proteinuria exists when more than 150 mg of protein is excreted per day. Massive proteinuria or the renal loss of more

than 750 mg/day is always abnormal and usually indicative of severe glomerular damage. In addition to the association with glomerular damage, proteinuria may also be present with abnormal plasma proteins or increased concentrations of normal proteins, or when the renal tubules fail to reabsorb the small amount of filtered protein. Although proteinuria is most often associated with significant pathology, patients may present with proteinuria without renal disease under conditions of stress, fever, dehydration, exercise, or congestive heart failure. Patients who have significant proteinuria are more likely to develop AKI postoperatively than those who do not. The incidence of hypoalbuminemia and subsequent sequelae is increased in patients with severe proteinuria. In concentrated urine samples, trace or 1+ proteinuria is a nonspecific finding, whereas 3+ or 4+ proteinuria suggests glomerular disease.

The kidneys share regulation of acid-base balance with the lungs, providing the sole pathway for the excretion of the 60 mEq of hydrogen ions produced per day. Urinary pH is a reflection of renal ability to acidify urine. Inability to excrete acid urine in the presence of systemic acidosis is indicative of renal insufficiency.^{55,56}

Laboratory Tests for Renal Function

Patients with suspected or known renal disease should be tested preoperatively to evaluate GFR and renal tubular function. Urine specific gravity (1.003 to 1.030), urine osmolality (65 to 1400 mOsm/L), and urine sodium concentration (130 to 260 mEq/day) reflect renal tubular function, whereas BUN concentration (10 to 20 mg/dL), plasma creatinine level (0.7 to 1.5 mg/dL), and creatinine clearance (110 to 150 mL/min) evaluate GFR.⁵⁷⁻⁵⁹

Blood Urea Nitrogen

Urea, the chief end product of protein metabolism, is formed in the liver. It is excreted by glomerular filtration, but significant amounts of urea are reabsorbed along the renal tubule. Although the normal range for BUN level is 10 to 20 mg/dL, it is altered by a variety of factors, including: (1) ingestion of protein, (2) anabolic and catabolic

states, (3) GFR, (4) state of hydration, and (5) reabsorption of urea by the nephrons. Because of the numerous extrarenal factors influencing BUN, it is a better indicator of uremic symptoms than of GFR. Levels below 8 mg/dL suggest overhydration or underproduction of urea, whereas those between 20 and 40 mg/dL suggest dehydration, high nitrogen levels, or decreased GFR. Levels higher than 50 mg/dL almost always indicate decreased glomerular filtration. Elevations of BUN level in the presence of normal serum creatinine concentration suggest a nonrenal cause of the elevation. In general, BUN level is a late indicator of renal disease because it does not increase in most patients until the GFR is reduced by more than 50%.⁴⁵

Serum Creatinine

Creatinine is a metabolite of creatine, a major muscle constituent. The daily rate of production of creatinine is constant and determined by skeletal muscle mass. Because creatinine is eliminated almost entirely by glomerular filtration, serum steady-state concentration is viewed as a reliable marker of glomerular function. Normal values range from 0.7 to 1.5 mg/dL, but the serum concentration can be lower in the elderly or in women who have reduced muscle mass. Patients with muscle wasting have lower levels, whereas those who are heavily muscled or those in acute catabolic states have higher values due to rapid muscle breakdown. Because the production and release of creatinine are relatively stable throughout the day and from day to day, serum levels are inversely related to GFR if a steady state exists. In other words, for every 50% reduction in GFR, creatinine level doubles. Excretion of drugs dependent on glomerular filtration may be significantly decreased despite only a slight elevation in serum creatinine level.

An elevation of both BUN and serum creatinine levels provides more information than an elevation of either level alone. The usual ratio of urea nitrogen to creatinine in the serum is 10 : 1. Increased ratios are seen with (1) increased urea input, (2) decreased circulatory blood volume, and (3) obstructive uropathy. Decreased ratios are seen with decreased urea input, increased creatinine production, and volume expansion.⁶⁰

Creatinine Clearance

Creatinine clearance is a specific test of GFR and the most reliable assessment tool for renal function which measures the glomerular ability to excrete creatinine into the urine for a given plasma creatinine concentration. Although not dependent on corrections for age or the presence of a steady state, a disadvantage of this test is the need for accurate 24-hour urine specimens. Creatinine clearance is calculated according to the following formula:

$$\text{GFR} = (\text{Urine creatinine} \times \text{Urine volume}) \div \text{Serum creatinine}$$

A 2-hour urine sample collected through a urinary catheter permits acceptable accuracy. In the absence of urine volume, creatinine clearance can be approximated with use of the following Cockcroft-Gault formula:

$$\text{GFR} = \frac{[(140 - \text{Age}] \times \text{Lean body weight [kg]})}{(72 \times \text{Serum creatinine [mg/dL]})}$$

where weight is expressed in kilograms. To compensate for their smaller muscle mass, when values for women are calculated, the weight should be multiplied by 0.85.

The normal range for creatinine clearance is 95 to 150 mL/min. Mild renal dysfunction is present when creatinine clearance is 50 to 80 mL/min, and moderate dysfunction is present at values below 25 mL/min. In patients with dysfunction, the administration of drugs dependent on renal excretion should be reduced, and fluid and electrolyte balance should be carefully monitored. Patients with creatinine clearance less than 10 mL/min are anephric and require dialysis for fluid and water hemostasis.⁶⁰

Other Tests

Advanced renal disease affects most organ systems. Additional tests that may be useful in patients with advanced renal disease include chest radiography, electrocardiography, complete blood

count, serum electrolytes, and acid-base studies.

Systemic Abnormalities and Advanced Renal Disease

Renal failure is characterized by a wide variety of biochemical disturbances. Although most organ systems are involved (see [Table 32.4](#)), only those most relevant to anesthetic management are discussed in this section.

Cardiovascular Alterations

Cardiovascular disease accounts for approximately 50% of all deaths in patients on hemodialysis with 26% mortality from sudden cardiac death.^{38,61} Hypertension and congestive heart failure often accompany end-stage renal disease. Ninety percent of the hypertension is volume dependent and related to sodium and water retention. The remaining 10% can be attributed to high circulatory levels of renin. The combination of hypertension, anemia, hypoalbuminemia, and circulatory overload secondary to salt and water retention contributes to peripheral and pulmonary edema and to an increased risk of developing congestive heart failure.

In nonsurgical settings, ischemic heart disease is the most common cause of death in patients with chronic renal failure. Multiple risk factors such as hypertension, hyperlipidemia, and abnormal carbohydrate metabolism contribute to this high incidence of ischemic heart disease.³⁸ It is a safe assumption that clinically significant coronary artery disease exists and the prudent anesthetist should evaluate the extent and stability of the disease prior to administering anesthetic agents. Correction of coronary lesions with coronary artery bypass grafting (CABG) is associated with better outcomes than coronary angioplasty in patients on hemodialysis. Improvement of symptoms is common after the CABG procedure.⁶² The advent of drug-eluting stents has led to numerous studies to determine the incidence of restenosis in hemodialysis patients.⁶³ The results of these studies remain inconclusive.

Fifty percent of patients with severe uremia will present with a

fibrous pericarditis. Signs and symptoms may include pain on deep inspiration or when lying down, and a friction rub over the pericardium noted during auscultation. An enlarged cardiac silhouette on chest radiography indicates pericardial effusion. Patients with uremic pericarditis occasionally develop a massive hemorrhagic effusion and cardiac tamponade, especially when anticoagulants are used for hemodialysis.⁶⁴

Uremic patients exhibit a wide range of hemodynamic abnormalities when studied during hemodialysis. The striking feature of these studies is the abnormal peripheral vasculature response to dialysis induced hypovolemia. Untreated hypovolemia decreases arterial pressure without compensatory increase in heart rate. Peripheral vascular resistance is unchanged or decreased, and cardiac output is increased.^{1,5,9}

Because the potential for significant cardiovascular complications exists, patients with advanced renal disease should undergo chest radiography and electrocardiography preoperatively.

Administration of antihypertensive drugs should be continued, blood pressure should be monitored, and signs and symptoms of cerebrovascular disease should be recorded. The blood pressure should be normal or slightly elevated before induction. Because adequate intravascular volume is necessary for hemodynamic stability, the patient's weight should ideally be 1 to 2 kg greater than dry weight at the end of the last dialysis before anesthetic induction.^{53,54}

Hematologic Changes

Normochromic, normocytic anemia is an inevitable finding in advanced renal disease. Hematocrit levels often decrease to the 20% to 30% range and generally parallel the degree of azotemia. The primary reason for anemia is a decrease in erythrocyte formation secondary to a decrease in production of erythropoietin by the failing kidney.^{65,66} In addition, some evidence suggests uremic toxins may inactivate erythropoietin or suppress bone marrow response. A second factor contributing to anemia in uremic patients is reduction of erythrocyte life span due to an increase in hemolysis secondary to the presence of an abnormal chemical environment. Additionally, blood loss from frequent sampling for laboratory

tests, loss in hemodialysis tubing, and a tendency for gastrointestinal bleeding further aggravate anemia.

Hematocrit and red-blood-cell indexes should be measured preoperatively, and their values should be checked against dialysis records to ensure no acute changes have occurred. Preoperative hematocrit levels are similar to those of a patient maintained on dialysis, suggesting patients can tolerate the chronic anemia; therefore routine transfusion of blood preoperatively is not recommended for these patients. If transfusion is necessary because of acutely decreased or poorly tolerated hematocrit values, no need exists to withhold red blood cell transfusions for fear of sensitization to histocompatibility antigens.⁶⁶

Exogenous administration of human recombinant erythropoietin corrects the anemia associated with chronic renal failure. The risks of treatment with erythropoietin include hypertension, vascular access clotting, and death. Adequate iron stores and good dialysis are essential if the response to recombinant erythropoietin or epoetin is to be maximized.^{67,68} There are two erythropoiesis-stimulating agents currently available to treat anemia in patients with chronic renal disease who are on dialysis: (1) epoetin (Procrit, Epogen), and (2) darbepoetin (Aranesp).

Patients with chronic uremia tend to bleed excessively. Although platelet counts are only mildly reduced, a defect in platelet function appears to be responsible for prolonged bleeding time and the tendency for excessive bleeding. Dialysis partially corrects platelet dysfunction, therefore dialysis 24 hours or less before surgical intervention is recommended.

Desmopressin is known to shorten bleeding time and increase circulating levels of factor VIII, the von Willebrand antigen, in uremic patients. Desmopressin is the agent of choice because of its rapid onset and minimal side effects. Repeated doses over time may increase bleeding time between treatments. Cryoprecipitate and conjugated estrogens also shorten bleeding time and may reduce blood loss.⁶⁹

Gastrointestinal Effects

Patients on dialysis have a high incidence of gastrointestinal mucosal inflammatory changes and are at high risk of

gastrointestinal bleeding perioperatively. The use of histamine-2 (H₂) blocking drugs or antacids is recommended throughout the perioperative period for decreasing the incidence of stress ulcers.⁵³

Infections

Infectious complications are common in patients with renal failure and represent a leading cause of death in dialysis-dependent patients. Protein malnutrition and abnormalities in neutrophil, monocyte, and macrophage function contribute to this problem. Mechanisms that lead to leukocyte dysfunction and increased susceptibility to infection are not known but may be related to uremia, immunosuppressive therapy, and increased exposure to invasive therapy. Frequent exposure to blood and blood products increases the risk of infection with hepatitis B and C and the human immunodeficiency viruses. Universal precautions are mandatory for the protection of both patients and health care providers.⁵⁷

Neurologic Effects

Neurologic symptoms associated with end-stage renal disease roughly parallel the degree of azotemia. Fatigue and weakness are early complaints, and untreated patients eventually become confused and comatose. Additional early symptoms include apathy, decreased mental acuity, and lethargy. Seizures may be associated with hypertensive encephalopathy. Peripheral and autonomic nervous system neuropathy is common. Autonomic neuropathy is associated with delayed gastric emptying and places the patient at risk for aspiration pneumonitis. Preoperative assessment should include the patient's baseline awareness and mental acuity.⁷⁰

Endocrine Abnormalities

Endocrine abnormalities in patients with end-stage renal disease include hyperparathyroidism and adrenal insufficiency. Hypocalcemia is common in patients with advanced renal disease, and hyperparathyroidism represents an appropriate compensatory increase in parathormone in response to a reduction in serum

calcium levels. Adrenal insufficiency is often secondary to exogenous steroid administration.⁷¹

Respiratory Effects

Respiratory complications associated with renal failure include pneumonitis and the “uremic lung.” Chest radiographs of the uremic lung reveal bilateral butterfly-shaped infiltrates indicative of pulmonary edema. Pulmonary congestion and edema are usually related to volume overload. Respiratory depression may be exaggerated when sedatives or opioids accumulate in the plasma due to reduced clearance.⁷²

Electrolyte Abnormalities

Abnormalities of water, electrolyte, and acid-base balance become more common as the degree of renal failure increases. With a normal diet, the kidneys typically excrete 40 to 60 mEq of hydrogen ions per day to prevent acidosis. Impaired ability of the kidney to excrete hydrogen ions with renal failure results in metabolic acidosis characterized by decreases in plasma pH and HCO_3^- concentration. Acidosis is usually moderate, but symptoms of anorexia, nausea, vomiting, and lethargy, which are common in uremic patients, may be partly related to acidosis.

Sodium ion excretion by the kidney normally varies according to intake. Patients with chronic renal failure lose this flexibility and have sodium wasting or retention. In early renal insufficiency with polyuria, an increased solute load for each intact nephron results in sodium wasting. In renal failure, the patient is more likely to retain sodium. Salt and water retention leads to circulatory overload, hypertension, edema, and congestive heart failure.

Although the ability to excrete magnesium is reduced in uremic patients, hypermagnesemia is generally not a serious problem. Magnesium intake is usually reduced because of anorexia, reduced protein intake, and decreased absorption from the gastrointestinal tract.

Calcium balance is controlled by parathyroid hormone, calcitonin, and vitamin D. Vitamin D control serum calcium balance, or cholecalciferol, must undergo activation to become

biologically available. Inability of the failing kidney to hydroxylate 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (active vitamin D) results in hypocalcemia. To maintain appropriate serum calcium levels calcium is liberated from the bone. Patients with chronic renal failure have skeletal disorders or osteodystrophy, and defective mineralization of bone predisposes patients to fractures. Special precautions should be taken when these patients are moved and positioned.

Potassium imbalance is one of the most serious disturbances occurring in patients with renal failure. Although hypokalemia may be associated with the polyuria of renal insufficiency, end-stage renal disease invariably leads to hyperkalemia. Although the major mechanism for hyperkalemia is the inability of distal nephrons to secrete potassium in exchange for calcium, systemic acidosis also contributes to potassium imbalance. Acidosis causes potassium ions to shift from intracellular to extracellular fluid.

Fatal dysrhythmias or cardiac standstill can occur when serum potassium levels reach 7 to 8 mEq/L. Dialysis is the most effective means of managing perioperative hyperkalemia, and hemodialysis is indicated when serum potassium exceeds 6 mEq/L. Other techniques for treating hyperkalemia include insulin in glucose infusions (25 to 50 g of glucose with 10 to 20 units of regular insulin) and administration of bicarbonate (50 to 100 mEq intravenously slowly). These measures promote rapid translocation of extracellular potassium to the intracellular space during hyperkalemic emergencies. Hyperventilation of the lungs with respiratory alkalosis lowers serum potassium concentration by approximately 0.5 mEq/L for every 10 mm Hg change in arterial CO₂ tension. Life-threatening cardiac dysrhythmias are treated with intravenous administration of calcium chloride. A typical dose may be 1 g in adults. Although calcium does not change the serum concentration of potassium, it antagonizes the cardiotoxic effects of hyperkalemia.

Unexpected hyperkalemia can develop rapidly, so it is important to measure potassium even when dialysis has been performed within 6 to 8 hours of surgery. Hyperkalemia occurs early postoperatively and is the primary reason patients with renal failure require dialysis within the first 24 hours after surgery.^{12,13,45}

A complete discussion of hyperkalemia, its symptoms, and treatment can be found in [Chapter 21](#).

Surgical procedures are becoming increasingly more common in anephric patients. The perioperative course of these patients may be complicated by a high incidence of untoward events increasing morbidity and mortality. These complications are related to the abnormal physiology of the anephric state and are predictable. Adverse outcomes are minimized by appropriate preoperative evaluation and preparation.⁴⁵ Pertinent points in the preoperative assessment and preparation of patients with end-stage renal disease are listed in [Box 32.5](#).

Anesthetic Management of Patients With Advanced Renal Disease

Preoperative preparation of patients with advanced renal disease should include an evaluation of recent laboratory measurements (i.e., electrolytes, coagulation, and creatinine), coexisting diseases, and current medications. Patients with end-stage renal disease should undergo preoperative determination of BUN and serum creatinine levels, complete blood count, bleeding-time measurement, and electrolyte studies. Special attention should be given to serum potassium, the type of and schedule for dialysis, and volume status. Additional information needed from this patient population is dry weight and “normal” preoperative concerns (e.g., nil by mouth [NPO] status, allergies).

Premedications

Discussions regarding premedication should take into consideration unexpected sensitivity to CNS depressants and delayed gastric emptying. Short acting benzodiazepines are useful as premedication. Midazolam is preferred because it has virtually no active metabolites, and the half-life is only slightly prolonged in renal failure patients. Although this drug is useful when it is carefully titrated, patients with renal disease may be more susceptible to the sedative-hypnotic effects of benzodiazepines than those without renal dysfunction.^{73,74}

Patients with renal failure should be monitored with a pulse oximetry prior to administering any sedative or CNS depressant. Reduced protein binding may be responsible for increased sensitivity to these drugs in patients with advanced renal disease. Protein binding of morphine decreases by 10% in the presence of chronic renal failure, altering free fraction only slightly because morphine is generally protein bound to such a small extent. Morphine is almost completely metabolized in the liver, resulting in two metabolites (morphine-3-glucuronide and morphine-6-glucuronide), which are both excreted by the kidney. Patients with kidney disease can develop high levels of morphine-6-glucuronide

and resultant respiratory failure. Morphine is not removed by dialysis.⁷⁴

Meperidine is more lipophilic than morphine. It is 60% protein bound and is metabolized to normeperidine, which has analgesic properties and stimulates the CNS system. Meperidine metabolites can cause convulsions when present in high concentrations, and cannot be removed by dialysis. Meperidine should be avoided in patients with renal failure.

Hydromorphone does not directly cause adverse effects in renal failure; however, its metabolite, hydromorphone-3-glucuronide does accumulate. For this reason, hydromorphone should be used with caution, although it can readily be removed by dialysis.⁷⁵

A review of publications on opioid use in patients with renal failure reveals that transdermal buprenorphine, methadone, fentanyl, and sufentanil appear to be safe in these patients. Anticholinergic drugs, such as atropine and glycopyrrolate, are partially dependent on renal elimination, although no reports of toxicity exist.

Gastric hyperacidity and gastrointestinal bleeding are common in patients with renal failure. H₂ blockers and magnesium-free antacids should be considered. Cimetidine has been used, but renal elimination accounts for 80% of total elimination, and elimination is impaired with reduced renal function. Although newer H₂ antagonists are now available, all H₂-receptor blockers are highly dependent on renal excretion. Metoclopramide is partly excreted unchanged in the urine and will accumulate in patients with renal failure.⁷³

Intraoperative Monitoring

The selection of monitors for a patient with diminished or absent renal function is based on the physiologic status of the patient and the proposed surgical procedure. Frequent measurements of blood pressure and continuous recording of temperature and heart rate and rhythm are essential. Electrocardiography may allow early detection of hyperkalemia, including observation of peaked T waves, prolongation of the PR interval, and absent P waves with widened QRS complex.

Care should be taken to place EKG leads in the appropriate position on the patient to facilitate early recognition of hyperkalemia. Because these patients are often chronically anemic, a further reduction in oxygen delivery secondary to hypoxia can be extremely hazardous. Pulse oximetry is essential for the early detection of arterial desaturations. Pulse oximetry and capnography are required in all patients. Minor surgical procedures in stable patients can be monitored noninvasively.⁵⁷

The decision to use invasive monitors depends on the patient's functional cardiac reserve and the severity and control of hypertension. Significant hypotension on induction of anesthesia is common in recently dialyzed patients. Continuous monitoring of arterial blood pressure is helpful when major surgical procedures are performed. A femoral or dorsalis pedis artery is sometimes used for cannulation because vessels in the upper extremities may be needed later for vascular shunts. Vascular volume and fluid replacement can be guided by central venous pressure monitoring. A pulmonary artery catheter is rarely indicated, because sophisticated evaluation of fluid status and ventricular function can be accomplished with echocardiography.³⁸

Vascular shunts and fistulas must be protected. Patency is easily monitored with Doppler imaging. Care must be taken to avoid the extremity with the shunt when placing blood pressure cuffs. Because of the immunocompromised state of these patients, strict aseptic technique is required during the placement of vascular catheters.^{76,77}

Regional Anesthesia

Regional anesthesia is well tolerated by patients with advanced renal disease, provided no significant coagulation disorder is present and MAP is maintained. Regional techniques avoid most of the pharmacokinetic and pharmacodynamic problems associated with general anesthetics and sedative drugs. Major concerns regarding this type of anesthesia include: (1) psychological intolerance, (2) coagulation abnormalities, (3) presence of peripheral neuropathies, (4) difficulty in making intravascular volume adjustments, (5) risk of infection, and (6) altered drug disposition.

Arteriovenous (AV) shunts or fistulas may be surgically created with the use of local infiltration or brachial plexus block. In addition to providing analgesia, brachial plexus blocks improve surgical conditions by providing maximum vascular vasodilation and abolishing vasospasm. Studies have shown brachial plexus blocks are associated with greater brachial artery blood flow than local anesthesia, greater fistula blood flow, and decreased maturation time.⁷⁸ Brachial plexus block and local infiltration techniques are good alternatives to general anesthesia for creation of AV fistula. Age, American Society of Anesthesiologists (ASA) class, and cardiac status are the determining factors for choice of anesthetic technique.

Data suggest a similar duration of anesthesia with brachial plexus blocks in patients with renal failure and normal renal function.⁷⁹ High-dose mepivacaine has been used successfully for brachial plexus block in patients with end-stage chronic renal failure. Brachial plexus anesthesia with 650 mg of plain mepivacaine did not result in serious systematic toxicity in these patients despite high mepivacaine plasma concentrations.^{80,81} Ropivacaine has a longer duration of action with higher plasma concentrations in renal dysfunction.⁷⁸ The use of clonidine (150 mcg) as an adjuvant for lidocaine in axillary blocks for AV fistula construction prolongs blockade, decreases heart rate and blood pressure, and provides sedative effects.⁸¹ Creating an AV fistula 6 months prior to the first dialysis cannulation is associated with a 95% success rate.⁸²

With regard to spinal or epidural anesthesia, patients with long-standing renal disease have often undergone multiple procedures and prefer general anesthetic techniques. In addition to the history, the uremic patient's bleeding time, platelet count, prothrombin time, partial thromboplastin time, and fibrinogen level should be evaluated before subarachnoid or epidural catheters are placed. Paraplegia secondary to hematoma formation with spinal anesthesia has been reported in patients with chronic renal failure and clotting abnormalities. A case of epidural hematoma in a surgical patient with chronic renal failure and epidural postoperative analgesia has been reported.⁸³ The only risk factor for development of epidural hematoma was a history of chronic renal failure. High-risk patients should be monitored closely for early

signs of cord compression such as severe back pain and motor or sensory deficits.^{5,9}

An opioid or opioid and local epidural solution rather than local solution alone allows continuous monitoring of neurologic function. If spinal hematoma is suspected, the patient should undergo immediate magnetic resonance imaging (MRI) or computed tomography (CT) scan, and decompressive laminectomy should be performed without delay.⁸³

Peripheral neuropathies should be discussed with the patient and documented before regional anesthesia is undertaken. The incidence of hypotension with subarachnoid or epidural blockade may be increased because of effects of chronic hypertension or hypovolemia related to recent dialysis. Correction of hypovolemia postoperatively is hazardous. Recession of the sympathetic block in patients who cannot undergo diuresis may lead to pulmonary edema. One must weigh the advantages of fluid infusion against the effects of pressor drugs with these factors in mind.

Patients with end-stage renal disease are often acidotic, and local anesthetic toxicity may be increased with acidosis. The onset and duration of blocks have also been shown to vary in these patients, leading to “patchy blocks” which may necessitate conversion to general anesthesia. Subarachnoid blockade induced with 3 mL of 0.75% bupivacaine developed more rapidly, attained a greater level, and was of shorter duration in patients with renal failure than in control patients. The slower onset of epidural anesthesia is an advantage in these patients.

General Anesthesia

Intravenous Drugs

Intravenous anesthetics can be used in patients with advanced renal disease, but the response of these patients may be more variable than normal. Variability arises from a complex interplay among changes in (1) volume of distribution (which is often increased), (2) protein binding (which may be decreased), (3) low pH, and (4) dependence on renal excretion for the parent drug or metabolites.

The action of many drugs is potentiated by metabolic abnormalities associated with renal failure. Highly protein-bound

drugs may have a greater target-organ effect in the presence of hypoalbuminemia. The acidemic state associated with renal failure may alter the proportion of the agent available to target tissue. Anemia associated with renal failure increases cardiac output and enhances delivery to the brain. Uremia alters the blood-brain barrier; this also increases sensitivity to intravenous drugs.

Ketamine and benzodiazepines are less heavily protein bound. The sympathomimetic effects of ketamine are frequently associated with an increase in blood pressure and cardiac output, which may be deleterious in hypertensive patients who are at risk for coronary artery disease or decreased left ventricular function. In addition, metabolites of ketamine depend on renal excretion and can accumulate in patients with renal failure.

The pharmacokinetic profile of narcotics can be altered in the presence of renal disease. Fentanyl is metabolized in the liver, and 85% of it appears in the urine and feces as inactive metabolites. Its slow elimination half-life is the result of a large volume of distribution. The effect is exaggerated in renal failure.⁷⁴ Chronic renal failure is associated with a decrease in alfentanil plasma protein binding, but it does not change plasma clearance of the drug. The volume of distribution at steady state is greater in patients with renal failure. Altered protein binding of alfentanil must be considered in patients with renal failure. Although the pharmacokinetics of sufentanil does not appear to be altered in patients with advanced renal disease, clearance and half-life are more variable in this group. Sufentanil should be carefully administered to these patients. Remifentanil is metabolized by nonspecific plasma esterases, and a significant reduction in clearance in patients with end-stage renal disease may be noted.²

Propofol has gained wide acceptance for both induction and maintenance of anesthesia and appears to be safe. Studies suggest, however, that patients with end-stage renal disease require a higher dose to achieve hypnosis. A hyperdynamic circulation in these anemic patients may be responsible. Propofol pharmacokinetics are unaltered by established renal failure. The time interval between cessation of a propofol infusion and eye opening is significantly shorter in renal failure patients compared with controls, although blood propofol concentrations are not significantly different on

emergence.^{2,5,9}

Dexmedetomidine, an α_2 -adrenergic agonist with sedative and analgesic properties, is cleared predominantly by the liver. Studies reveal minimal pharmacokinetic differences between healthy volunteers and patients with renal transplant. There were no reported differences in hemodynamics during administration of dexmedetomidine, but patients with renal failure exhibited prolonged duration of sedation.⁸⁴

Volatile Anesthetic Agents

Inhalation agents offer some advantage in patients with renal failure. Although biotransformation of some agents may produce metabolites excreted by the kidneys, elimination of volatile agents does not rely on renal function. Volatile agents potentiate neuromuscular blocking drugs, allowing administration of reduced doses. Although the potency of these agents allows them to be administered without nitrous oxide, excessive depth of anesthesia may lead to a depression of cardiac output. Reductions in cardiac output and tissue blood flow must be avoided in these anemic patients if tissue oxygen delivery is to be maintained.

A theoretic disadvantage of inhalation agents relates to biotransformation and nephrotoxic potential, although this disadvantage is not associated with the modern inhalation anesthetics. Fluoride levels after isoflurane anesthesia increased by only 1 to 2 μmol , and desflurane is metabolized approximately one-tenth as much as isoflurane and is the least metabolized of the currently available volatile agents. In studies of patients and volunteers administered desflurane for prolonged periods, no evidence of renal, hepatic, or hematologic toxicity was observed.

Some practitioners may avoid use of sevoflurane in patients with severe renal dysfunction because of the potential for nephrotoxicity. Studies do not support this concern and there is little evidence to support the avoidance of sevoflurane. All the current volatile anesthetics are safe in patients with renal disease.^{2,5,9}

In summary, both regional and general anesthesia has been used successfully in patients with advanced renal disease. Advantages and disadvantages of both techniques are listed in [Table 32.5](#).

TABLE 32.5**Regional Versus General Anesthesia**

Technique	Advantages	Disadvantages
Regional	Patient responsiveness Minimal changes in renal hemodynamics May shorten hospital stays Allows for earlier detection of capsular tears and bladder perforation Lower incidence of postoperative nausea and vomiting Reduced amount of operative blood loss and the incidence of deep vein thrombosis with transurethral resection of prostate (TURP)	Presence of peripheral neuropathy Tendency for bleeding Patient anxiety Less suitable for prolonged procedures Hypotension with sympathetic block; may cause reluctance to expand volume
Volatile anesthetics	Good airway control Blood pressure control Duration not dependent on urinary excretion Less neuromuscular blocking with drugs required FiO ₂ can be increased because N ₂ O not necessary	Alterations in renal hemodynamics Decreased cardiac output Hypotension Increased incidence of postoperative nausea and vomiting
Intravenous anesthetics	Hemodynamic stability	Unpredictable response Hypertension Greater need for N ₂ O and neuromuscular blockers

FiO₂, Fraction of inspired oxygen; N₂O, nitrous oxide.

Neuromuscular Blocking Drugs

The appropriate use of neuromuscular blocking drugs in patients with advanced renal disease has received much attention over the years. At one time, caution was advised in all cases of the use of a muscle relaxant in patients with renal disease due to concerns of prolonged duration of action. It was further theorized that, as the anticholinesterase or relaxant antagonist level decreased, the patient would be at risk of postoperative residual neuromuscular blockade. In general, the short and intermediate acting relaxants are used in patients with renal disease but a longer duration of action may be expected. The benzoisoquinoline relaxants mivacurium, cisatracurium, and atracurium are the least affected.⁸⁵ A complete discussion of the neuromuscular blocking drugs and renal disease can be found in [Chapter 12](#).

Succinylcholine.

Several problems have been associated with the use of

succinylcholine in patients with renal failure. Succinylcholine is metabolized by hepatic-derived pseudocholinesterase to succinic acid and choline. A metabolic precursor of these two compounds is succinylmonocholine, which has some nondepolarizing blocking activity and is eliminated by the kidneys. Prolongation of succinylcholine has also been associated with depressed levels of pseudocholinesterase in uremic patients who require hemodialysis.

Serum potassium increases by approximately 0.5 mEq/L in both normal patients and those with renal failure. This elevation in extracellular potassium is not reliably prevented by pretreatment with a nondepolarizing muscle relaxant. The rise in serum potassium level is particularly dangerous in uremic patients who are hyperkalemic. The use of succinylcholine is inadvisable unless a patient has undergone dialysis within 24 hours before surgery and the potassium concentration is less than 5.5 mEq/L. Succinylcholine is safe in normokalemic patients who have recently undergone dialysis.⁸⁵

Pancuronium.

Up to 80% of pancuronium is excreted in the urine. Biliary excretion accounts for much of the nonrenal elimination. A significant portion of the renal excretion of pancuronium occurs after its biotransformation to a less active metabolite. Pancuronium has a prolonged terminal elimination half-life in patients with reduced renal function. Because of its high dependence on renal excretion and long-acting classification, it should be avoided in patients with renal dysfunction.⁸⁵

Atracurium, Cisatracurium, and Mivacurium.

Initial reports indicated the action of neither atracurium nor vecuronium was prolonged in patients with decreased renal function; however, it now appears this is true only for atracurium. Atracurium and cisatracurium are broken down by Hoffman elimination and non-esterase-dependent hydrolysis to inactive products. Neither process is dependent on renal excretion for termination of action. Atracurium is less potent and has a shorter duration of action than cisatracurium. However, atracurium produces histamine release, which limits its desirability and it is

rarely used today. CKD does not alter pharmacokinetics or pharmacodynamics of atracurium. Cisatracurium and mivacurium pharmacodynamics is not changed but there is a slight slowing of onset. Many clinicians consider these the drugs of choice in patients with renal failure.⁸⁵

Vecuronium.

Approximately 30% of administered vecuronium is excreted via the renal system, and the duration of neuromuscular blockade is longer in patients with renal failure than in those without renal failure. Accumulation results from reduced clearance and a prolonged half-life. If vecuronium is used, a low dose is recommended, and repeated administration should be avoided. Careful neuromuscular monitoring is essential. Vecuronium neuromuscular blockade is rapidly reversible with dialytic treatment.⁸⁶

Rocuronium.

Rocuronium is the most commonly used nondepolarizing neuromuscular blocking drug. It has a rapid onset of action, producing good to excellent conditions for tracheal intubation in 60 to 90 seconds in humans. It has no clinically significant cardiovascular effects and an intermediate duration of action. A rapid onset is particularly attractive in these patients because they are subject to autonomic neuropathy and delayed gastric emptying. Rocuronium is excreted primarily in the bile, although renal excretion occurs up to 33% of the time. Renal failure reduces the clearance of rocuronium by 39%. The duration of action and recovery time are significantly prolonged in patients with renal failure.⁸⁷ In patients with renal failure, sugammadex (4 mg/kg) effectively and safely reversed profound rocuronium induced neuromuscular block, but the recovery was slower than healthy patients.⁸⁸ Due to the prolonged sugammadex-rocuronium complex exposure in patients with severe renal impairment, researchers caution that current safety experience is insufficient to support recommended use of sugammadex in this population.⁸⁹ Hemodialysis using a high-flux dialysis method is effective in removing sugammadex and the sugammadex-rocuronium complex if necessary in patients with severe renal impairment.⁹⁰

Intravenous Fluid Management

Perioperative management of fluids and electrolytes in patients with renal disease is critical. The state of hydration affects renin, aldosterone, and antidiuretic levels. Dehydration and hypovolemia lead to elevations in these hormones and to a decline in urinary output. Volume overload can lead to the development of pulmonary edema.

Perioperative Renal Function

Surgical patients at high risk for AKI, or those with advanced disease not requiring hemodialysis, present unique challenges. Preservation of renal function intraoperatively is dependent on the maintenance of intravascular volume and cardiovascular stability, as well as the avoidance of events causing renal vasoconstriction. Intraoperatively, urinary output is the most immediate monitor for renal function. A urinary output of 0.5 to 1 mL/kg per hr perioperatively is recommended, because urinary output less than 0.5 mL/kg per hr is a risk factor for renal injury (see RIFLE and AKIN classifications in [Table 32.2](#)). Serum creatinine is a more specific assessment of renal function than urinary output.⁹¹

Patients with normal or mildly compromised renal function should receive balanced salt solutions at 3 to 5 mL/kg per hr. A bolus of 500 mL should improve decreased urine output related to hypovolemia. Use of mannitol or furosemide to increase urine output may further exacerbate volume depletion and should be administered cautiously. Potassium-containing solutions (lactated Ringer's) are contraindicated in anuric patients.

Dialysis patients present a unique challenge to the anesthetist. This population requires a narrow window of control between hypovolemic and fluid overloaded states. Insensible losses are replaced with 5 to 10 mL/kg of 5% glucose in water (D₅W). If any urine is produced, it may be replaced with 0.45% saline.

The greater expected fluid losses of thoracic and abdominal surgery cases may require significant volume replacement. A balanced salt solution, 5% albumin, or a combination thereof is

recommended for replacing these larger volumes in patients with, or at risk for, kidney disease or injury. The administration of blood products should be reserved for patients who need increased oxygen-carrying capacity. The safety of synthetic colloids in patients with preexisting renal dysfunction still remains unclear, although research supports that synthetic colloids are not well tolerated by patients with ESRD.⁹²⁻⁹⁴

Renal Insufficiency

In patients with renal insufficiency, volume deficits should be replaced preoperatively, as in normal patients. Basal fluids must be carefully regulated because these patients cannot tolerate much deviation. Overall basal fluid requirements must be related to metabolic rate and designed to provide an overall fluid balance to form isotonic urine, which will facilitate excretion of electrolytes and waste products. Intraoperative losses greater than 10% to 15% of the blood volume should be replaced with colloid solution on a 1 : 1 basis after red blood cell losses are corrected. Smaller losses can be replaced with the usual 3 : 1 ratio of crystalloid infusion to blood loss. Third-space losses are ideally replaced initially with crystalloid solution without potassium or excess chloride. Initial third-space losses should be replaced with crystalloid solution at a rate of 2 to 3 mL/kg per hr. The critical goal in patients with renal insufficiency is sustaining blood volume and preventing hypotension and subsequent hypoperfusion. Monitoring of colloid osmotic pressure and hemoglobin can guide the choice between crystalloid and colloid infusions. If hemoglobin and colloid osmotic pressure are increasing, crystalloid solution is clearly indicated. If they are decreasing, crystalloid solution should be withheld in favor of colloid solution. Close monitoring of blood pressure, heart rate, CVP, pulmonary artery occlusion pressure, and cardiac output also guides fluid titration. This is especially true in patients with cardiac or respiratory compromise.⁹⁵

End-Stage Renal Disease

With regard to perioperative fluid management, patients with end-stage renal disease who are hemodialysis dependent require special

attention. Although these patients are similar to normal patients in terms of fluid deficit, basal, and third-space requirements, they have a very narrow margin of safety. Ability to compensate for either fluid excess or fluid deficiency progressively declines as renal function is lost.

Fluid deficits must be replaced preoperatively in patients with end-stage renal disease. If deficits exceed 10% to 15% of the blood volume, invasive monitoring is justified. Dialysis is recommended on the day before anesthesia to allow time for equilibration of fluid and electrolyte shifts common with dialysis. Electrolyte levels, particularly potassium, must be checked before anesthesia. If the serum potassium is markedly elevated, attempts should be made to lower the serum level prior to administration of anesthetics. Many facilities having a large population of ESRD patients have developed clinical guidelines to manage severe potassium derangements.³⁶

Basal fluids in patients with ESRD should be replaced in a manner similar to that for patients with renal insufficiency. Volume restriction is recommended for intraoperative losses. Third-space losses should be replaced with a balanced salt solution that does not contain potassium and small amounts of chloride. Close monitoring of hemoglobin and cardiac filling pressures is indicated for all major procedures. Patients with ESRD generally require dialysis within 24 to 36 hours after major surgery.⁹²⁻⁹⁴

Uremia

Deficit replacement in patients with uremia must be guided by hemodynamic monitoring. Basal fluids should be replaced with red blood cells, fresh frozen plasma, or colloid solutions and third-space losses are best replaced with crystalloid solutions in association with frequent monitoring of hemoglobin. Cardiac filling pressures should be checked when warranted by the surgical procedure. A moderate degree of volume overload is not a grave problem. Many uremic patients require dialysis within 24 to 36 hours for the removal of mobilized fluid and the control of hypertension.

Although volume overload is most often emphasized in patients with end-stage renal disease, complications of hypovolemia are also

serious. Hypotension associated with hypovolemia increases the risk of thrombosis of the arteriovenous fistula and predisposes to cardiac and cerebral ischemia. Hemodynamic goals include the avoidance of hypotension and gross fluid overload. This can be accomplished only through careful titration with the patient well monitored.^{96,97}

Cystoscopy

Almost all urological surgical procedures that are not “open” are performed via cystoscope and in the lithotomy position. Urological procedures performed via a cystoscope can be very quick (i.e., diagnostic cystoscopy) or last several hours (i.e., stone retrieval). A short acting spinal anesthesia is an ideal anesthetic technique for urological procedures performed through a cystoscope. The insertion of the cystoscope is very stimulating for the patient so it is important to attenuate the surgical stress response by deepening the patient very early in the maintenance phase. This can be accomplished with the sympathectomy associated with spinal anesthesia or a deep anesthetic plane when using a general technique. Spinal anesthesia provides analgesia and loss of muscle movement, as well as permitting real time assessment of mental status. When using general anesthesia technique, a laryngeal mask airway with spontaneous respirations is appropriate practice for airway management unless aspiration is a concern.

Extracorporeal Shock-Wave and Laser Lithotripsy

Nephrolithiasis (renal calculi) is a common condition, with a lifetime prevalence of approximately 9% in the United States. Although many renal calculi or “stones” are asymptomatic, patients with symptomatic stones often require immediate treatment. Approximately 1 to 2 million emergency room visits annually are for a primary diagnosis of renal colic or renal calculus with acute obstruction. The economic burden of urolithiasis is immense. In 2014, the total health care expenditures reached nearly \$4.5 billion annually, and this figure increased to \$5.3 billion when the indirect costs of lost workdays were included. Approximately 80% of upper urinary tract stones are calcium-based (composed of calcium oxalate, calcium phosphate, or brushite), with the remaining 20% composed of uric acid, struvite, cystine, or, rarely, other components.⁹⁸

CT of kidneys, ureters, and bladder (CT KUB) can identify more than 99% of stones. Ultrasound is an alternative. If a ureteric stone is less than 5 mm in diameter, it is expected it will pass without intervention. Initially medical management is attempted for stones between 5 and 10 mm in diameter, but urology input is more likely to be necessary as up to 50% of these may require intervention. Stones that are greater than 10 mm in diameter should be discussed with the urology service as they are unlikely to pass spontaneously.⁹⁹

Extracorporeal shock-wave lithotripsy (ESWL) is the only noninvasive urinary stone treatment. The technique uses high-energy ultrasonic or pneumatic shock waves or lasers to fragment renal calculi into small particles. ESWL is used for stones less than 10 to 20 mm in the proximal or midureter. Stones of any size located in the distal ureters are removed using ureterorenoscopy. Success rates are highly variable, ranging from 30% to 100%. ESWL uses an external source to deliver pulses of energy into a fluid chamber, generating a shock wave. The shock wave is transmitted unimpeded through the fluid and transmitted through soft tissue

(which has approximately the same density as fluid) until abrupt change in acoustic density from tissue to stone impedes the shock wave forward movement. By focusing the shock waves on a single focal point, the lithotripter concentrates energy at the stone location. Stone fragmentation by shock waves occurs as a consequence of both direct mechanical stress from the incident shock wave and indirect forces as a result of collapse of cavitation bubbles generated by the trailing negative-pressure wave. When lithotripsy fails to resolve the stone, more invasive techniques are employed such as percutaneous nephrolithotomy and ureteroscopy.^{100,101}

Techniques

Shock-wave lithotripsy is an outpatient procedure usually performed in a hospital, ambulatory surgery center, or a mobile lithotripter. Initially, all ESWL was accomplished in water baths. Modern lithotripters create a connection with high-acoustic gel or oil or ionized water bags instead of submersion, providing for a more portable and convenient treatment regimen. Connections between the patient and the shock waves may be diminished by air pockets in the gel or oil requiring an increased number of shocks and therefore greater risk of tissue damage.^{102,103}

Several types of lithotripters are in clinical use, and they differ in the way they generate the shock waves. Electrohydraulic (spark-gap) lithotripters rely on an underwater discharge of a high-voltage spark that rapidly vaporizes the surrounding water, generating spherically expanding shock waves. Electromagnetic lithotripters are composed of an electromagnetic coil and a closely approximated metallic plate (or membrane) inside a water-filled shock tube. Piezoelectric lithotripters produce shock waves with the use of a spherical dish containing an array of small ceramic elements.¹⁰² Ultrasonic waves fragment stones and allow them to pass in urine. Lasers may not be as effective with larger stones (greater than 1.5–2.0 cm).^{104,105}

Water Immersion

The original ESWL procedure required patients to be strapped in a chair in a semi-reclining position, followed by submersion in water

up to the clavicle. This technique is not used today, but the principles underlying the surgical procedure are similar. The focused, reflected shock wave passes through water entering flank soft tissue. Significant effects on several systems may occur (Box 32.6).^{100,106} Electrocardiograph (ECG) lead placement is important and should be coordinated with the surgeon. A high-quality tracing is critical because the R wave is used to trigger the shocks. Synchronization of the shock wave to the ECG has reduced the incidence of cardiac dysrhythmias, most commonly supraventricular or premature ventricular complexes, but has not totally eliminated them. Atropine or glycopyrrolate may be given at the request of the surgeon to increase the heart rate and thus the shock wave rate.¹⁰⁶

Side Effects Associated With Extracorporeal Shock Wave Lithotripsy

- Hypothermia, hyperthermia
- Cardiac arrhythmias
- Skin bruising hematomas
- Petechiae, soft tissue swelling at site
- Renal edema
- Renal hematoma
- Lung injury
- Flank pain
- Hypertension, hypotension
- Nausea, vomiting
- Respiratory difficulties

Contraindications and Complications

Contraindications to shock-wave lithotripsy include: (1) active urinary tract infection, (2) uncorrected bleeding disorder or coagulopathy, (3) distal obstruction, and (4) pregnancy. Obesity and orthopedic or spinal deformities may make positioning difficult.^{100,102} Dose-dependent hemorrhagic lesions can develop on the kidneys, secondary to vascular damage.¹⁰⁴⁻¹⁰⁶ The colon, hepatic structure, lungs, spleen, pancreas, abdominal aorta, ileac veins, or any structure in the abdominal region may be perforated, ruptured, or otherwise damaged. Moderate to severe hemorrhage may occur, but usually resolves spontaneously; patients with clotting disorders are at an increased risk. Hematuria develops in most patients, secondary to blood vessel rupture. Diabetes, new-onset hypertension, or permanently decreased renal function may result.¹⁰⁷

Anesthesia

Patients will not tolerate ESWL without anesthesia. Various anesthetic techniques have been used. General anesthesia is advantageous because of its rapid onset and control of patient movement. Other techniques include spinal or epidural anesthesia, patient-controlled analgesia, monitored anesthesia care, and topical anesthesia with eutectic local anesthetics. Continuous infusions of propofol, ketamine, and alfentanil have been used alone or with midazolam. Regional anesthesia provides effective analgesia with a T4 to T6 level. A short-acting spinal anesthetic using 50 mcg of sufentanil alone is popular. Epidural catheters and dressings may cause absorption of some of the shock wave, decreasing the efficacy of treatment. Akinesia is critical in reducing number and duration of treatments, determining efficacy of ESWL, and preventing potential tissue damage. General anesthesia or deep sedation techniques decrease the risk of patient movement.^{100,102,107}

Preoperative preparation includes the discontinuation of aspirin-containing medications, anticoagulants, platelet inhibitors, and nonsteroidal antiinflammatory agents for 7 to 10 days before the procedure and documentation of a negative urine culture to prevent postoperative urinary tract infection or sepsis. In women of childbearing age, a pregnancy test is administered if ionizing radiation is to be used during the procedure. Depending on stone

composition (i.e., size, radiopacity, location) patients may be advised to drink clear liquids, take a laxative, or both the day before the procedure to enhance stone visualization. Fasting protocols are within standard guidelines for anesthesia.¹⁰²

For lithotripsy to be most effective, the calculus must remain at the focal point. Because patient movement and patterns of respiration can change kidney and calculus position, movement must be minimized and ventilation carefully controlled. The number and intensity of shock waves can be reduced when calculus movement is minimized.¹⁰⁸ An obstructed kidney or a patient exhibiting signs and symptoms of infection qualifies as an emergency case. Adequate hydration is encouraged postoperatively to promote diuresis of fragments and decrease hematuria. Close proximity to lasers may cause corneal damage; strict laser protocols should be employed (i.e., eye protection).¹⁰²

Percutaneous Nephrolithotomy

Removal of kidney stones or calculi 25 mm or smaller also can be accomplished through percutaneous nephrolithotomy. This procedure requires general anesthesia and postoperative hospitalization. Calculi are removed via a rigid operating scope inserted in the lower renal calyx under intermittent fluoroscopy. Once located, calculi are pulverized by using laser, electrohydraulic, or ultrasound probes placed directly on the stones. The procedure is performed with the patient in the prone or supine position; therefore, associated anesthetic considerations apply. The following is a list of complications of percutaneous nephrolithotomy.^{109,110}

Minor	Major
Pain	Septicemia
Fever	Bleeding
Urinary tract infection	Pelvic or ureteral tears
Renal colic	Pneumothorax
	Hemothorax
	Anaphylaxis secondary to contrast dye

Transurethral Resection of the Prostate

Surgical Technique

Benign prostatic hyperplasia (BPH) is the most common benign adenoma in men. Up to 40% of men will require intervention for urinary difficulty, and the frequency of those seeking medical treatment is increasing, due in part to the increase in life expectancy. Medical management consists of pharmacotherapy, which may be combined with a minimally invasive technique. Drugs such as the α -blocking agents, alfuzosin (Uroxatral), tamsulosin (Flomax), doxazosin (Cardura), and terazosin (Hytrin) or the 5- α -reductase (5AR) inhibitors, finasteride (Proscar) and dutasteride (Avodart), are used alone or more often in combination. Laser therapy seems useful for selected patients with small glands. Transurethral microwave treatment and intraprostatic stents may be useful in high risk patients. Transurethral resection of the prostate (TURP) is one of the most commonly performed surgical procedures in men older than 60 years of age. It is being performed less frequently as medical management improves; however, it remains the gold standard in surgical treatment approaches.^{111,112}

The procedure consists of opening the outlet channel from the bladder using a resectoscope in the urethra to electrically cut away the obstructing median and lateral lobes of prostate tissue. Bleeding is controlled by coagulation current. For visualization of the area, the bladder is distended and continuous irrigation is used to wash away blood and dissected prostatic tissue. These patients are often at greater anesthetic risk because they are elderly and more likely to have cardiovascular or pulmonary problems. TURP syndrome is a rare but potentially fatal surgical complication. The incidence is reported to range from 0.78% to 1.4% of procedures. Severe TURP syndrome is extremely rare, but the mortality rate may be as high as 25%. It may occur as early as 15 minutes after the start of resection up to 24 hours postoperatively.¹¹¹ The hallmark clinical symptoms are procedure related due to a combination of water intoxication, fluid overload, and hyponatremia. The

pathophysiology and clinical features of TURP syndrome are summarized in [Table 32.6](#). Other complications of the procedure include excessive bleeding, bladder perforation, and infection. Average surgical parameters associated with a transurethral resection of the prostate are given in [Table 32.7](#). Improved surgical techniques and knowledge of the pathophysiology, prevention, and management of TURP syndrome has minimized the risks of this procedure.^{111,113–116}

TABLE 32.6
Pathophysiology and Clinical Features of TURP Syndrome

Pathophysiology	Clinical Features
Fluid overload	Hypertension, bradycardia, arrhythmia, angina, pulmonary edema and hypoxemia, congestive heart failure and hypotension
Water intoxication or hypo-osmolality	Confusion and restlessness; twitching or seizures, lethargy or coma, dilated, sluggish pupils, papilledema, low-voltage EEG, hemolysis
Hyponatremia	CNS changes as above, reduced inotropy, widened QRS complex, low-voltage ECG, T-wave inversion on ECG
Glycine toxicity	Nausea and vomiting, headache, transient blindness, loss of light and accommodation reflexes (blink reflex preserved), myocardial depression, ECG changes
Ammonia toxicity	Nausea and vomiting, CNS depression
Hemolysis	Anemia, acute renal failure, chills, clammy skin; chest tightness and bronchospasm; hyperkalemia resulting in malignant arrhythmias or bradyasystole
Coagulopathy	Severe bleeding, primary fibrinolysis, disseminated intravascular coagulation

systems. In Miller RD, et al., eds. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier Saunders 2015.

Complications

Fluid Absorption

A number of complications are associated with resection of the prostate. Large amounts of irrigating solution can be absorbed through prostate venous sinuses. The amount absorbed and the rate of absorption depend on the glandular: (1) size to be resected, (2) congestion, (3) duration of resection, (4) irrigating solution pressure, (5) number of sinuses open at any one time, and (6) the experience of the resectionist.¹¹⁷⁻¹¹⁹ An average of 10 to 30 mL of fluid can be absorbed per minute of resection time, and 6 to 8 L can be absorbed in cases that last up to 2 hours.^{5,113} The uptake of 1 L of irrigant into the circulation within 1 hour can decrease the serum sodium 5 to 8 mEq/L. In general, limiting resection time to 1 hour is desirable.

Complications may occur with irrigation solutions, as determined by their osmolality and solute composition. Various types of irrigating fluid have been used. Although distilled water is associated with the least optical impairment, hemolysis of red blood cells occurs due to the hypotonic composition.¹²⁰ Normal saline or lactated Ringer's solution is highly ionized and promotes dispersion of high current from the resectoscope. Current irrigating solutions typically consist of Cytal (sorbitol 2.7% and mannitol 0.54%), glycine 1.2% or 1.5%, or physiologic saline.¹¹¹

Complications specifically related to absorption of irrigating fluid include: (1) volume overload with pulmonary edema, (2) dilutional hyponatremia, (3) hypoosmolality, (4) cardiac effects, (5) retinal toxic effects (with glycine), and (6) hyperglycemia. As fluid enters the vascular compartment, intravascular pressure and myocardial work increase. The fluid dilutes plasma proteins and electrolytes, and the change in intravascular pressure favors movement of fluid from the vascular to the interstitial compartment and is poorly tolerated by patients with a cardiovascular disease. Cardiac dysrhythmias may also develop. Progressive increases in blood pressure, CVP, or pulmonary artery wedge pressure (when

monitored) suggest hypervolemia. Mannitol irrigating solutions have been reported to contribute to the development of pulmonary edema and hyponatremia.^{118,121,122}

Absorption of irrigating fluid also leads to dilutional hyponatremia and hypoosmolality. Sodium is a major cation of extracellular fluid, and is responsible for the depolarization of excitable cells and the propagation of action potentials. The severity and speed of the drop in sodium are related to the resulting symptoms. The decrease in sodium produces an osmotic shift of fluid resulting in brain edema, increases in intracranial pressure, and neurologic symptoms. Hyponatremia usually results from water excess rather than from sodium loss. CNS symptoms associated with hyponatremia range from restlessness, headache, irritability, and confusion to blindness, coma, and seizures.

Serum sodium (Na^+) concentrations of 120 mEq/L appear to be borderline for the development of severe reactions, which are mainly ECG and CNS changes. Electrocardiographic changes characterized by widening of the QRS complex and ST-segment elevation are seen when the serum level decreases to 115 mEq/L. At levels less than 100 mEq/L, ventricular tachycardia and fibrillation can occur.^{115,123,124} The irrigating fluid should be warmed to prevent the development of hypothermia and possible detrimental shivering.¹²⁵

CNS symptoms associated with hyponatremia include restlessness, confusion, nausea, vomiting, coma, and convulsions. A change in mental status may be the first sign of developing hyponatremia. These symptoms can be detected more easily in patients receiving regional anesthesia. CNS symptoms are hidden under general anesthesia. Transient hyperglycemia and hypokalemia have been reported when glucose irrigation solutions have been used.^{113,115,120}

Bladder Perforation

Perforation of the bladder is another potential complication of prostatic surgery; however, recent advances in technology have reduced its incidence. Symptoms vary, depending on whether the rupture is intraperitoneal or extraperitoneal. Pathophysiology and clinical features of bladder perforation and TURP syndrome are

noted in [Box 32.7](#).¹¹⁸ These symptoms are better recognized when the patient has regional anesthesia, particularly when the regional technique does not produce a high block. With general anesthesia, only the surgeon can appreciate the inability to recover bladder fluid as a sign of perforation. The kidney may excrete small amounts of intraperitoneal fluid. However, if hemodynamic compromise occurs, suprapubic drainage is effective for removal of [Box 32.7](#) excess intraperitoneal fluid.

Key Points for Anesthesia Management of Transurethral Resection of Prostate

- TURP syndrome is caused by disturbance of intravascular volume and/or serum osmolality.
- Five questions to ask prior to a TURP:
 1. What is the irrigation fluid? (Glycine, Cytal, or Physiologic saline?)
 2. What is the bag height over the prostate?
 3. What is the size of the prostate?
 4. What is the expected duration of procedure?
 5. What is the surgical operating position (avoid Trendelenburg)?
- Techniques for detection of pending TURP syndrome include measurement of serum sodium, monitoring for fluid overload, assessment of mental status, and ethanol breath analysis.
- Treat symptomatic (mental status changes, seizures, hypotension) patients aggressively; treat asymptomatic aberrant lab values (hyponatremia, hyperglycemia) very slowly, if at all.

- CNS symptoms of headache, irritability, confusion, nausea, and vomiting are early warning signs of TURP syndrome.

CNS, Central nervous system.

Adapted from Hawary A, et al. Transurethral resection of the prostate syndrome: almost gone but not forgotten. *J Endourol.* 2009;23(12):2013–2020; Malhotra V, Sudheendra V. Complications of transurethral surgery. In Atlee JL, ed. *Complications in Anesthesia.* 2nd ed. Philadelphia: Elsevier; 2007:843–845; Gravenstein D, Hahn RG. TURP syndrome. In Lobato EB, et al., eds. *Complications in Anesthesiology.* Philadelphia: Lippincott Williams & Wilkins; 2008:474–491.

Glycine Absorption

Absorption of glycine has been associated with toxicity. Although glycine, a normal amino acid is a major inhibitory transmitter, particularly in the retina, toxic effects may occur from absorption during the procedure. Absorption of 1.5% glycine can cause a deterioration of vision. TURP blindness is caused by retinal dysfunction from glycine toxicity.^{111,113} Clinical signs and symptoms of excess glycine absorption include nausea, vomiting, fixation and dilation of the pupils, weakness, muscle incoordination, and hypotension due to a decrease in the release of catecholamines.¹¹³

Glycine may also result in encephalopathy and seizure activity due to N-methyl-D-aspartate (NMDA) receptor stimulation and CNS toxicity. CNS symptoms are a consequence of its biotransformation in the liver to ammonia. Ammonia toxicity may result in encephalopathy, delayed awakening, and even coma in the postoperative period.¹¹¹ Other signs and symptoms of glycine toxicity include nausea, vomiting, headache, malaise, and weakness.

Skin Burns

The use of high voltage for cutting and coagulation during TURP may result in skin burns. Newer technology for TURP, including bipolar enucleation of the prostate and laser therapy, reduces the risk of skin burns when compared with monopolar techniques.¹²⁶ Electrocardiography pads may be placed at other sites so that potential burns are avoided. Many patients who undergo TURP have pacemakers. Depending on the age of the pacemaker, these

devices must be converted to a fixed rate unless they are designed to operate in the presence of applied currents.^{113,127}

Blood Loss

Significant bleeding occurs in less than 1% of TURP cases. Blood loss during TURP is generally related to: (1) weight of the resected tissue, (2) resection time, and (3) skill of the surgeon.¹¹⁹ Increased blood loss occurs with greater than 45 g of resected tissue and procedures lasting longer than 90 minutes. Assessment of blood loss may be difficult because of the dilution of blood in irrigating fluid. Hematocrit may be increased, decreased, or unchanged, depending on the amount of fluid in the intravascular space at the time. Blood transfusion should be based on preoperative hematocrit, the duration and difficulty of resection, and a general assessment of the patient. A 2011 study of 951 robotic-assisted laparoscopic prostatectomies noted that men with larger prostates and median lobes requiring longer operative times experienced higher blood loss. Resected tissue less than 30 g generally required no transfusion. Thirty to eighty grams resected possibly required up to 2 units of red blood cells, and greater than 80 g up to 4 units.^{2,128}

Prevention of TURP Syndrome.

Prevention of TURP syndrome is, of course, the most important approach. Early identification of evolving symptoms is vital to avoid serious morbidity. Suggested preventative measures include: (1) avoid the Trendelenburg position as it promotes fluid absorption, (2) limit resection time to less than 1 hour, (3) keep prostate capsule intact until the end of the resection, (4) place irrigating fluids less than 60 cm above the prostate gland, (5) measure electrolytes during and after the procedure as indicated; and (6) use a regional technique with light sedation so that mental changes can be identified.¹²⁹

Treatment of TURP Syndrome.

An asymptomatic patient with mild hyponatremia only requires monitoring and observation. Mild symptoms can be managed with

supportive treatment such as antiemetics, atropine, vasopressors, or diuretics, and careful observation as indicated.

If TURP syndrome is detected intraoperatively, bleeding points should be coagulated and surgery completed as soon as reasonable. Severe hyponatremia less than 120 mEq/L must be treated. The challenge is to promptly institute treatment while avoiding overtreatment. The most feared complication of rapid correction of acute hyponatremia is central pontine myelinolysis, also referred to as *osmotic demyelination syndrome* (ODS). The etiology is unclear; however, osmotic stress appears to cause changes in neuronal cells and the release of myelin toxins. Symptoms usually occur approximately 1 week after the osmotic stress and may include seizures, palsy, dysarthria, paralysis, mental changes, and coma. Hypertonic saline (3% to 5% sodium chloride) should be given at a rate no greater than 100 mL/hr. Sodium correction should not exceed 0.5 mEq/L per hr or 8 mEq/day. Severe symptoms may require initial doses of 1–2 mEq/L per hr. Target levels for correction are 120 mEq/L. If 3%–5% sodium chloride is not immediately available, 9% sodium bicarbonate can be administered to treat severe hyponatremia until 3%–5% sodium chloride becomes available. Suggestions for the management of TURP syndrome and [Bladder Perforations](#) are given in [Box 32.8](#).

Management of TURP Syndrome and Bladder Perforation

- Asymptomatic or mildly symptomatic patients should be observed and monitored.
- Severe TURP syndrome requires immediate aggressive therapy if the patient is to survive. The following measures are suggested:
 - Terminate the surgery as soon as possible.
 - Administer 20 mg of intravenous (IV) furosemide.
 - Immediately obtain the following laboratory tests; hematocrit; serum electrolyte, creatinine, and glucose concentrations; serum osmolality (if available); arterial blood gas analyses; and 12-lead

ECG.

- Continue or start the administration of normal saline. Hypertonic saline (3% or 5%) may be administered (at a rate < 100 mL/hr) if the serum sodium concentration is less than 100 mEq/L, severe central nervous system side effects of hyponatremia and hypo-osmolality are evident, or reduced inotropy results in cardiovascular collapse.
- Administer IV midazolam in 1 mg incremental doses to treat twitching or seizures; a barbiturate may be added if seizures persist.
- Auscultate chest and obtain chest radiographs to detect pulmonary edema. Intubate and mechanically ventilate the patient at the earliest evidence of pulmonary edema.
- Transfuse packed red blood cells as necessary.
- If bleeding continues, investigate for disseminated intravascular coagulation (DIC) or primary fibrinolysis. DIC is treated with crystalloids and blood products to achieve hemodynamic stability and normal coagulation. Primary fibrinolysis responds well to amino-caproic acid (Amicar) administered as an IV infusion of 3 to 5 g in the first hour, followed by continuous IV infusion at 1 g/hr until the bleeding is controlled.
- Institute invasive monitoring and provide supportive therapy to maintain circulation and pulmonary function and to prevent renal failure.

Bladder Perforation

As soon as bladder perforation is detected, undertake the following measures:

- Stop surgery and achieve hemostasis.
- Treat hypotension with IV crystalloids, vasopressors, and inotropes.

- Obtain a hematocrit. Start blood transfusion if brisk bleeding continues. Occult blood loss into the intraperitoneal or retroperitoneal space may occur.
- Perform a cystourethrogram to locate the perforation.
- For most perforations, suprapubic cystotomy, an indwelling Foley catheter, and (occasionally) ureteral stents are sufficient. In some instances, immediate exploratory laparotomy may be necessary to control bleeding and repair the perforation.

In Lobato EB, et al., eds. *Complications in Anesthesiology.* Philadelphia: Lippincott Williams & Wilkins; 2008:474–491.

Anesthesia for TURP Procedures.

Spinal and general anesthesia techniques are both used for TURP procedures. Spinal anesthesia is considered the anesthetic of choice because the early signs and symptoms of TURP syndrome, hypervolemia, and bladder perforation are more easily detected in a responsive patient. Under general anesthesia, cardiovascular changes must be relied on to diagnose complications.^{130–132} Pain impulses from the bladder neck and prostate are propagated by afferent parasympathetic fibers originating primarily from the second and third sacral roots in concert with the pelvic splanchnic nerves. The sympathetic nerves via the hypogastric plexus, which is derived from T11 to L2 nerve roots, transmit sensation from the bladder.⁵ As a result, a T10 sensory level is necessary for adequate anesthesia. Intrathecal opioids are commonly included with the local anesthetic. Cautious fluid loading may be used to minimize spinal anesthesia-induced hypotension. Although general anesthesia may mask early complications, it may be desirable in the patient who requires pulmonary support or who cannot tolerate a fluid load for compensation of a loss of sympathetic tone. All inhalation agents have been used successfully.^{111,113,121} Some key points for anesthesia management of TURP are given in [Box 32.8](#).

Laparoscopic Urologic Surgery

Laparoscopy is the process of inspecting the abdominal cavity through an endoscope. Laparoscopy started in the mid-1950s in gynecological surgeries. Over the years, laparoscopy for general and urologic surgery has become a common procedure.

Advantages and disadvantages of laparoscopic surgery are found in [Box 32.9](#). Some examples of surgical procedures that can be done laparoscopically include varicocelectomy, percutaneous stone [Box 32.9](#) nephrectomy, transplants, and radical prostatectomy.¹³³

Advantages and Disadvantages of Laparoscopic Renal Surgery

Advantages

- More precise operative procedure due to magnification of operative site
- Reduced postoperative pain
- Improved cosmetic results
- Quicker return to normal activities
- Reduction in hospital length of stay
- Reduction of cost of care
- Less intraoperative bleeding
- Fewer postoperative pulmonary infections
- Fewer postoperative wound infections
- Reduced metabolic derangements
- Better postoperative respiratory function

Disadvantages

- Potential for extravasation of insufflated carbon dioxide to retroperitoneal space and thorax
- Potential for postoperative airway compromise secondary to subcutaneous emphysema and pharyngeal obstruction
- Increased incidence of acidosis due to absorption of carbon dioxide
- Higher incidence of intraoperative oliguria potentially due to perirenal pressure from pneumoperitoneum
- Potentially longer duration than open procedure

Carbon dioxide is the most universally used agent for insufflating the abdominal cavity to facilitate view during this procedure. Several pathophysiologic changes can occur after carbon dioxide pneumoperitoneum and the extremes of patient positioning. Preparation for hemorrhage and conversion to an open procedure are critical.¹³⁴ Most of the considerations for laparoscopic surgery are in [Chapter 34](#), but two unique problems specific to urologic surgery are worth noting.

The urogenital system is a retroperitoneal system. As such, carbon dioxide insufflated in this space communicates freely with the thorax and subcutaneous tissue. Subcutaneous emphysema can occur and may extend to the head and neck. In severe cases, it may lead to submucosa swelling and airway compromise in the unprotected airway.¹³⁵

Carbon dioxide is absorbed from the peritoneal cavity and acidosis may develop. Because the carbon dioxide insufflation, together with steep Trendelenburg position and long procedures, may increase intraabdominal and intrathoracic pressure, controlled ventilation is mandatory. Intraoperative pressure greater than 10 mm Hg results in hemodynamic alterations, including decreased cardiac output and increased systemic vascular resistance. The pneumoperitoneum can cause renal cortical vasoconstriction due to activation of the sympathetic nervous system. Decreased renal

perfusion activates the renin-angiotensin-aldosterone system, which causes vasoconstriction. These effects are additive to those seen with surgical stress. Renal and hepatic perfusion may be altered.^{133,134,136,137} Some suggested techniques to minimize the effect of positive pressure pneumoperitoneum include: (1) employ lower insufflation pressures, (2) operate in a gasless environment, (3) substitute inert gas for carbon dioxide, (4) use drugs to antagonize the neuroendocrine response, (5) expand volume, and (6) use mechanical devices. It has been reported that the use of intermittent sequential pneumatic compression, activated over the lower limbs 15 minutes after the pneumoperitoneum, improves splanchnic and renal perfusion. This technique augments cardiac output and lowers systemic vascular resistance.¹³⁸ A complete discussion of laparoscopic surgery can be found in [Chapter 34](#).

Robotic Urologic Surgery

Robotic-assisted surgery is becoming increasingly more popular for managing various urologic procedures.¹³⁹ Major urologic surgery has two main categories. The first is upper tract surgery such as simple or radical nephrectomy, radical nephroureterectomy or nephron-sparing surgery. The second category is pelvic surgery, such as radical cystectomy, with urinary diversion and radical prostatectomy.¹³⁷

It is performed using the da Vinci surgical system (Intuitive Surgical Mountain View, CA). It consists of a surgeon's console for surgical work, a surgical cart housing video and lighting equipment, and a robotic tower supporting three or four robotic arms. Fig. 35.1 shows the da Vinci Si surgical system.

Robotic technology provides the surgeon with an enhanced and magnified 3D view, a reduction in scattered ambient light, reduced surgeon fatigue, hand tremor, and improved manual dexterity. This technology also provides a predominantly bloodless field.^{140,141} Pyeloplasties to correct hydronephrosis, nephrectomies, and bladder augmentation robotic procedures are being employed in the pediatric population.^{142,143}

Cost savings are noted in managing adverse outcomes and decreased hospital length of stay, but these savings are not enough to offset the direct costs of purchasing and maintaining the robotic equipment. Competition from medical equipment companies may eventually lower these direct costs.¹⁴⁴ Patient outcomes are similar or improved from open and laparoscopic surgical approaches.^{139,145,146} Wang (2008) reported decreased blood loss, decreased transfusion requirements and shorter hospital stays.¹⁴⁷ Complications are commonly related to patient position, length of surgical time, and surgeon skill level.¹⁴¹

Robotic surgery necessitates a coordinated approach by anesthetist and surgeon because the surgery is performed using a modified laparoscopic technique and can be long in duration. The patient is placed in steep Trendelenburg position, with the addition of lithotomy positioning in prostatectomy surgery. Major complications of surgery in the Trendelenburg position include: (1)

neuropathies, (2) CVP elevation, (3) intraocular/intracranial pressure elevation, (4) increased pulmonary venous pressure, (5) decreased pulmonary compliance, (6) reduced functional residual capacity, and (7) swelling of the face, eyelids, conjunctivae, and tongue.^{5,146,148,149}

Significant pulmonary alterations, such as profound hypercarbia, can develop in the perioperative environment. Although most patients with impaired gas exchange due to diaphragmatic and chest wall restriction will quickly resolve to 15% of baseline within minutes when returned to supine position, increased BMI and smoking history significantly increases the risk of prolonged respiratory compromise.¹⁴⁹

Fluid replacement should be carefully monitored. Overhydration can distort anatomical surgical landmarks and lead to profound fluid shifts in radical prostatectomy and cystectomy procedures.¹⁴⁵ Facial swelling requires careful airway assessment prior to extubation as reintubation may be difficult due to altered anatomical landmarks and edematous soft tissue. Anesthetic considerations for robotic procedures are summarized in [Box 32.10](#). Common management principles for urological robot assisted surgery are noted in [Box 32.11](#). A complete discussion of anesthesia [Box 32.10](#) assisted surgery can be found in [Chapter 35](#).

Anesthetic Considerations With Robot-Assisted Surgery

Prolonged lithotomy position predisposes to:

- Lower (and rarely upper) extremity nerve injury (particularly femoral nerve)
- Pressure areas and compartment syndrome of the lower limbs

Prolonged Trendelenburg position predisposes to:

- Ocular injury including corneal abrasions and ischemic optic neuropathy caused by high intraocular pressures
- Laryngeal (and facial) edema and respiratory distress

- Risk of cerebral edema, as well as increased intracranial pressure, due to reduction in cerebral venous return due to the high intraabdominal pressures and head-down position
- Decreased functional residual capacity and decreased pulmonary compliance causing increased ventilatory pressures and increased atelectasis

Prolonged pneumoperitoneum predisposes to:

- Carbon dioxide subcutaneous emphysema (up to 4% of cases)
- Carbon dioxide air embolism is also possible

Box 32.11

Common Management Principles for Urological Robot-Assisted Surgery

- *Duration:* approximately 3 to 4 hours (surgical time, 2–3 hours)
- *Incision:* multiple robotic-arm trocars with surgical instruments attached
- *Positioning:* steep head-down lithotomy (approximately 27 degrees), arms wrapped by sides
- Warn patient about sore throat, due to the endotracheal tube, facial edema, catheter insertion, lower abdominal (and sometimes penile) pain, and the need for early mobilization
- Drugs to reduce gastric acid and increase gastric emptying (e.g., omeprazole 40 mg by mouth and metoclopramide 10 mg by mouth)
- Thromboembolic stockings (if not contraindicated)

- All invasive lines on 1 side (opposite side to robot assistant; usually the left) for less interference during procedure (normally a 16-gauge intravenous cannula and 20-gauge arterial cannula)
- Anesthetize patient on the surgical table, lying directly on gel pad, with gel head support
- General anesthesia, endotracheal tube (taped not tied to avoid cerebral venous congestion), positive pressure ventilation (optimal positive end-expiratory pressure)
- Orogastric tube (for gastric deflation) and oral temperature probe
- Saline-soaked ribbon gauze throat pack (to protect against gastric contents refluxing up lacrimal ducts and causing corneal burns)
- Eye protection with lubricating ointment, tape, and padding
- Padded right-angled bar placed just caudad to the patient's chin to protect head from surgical instruments
- Arms wrapped by patient's sides, which limits intraoperative access: plan lines appropriately and attach patient identification to forehead after routine safety checks
- Arterial transducer on board fixed at the level of the shoulder
- Forced-air warmer to upper chest and fluid warmer
- Bolsters under knees, gel pads under ankles, and calf pumps
- Steep head-down position (try for 27 degrees, depending on patient body habitus and ventilatory pressures); some centers use shoulder bolsters
- Preincision surgical antibiotic prophylaxis as per local protocol
- IV dexamethasone to decrease inflammation and swelling
- Buscopan reduces bladder spasm in recovery (can increase heart rate)

- Remifentanyl infusion with volatile maintenance in oxygen/air mix is used most commonly
- Avoid any patient movement during robotic instrumentation
- With careful attention to airway pressures, a second dose of muscle relaxant is rarely required
- Limit fluid therapy during procedure while lower renal tract is disrupted. For most surgery, this requires less than 800 mL. Then administer up to 1200 mL (approximately) of crystalloid once urethra is reconnected by the surgeon (communicate closely): total 2000 mL
- Blood loss is usually less than 300 mL

Surgical Conclusion

- As soon as robot is disengaged, flatten patient out and perform recruitment maneuvers to the lungs
- Consider spinal after discussion with surgeon before emergence (if bladder spasm is a problem, spinal is advised): no opiate, aim to cover 3 hours after surgery
- Sit patient up as soon as surgery is complete: slow wake up over 10 to 15 minutes while remifentanyl action wears off (this period reduces cerebral edema and risk of agitation and confusion postoperatively)
- Ensure normocapnia and cuff leak before extubation
- Postoperative pain is normally only mild to moderate
- Regular multimodal analgesia, antiemetic, and venous thromboembolic prophylaxis

Adapted from Cockcroft JO, et al. Anesthesia for major urologic surgery. *Anesthesiol Clin.* 2015;33(1):165–172.

Renal Transplantation

Renal transplant procedures have been a mainstream treatment for end-stage renal disease patients for years. Although brain dead donors still comprise the largest segment of the donor pool, living related donors are rapidly increasing due to improved surgical techniques, post transplantation management, and social media marketing efforts. Please see [Chapter 41](#) for complete information on renal organ transplantation.

Open Nephrectomy

Nephrectomy procedures are performed either laparoscopically or open and can be partial or total removal of the kidney, typically from tumors or polycystic disease. Laparoscopic and robotic techniques are rapidly replacing the open nephrectomy procedures due to more rapid recovery and decreased postoperative complications.¹³⁴ Open nephrectomies are typically performed in the jackknife lateral position with a raised kidney rest or other “bump” to displace the kidney to a more superficial location facilitating surgical access. Significant cardiopulmonary compromise may occur from the surgical position. The vena cava may be compressed by the kidney rest, decreasing venous return and blood pressure. Decreased respiratory compliance, increase in peak airway pressures, and atelectasis development in the dependent lung are common. The procedure is very stimulating and appropriate attenuation of the stress response should be the cornerstone of the anesthetic plan, such as a combined epidural/general anesthetic.¹⁵⁰ Third-spacing and the development of dependent edema may be significant due to surgical positioning and length of surgery. Vocal cord edema should be considered if the patient exhibits scleral edema, and it may be prudent to keep the patient intubated postoperatively. Other anesthetic concerns are related to major abdominal procedures. Postoperative pain management should be initiated perioperatively or early in the recovery phase.

Summary

Anesthetic management of the patient during the perioperative period for renal procedures depends upon an understanding of both normal renal function and pathophysiologic changes in the organ system. In addition to normal anatomy and physiology, this chapter highlighted ways to assess renal function and changes in renal function secondary to anesthetics. Various stages of renal pathology were identified and management of patients with acute and chronic renal failure emphasized. Rare and common urologic procedures were identified, and pertinent anesthetic considerations discussed for each procedure.

Hepatobiliary and Gastrointestinal Disturbances and Anesthesia

Shawn B. Collins, Cheryl A. Johnson

The hepatobiliary system plays an integral role in anesthetic management. An intimate familiarity with diseases of the hepatobiliary and gastrointestinal (GI) systems can help avoid negative anesthetic outcomes. The liver is the largest internal organ, and plays a critical role in maintaining the homeostasis of many other physiologic processes, including, notably, drug metabolism. As such, acute or chronic liver dysfunction can impair the intended response to anesthesia.¹

The purpose of this chapter is to give an overview of pathophysiologic processes specific to the hepatobiliary and GI system that are commonly encountered by the anesthetist. Fundamental relevant anesthetic considerations are described. More specifically, this chapter reviews the anatomy, physiology, and pathophysiology of the liver, including evaluation of liver function, anesthesia effects on liver function, and perioperative management of patients with liver disease. The chapter continues with diseases of the biliary tract, esophagus, stomach, peritoneum, intestinal tract, and spleen, and anesthetic management of patients with conditions affecting these systems. Special consideration is given to carcinoid tumors.

Liver Disease

Anatomic, Physiologic, and Pathophysiologic Considerations

Located in the thoracic portion of the abdominal cavity, the liver is the largest organ in the body. It generally extends from rib 7 to rib 11 along the right midaxillary line. The liver spans an area from the right hypochondrium to a portion of the left hypochondrium, and is classically divided into four lobes, which may be subdivided into multiple segments as described, for example, by the Couinaud system.² These subdivisions are based on the anatomic proximity of the hepatic and portal veins, though multiple classifications with different terminology are used, and no system is recognized as superior.

The functional unit of the liver is the hepatic lobule or acinus. The acinus forms around a portal canal consisting of a portal venule, a hepatic arteriole, a bile ductule, a lymphatic vessel, and nerves. The acinus architecture radiates around a central vein that empties into the hepatic veins and then into the vena cava (Fig. 33.1). There are between 50,000 and 100,000 hepatic lobules in a normal liver.

FIGURE 33.1 Anatomy of the portal circulation. Blood vessels that constitute the portal circulation and hepatic outflow tracts are depicted. (From Feldman M, et al., eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 10th ed. Philadelphia: Elsevier, 2016:1525.)

The filtering function of the liver has a prominent physiologic role. Blood from the gut contains large quantities of colonic bacilli, and more than 99% of the bacterial load is removed by Kupffer cells (macrophages) that line the hepatic sinuses.³ Endothelial cells that line the hepatic sinuses permit diffusion of large plasma proteins and other substances into the extravascular spaces in the liver. This phenomenon results in a large quantity of lymph that is nearly equal in protein concentration to plasma.

The metabolic functions of the liver require a significant quantity of blood, which comes from arterial and venous sources. The portal vein and the hepatic artery provide the primary blood supply to the liver, delivering approximately 1.5 L/min of blood flow. The hepatic artery branches off of the abdominal aorta and delivers 400 to 500 mL/min of oxygenated blood. According to the anatomic peculiarity of the double afferent blood supply of the liver, 75% to 80% of the blood entering the liver is partially deoxygenated venous blood supplied by the portal vein, which collects all the blood that leaves the spleen, stomach, small and large intestine,

gallbladder, and pancreas. The blood entering the liver via the hepatic portal vein contains some oxygen and is high in nutrients that have been absorbed from the digestive tract into the mesenteric and portal veins. Hepatic venous blood supply (shown in Fig. 33.2) is responsible for 70% of blood flow to the normal liver (approximately 1 L/min), but only 50% of the liver's oxygen supply. The dual supply of blood allows the liver to be relatively resistant to hypoxemia. The combined blood from both sources joins in the hepatic sinusoidal channels lying between the layers of cells in the lobule. These channels serve as capillaries. Endothelial cells and Kupffer cells line the sinusoids. Bile canaliculi are located between hepatocytes; these canaliculi empty into terminal bile ducts. A coalescence of central veins from hepatic lobules forms the hepatic veins, which empty into the inferior vena cava. An extensive arcade of lymphatic vessels is also present within the layer of cells.⁴

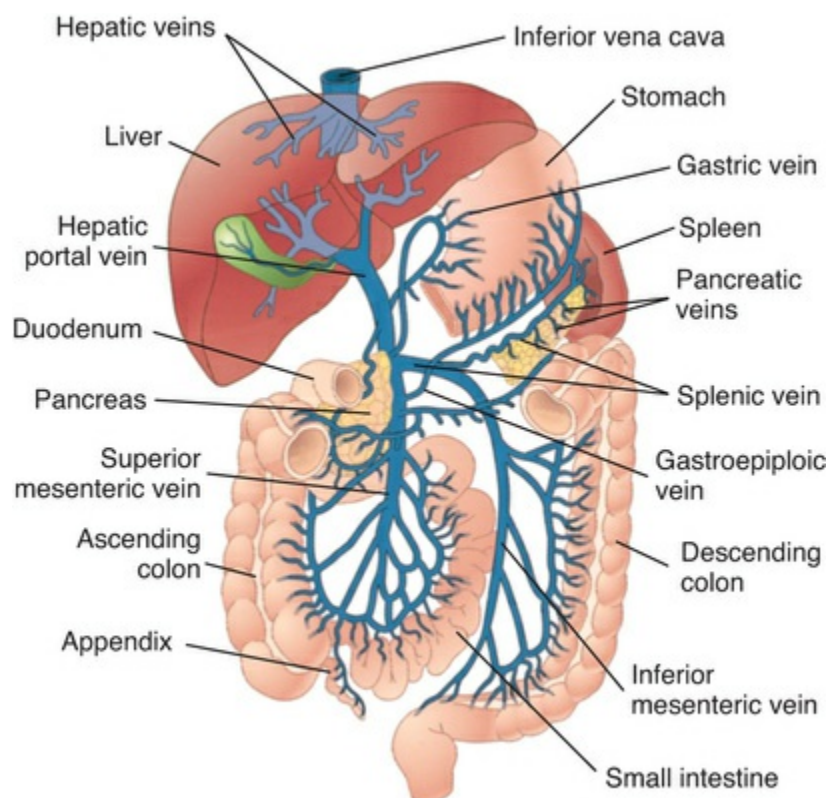

FIGURE 33.2 Hepatic portal circulation. In this unusual circulatory route, a vein is located between two capillary beds. The hepatic portal vein collects blood from capillaries in visceral structures located in the abdomen and empties into the liver for distribution to the hepatic capillaries.

Hepatic veins return blood to the inferior vena cava. *I*, inferior; *L*, left; *R*, right; *S*, superior. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 9th ed. St Louis: Elsevier; 2016:687.)

The mean pressure in the hepatic artery is similar to that in the aorta, whereas portal vein pressure has been reported to range from 6 to 10 mm Hg in humans. This relatively low pressure allows the liver to function as a circulatory reservoir. The hepatic blood volume may expand considerably in patients with cardiac failure. It serves as an important blood reservoir in case of bleeding episodes, and compensates for up to 25% of the volume lost from hemorrhage by the immediate expulsion of blood from the capacitance vessels.⁵ Both α - and β -receptors are present in the hepatic arterial circulation, but only α -receptors are found in the portal circulation. There is disagreement as to whether the hepatic arterial vasculature exhibits autoregulation of blood flow. Portal blood flow is dependent on the combined venous outflow from the spleen and GI tract. A decrease in either portal or arterial blood flow induces a compensatory increase in the blood flow delivered by the other system.⁶

Potent inhaled anesthetics can affect hepatic blood flow, and particularly the portal blood flow, but current evidence suggests that flow is well-maintained relative to oxygen demand. None of the present anesthetics adversely influence hepatic integrity by affecting hepatic blood flow.⁷ The effects of volatile anesthetics on hepatic blood flow are shown in [Table 33.1](#).

TABLE 33.1

Effect of Selected Volatile Anesthetics on Hepatic Blood Flow

Volatile Anesthetic	Hepatic Artery Blood Flow	Portal Vein Blood Flow
Desflurane	Moderate dose-dependent decrease	Moderate dose-dependent decrease
Isoflurane	Minimal dose-dependent decrease	Minimal dose-dependent decrease
Sevoflurane	Minimal dose-dependent decrease	Minimal dose-dependent decrease

Changes in hepatic artery or portal vein blood flow may not result in an overall change in total hepatic flow, due to the hepatic artery buffer response (HABR). This response is a semireciprocal autoregulatory mechanism whereby changes in portal flow inversely affect hepatic arterial flow.⁵ Similar rates of total hepatic

flow between administration of two different anesthetic agents implies that the HABR is intact.

The liver has many physiologic functions, including synthesis and metabolism of various essential proteins, lipids, and hormones (Box 33.1). There are no artificial devices that can duplicate all of the **Box 33.1** functions of the liver.

Selected Essential Physiologic Functions of the Liver

- Carbohydrate metabolism
- Gluconeogenesis
- Glycogenolysis
- Glycogenesis
- Protein synthesis
- Albumin (maintenance of osmolarity)
- Thrombopoietin (platelet production)
- Amino acid synthesis
- Protein metabolism
- Bile production
- Lipid metabolism
- Lipogenesis
- Cholesterol synthesis
- Coagulation factor synthesis
- Production of factors I, II, V, VII, IX, X, and XI
- Insulin clearance

- Drug metabolism/transformation
- Bilirubin metabolism

Carbohydrate Metabolism

Because nutritional ingestion and energy demand may not be synchronous, the body relies upon a dynamic system of energy storage and utilization. Glucose is the primary fuel source for many cells of the body (e.g., kidney, red blood cells) and the preferred energy source for other tissues (e.g., brain). To maintain a steady blood glucose level, the liver moderates gluconeogenesis and glycogenolysis.

Gluconeogenesis is the formation of glucose from the noncarbohydrate molecules lactate and pyruvate, as well as amino acids, all of which are products of anaerobic and catabolic metabolism. It is stimulated by a decrease in glycogen stores. During periods of fasting, the liver maintains blood glucose at relatively normal levels through glycogenolysis. Initiated by epinephrine and glucagon, glycogenolysis is the process of liberating glucose from glycogen stores found in the liver (and skeletal muscle). Hypoglycemia may therefore be encountered in patients with severe liver disease due to dysfunctions in insulin clearance, a decrease in glycogen capacities, and impaired gluconeogenesis. Because these processes deplete stored nutrients, the body's energy needs can only be maintained for a limited time.

Protein Synthesis

Protein synthesis occurs primarily in the liver; this excludes immunoglobulins, which are produced by the humoral immune system. With significant liver disease, a reduction in circulating plasma protein will result in a decrease in plasma oncotic pressure. Additionally, drugs bound to proteins produced by the liver will have a greater unbound fraction if circulating proteins are reduced due to liver disease. In addition, overexpansion of the interstitial space and third-spacing secondary to derangements in plasma oncotic pressure result in a large increase in the volume of distribution of clinically used medications. Clinical concerns should

therefore focus on the potential for an exaggerated effect with a given dose of drug, particularly a drug that is highly protein bound. The amount of nondepolarizing muscle relaxant may also need to be increased to achieve a given level of blockade. This is secondary to an increased volume of distribution of the drug (secondary to alterations in plasma protein binding and body fluid shifts). Plasma cholinesterase, which is produced in the liver, may also be deficient. This condition may prolong the effects of succinylcholine and enhance the potential toxicity of ester local anesthetics.

Protein Metabolism

Other roles in protein metabolism performed by the liver include the synthesis of lipoproteins (important for lipid transport in the blood), the deamination of amino acids into carbohydrates and fats for production of adenosine triphosphate through citric acid cycle oxidation, and the production of urea for the removal of ammonia, which is formed by hepatic deamination processes and bacteria in the gut.

Bilirubin Metabolism

Bilirubin is a breakdown product of heme metabolism, and is often classified as unconjugated or conjugated. Heme is converted to unconjugated bilirubin in the reticuloendothelial cells of the spleen. This unconjugated bilirubin is not soluble in water and is neurotoxic at sufficiently high levels. It is then bound to albumin and transported to the liver. Once in the liver, the unconjugated bilirubin is conjugated with glucuronic acid. Bilirubin is then incorporated into the bile and secreted into the intestine, where it is metabolized by bacterial enzymes and predominantly excreted in the feces.

Bile Production

The liver aids intestinal digestion by forming bile and secreting it into the common bile duct (CBD). Hepatocytes in each lobule continuously secrete fluid that contains phospholipids, cholesterol, conjugated bilirubin (the end product of hemoglobin metabolism),

bile salts, and other substances. Bile is stored and concentrated in the gallbladder. In response to the intestinal hormone cholecystokinin (CCK), bile is released by the gallbladder. The presence of fat and protein in the duodenum initiates contraction of the gallbladder and movement of bile via the CBD. This duct merges with the pancreatic duct at the ampulla of Vater, which empties into the duodenum via the sphincter of Oddi (major duodenal ampulla). Obstruction of either of these ducts may result in pathologic illness that may necessitate surgical correction.

Ductal patency may be confirmed by radiologic evaluation. Endoscopic retrograde cholangiopancreatography (ERCP) is performed by passing an endoscope into the lower GI tract and locating the major duodenal ampulla. The ampulla is cannulated and examined using radiographic dye to determine whether the blockage is due to a CBD stone. If a stone is present, it can typically be retrieved endoscopically. Sphincterotomy also may be performed to facilitate removal of CBD stones. Correction of ductal stenosis also may require sphincterotomy or insertion of a stent.

Bile secretion assists in the absorption of fat and fat-soluble vitamins (vitamins A, D, E, and K). The metabolic end products of many drugs are also removed via the bile. Liver disease may result in impaired bile production or flow, leading to steatorrhea, vitamin K deficiency, and delayed removal of active drug metabolites.

A deficiency in vitamin K results in coagulopathy due to impaired production of clotting factors II (prothrombin), VII, IX, and X.⁸ Except for factor VIII, which is produced in endothelial cells, the liver is responsible for producing all clotting factors. Hepatocellular disease therefore results in decreased clotting factor levels and abnormal bile production. Impaired bile production ultimately manifests as altered production of vitamin K–dependent clotting factors.

Intrahepatic obstruction of blood flow (due to disease pathology) ultimately causes portal hypertension. A consequence of the resultant transmission of backward pressure is congestive splenomegaly, leading to platelet sequestration and thrombocytopenia. Therefore, severe liver disease with portal hypertension induces coagulopathy not only as a result of impairment in hepatic coagulation factor production, but also as a

result of a decrease in the number of circulating functional platelets. In the presence of biliary deficiency, parenteral vitamin K administration helps correct coagulopathy. However, significant hepatocellular disease may dictate the need for fresh frozen plasma (FFP) for immediate correction of coagulation factor deficits.

The use of subarachnoid and epidural blockade should be avoided in the presence of coagulopathy. Abnormalities in parameters such as prothrombin time (PT), activated partial thromboplastin time (aPTT), and platelet count are a relative contraindication to these techniques; procedures in which bleeding is a possibility are often postponed when the international normalized ratio (INR [PT]) is greater than 1.5. Nasopharyngeal instrumentation and invasive procedures must be performed cautiously and carefully in the presence of increases in PT and aPTT, a low platelet count, or other laboratory signs that arouse suspicion of coagulopathy.

Insulin Clearance

The liver is the main site for insulin clearance, removing 50% during the first portal passage, but this percentage varies widely under different conditions.⁹ In patients with obesity, hyperinsulinemia, an insulin-resistant state, dyslipidemia, or type II diabetes mellitus, insulin clearance by the liver decreases. In insulin-resistant states, a reduction in hepatic insulin extraction leads to substantial peripheral hyperinsulinemia (due to insulin hypersecretion and reduced hepatic extraction of insulin).¹⁰

Drug Metabolism/Transformation

The enzyme systems involved in the biotransformation of drugs are primarily located in the liver. Proper hepatic function is necessary to maintain the pharmacokinetic machinery detailed in [Chapter 6](#). Orally administered drugs may be metabolically inactivated in the liver before reaching the systemic circulation. This first-pass metabolism may limit the oral availability of highly metabolized drugs. Within the liver, phase I and phase II reactions are responsible for the metabolism of many exogenous substances and most drugs. The subsequent products are then excreted via

excretory transporters on either the canalicular or sinusoidal membranes (Box 33.2).¹¹ The end products of these processes (except in the case of a prodrug or an active metabolite) are the result of deactivation and transformation of substances into benign **Box 33.2** products that are capable of being excreted in the bile or urine.

Drug Metabolism in the Liver

Phase I Reactions

- Functionalization reactions
- Addition or exposure of a functional group (e.g., oxidation, reduction, hydrolysis)
- Typically result in the loss of pharmacologic activity (excluding prodrugs)
- Important for metabolizing many of the anesthetic drugs (e.g., midazolam, diazepam, codeine, phenobarbital, inhalation anesthetics, propofol)

Phase II Reactions

- Conjugation reactions
- Phase I product (substrate) conjugation with a second molecule
- Lead to the formation of a covalent linkage between a functional group and glucuronic acid, sulfate, glutathione, amino acid, or acetate (e.g., morphine, acetaminophen)

The cytochrome P450 (CYP) class of enzymes are primarily responsible for phase I reactions. More than 50 CYPs have been identified in humans, yet nearly 50% of currently manufactured drugs are metabolized by a single CYP.¹² Differences in the rate of metabolism of a drug can be due to drug interactions. When two drugs that are metabolized by the same enzyme system are coadministered, the rate of metabolism can be either decreased or increased. Enzyme induction hastens metabolism of certain

coadministered medications (e.g., ethanol, barbiturates, ketamine, some benzodiazepines) and promotes tolerance to other medications metabolized by the same enzyme class. This relative tolerance can increase the clinical requirement for other drugs (e.g., sedatives, opioids, steroid muscle relaxants). Conversely, coadministration of drugs metabolized by the same CYP (e.g., cimetidine, chloramphenicol) will compete for binding to the enzyme's active site. This can result in enzyme inhibition of metabolism of one or both of the drugs and lead to elevated plasma levels, culminating in increased sensitivity or toxicity.

Tolerance to certain drugs results from overproduction of enzymes within hepatic enzyme systems, including the CYP system. Drugs capable of inducing this process include ethanol, benzodiazepines, ketamine, barbiturates, and phenytoin. The result is an increased clinical requirement for certain drugs such as sedatives, opioids, and muscle relaxants (e.g., vecuronium and rocuronium).

Certain drugs, such as lidocaine, morphine, meperidine, and propranolol, are highly dependent on hepatic extraction from the circulation for sufficient metabolism. Decreased blood flow to the splanchnic circulation, which occurs during hypotensive states and can even occur during an uneventful laparotomy, may decrease the metabolic clearance of these drugs. Anesthetic drug metabolism is discussed further in [Chapter 6](#).

Laboratory Evaluation of Liver Function

No single laboratory test reliably assesses liver function. As stated previously, the huge capacity and functional reserve of the liver allow for significant disease processes to develop before evidence of liver failure is reflected in abnormal laboratory findings; abnormalities do, however, aid in differentiating parenchymal from obstructive disorders. Parenchymal disorders reflect dysfunction at the hepatocellular level, whereas obstructive disorders reflect disease processes caused by dysfunctional bile excretion.

Ammonia is cleared by the liver and may be used to evaluate hepatic encephalopathy, but ammonia levels do not correlate well with the severity of the clinical presentation. As such, its usefulness is limited. Bilirubin levels also reflect hepatic clearance

effectiveness, but it is elevated in most significant liver diseases and does not have specific diagnostic value. Albumin synthesis occurs in the liver, and hypoalbuminemia can indicate chronic liver disease once nonhepatic etiologies have been ruled out. Because albumin has a half-life of 14 to 21 days, quantitative values derived from laboratory analysis will be slow to decrease in relation to worsening liver function, making it an unreliable indicator of hepatic synthetic function in acute liver injury. The most common reason for a low albumin is chronic liver failure caused by cirrhosis. The serum albumin concentration is usually normal in chronic liver disease until cirrhosis and significant liver damage has occurred. In advanced liver disease, the serum albumin level may be less than 3.5 g/dL. Biochemical markers of liver function are identified in [Table 33.2](#).

TABLE 33.2
Clinical Significance of Liver Biochemical Tests

Test (Normal Range*)	Basis of Abnormality	Associated Liver Diseases	Extrahepatic Origin
Aminotransferases			
ALT (10–55 units/L) AST (10–40 units/L)	Leakage from damaged tissue	<i>Mild to moderate elevations:</i> Many types of liver disease <i>Marked elevations:</i> Hepatitis (viral, toxic, autoimmune, and ischemic) AST/ALT > 2 suggests alcoholic liver disease or cirrhosis of any etiology	ALT is more specific than AST for hepatic injuries AST nonspecific: can originate from skeletal muscle, red blood cell, kidney, pancreas, brain, and myocardium
AP (45–115 units/L)	Overproduction and leakage into serum	<i>Moderate elevations:</i> Many types of liver disease <i>Marked elevations:</i> Extrahepatic and intrahepatic cholestasis, diffuse infiltrating disease (e.g. tumor, MAC), rarely alcoholic hepatitis	Bone growth or disease (e.g., tumor, fracture, Paget disease), placenta, intestine, and tumors
GGTP (0–30 units/L)	Overproduction and leakage into serum	Same as for AP; induced by ethanol and drugs GGTP/AP > 2.5 suggests alcoholic liver disease	Kidney, spleen, pancreas, heart, lung, and brain
5' nucleotidase (0–11 units/L)	Overproduction and leakage into serum	Same as for AP	Found in many tissues, but serum elevation is relatively specific for liver disease
Bilirubin (0–1 mg/dL)	Decreased hepatic clearance	<i>Moderate elevations:</i> Many types of liver disease <i>Marked elevations:</i> Extrahepatic and intrahepatic bile duct	Increased breakdown of hemoglobin (resulting from hemolysis, disordered erythropoiesis, resorption of hematoma) or myoglobin

		obstruction; viral, alcoholic, or drug-induced hepatitis; inherited hyperbilirubinemia	(resulting from muscle injury)
Prothrombin time (PT) (10.9–12.5 seconds) (international normalized ratio [INR]: 0.9–1.2)	Decreased synthetic capacity	Acute or chronic liver failure (prolonged PT unresponsive to vitamin K) Biliary obstruction (prolonged PT usually responsive to vitamin K administration)	Vitamin K deficiency (secondary to malabsorption, malnutrition, antibiotics, consumptive coagulopathy)
Albumin (3.5–5.0 g/dL)	Decreased synthesis; increased catabolism	Chronic liver failure	Nephritic syndrome, protein-losing enteropathy, vascular leak, malnutrition, malignancy, infections, and inflammatory states

*The normal values shown in this table are for adult men and will vary with the methodology used in testing.

ALT, Alanine aminotransferase; *AP*, alkaline phosphatase; *AST*, aspartate aminotransferase; *GGTP*, gamma glutamyl transpeptidase; *INR*, international normalized ratio; *MAC*, mycobacterium avium complex; *PT*, prothrombin time.

Serum transferases (transaminases) are the most sensitive marker for identifying acute hepatic injury. Elevations in transferase levels are common to all forms of liver injury, but the degree of elevation combined with physical examination and patient symptoms can aid in the differential diagnosis of probable types of hepatic disease.

Patients who present soon after passing CBD stones can be misdiagnosed with acute hepatitis, as aminotransferase levels often increase immediately, whereas alkaline phosphatase and γ -glutamyl transferase levels do not become elevated for several days. Asymptomatic patients with isolated, mild elevation of either unconjugated bilirubin or γ -glutamyl transferase levels usually do not have liver disease, and generally do not require extensive evaluation.¹³

Overall hepatic function can be assessed by applying the values for albumin, bilirubin, and PT in the Child-Pugh classification system, which is a modified version of the earlier Child-Turcotte grading system (Table 33.3).¹⁴

TABLE 33.3

Grading Liver Function Using the Child-Pugh Classification System

--

Feature	Points		
	1	2	3
Albumin	> 3.5 g/dL	2.8–3.5 g/dL	< 2.8 g/dL
Bilirubin	< 2 mg/dL	2–3 mg/dL	> 3 mg/dL
Prolongation of Prothrombin time (INR)	< 4 sec (< 1.7)	4–6 sec (1.7–2.3)	> 6 sec (> 2.3)
Ascites Encephalopathy	None	Controlled Minimal (1 and 2)	Refractory Advanced (3 and 4)

The Child-Pugh class is calculated by adding the points based on the five features: class A = 5 or 6; class B = 7–9; class C = 10 and higher. The classes indicate the severity of liver dysfunction: class A is associated with a good prognosis, and class C is associated with limited life expectancy.

INR, International normalized ratio.

Effects of Anesthesia on Liver Function

Patients with liver disease who require surgery are at greater risk for surgical- and anesthesia-related complications than those with a healthy liver.¹⁵ The degree of risk is dependent on the anesthetic technique and associated sequelae, the surgery being performed, and the specific type of liver disease and its severity.

Volatile Anesthetic Selection

Given the global nature of general and regional anesthesia, administration of an anesthetic agent may reduce hepatic blood flow in a dose-dependent manner. The reduction in mean arterial pressure and cardiac output (CO) frequently seen with the use of volatile anesthetics results in a proportional reduction in hepatic blood flow. Another factor that impairs hepatic blood flow is the vasoconstrictive response of the splanchnic circulation; this response occurs as a sympathetic reflex to reduced mean arterial pressure. Isoflurane increases hepatic blood flow through direct vasodilatory properties. This effect is likely offset, however, by a reduction in portal blood flow. Hypotension secondary to regional anesthetic-induced sympathectomy (e.g., epidural or subarachnoid blockade) is primarily responsible for the reduced splanchnic blood flow associated with the use of these techniques.

All of the volatile anesthetics have also been shown to reduce hepatic blood flow. Halothane causes the greatest reduction, and desflurane has slightly greater hepatic effects than sevoflurane and

isoflurane. A rise in serum glutathione-S-transferase levels indicates a decrease in splanchnic circulation, which causes a transient reduction in hepatocyte oxygenation. One study has shown that liver function is well-preserved after administration of desflurane.¹⁶ Sevoflurane undergoes hepatic biotransformation, producing organic and inorganic fluoride ions. In humans, the serum levels of inorganic fluoride ion secondary to sevoflurane metabolism are generally below nephrotoxic levels. Anesthetic agents may reduce hepatic blood flow by 30% to 50% after induction. Animal data suggest, however, that isoflurane and sevoflurane cause less perturbation in hepatic arterial blood flow than other inhaled anesthetic agents; the use of these agents is therefore preferred for patients with liver disease. Studies are underway to determine the influence of sevoflurane biotransformation on renal and hepatic function, but no significant clinical toxicity has yet been reported, so it appears to be safe for clinical use.^{17,18}

In developed countries, the clinical use of halothane has been superseded by the newer low-solubility agents desflurane and sevoflurane. Halothane, however, is still in use in some countries, and remains on the 2015 World Health Organization Model List of Essential Medicines, which is a list of minimum medical needs for a basic health care system. Continued awareness of the potentially deleterious effect of halothane on hepatic function is therefore justified.

Halothane administration is associated with two types of postoperative liver injury. Minor injury in 10% to 30% of patients may result in elevations in alanine aminotransferase (ALT) levels during postoperative days 1 through 10. The risk of hepatotoxicity is higher after repeat exposure to halothane. Major injury involves halothane-induced hepatotoxicity, which is a severe hepatic reaction with elements of autoimmune allergy. Halothane-induced liver damage is also referred to as *halothane hepatitis*, due to a similar clinical presentation. Clinical features of halothane hepatitis are listed in [Box 33.3](#). Hepatic necrosis may be seen histologically, and the case fatality rate ranged from 14% to 71% (before liver transplant was an option). Evidence for the role of hypersensitivity is found in the increased susceptibility and shortened latency after repeat exposure, which are hallmark symptoms and signs of drug

allergy. An estimated 1 in 10,000 patients develops postoperative jaundice after halothane exposure. In this population, a viral source of infection is more likely to be the cause, for instance, as a complication of intraoperative blood transfusion.

Clinicopathologic Features of Halothane Hepatitis

- Estimated incidence
- *After first exposure: 0.3 to 1.5 per 10,000*
- *After multiple exposures: 10 to 15 per 10,000*
- Female-to-male ratio 2 : 1
- Latent period to first symptom
- *After first exposure: 6 days (11 days to jaundice)*
- *After multiple exposures: 3 days (6 days to jaundice)*
- Risk Factors
- Older age
- Female gender
- Two or more exposures documented in 60% to 90% of cases
- Obesity
- Familial predisposition

- Induction of CYPE1 by phenobarbital, alcohol or isoniazid
- Clinical Features
- Jaundice as presenting symptom in 25% (serum bilirubin: 3–50 mg/L)
- Fever in 75% (precedes jaundice in 75%); chills in 30%
- Rash in 10%
- Myalgia in 20%
- Ascites, renal failure, and/or gastrointestinal hemorrhage in 20% to 30%
- Eosinophilia in 20% to 60%
- Serum ALT and AST levels: 25–250 × ULN
- Serum alkaline phosphatase level: 1–3 × ULN
- Histopathologic Features
- Zone 3 massive hepatic necrosis in 30%; submassive necrosis in 70% (autopsy series)
- Inflammation usually less marked than in viral hepatitis

- Eosinophilic infiltrate in 20%
- Granulomatous hepatitis occasionally
- Course and Outcome
- Mortality rate (pretransplantation era): 10% to 80%
- Symptoms can resolve within 5–14 days
- Full recovery can take 12 weeks or longer
- Chronic hepatitis not well documented
- Adverse Prognostic Findings
- Age > 40 years
- Obesity
- Short duration to the onset of jaundice
- Serum bilirubin level > 20 mg/dL
- Coagulopathy

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *CYP2E1*, cytochrome P450 2E1; *ULN*, upper limit of normal.

From Lewis JH. Liver disease caused by anesthetics, chemicals, toxins, and herbal preparations. In: Feldman M, et al., eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 10th ed. Philadelphia: Elsevier Saunders; 2016:1449.

Opioid Effects

Spasm of the Oddi sphincter may cause biliary colic, or it may cause a false-positive result on intraoperative cholangiography. All opioids have been implicated in causing spasm of the Oddi sphincter, and the more potent the opioid, the greater the resultant increase in biliary pressure. The cause of the spasm is unclear, but its occurrence may be reduced with judicious titration of the anesthetic. There is a low incidence of spasm even when a fentanyl-based anesthetic is used. The treatment of suspected spasm of the Oddi sphincter involves administration of naloxone or nalbuphine. Atropine, glycopyrrolate, glucagon, and nitroglycerin also have been shown to be effective.

Anesthesia-Related Activity: Mechanical Ventilation

The sequelae of mechanical ventilation have been implicated as a contributing factor in reduced hepatic blood flow. Positive pressure ventilation can result in airway pressures that adversely affect venous delivery to the right atrium. Increased airway pressures also result in reduced CO,¹⁹ with a consequent reduction in hepatic blood flow. Positive end-expiratory pressure further exacerbates this condition. Impairment of hepatic blood flow under these conditions may result from increased hepatic venous pressure due to increased intrathoracic pressure and from increased reflex sympathetic tone due to reduced CO. Hypercapnia and acidosis have vasodilatory effects on the hepatic circulation that result in increased blood flow, whereas hypocapnia and alkalosis exert vasoconstricting effects that result in decreased flow. The interplay of various intraoperative variables (e.g., surgical site, ventilatory mode, direct and indirect effects of the anesthetics used, physiologic responses to intraoperative events) influences the degree of variation in hepatic blood flow.

Site of Surgery

The surgical site (particularly an intraabdominal surgical site) has also been implicated as a cause of decreased hepatic blood flow

(Table 33.4) in surgical patients with liver disease. Traction on the abdominal viscera may cause reflex dilation of splanchnic capacitance vessels, and thereby lower hepatic blood flow.

TABLE 33.4
Reported Surgery Risk in Patients With Liver Disease

Liver Disease	Type of Surgery	Mortality	Prognostic Factors
Cirrhosis	Nonlaparoscopic biliary surgery	20%	Ascites, prothrombin time, albumin
	Peptic ulcer surgery	54%	Prothrombin time, systolic blood pressure, hemoglobin
	Umbilical herniorrhaphy	13%	Urgent surgery
	Colectomy	24%	Hepatic encephalopathy, ascites, albumin, hemoglobin
	Abdominal surgery for trauma	47%	
	Emergency abdominal surgery	57%	Child-Pugh class, urgent surgery
	Laparoscopic cholecystectomy	0.9% to 6%	
	Emergency cardiac surgery	80%	Child-Pugh class
	Elective cardiac surgery	3% to 46%	Child-Pugh class
	Knee replacement	0%	
	TURP	6.7%	
Chronic hepatitis	Various types	0%	
Hepatitis C	Laparoscopic cholecystectomy	0%	
Acute hepatitis	Exploratory laparotomy	Up to 100%	
Obstructive jaundice	Abdominal surgery	5% to 60%	Hemoglobin, bilirubin, malignancy

TURP, Transurethral resection of the prostate.

Additional factors that may contribute to decreased hepatic blood flow intraoperatively include hypotension, hemorrhage, administration of vasoactive drugs, and pneumoperitoneum during laparoscopic surgery.^{5,20}

Diseases of the Liver

Signs and symptoms indicating liver disease vary widely depending on the etiology of the underlying pathologic process. The decline in liver function may be acute, related to drug toxicity or infection, or it may follow a chronic subclinical course. The following discussion focuses on the more commonly encountered

diseases of the liver and offers guided clinical anesthetic implications.

Acute Hepatitis

Acute hepatitis presents a variable clinical picture. Manifestations may extend from mild inflammatory increases in serum transaminase levels to fulminant hepatic failure. The cause of this syndrome is usually exposure to an infectious virus. Other causes include exposure to hepatotoxic substances and adverse drug reactions.

Viral Hepatitis

Hepatitis is a generic term that means liver inflammation. Hepatitis may be caused by several factors (e.g., toxins, alcohol, medications, viral or bacterial infections, autoimmune diseases). Viral hepatitis is the leading cause of liver cancer and the most common reason for transplantation.²¹

Although several types of hepatitis viruses are known to cause illness, typically only hepatitis A, B, and C (infections caused by the hepatitis A virus, hepatitis B virus [HBV], and hepatitis C virus, respectively) affect persons living in the United States.²¹ Hepatitis D requires co-infection with HBV; hepatitis E virus diagnosis is made by exclusion after travel to an endemic area (e.g., South/Central America or Southeast Asia). Hepatitis A and E are transmitted by the oral-fecal route, and hepatitis B, C, and D are transmitted by contact with body fluids and physical contact with disrupted cutaneous barriers.

The common clinical course of viral hepatitis begins with a 1- to 2-week prodromal period, the signs and symptoms of which include fever, malaise, nausea, and vomiting. Progression to jaundice typically occurs, with resolution within 2 to 12 weeks. However, serum transaminase levels often remain elevated for up to 4 months. If hepatitis B or C is the cause, the clinical course is often more prolonged and complicated. Cholestasis may manifest in certain cases. Fulminant hepatic necrosis in certain individuals is also possible. [Table 33.5](#) lists the major characteristics of hepatitis types A, B, C, D, and E.

TABLE 33.5**Five Types of Acute Viral Hepatitis**

Hepatitis Virus	Size (nm)	Genome	Route of Transmission	Incubation Period (Days)	Fatality Rate	Chronic Rate	Antibody
A	27	RNA	Fecal-oral	15–45 (mean = 25)	1%	None	Anti-HAV
B	45	DNA	Parenteral Sexual	30–180 (mean = 75)	1%	2% to 7%	Anti-S Anti-HBc Anti-HBe
C	60	RNA	Parenteral	15–150 (mean = 50)	< 0.1%	70% to 85%	Anti-HCV
D (delta)	40	RNA	Parenteral Sexual	30–150	2% to 10%	2% to 7% 50%	Anti-HDV
E	32	RNA	Fecal-oral	30–60	1%	None	Anti-HEV

HAV, Hepatitis A virus; *HBc*, hepatitis B core; *HBe*, hepatitis B e-antigen; *HBs*, hepatitis B surface; *HCV*, hepatitis C virus; *HDV*, hepatitis D virus; *HEV*, hepatitis E virus.

From Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*. 24th ed. Philadelphia: Elsevier; 2012.

Drug-Induced Hepatitis

Drug-related injury to the liver results from an idiosyncratic reaction to a substance or an overdose resulting in toxicity. Genetic predisposition is presumed to be the most critical determinant. Important risk factors include age, gender, exposure to other substances, a history or family history of previous drug reactions, other risk factors for liver disease, and concomitant medical conditions.²²

Alcoholic hepatitis is probably the most common form of drug-induced hepatitis, and results in fatty infiltration of the liver (causing hepatomegaly), with impairment of hepatic oxidation of fatty acids, lipoprotein synthesis and secretion, and fatty acid esterification.⁶

Chronic Hepatitis

Chronic hepatitis occurs in 1% to 10% of acute hepatitis B infections and in 10% to 40% of hepatitis C infections,⁶ but does not occur in

hepatitis A infections.

Because chronic persistent hepatitis is limited to portal areas and is relatively benign, hepatic cellular integrity is preserved, and progression to cirrhosis is rare. Chronic lobular hepatitis involves recurrent exacerbations of acute inflammation; as in persistent hepatitis, progression to cirrhosis is rare.

Chronic active hepatitis is progressive and results in hepatocyte destruction, cirrhosis, and progressive deterioration of hepatic function. Hepatic failure and fatal chronic hepatitis are marked by clinical manifestations such as multiorgan system failure (e.g., hepatorenal syndrome [HRS]), encephalopathy, and hemorrhage from esophageal varices. Exposure to certain drugs (e.g., methyldopa, isoniazid, and nitrofurantoin) and the presence of autoimmune disorders (e.g., systemic lupus erythematosus) are potential causative factors implicated in hepatic failure, though hepatitis B or C are more typical.

Other symptoms present in chronic hepatitis include marked fatigue and jaundice; thrombocytopenia, glomerulonephritis, myocarditis, arthritis, and neuropathy may also be present. Plasma albumin levels are usually low as a result of synthetic dysfunction, and the PT is prolonged.

Anesthetic Management for Patients With Hepatitis

Research indicates that mild chronic hepatitis confers no additional risk of surgical morbidity or mortality during laparoscopic cholecystectomy.²³ Surgical outcomes in patients with acute hepatitis are less well studied, and recommendations suggest that elective surgery should be postponed until normalization of biochemical profiles. Existing studies are many decades old, and the statistical risks associated may not reflect improvements in surgical techniques and anesthetic management. Anesthetic management recommendations for patients with hepatitis are

Box 33.4 [Box 33.4.](#)

Anesthetic Management of the Patient With Acute Hepatitis

Preserve hepatic blood flow:

- Use isoflurane or desflurane and avoid halothane
- Maintain normocapnia
- Avoid PEEP if possible
- Provide adequate/liberal intravenous hydration
- Consider regional anesthesia if coagulation is acceptable and the procedure allows

Avoid medications with potential for hepatotoxicity or inhibition of CYP450:

- Halothane
- Acetaminophen
- Sulfonamides
- Tetracycline
- Penicillin
- Amiodarone

Thoughtful titration of neuromuscular blocking agents may be prolonged in patients with liver disease because of:

- Reduced pseudocholinesterase activity
- Decreased biliary excretion
- Larger volume of distribution

CYP450, Cytochrome P450; *PEEP*, positive end-expiratory pressure.

Operative procedures performed in patients with alcohol

intoxication are likely to be associated with increased perioperative complications, and anesthetic management must be well planned (Box 33.5). Surgery performed in those undergoing alcohol withdrawal is associated with an increased mortality rate. If surgery is of urgent or emergent nature, attention must be paid to managing comorbidities, with a focus on risk reduction and **Box 33.5** symptom management.

Management Recommendations for the Acutely Intoxicated Patient

- Anesthetic requirement is reduced
- Acute intoxication reduces MAC
- Aspiration precautions are needed
- Full stomach, alcohol-related impaired pharyngeal reflexes
- Alcohol increases GABA receptor activity
- Enhanced effects of benzodiazepines, barbiturates, propofol, other CNS depressants
- Alcohol inhibits NMDA receptors
- Reduces CNS excitability

CNS, Central nervous system; *GABA*, gamma-aminobutyric acid; *MAC*, maximum allowable concentration; *NMDA*, N-methyl-D-aspartate.

Cirrhosis

The term *cirrhosis* derives from the Greek word meaning yellowish or tawny, and describes the coloration of the diseased liver. Cirrhosis is defined as the histologic development of regenerative nodules surrounded by fibrous bands in response to chronic liver injury, which leads to portal hypertension and end-stage liver disease.²⁴ Cirrhosis may be caused by a variety of diseases (Box

33.6), but the resultant anatomic alterations secondary to hepatocyte necrosis are the primary cause of the deterioration in liver function. Over time, the liver parenchyma is replaced by fibrous and nodular tissue, which distorts, compresses, and obstructs normal portal venous blood flow. Portal hypertension develops and impairs the ability of the liver to perform various metabolic and synthetic

Box 33.6

Causes of Cirrhosis

Viral

- HBV
- HCV
- HDV

Autoimmune

- Autoimmune hepatitis
- PBC
- PSC

Toxic

- Alcohol
- Arsenic

Metabolic

- α_1 -Antitrypsin deficiency
- Galactosemia
- Glycogen storage disease

- Hemochromatosis
- Nonalcoholic fatty liver disease and steatohepatitis
- Wilson disease

Biliary

- Atresia
- Stone
- Tumor

Vascular

- Budd-Chiari syndrome
- Cardiac fibrosis

Genetic

- CF
- Lysosomal acid lipase deficiency

Iatrogenic

- Biliary injury
- Drugs: high-dose vitamin A, methotrexate

CF, Cystic fibrosis; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D (delta) virus; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.

From Kamath PS, Shah VH. Overview of cirrhosis. In Feldman M, et al., eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 10th ed. Philadelphia: Elsevier; 2016:1255.

Characteristics of cirrhosis are presented in [Table 33.6](#).

Obstructive engorgement of vessels within the portal system ultimately results in the transmission of increasing retrograde pressure to the splanchnic circulation. The progressive reversal of portal venous blood flow results in the formation of esophageal varices and splenomegaly. As portal hypertension persists, physical changes can be seen systemically (Fig. 33.3).

TABLE 33.6

Laboratory Tests and Findings in Cirrhosis

Laboratory Finding	Description	Cause
AST/ALT	Normal or modest increase	Leakage from damaged hepatocytes
Bilirubin	Increased (important predictor of mortality)	Cholestasis, systemic inflammation
Albumin	Decreased in advanced cirrhosis	Decreased production; sequestered in ascites
Prothrombin time	Decreased in advanced cirrhosis	Decreased hepatic production of factor V/VII
Sodium imbalance	Hyponatremia	Inability to excrete free water (increased ADH)
Anemia	Low hemoglobin Low red blood cell count	Folate deficiency, hypersplenism, varices
Thrombocytes	Thrombocytopenia	Hypersplenism, decreased hepatic thrombopoietin production

AST/ALT, Aspartate aminotransferase/alanine aminotransferase ratio; *ADH*, antidiuretic hormone.

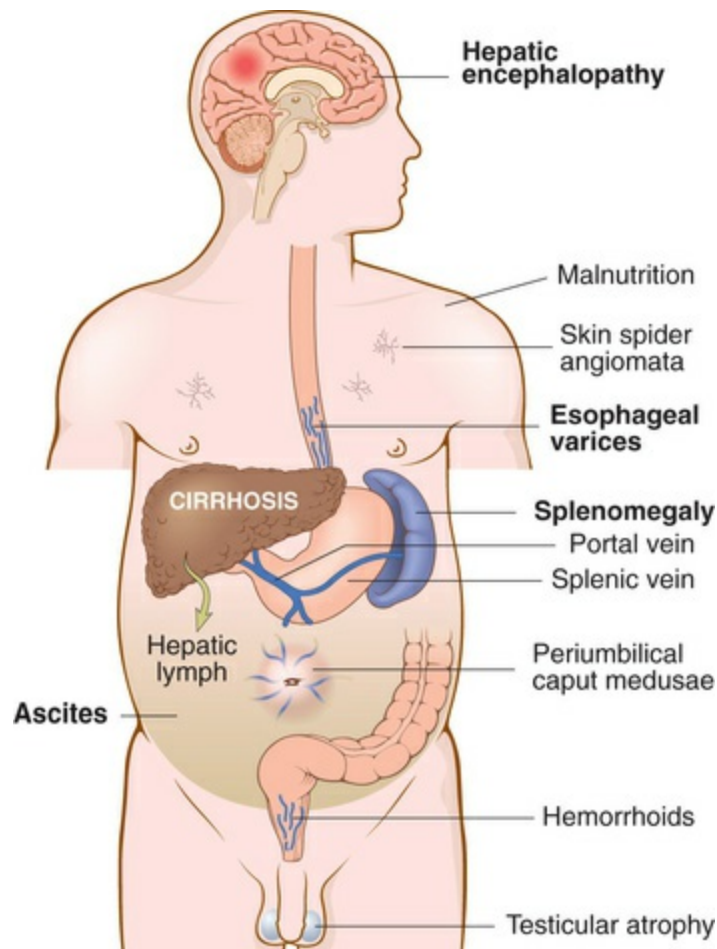

FIGURE 33.3 The major clinical consequences of portal hypertension in the setting of cirrhosis, shown for men. In women, oligomenorrhea, amenorrhea, and sterility are frequent, as a result of hypogonadism. (From Kumar V, et al., eds. *Robbins Basic Pathology*. 9th ed. Philadelphia: Elsevier; 2013:609.)

The development of esophageal varices places the patient at risk for spontaneous, severe, upper-GI hemorrhage. Development of ascites (related to altered intravascular osmolarity) results in fluid retention and impairment of the renin-angiotensin system. The subsequent reduction in renal perfusion progresses to eventual renal failure concomitant with hepatic failure. This is referred to as *hepatorenal syndrome* (HRS). HRS is a severe complication of advanced liver cirrhosis that occurs in patients with ascites and marked circulatory dysfunction. HRS is functionally related to extreme renal vasoconstriction.²⁵ Patient prognosis is very poor once disease has progressed to this stage. Further failure of the liver to clear nitrogenous compounds (ammonia) from the blood contributes to the development of progressive mental status

changes (encephalopathy), ultimately leading to coma and death, if untreated. Recommendations for anesthetic preparation and management for patients with cirrhosis are shown in [Box 33.7](#).

Anesthetic Preparation and Management in Cirrhosis

Preserve hepatic blood flow.

Avoid halothane (isoflurane is the best-studied alternative, and better preserves flow).

Consider regional anesthesia if procedure and coagulation allow.

- Maintain normocapnia
- Avoid PEEP if possible
- Provide generous volume maintenance

Avoid medications with situational potential hepatotoxicity when possible. Examples:

- Acetaminophen, particularly in the alcoholic patient
- Sulfonamides, tetracycline, and penicillins
- Amiodarone

Anticipate presence, development, or abnormalities of:

Coagulation

- Attempt to correct prothrombin time to within 2 sec of normal
- Consider cryoprecipitate if fresh frozen plasma is ineffective or fibrinogen abnormality exists
- Correct thrombocytopenia approximately for the procedure
- Anticipate higher than normal blood loss during the procedure

Hemodynamics

- Anticipate relative hypovolemia, worsened by treatment of ascites
- Assess for the presence of high cardiac output and low peripheral resistance
- Suspect portal hypertension and/or variceal bleeding, even without history
- Anticipate depressed response to inotropes and vasopressors
- Consider invasive monitoring

Pharmacokinetics and Pharmacodynamics

- Altered volume of distribution may occur
- Decreased serum albumin, increased gamma globulins
- Intravascular volume unpredictable, especially with ascites treatment
- Portosystemic shunted blood bypasses liver
- Drugs that are highly extracted by liver are especially affected
- Increased sensitivity to sedative medications may be present.

PEEP, Positive end-expiratory pressure.

Perioperative Considerations in Liver Disease

Preoperative Assessment

Preoperative assessment of patients with hepatic dysfunction necessitates the collection of diagnostic laboratory markers and physical characteristics indicative of the type and severity of liver disease present. Acute derangements in hepatic function should be identified, and the risks of surgery must be weighed against the risk

of postponing the planned procedure until the physical status of the patient is improved. Urgent or emergent surgery may preclude a rigorous diagnostic workup, so it is incumbent on the anesthetist to focus on the implications of the disease process and prioritize care to minimize further physiologic insult.

The Model for End-stage Liver Disease (MELD) score and the Child-Pugh score have been reported to be correlated with postoperative morbidity and mortality in patients with end-stage liver disease.²⁶ The Child-Pugh score was described earlier (see [Table 33.3](#)). MELD is a scoring system that assesses the severity of chronic liver disease. It is useful in prioritizing recipients for liver transplant, as it predicts the outcome based on the calculated score. MELD uses the patient's values for serum bilirubin, serum creatinine, and the INR(PT) to predict survival (interpretation of MELD score is given in [Table 33.7](#)).

TABLE 33.7
MELD Score Prediction of 90-Day Mortality

MELD Score	Mortality
> 40	71.3%
30–39	52.6%
20–29	19.6%
10–19	6.0%
< 9	1.9%

MELD, Model for end-stage liver disease.

$$\text{MELD} = 3.78 [\text{Ln serum bilirubin (mg/dL)}] + 11.2 [\text{Ln INR}] + 9.57 [\text{Ln serum creatinine (mg/dL)}] + 6.43$$

The MELD calculation is more cumbersome than calculation of the Child-Pugh scores, and online calculators are available (e.g., <http://www.mayoclinic.org/meld/>).

MELD scores have largely replaced the older Child-Pugh scoring system, and recent evidence supports the use of MELD in non-transplant settings.^{27,28} Multivariate analysis of a 2007 study of 772 patients with cirrhosis undergoing major digestive, orthopedic, or cardiovascular surgery (586 patients underwent GI surgery)

revealed that the MELD score, American Society of Anesthesiologists' physical status, and age were predictors of mortality.²⁶

The existence of jaundice, prolonged PT, ascites, encephalopathy, hypoalbuminemia, portal hypertension, renal insufficiency, hyponatremia, infection, and anemia have been proposed as risk factors for adverse outcomes in surgical patients.²⁹ In patients with cirrhosis undergoing surgery, preoperative assessment is crucial. The high risk of mortality and morbidity can be reduced by addressing coagulopathy, ascites, renal dysfunction, hyponatremia, hepatic encephalopathy, malnutrition, pulmonary conditions, cardiac conditions, and anemia, and administering antibiotic prophylaxis.³⁰

Relevant information including past or current jaundice, ascites, hepatitis, blood transfusion, or substance abuse can be obtained from the patient history and by physical examination. Reviewing previous anesthetic records also may provide guidance for developing an anesthetic plan. Physical signs such as petechiae, jaundice, ascites, dependent edema, altered mental status, and asterixis (tremor of the wrist indicative of hepatic encephalopathy) suggest the presence of significant liver disease. Laboratory assessment may include the following:

- Albumin (normal values: 3.5–5 g/dL)
- Bilirubin
- PT/INR
- Creatinine
- Serum liver enzyme levels: alanine transaminase (ALT test), aspartate aminotransferase, alkaline phosphatase, lactic dehydrogenase, γ -glutamyl transpeptidase
- Complete blood count
- Serum electrolyte and glucose levels
- Blood type and screen or crossmatch based on planned surgery and patient condition

Effects of Hepatic Dysfunction on Other Organ Systems

Cardiovascular Considerations

Cardiovascular complications of cirrhosis include cardiac dysfunction; abnormalities in the central, splanchnic, and peripheral circulation; and hemodynamic changes caused by humoral and nervous dysregulation.³¹ Increased levels of endogenous vasodilators such as vasoactive intestinal peptide, ferritin glucagon, and others result in a hyperdynamic circulatory state. Cardiovascular changes associated with liver disease include the following:

- Increased CO
- Decreased systemic vascular resistance
- Decreased arterial blood pressure
- Systemic collateral circulation
- Arteriovenous shunting
- Portal hypertension
- Esophageal varices
- Cardiomyopathy
- Congestive heart failure

Fluid Balance and Renal Considerations

Severe hepatic disease disrupts the fluid balance, which manifests as ascites and edema. Ascites is the most common complication of cirrhosis, and is associated with an increased risk of infections, renal failure, and poor long-term outcome.³² The absolute intravascular volume is typically increased, but therapeutic paracentesis, diuretic therapy, and arteriovenous shunting create a relative hypovolemia. Severe hepatic disease (e.g., advanced cirrhosis) may result in impairment of compensatory mechanisms that initiate displacement of blood from the hepatic vascular reservoir into systemic circulation in response to sympathetic stimulation or hemorrhage.

Perioperative concerns focus on the intravascular volume and on electrolyte imbalances. Diuretic therapy should be instituted in the presence of volume overload, with special attention paid to maintaining normotension and the electrolyte balance.

Perioperative preservation of adequate renal perfusion is of the utmost importance. Water restriction, controlled isotonic intravenous (IV) fluid administration, and potassium replacement may be necessary components of the preoperative plan of fluid therapy.

Fluid and electrolyte disturbances associated with liver disease include the following:

- Hypoalbuminemia
- Sodium retention
- Progressive decline in renal function
- Decreased free water clearance
- Dilutional hyponatremia
- Hypokalemia

Intraabdominal ascites exerts a profound influence on several organ systems, including the renal system. As cirrhosis progressively worsens, excessive hydrostatic pressure develops within the lymphatic and hepatic venous systems. This phenomenon, coupled with impaired albumin synthesis, produces decreased plasma oncotic pressure within the liver vasculature, and an exudative process results. Protein-rich fluid accumulates within the peritoneum, resulting in electrolyte abnormalities. The misplacement of fluids within peritoneum establishes an osmotic gradient, leading to a relative intravascular hypovolemia and sodium retention.

HRS is a clinical condition of renal failure that occurs in patients with chronic liver disease, advanced hepatic failure, and portal hypertension; it is characterized by impaired renal function and marked abnormalities in arterial circulation and in the activity of vasoactive systems.³³ HRS may occur as a consequence of GI hemorrhage, sepsis, or surgery, or as a result of aggressive diuretic therapy, all of which place patients at risk for abnormalities in renal perfusion. Signs of HRS include progressive ascites, azotemia, oliguria, and eventually multisystem organ failure. Hepatic transplantation remains the only definitive treatment for HRS, and supportive therapy must be instituted until an organ match is made. The aim of most HRS therapy is to increase renal blood flow through renal vasodilation and vasoconstriction of splanchnic

circulation.³³ Current treatment options for HRS are listed in [Box 33.8](#)

Management of Hepatorenal Syndrome (HRS)

Measures to Prevent Variceal Bleeding (e.g., β -blockers, band ligation)

- Pentoxifylline for severe alcoholic hepatitis

Prevention of HRS

- Avoid intravascular volume depletion (diuretics, lactulose, GI bleeding, large-volume paracentesis without adequate volume repletion)
- Judicious management of nephrotoxins (ACEIs, ARBs, NSAIDs, antibiotics)
- Prompt diagnosis and treatment of infections (SBP, sepsis)
- SBP prophylaxis

Treatment of HRS

- Stop all nephrotoxic agents (ACEIs, ARBs, NSAIDs, diuretics)
- Antibiotics for infections:
- IV albumin—bolus of 1 g/kg per day on presentation (maximum dose: 100 g daily). Continue at dose of 2060 g daily as needed to maintain central venous pressure between 10 and 15 cm H₂O.
- Vasopressor therapy (in addition to albumin):

- Midodrine and octreotide—begin midodrine at 2.5–5 mg orally three times daily and increase to a maximum dose of 15 mg three times daily. Titrate to an MAP increase of at least 15 mm Hg; begin octreotide at 100 mcg subcutaneously three times daily and increase to a maximum dose of 200 mcg subcutaneously three times daily, or begin octreotide at a 25-mcg IV bolus and continue at a rate of 25 mcg/hr.

or

- Norepinephrine—0.1–0.7 mcg/kg per min as an IV infusion. Increase by 0.05 mcg/kg per min every 4 hr and titrate to an MAP increase of at least 10 mm Hg.
- Duration of vasopressor treatment is generally a maximum of 2 weeks until reversal of hepatorenal syndrome or liver transplantation
- Evaluation of patient for liver transplantation

ACEIs, Angiotensin-converting enzyme inhibitors; *ARBs*, angiotensin receptor blockers; *GI*, gastrointestinal; *MAP*, mean arterial pressure; *SBP*, spontaneous bacterial peritonitis; *NSAIDs*, nonsteroidal antiinflammatory drugs.

Hematologic Considerations

Anemia is commonly encountered in advanced hepatic disease. The reduction in the number of red blood cells is due to hemolysis, folate deficiency, hemorrhage, and bone marrow suppression.

Multiple factors can contribute to the development of thrombocytopenia, including splenic platelet sequestration, bone marrow suppression by chronic hepatitis C infection, and antiviral treatment with interferon-based therapy.³⁴ Reductions in the level or activity of the hematopoietic growth factor thrombopoietin may also play a role. Failure of hepatic synthetic processes results in clotting-factor deficiencies, decreased blood viscosity, and enhanced fibrinolysis resulting from decreased clearance of fibrinolytic factors.

In the context of hepatic dysfunction, excessive blood transfusion may exacerbate encephalopathy, owing to the breakdown of red blood cells and the subsequent increase of protein-rich by-products in the plasma—by-products that would ordinarily be metabolized by hepatocytes. When indicated, FFP, platelet, and cryoprecipitate transfusion should be undertaken to correct coagulation deficiencies before surgery.³⁵

Respiratory Considerations

A decline in pulmonary function can be predicted in patients with severe hepatic disease. Arterial hypoxemia is common in the context of hepatic disease, and is often multifactorial (e.g., ascites, hepatic hydrothorax, and chronic obstructive pulmonary disease in patients with alcoholism)³⁶. Hepatopulmonary syndrome (HPS) is defined as the triad of liver disease, arterial deoxygenation, and widespread pulmonary vasodilation. HPS can, however, appear in patients with acute and chronic noncirrhotic portal hypertension. The exact pathogenesis of HPS is still being explored, but precapillary dilation in the lungs appears to play a central role, leading to shunting of blood into the pulmonary vasculature, ventilation-perfusion mismatch, and an increased alveolar-arterial oxygen saturation gradient. One of the characteristics of HPS is intrapulmonary vascular dilation.³⁶ The preoperative focus is on baseline measurement of oxygen tension or saturation and improving reversible pulmonary dysfunction (e.g., elective thoracentesis/paracentesis). Preoperative sedatives and opioids should be carefully considered or omitted based on underlying pathology and the patient's current physical status.

Central Nervous System Considerations

Hepatic encephalopathy is a chronic, debilitating complication of hepatic cirrhosis, and encompasses a wide spectrum of potentially reversible neuropsychiatric abnormalities seen in patients with liver dysfunction. Neurologic impairment stems from various metabolic abnormalities that are a direct result of the failing liver. The inability to clear neurotoxins generated in the gut (e.g., ammonia, short-chain fatty acids, mercaptans, manganese) results in a cascade of systemic disorders, including alterations in mental status that range from subtle personality change to coma. Ammonia is produced in the GI tract by bacterial degradation of amines, amino acids, purines, and urea. Once formed, ammonia is detoxified by hepatocytes in the liver. In hepatic failure, there is a decrease in functioning hepatocytes. The alterations in hepatic portal flow (shunting) that accompany cirrhosis permit ammonia to enter the systemic circulation. Ammonia causes neurotransmitter abnormalities and induces injury to astrocytes that is partially mediated by oxidative stress. These disturbances lead to astrocyte swelling and brain edema, which appear to be involved in the pathogenesis of neurologic manifestations.³⁷ It is noteworthy that the mechanism of encephalopathy cannot fully be attributed to ammonia; some patients with encephalopathy have normal ammonia levels, yet others with elevated ammonia levels have no encephalopathic symptoms. Research into the pathogenesis of hepatic encephalopathy is ongoing, but therapy continues to focus on pharmacologic reduction of ammonia levels with nonabsorbable disaccharides (e.g., lactulose) and antimicrobial agents (e.g., neomycin, rifaximin) that reduce the bacterial production of ammonia and other bacteria-derived toxins by suppressing proliferation of the intestinal flora.³⁸ When possible, the use of benzodiazepine and other sedatives should be avoided in patients with altered mental status.

Intraoperative Anesthetic Considerations

Monitoring

After thorough preoperative evaluation, anesthetic management of

patients with liver disease requires consideration of the underlying pathophysiology and the attendant alterations in pharmacokinetics/pharmacodynamics for each medication administered.

Routine intraoperative monitoring may be sufficient for patients with mild hepatic dysfunction undergoing minor surgery. As previously discussed, morbidity and mortality are higher in patients with advanced liver disease. Regarding electrocardiography (ECG) monitoring, a five-cable ECG lead system is preferred over a three-cable ECG system in such patients, in that it allows monitoring of a true chest lead. With the latter, only a modified chest lead can be used. Myocardial ischemia can be identified by the presence of an ST segment depression of at least 1 mm. Monitoring of ST segment trends in leads II, V₄, and V₅ can detect 96% of ST segment changes.³⁹

Each of these recommendations presumes that the anesthesia provider has properly configured the computerized ST segment analysis software (e.g., verified that the ST point has been positioned over the J point and that the electrodes have been properly placed on the body). Given the potential for hemodynamic lability related to alterations in intravascular status, ascites, electrolyte irregularities, and cardiac comorbidity (e.g., cardiomyopathy), attention should be paid to ST segment analysis for signs of cardiac ischemia. In the absence of an ST segment fingerprint, leads III and V₃ are advocated for the detection of ST segment elevation or depression.⁴⁰

Invasive hemodynamic monitoring may be indicated for patients with cirrhosis and other conditions that involve severe hepatic dysfunction. Arterial cannulation permits beat-to-beat measurement of blood pressure (BP) and provides immediate access for blood withdrawal if laboratory analysis is indicated intraoperatively. Patients with cirrhosis frequently require hemodynamic monitoring, including CO assessment, particularly when admitted to the intensive care unit or when undergoing surgery.^{28,41} Arterial cannulation also permits the usage of minimally invasive CO monitors. Noninvasive cardiac monitors are not universally reliable, and may be considered unreliable in cirrhotic patients with hyperdynamic circulation.⁴¹ Cirrhosis is

associated with a pattern of alterations in the cardiovascular system, known as *cirrhotic cardiomyopathy*, which is characterized by hyperdynamic circulation, elevated baseline CO, reduced peripheral vascular resistance, and decreased ventricular response to physiologic, pharmacologic, and surgical stressors. Furthermore, cirrhotic patients commonly have peripheral autonomic neuropathy, which may result in pronounced hemodynamic instability.⁴¹

Surgeries such as liver transplant (discussed in [Chapter 41](#)) or hepatic resection require additional preparation in anticipation of extensive blood loss. As such, large-bore peripheral and central venous access is necessary for rapid fluid administration, administration of vasopressor medications, and invasive monitoring (e.g., central venous pressure [CVP], pulmonary artery catheter), especially if cardiac disease is present. Transesophageal echocardiography (TEE) monitoring also may be used in the absence of esophageal varices or significant coagulopathy.

Additional considerations for hepatic comorbidity may include blood glucose monitoring (e.g., hypoglycemia during hepatic vascular occlusion), forced air and fluid warming to prevent hypothermia (related to prolonged surgery with an open abdomen coupled, with large volumes of blood loss and fluid replacement), and coagulation profile monitoring and correction with FFP, as necessary.

Anesthetic Technique and Medication Choices

In patients with severe hepatic disease, hepatic arterial blood flow does not increase when the portal blood flow and/or oxygen content in the portal venous blood decrease. This could lead to a decrease in hepatic blood and oxygen supply, with subsequent hepatic oxygen deprivation.⁴² Any anesthetic plan must focus on the maintenance of arterial BP and CO. Often, it is not the specific anesthetic agents chosen that matter most, rather the care with which they are administered. General anesthesia can be performed safely for patients with liver disease; regional anesthesia also can be used, but coagulopathy should be considered as a contraindication to many types of nerve blockade.

Volatile anesthetic considerations were discussed earlier, with an

emphasis on selecting agents that are metabolized minimally or not at all (e.g., desflurane, sevoflurane, isoflurane).

Nitrous oxide should be avoided in open abdominal cases because of the potential for expansion of the bowel and theoretic risk of exacerbating a venous embolism resulting from positional entrainment of air. Propofol has been used safely in patients with liver disease, and may be considered for use as an induction agent. The effects of benzodiazepines may be exaggerated and prolonged.^{20,43}

Neuromuscular blockade selection should be based on patient physical status and the nature of the surgery (e.g., elective or urgent/emergent). Rapid sequence induction may be prudent in the cirrhotic patient with impaired gastric function and increased abdominal pressure related to ascites (Fig. 33.4). In chronic liver failure, succinylcholine may exhibit a prolonged duration of action because of decreased synthesis of plasma cholinesterase by the liver. Due to the long half-life of plasma cholinesterase (14 days), decreased plasma cholinesterase is less likely to be seen in acute liver failure. Nondepolarizing neuromuscular blocking drugs (e.g., rocuronium) used for induction or maintenance should be titrated cautiously, with the expectation that the duration of action will be extended if hepatic metabolism and clearance are impaired. In patients with cirrhosis, the duration of action of vecuronium is prolonged.²⁰ Liver disease increases the volume of distribution and elimination half-life of rocuronium, but not its rate of clearance. The decreased elimination of rocuronium in patients with liver disease prolongs its duration of action, particularly with larger initial doses or prolonged administration. Onset time is slowed in patients with cirrhosis, most likely due to the increased volume of distribution.^{20,44} A better option after intubation may be cisatracurium, which is metabolized independently of hepatic function and relies on Hoffman elimination (sensitive to temperature and pH).

FIGURE 33.4 Ascites in a patient with alcoholic cirrhosis showing distended abdomen; dilated superficial collateral veins; hemorrhagic scratch marks due to pruritus and coagulopathy; umbilical varices; plaster in left iliac fossa indicating diagnostic paracentesis. (From Forbes A, et al., eds. *Atlas of Clinical Gastroenterology*. 3rd ed. Oxford: Mosby Ltd; 2005.)

Opioid activity is dependent on hepatic metabolism, and they should be administered cautiously. Coexisting pulmonary dysfunction may be worsened postoperatively by the prolonged sedative and respiratory depressant effects of opioids used perioperatively. Fentanyl is primarily metabolized by the CYP3A4 system. Administration of CYP3A4 substrates or inhibitors can increase opioid concentrations, thereby prolonging and intensifying analgesic effects and adverse opioid effects, such as respiratory depression.⁴⁵ Hepatic dysfunction has a direct impact on the CYP metabolic system.

Morphine is metabolized in a phase II reaction, undergoing glucuronidation in the liver, and should be titrated cautiously or avoided in patients with significant liver disease. Elimination of alfentanil is reduced in patients with liver disease; its volume of distribution is increased, and protein binding is reduced by the lack of α_1 -acid glycoprotein.¹⁴ Remifentanil has a very short half-life due to its metabolism by nonspecific esterases in the blood, and is not reliant on hepatic or renal function. Perhaps the most compelling

evidence for the lack of effect of hepatic dysfunction on the pharmacokinetics of remifentanyl is that its kinetics do not change during the anhepatic phase of orthotopic liver transplantation.⁴⁶

Diseases of the Biliary Tract

Biliary tract disease is often characterized by a suppression or cessation of bile flow. The most common cause of cholestasis is obstruction of the biliary tract outside of the liver. Symptomatic presentation of obstruction and/or an inflammatory process can be attributed to gallstones, stricture, tumor, infection, or ischemia. Gallstone formation is most likely caused by physicochemical abnormalities in the formation of bile. Approximately 90% of gallstones appear as radiolucent structures composed of hydrophobic cholesterol crystals. Calcium bilirubinate generally accounts for the composition of the remaining percentage. Stones composed of calcium bilirubinate are usually seen in patients with cirrhosis and hemolytic anemia. An estimated 15 to 20 million adults in the United States have biliary tract disease, as evidenced by the presence of gallstones.⁴⁷

Anatomic and Physiologic Overview

The biliary tract is the excretory conduit for the liver. It is composed of (1) the intrahepatic ducts, which collect bile from the liver segments; (2) the coalescence of the intrahepatic ducts and the right and left hepatic ducts; (3) the common hepatic duct, which is formed by the junction of the right and left hepatic ducts in the liver hilum; (4) the gallbladder, which serves as a bile reservoir; (5) the cystic duct, which joins the gallbladder to the CBD; and (6) the CBD, which begins at the junction of the cystic duct and the common hepatic duct and terminates in the lumen of the duodenum.⁴⁷

The gallbladder is a pear-shaped organ capable of holding 30 to 60 mL of fluid, and is attached to the liver in a shallow depression at the inferior junction of the right and left hepatic lobes. The gallbladder drains into the cystic duct, which is usually 1 cm to 5 cm long and arises from the narrow end, or infundibulum, of the gallbladder. The cystic duct drains into the common hepatic duct. The CBD arises from the junction of the cystic duct and the common hepatic duct, and is approximately 6 mm in diameter. It

passes behind the duodenum to the right of the gastroduodenal artery, traversing the head of the pancreas before entering the second part of the duodenum. The distal CBD may join with the pancreatic duct before entering the duodenum via the ampulla of Vater (Fig. 33.5). At the termination, these ducts are enveloped in smooth muscle, the sphincter of Oddi, which provides a barrier to intestinal bacteria to maintain the sterile environment of the biliary tract. The biliary tract can be obstructed here by a pancreatic tumor.

FIGURE 33.5 Anatomy of the biliary tract. (From Townsend CM, et al., eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Elsevier; 2008:1548.)

Arterial blood supply to the gallbladder is furnished by the cystic artery, which is a branch of the right hepatic artery. The biliary ducts receive their blood supply distally from the gastroduodenal, retroduodenal, and posterosuperior pancreatoduodenal arteries, and proximally from the right hepatic and cystic arteries. Venous drainage flows into the portal vein. Lymphatic drainage flows into a cystic duct node located between the cystic duct and the common hepatic duct.

The area known as the *cystohepatic triangle* (*Calot's triangle*) is bound by the common hepatic duct, the liver, and the cystic duct, and is a critical region that contains the cystic artery, the right

hepatic artery, the cystic duct lymph node, and sometimes an aberrant right segmental bile duct. This area must be carefully dissected during cholecystectomy to avoid damaging these vital and friable structures.

The gallbladder mucosa secretes a protective mucus that prevents caustic damage by bile salts. After food is ingested, the gallbladder contracts, emptying its contents (bile) into the duodenum to assist in the digestive processes. Gallbladder contraction is primarily hormonally regulated through the action of CCK. The release of CCK from duodenal cells is mediated by the presence of intraluminal amino acids and fat. Vagal stimulation also serves a role (secondary to the role of CCK). Indeed, vagotomy is associated with impaired gallbladder contraction and an increased prevalence of gallstones.³⁵

Bile is the combined secretory product of the hepatocyte and biliary tract epithelial cells, and has three main functions: (1) to emulsify and enhance absorption of ingested fats and fat-soluble vitamins; (2) to provide an excretory pathway for bilirubin, drugs, toxins, and immunoglobulin A (IgA); and (3) to maintain duodenal alkalization. The combined output of the ductal cells and hepatocytes is 500 to 1000 mL/day which is excreted into the bile canaliculi. The bile ducts, gallbladder, and sphincter of Oddi modify, store, and regulate the flow of bile. The gallbladder concentrates and stores hepatic bile during the fasting state and delivers bile into the duodenum in response to a meal. Because the usual capacity of the gallbladder is only approximately 30 to 60 mL, the remarkable absorptive capacity of the gallbladder accounts for its ability to store much of the bile produced each day.⁴⁷ Absorbed bile is returned via the portal venous system to the liver.

Hepatocytes secrete bilirubin (the metabolic waste product of heme metabolism), cholesterol, bile salts, lecithin, water, and electrolytes. The epithelial cells contribute water and more electrolytes. Vagal stimulation, secretin, CCK, and gastrin stimulate ductular cell secretion and increase bile flow. In addition, bile acids serve as a positive-feedback mechanism for inducing hepatocyte and ductular secretion of bile. Gallbladder filling during fasting occurs with relaxation and contraction of the sphincter of Oddi. The sphincter of Oddi is a complex structure that is functionally

independent from the duodenal musculature. It creates a high-pressure zone between the bile duct and the duodenum. The sphincter regulates the flow of bile and pancreatic juice into the duodenum, prevents the regurgitation of duodenal contents into the biliary tract, and diverts bile into the gallbladder. Vasoactive intestinal peptide induces relaxation of the sphincter of Oddi, whereas somatostatin, an inhibitory peptide, induces contraction. In states of prolonged fasting, the risk of gallstone formation increases, because of the lack of CCK stimulation and consequent biliary stasis.⁴⁷

Cholecystitis

Cholecystitis symptoms are usually the result of obstruction, infection, or both. Obstruction can be extramural (e.g., pancreatic cancer), intramural (e.g., cholangiocarcinoma), or intraluminal (e.g., choledocholithiasis). Acute cholecystitis is related to gallstones in 90% to 95% of cases. Obstruction of the cystic duct leading to biliary colic is the initial event in acute cholecystitis. If the cystic duct remains obstructed, the gallbladder distends, and the gallbladder wall becomes inflamed and edematous. Obstruction of the cystic duct by gallstones results in a triad of sudden right upper quadrant tenderness, fever, and leukocytosis.

Inspiratory effort usually accentuates the pain (Murphy sign). Increases in plasma bilirubin, alkaline phosphatase, and amylase levels frequently occur. Ileus and localized tenderness may indicate perforation with peritonitis. Leukocytosis and fever are often present. Jaundice indicates complete obstruction of the cystic duct. Symptoms are frequently confused with those of myocardial infarction. Differential diagnosis is accomplished through serial ECG evaluations and laboratory analysis of serum enzymes specific to cardiac muscle. Cholescintigraphy (a contrast study that evaluates gallbladder excretion of a radiographically labeled substance) and ultrasonography are often used for clinical confirmation of the diagnosis.³⁵

For most patients, the treatment for acute cholecystitis is cholecystectomy, but for those who are critically ill, the risk of general anesthesia may be greater than the benefit of a surgical procedure. An alternative, temporary treatment for these high-risk

patients is decompression and drainage of the gallbladder through the insertion of a cholecystostomy tube. This minimally invasive procedure can be performed with local anesthetic infiltration and IV sedation.⁴⁸

Patients with symptoms indicative of acute cholecystitis are often volume depleted due to oral intake intolerance, vomiting, and possible preoperative nasogastric (NG) evacuation of gastric contents. Dehydration calls for preoperative IV fluid replacement. Gastric suction may be warranted in the presence of ileus. The presence of free abdominal air, as determined by abdominal radiography or symptoms of an acute abdomen (e.g., fever, ileus, rigid and painful abdomen, vomiting, dehydration), suggests a ruptured viscus, possibly including perforation of the gallbladder. Under these circumstances, emergency exploratory laparotomy is undertaken.

Cholelithiasis and Choledocholithiasis

Acute obstruction of the CBD often produces symptoms similar to those seen in patients with cholecystitis. Recurrent bouts of acute cholecystitis induce the development of fibrotic changes in gallbladder structure, thereby impeding the ability of the gallbladder to adequately expel bile. The presence of Charcot's triad (i.e., fever and chills, jaundice, right upper quadrant pain) aids in establishing the diagnosis of acute ductal obstruction. Weight loss, anorexia, and fatigue complete the symptomatology. Diagnostic modalities include radiography, transhepatic cholangiography, ultrasonography, cholescintigraphy, and computed tomography (CT) scan. A dilated CBD and biliary tree are typically observed in these studies.

The use of ERCP in patients with suspected CBD stones not only confirms the diagnosis but also provides ductal clearance of the stones and sphincterotomy before subsequent laparoscopic cholecystectomy. It is relatively more complex than routine endoscopies, and requires adequate sedation, analgesia, and patient cooperation. Patients undergoing ERCP have been found to be more anxious as compared with those undergoing a routine esophagogastroduodenoscopy (EGD). Restlessness and lack of cooperation have been reported to be one of the causative factors

for post-ERCP complications such as duodenal perforation and pancreatitis. The choice of sedative is chiefly governed by the user and the patient history. Similarly, the level of sedation is also dependent on the clinical condition of the patient and the degree of patient cooperation.⁴⁹ Patients presenting for ERCP often have comorbidities. Endoscopic clearance of stones from the CBD can prevent the need for an open operation if expertise in laparoscopic CBD exploration is not available. Patients with worsening cholangitis caused by ascending bacterial infection of the biliary system, ampullary stone impaction, biliary pancreatitis, multiple comorbidities, or cirrhosis are considered good candidates for preoperative endoscopic therapy.⁴⁷

Anesthetic Considerations in Gallbladder and Biliary Tract Disease

Removal of gallstones is undertaken not only to relieve symptoms but also to prevent further sequelae, including cholecystitis, cholangitis, jaundice, pancreatitis, and peritonitis, all of which may result from stasis or impediment to bile flow. Contraindications to laparoscopic cholecystectomy include coagulopathy, severe chronic obstructive pulmonary disease, end-stage liver disease, and congestive heart failure.

Since the introduction of laparoscopic cholecystectomy, the number of cholecystectomies performed in the United States has increased from approximately 500,000 per year to 700,000 per year. More than 90% of cholecystectomies are performed laparoscopically. Laparoscopic cholecystectomy is now often performed in the relatively healthy patient on an outpatient basis, with discharge either later on the day of the surgery or, occasionally, after an overnight stay in the hospital. Postoperative pain management is typically less challenging with laparoscopic surgery.

Induction is standard or rapid sequence induction with oral endotracheal intubation. The use of abdominal carbon dioxide insufflation to effect adequate exposure of anatomic structures mandates general endotracheal intubation anesthesia to effectively seal the airway and prevent passive aspiration of gastric contents.

Maintenance requires muscle relaxation with appropriate reversal. An orogastric tube should be inserted to decompress the stomach. Prophylactic antiemetics are needed due to the peritoneal irritation of insufflation, opioid use, and intravascular volume depletion. The peritoneal cavity must be insufflated for surgical exposure.

Insufflation of the abdomen with carbon dioxide impedes diaphragmatic excursion, causing a decrease in functional residual capacity, a decrease in closing capacity, and an increase in peak inspiratory pressure. Retroperitoneal insufflation may lead to hypotension, and necessitates repositioning of the trocar. Insufflation with carbon dioxide causes a rise in the carbon dioxide partial pressure, unless ventilation is controlled. Abdominal insufflation may lead to hypercarbia in the presence of inadequate ventilation. Special attention should be paid to the potential need for ventilator setting adjustment with insufflation. In the setting of intraabdominal insufflation, using pressure control ventilation rather than a volume control mode may be the best means of preventing alveolar derecruitment (measured at the bedside by a pressure-volume curve method), as it provides physiologic minute ventilation while minimizing the risk of barotrauma. The use of a reverse Trendelenburg position during laparoscopic cholecystectomy may induce a variable degree of hemodynamic compromise by impeding venous return. Occult hemorrhage is also possible, and may go undetected.

Insufflation also leads to increased intraabdominal pressure (IAP). An IAP of 20 to 25 cm H₂O leads to increased CO and CVP secondary to changes in the volume of the venous return of blood. An IAP greater than 30 to 40 cm H₂O may lead to decreased CVP and CO secondary to reduced right ventricular preload. Insufflation to a pressure of approximately 15 mm Hg is routine. Abdominal insufflation also displaces the abdominal viscera and diaphragm in a cephalad direction, which places extra pressure on the lower esophageal sphincter (LES), thereby increasing the risk of gastric reflux.

All maintenance anesthetic drugs may be used. Some surgeons request that nitrous oxide not be used, to reduce the risk of bowel expansion, which could hinder surgical exposure. In the presence of hepatic dysfunction, isoflurane, desflurane, and sevoflurane are

safe. The choice of muscle relaxant depends on the patient's ability to tolerate possible side effects of the drug, the drug's dependence on hepatic clearance, and the length of the procedure to be performed. Awake extubation is performed after the patient's airway reflexes have recovered adequately. The laparoscopic approach offers the benefit of reduced postoperative pain secondary to smaller abdominal incisions. Patients may experience shoulder pain from pneumoperitoneum, which is usually self-limiting. Evacuation of the pneumoperitoneum with a Valsalva maneuver prior to closing will assist in alleviating postoperative pain. Severe postoperative pain may be reduced by patient-controlled analgesia, intercostal nerve blocks, or neuraxial opioid administration. Abdominal pain or other symptoms originally attributed to the gallbladder may persist or recur months or years after cholecystectomy. Anesthesia for laparoscopic surgery is discussed in [Chapter 34](#).

Open cholecystectomy may be indicated for patients who are emergently ill, patients with an existing infection, or patients in whom laparoscopy poses a particularly formidable technical challenge (e.g., in cases of morbid obesity or intraabdominal adhesions secondary to previous abdominal surgery or peritonitis). Patients who undergo open cholecystectomy often experience more complications, including a greater likelihood of severe postoperative pain and respiratory splinting (caused by the use of a right subcostal or upper abdominal midline incision), with the risk of postoperative respiratory embarrassment in the susceptible patient. Patients who have experienced severe traumatic injury or who require aggressive intensive care for multiorgan disease are at particular risk for developing acute cholecystitis secondary to the stress of severe illness. Patients with significant comorbidities, including advanced age, who undergo prolonged or complex surgical procedures (e.g., trauma surgery, cardiac surgery with cardiopulmonary bypass, abdominal aneurysm repair) that are complicated by perioperative hemodynamic lability are also at greater risk for ischemia of the abdominal viscera. The result may be the development of an acute, postoperative abdominal crisis. Under these circumstances, exploratory laparotomy for an acute abdomen may reveal necrosis and perforation of the gallbladder.

This places the patient at extreme risk for developing peritonitis. The acute critical nature of the presenting illness, superimposed upon preexisting patient comorbidities, is another factor potentially complicating perianesthetic management of the patient.³⁵

Full-stomach precautions should be used during the induction of and emergence from anesthesia, particularly in the presence of abdominal distention or ileus. Patients with jaundice require a more thorough preparation, owing to the likelihood of a variable degree of hepatic dysfunction. This may make for greater susceptibility to hemorrhage, exaggerated drug effects, and fluctuation in hemodynamics. Invasive hemodynamic monitoring and preparation for blood product transfusion are influenced by the patient's clinical status.

CBD exploration may be carried out in conjunction with cholecystectomy, if necessary. Glucagon may be requested by the surgeon for its spasmolytic effect in the GI system and its ability to relax the sphincter of Oddi. Note that glucagon may cause nausea at doses greater than 2 mg.

Diseases of the Esophagus

Anatomic and Physiologic Overview

Esophagus is derived from the Greek words *oiso*, which is the future tense of *phero* (to carry), and *phagein* (food).⁵⁰ Approximately 18 cm to 25 cm long, the esophagus is a hollow, muscular tube that serves to carry food or liquid to the stomach. The esophagus has three segments: cervical, thoracic, and abdominal. The cervical esophagus is bordered anteriorly by the trachea, bilaterally by the common carotid arteries, internal jugular veins, and vagal nerves, and posteriorly by the cervical muscles. Proximally, the esophagus begins where the inferior pharyngeal constrictor merges with the cricopharyngeus, an area of skeletal muscle known functionally as the upper esophageal sphincter.⁵¹ At rest, the upper esophageal sphincter prevents entrainment of air by muscle contraction, which creates a high pressure zone.

Although collapsed when unused, the esophagus is capable of expanding to permit passage of substances; however, it remains the narrowest of the digestive tubes. Peristaltic action pushes solid matter distally toward the stomach. The LES, contracted at rest to prevent passage of gastric contents proximally into the esophagus, relaxes to permit passage of food into the stomach.

Sympathetic and parasympathetic innervation regulates esophageal muscle tone. Peristaltic activity is regulated by parasympathetic innervation via the vagus nerves. Esophageal muscular contraction and LES relaxation are regulated by stimulation of cranial nerves IX, X, and XI. Sympathetic fibers act on Auerbach's (myenteric) plexus to modulate motor activity.

Esophageal Disorders

Disorders affecting esophageal motility or sphincter tone may create generalized symptoms of dysphagia, heartburn, or chest pain. Primary esophageal motility disorders include achalasia and gastroesophageal reflux disease (GERD). Achalasia is characterized by impaired relaxation of the LES, and may develop secondary to systemic disease states, including diabetes, stroke, amyotrophic

lateral sclerosis, and certain connective tissue diseases such as amyloidosis and scleroderma. Chronic achalasia results in dilation of the distal esophagus, and regurgitation becomes more frequent when larger amounts of food and fluid are retained. GERD is a consequence of the failure of the normal antireflux barriers to protect against frequent and abnormal amounts of gastroesophageal reflux. Symptoms range from heartburn to extraesophageal manifestations (e.g., pulmonary, ear, nose, or throat symptoms).

Chronic GERD can result in abnormal epithelial changes in the esophagus that predispose the tissue to developing a malignancy. Damage to the esophageal epithelium results in columnar epithelium replacing the normal stratified squamous cells in the distal esophagus, a condition that is referred to as *Barrett's esophagus*. These changes create no symptoms, but are a cautionary risk factor associated with adenocarcinoma of the esophagus.

In many patients, GERD may be managed conservatively with pharmacologic therapy, and surgery is withheld until medical management proves unsuccessful. Medication therapy may include antacids, mucosal protective medications, histamine (H₂) receptor blockers, proton pump inhibitors, and prokinetics designed to facilitate emptying of the stomach. Aside from failed medical therapy, other surgical indications include a mechanically defective cardiac sphincter, recurrence of symptoms after discontinuing treatment, and unacceptable side effects related to medications.

Hiatal Hernia

Hiatal hernia refers to conditions in which elements from the abdominal cavity, most commonly the stomach, herniate through the esophageal hiatus into the mediastinum.⁵² Hiatal hernias are classified as type I to type IV. Type I, the sliding type, is formed by the movement of the upper stomach through an enlarged hiatus. In type II, the paraesophageal type, the esophagogastric junction remains in normal position, but all or part of the stomach moves into the thorax and assumes a paraesophageal position. A type III has been identified that combines the features of sliding and paraesophageal hernias (Fig. 33.6). Type IV hiatal hernias are those

in which other organs, such as the colon or small bowel, are contained in the hernial sac formed by a large paraesophageal hernia.⁵³

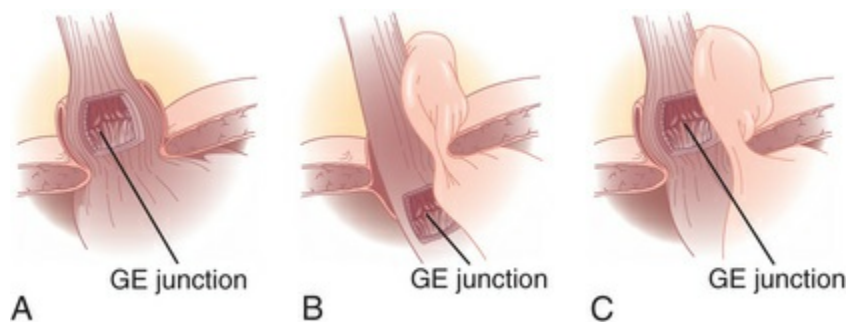

FIGURE 33.6 Three types of hiatal hernia. **A**, Type I, or sliding hernia. **B**, Type 2, or rolling hernia. **C**, Type 3, or mixed hernia. *GE*, Gastroesophageal. (From Townsend CM, et al., eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia: Elsevier 2017:1044.)

The contribution of hiatal hernia to GERD is controversial,⁵⁴ but data confirm the importance of hiatal hernia in patients with more severe esophagitis, peptic stricture, or Barrett's esophagus. Several surgical approaches may be used to reduce and correct hiatal hernia, although the laparoscopic Nissen fundoplication remains common. Collis-Nissen elongation gastroplasty may be superior to Nissen fundoplication for select patients with Barrett's esophagus, because of the reflux-induced shortening of the esophagus, but the choice of which procedure to perform is often made intraoperatively.^{55,56} Anesthetic management may include aspiration prophylaxis, as discussed previously. Application of cricoid pressure has been shown to decrease LES. However, normal gastric pressures remain; consequently, the value of cricoid cartilage pressure in rapid sequence induction has been questioned, although it remains a frequent technique in clinical practice.⁵⁷

Anesthetic Considerations in Esophageal Disease

Special considerations may be necessary for patients with active esophageal disease. Occult disease (asymptomatic) is generally less

concerning than uncontrolled disease states that manifest with reflux symptoms. A preoperative history of symptoms that indicate the presence of gastric reflux warrants aspiration prophylaxis during general anesthesia induction and emergence. Although best practice data do not support a specific regimen, modifying the acidity and/or volume of gastric contents remains a common preoperative practice. For maximum benefit, it is imperative to have an understanding of the pharmacokinetic/pharmacodynamic profile of selected preoperative medications.

Rapid sequence induction with cricoid pressure may serve to hasten protection of the airway with a cuffed endotracheal tube (ETT) and limit opportunity for aspiration of gastric contents. Usage of a laryngeal mask airway (LMA) remains controversial in patients with active reflux disease. The absence of definitive airway protection with LMA must be carefully considered, and a reasonable indication against endotracheal intubation should be present prior to implementation.

Diseases of the Stomach

Anatomic and Physiologic Overview

The principal function of the stomach is to prepare ingested food for digestion and absorption before it is moved into and through the small intestine. The initial period of digestion requires solid components of a meal to be stored for several hours while they undergo a reduction in size and are broken down into their basic metabolic constituents.

Receptive relaxation is a process whereby the proximal portion of the stomach relaxes in anticipation of food intake. This relaxation enables liquids to pass easily from the stomach along the lesser curvature, whereas the solid food settles along the greater curvature of the fundus. In contrast to liquids, emptying of solid food is facilitated by the antrum, which pumps solid food components into and through the pylorus. The antrum and pylorus function in a coordinated fashion, allowing entry of food components into the duodenum and also returning material to the proximal stomach until it has been processed appropriately for delivery into the duodenum.

In addition to storing food, the stomach participates in digestion of a meal. An example of this is the enzymatic breakdown of starch through the activity of salivary amylase. For this to work, the pH within the center of the gastric bolus needs to be greater than 5. Peptic digestion metabolizes a meal into fats, proteins, and carbohydrates by breaking down cell walls. Although the duodenum and proximal small intestine are primarily responsible for digestion of a meal, the stomach facilitates this process.⁵⁸

The stomach is essentially composed of three sections. The thin-walled and distensible proximal portion (fundus) is located in the upper abdomen, and its function is primarily storage. The body of the stomach represents the largest portion. The body also contains most of the parietal cells, and is bound on the right by the relatively straight lesser curvature and on the left by the longer greater curvature. The thick-walled distal portion of the stomach (pylorus) is responsible for mixing food and releasing it slowly through the

pyloric sphincter into the duodenum. The relationship of the stomach to the other abdominal organs is noted in (Fig. 33.7).

FIGURE 33.7 Position of the stomach relative to the other principal organs of the upper abdomen. *I*, Inferior; *L*, left; *R*, right; *S*, superior. (From Patton KT, Thibodaux GA. *Anatomy & Physiology*. 9th ed. St Louis: Elsevier; 2016:883.)

Most of the blood supply to the stomach is from the celiac artery. There are four main arteries: the left and right gastric arteries along the lesser curvature, and the left and right gastroepiploic arteries along the greater curvature. In addition, a substantial quantity of blood may be supplied to the proximal stomach by the inferior phrenic arteries and by the short gastric arteries from the spleen (Fig. 33.8). Major autonomic innervation is furnished by two branches of the vagus nerve, the right posterior (celiac) branch and the left anterior (hepatic) branch.

FIGURE 33.8 Blood supply to the stomach and duodenum with anatomic relationships to the spleen and pancreas. *a*, Artery; *L*, left; *R*, right; *v*, vein. (From Yeo CJ, et al. *Shackelford's Surgery of the Alimentary Tract*. 7th ed. Philadelphia: Elsevier; 2013:641.)

The gastric wall consists of an external serosal layer that covers an inner oblique, a middle circular, and an outer longitudinal layer of smooth muscle. The middle layer of smooth muscle is circular, and is the only complete muscle layer of the stomach wall. At the pylorus, this middle circular muscle layer becomes progressively thicker, and functions as a true anatomic sphincter between the stomach and duodenum.

The submucosa, which lies between the muscularis externa and mucosae, is a collagen-rich layer of connective tissue that is the strongest layer of the gastric wall. The submucosa contains the rich anastomotic network of blood vessels, lymphatic vessels, and Meissner plexus of autonomic nerves. The mucosa consists of surface epithelium, lamina propria, and muscularis mucosae. The latter is on the luminal side of the submucosa, and is probably responsible for forming the rugae that greatly increase epithelial

surface area. It also marks the histologic boundary for invasive and noninvasive gastric carcinoma.⁵⁸

Within the gastric mucosa reside the glands that are responsible for the significant physiologic role that the stomach plays during the digestive processes. The functions of the glands and the cells lining the glands vary according to the region of the stomach in which they are found. Within the fundic mucosa lie mucus-secreting glands that provide a protective barrier against the acid outflow of the parietal cells, which are located in the same region of the stomach. The stomach has an endocrine function, as demonstrated by the secretion of pepsinogen by chief cells and serotonin by other cells. The antrum contains cells that secrete mucus (surface epithelial cells and mucous cells) and gastrin (G cells). The two important sphincters are the LES at the gastroesophageal junction and the pyloric sphincter at the gastroduodenal junction.

The stomach is very distensible, can store up to 1.5 L of fluid without any increase in gastric pressure, and normally stores food for up to 4 hours. The sight and smell of food stimulate acid and pepsinogen production. Gastrin is the major hormonal regulator of the gastric phase of acid secretion after a meal. Gastrin is released by the G cells in response to gastric distention, which stimulates parietal-cell acid (hydrochloric acid) secretion. The duodenum and upper jejunum also secrete a small amount of gastrin. Luminal acid suppresses gastrin feedback (negative feedback).

Pepsinogen and gastrin release are vagally mediated. Acid in duodenal contents induces the release of secretin, which further inhibits gastrin release and acid production. Acid in the antrum also stimulates the release of somatostatin. Somatostatin directly inhibits parietal cell acid secretion, and also indirectly inhibits acid secretion through inhibition of gastrin release and down-regulation of histamine release. Pancreatic bicarbonate release is also stimulated by duodenal acidity.

Gastric acid secretion by parietal cells is regulated by three local stimuli: acetylcholine, gastrin, and histamine. These three stimuli account for both basal and stimulated gastric acid secretion. Acetylcholine is the principal neurotransmitter modulating acid secretion, and is released from the vagus and parasympathetic

ganglion cells. Gastrin has hormonal effects on the parietal cells, and stimulates histamine release. Histamine has paracrine-like effects on the parietal cells, and plays a central role in the regulation of acid secretion by parietal cells after its release from enterochromaffin-like (ECL) cells. Somatostatin inhibits gastric acid secretion. Release of somatostatin from antral D cells is stimulated in the presence of intraluminal acid at a pH of 3 or less. After its release, somatostatin inhibits gastrin release and also modifies histamine release from ECL cells. In some patients with peptic ulcer disease (PUD), this negative feedback response is defective. Consequently, the precise state of acid secretion by parietal cells is dependent on the overall influence of the positive and negative stimuli.⁵⁸

Other gastric functions include providing a barrier against ingested pathogens. This goal is accomplished through the maintenance of a highly acidic environment and through a functional role in immunosurveillance. The stomach heats or cools ingested substances as needed to maintain normothermia. Parietal cells also secrete intrinsic factor (in addition to hydrochloric acid), which facilitates ileal vitamin B₁₂ absorption.

Peptic Ulcer Disease

A gastric ulcer is defined by the loss of mucosa (including muscularis mucosae) due to inflammation. Ulcers may extend into the submucosa and even into the muscularis propria. All ulcers begin as erosions, but not all erosions progress to ulcers. Ulcers may be acute or chronic. Peptic ulcers are considered chronic, and are most often solitary. They may occur in any portion of the GI tract that is exposed to acid-peptic juices. Approximately 98% of peptic ulcers occur in the stomach and duodenum.

It is now believed that 90% of duodenal ulcers and roughly 75% of gastric ulcers are associated with *H. pylori* infection. *H. pylori* is detected in the stomach of almost all patients with duodenal peptic ulcer and in more than 90% of gastric ulcer patients who are not nonsteroidal antiinflammatory drug (NSAID) users (after *H. pylori* infection, ingestion of NSAIDs is the most common cause of PUD). Eradication of *H. pylori* facilitates healing of peptic ulcers, and,

essentially, prevents their recurrence.⁵⁹

The most common complications of PUD, in order of prevalence, are hemorrhage, perforation, and obstruction. Approximately one-third of patients experience at least one of these complications during the course of their PUD; pyloric channel ulcers are the ulcers that are most commonly associated with complications, particularly obstruction. Bleeding occurs when the ulcer erodes underlying blood vessels. Ulcers may perforate into adjacent organs, such as the pancreas (most common) or the liver.

Gastric outlet obstruction may develop as a result of distortion and narrowing of the pyloric area due to fibrosis, edema, or smooth muscle spasm resulting from chronic ulcer disease. It occurs almost exclusively in patients with long-standing peptic ulcers of the pyloric channel or duodenum. Surgical repair or endoscopic pyloric dilation with stents are often necessary to alleviate the symptoms of gastric outlet obstruction.^{59,60}

A chronic overabundance of hydrochloric acid and pepsin (from various causes) results in erosion of the protective mucous layer of the stomach and duodenum, eventually leading to ulcerative lesions extending beyond the mucosal barrier into the submucosa and muscularis epithelial layers, and sometimes into the serosal layer. In the case of LES incompetence, ulcerative involvement of the esophagus may develop.

A chronic ulcerative lesion in the duodenum constitutes duodenal ulcer disease. This classification also includes lesions that occur before the pylorus in the lower antrum of the stomach, due to the similarity in symptoms and responses to therapy. Men 45 to 65 years of age and women older than 55 years have the highest incidence of duodenal ulcer disease. Affected patients possess twice the number of acid-secreting parietal cells.⁶¹

Gastritis

Stress gastritis, an inflammatory disorder of the gastric mucosa, has been referred to as *stress ulcerations*, *stress erosive gastritis*, and *hemorrhagic gastritis*. These lesions may lead to life-threatening gastric bleeding, and by definition occur after physical trauma, shock, sepsis, hemorrhage, or respiratory failure. They are characterized by multiple, superficial (nonulcerating) erosions that

begin in the proximal or acid-secreting portion of the stomach and progress distally. They also may occur in the setting of central nervous system disease such as that seen with Cushing ulcer, or as a result of thermal burn injury involving more than 30% of the body surface area (Curling ulcer).

Although the precise mechanisms responsible for the development of stress gastritis remain to be fully elucidated, current evidence suggests a multifactorial etiology including drugs, chemicals, or *H. pylori* infection. These stress-induced gastric lesions appear to require the presence of acid. Stress is considered to be present when hypoxia, sepsis, or organ failure occurs. Other factors that may predispose to the development of these lesions include impaired mucosal defense mechanisms against luminal acid such as a reduction in blood flow, a reduction in mucus, a reduction in bicarbonate secretion by mucosal cells, or a reduction in endogenous prostaglandins.⁵⁸ *H. pylori* has been identified as a major etiologic factor of gastritis-associated disease, as well as gastric and duodenal ulcers and gastric carcinoma, but it should be noted that at present *H. pylori* is not recognized as a serious occupational hazard, despite the fact that anesthesia providers are frequently exposed to potential oral and ambient routes of transmission.⁶¹ Epidemiologic findings indicate a higher prevalence of this organism in older adults, individuals of lower socioeconomic status, and those born outside the United States. Infected patients undergoing stress are at greatest risk for exacerbation of the infection, with potential development of gastric and duodenal ulceration. All these factors render the stomach more susceptible to damage from luminal acid, with resultant hemorrhagic gastritis.

Any patient with upper GI bleeding requires prompt and definitive fluid resuscitation with correction of any coagulation or platelet abnormalities. If blood is required, it should be administered without delay, and if there are specific clotting abnormalities or platelet deficiencies, FFP and platelets should likewise be administered. In patients being treated for sepsis, broad-spectrum antibiotic treatment and control of the source of infection need to be undertaken. Treatment of the underlying sepsis plays a major role in treating the underlying gastric erosions. Saline lavage of the stomach through an NG tube will help remove any

pooled blood and prevent gastric distention, which stimulates gastrin release. NG decompression also removes noxious substances such as bile and pancreatic juice that could potentially further compromise the stomach. More than 80% of patients who present with upper GI hemorrhage stop bleeding when this approach is used. When the NG tube aspirate is clear, indicating that bleeding has ceased, intraluminal gastric pH should be maintained at greater than 5.0 with antisecretory agents. If the pH can be maintained above 5.0, more than 99.9% of acid will be neutralized, and pepsin will be inactive. Usually, this involves the use of proton pump inhibitors or, alternatively, H₂-receptor antagonists with or without combination antacid therapy. There is little evidence to suggest that endoscopy with electrocautery or heater probe coagulation has any benefit in the therapy of bleeding from acute stress gastritis.⁵⁸

Gastric mucosal acidosis has been reported frequently in critically ill patients with respiratory failure and underlying coagulopathy, hepatic cirrhosis, hyperparathyroidism, obstructive airway disease, rheumatoid arthritis; patients undergoing prolonged, complex surgical procedures; and patients undergoing cardiopulmonary bypass. Gastritis associated with gastric mucosal acidosis is associated with increased perioperative morbidity and mortality. The splanchnic viscera is particularly vulnerable to decreased circulatory blood flow in the presence of inflammation, with the potential for breakdown of intestinal barrier function. This results in the translocation of bacteria and endotoxins into the bloodstream, leading to systemic sepsis. Ischemia and acidosis of the gut are the primary causative factors for erosion of the gut barrier function.³⁵

Therapeutic Options in Peptic Ulcer Disease

The clinician has three major goals when faced with a patient with peptic ulcer disease: symptoms need to be relieved, the ulcer needs to heal, and recurrence needs to be prevented. The major medical therapies and treatments used for the control of PUD focus on *H. pylori*. Adjuncts include oral antacids, H₂-receptor antagonists, proton pump inhibitors, sucralfate, and antibiotics. A proton pump

inhibitor such as omeprazole is used in duodenal ulcer management. EGD and surgical treatment are reserved for patients who continue to experience intractable symptoms despite aggressive medical therapy, or to treat complications. These complications are often of an urgent nature and consist of GI hemorrhage, ulcerative perforation into adjacent structures such as the pancreas or jejunum, and obstruction.^{62,63}

Antacid use for the medical treatment of PUD has potential complications that are of interest to the anesthetist. Antacids may produce an acid rebound in which gastric acid secretion increases after acid is neutralized by calcium-containing antacids. Another condition that may result from antacid therapy is the milk-alkali syndrome. In this condition, hypercalcemia, alkalosis, and an elevated blood urea nitrogen level may develop from the daily ingestion of large quantities of calcium-containing antacids and milk. Manifestations of this syndrome include skeletal muscle weakness and polyuria. Ingestion of large quantities of aluminum-containing antacids may result in acute hypophosphatemia because of increased binding of intestinal phosphorus. Skeletal muscle weakness and fatigue follow chronic overuse, resulting in pathologic fractures and osteoporosis.³⁵

Hydrochloric acid secretion is blocked by H₂ antagonists, thereby promoting the healing of duodenal ulcers. All four available H₂-receptor antagonists (cimetidine, ranitidine, famotidine, and nizatidine) suppress basal acid output, as well as acid output stimulated by meals. After IV administration, all four agents are eliminated principally through renal excretion. For cimetidine and famotidine, it is recommended that the doses be cut in half in patients whose creatinine clearance is 15 to 30 mL/min. For nizatidine and ranitidine, the dose should be halved if the creatinine clearance is less than 50 mL/min.⁶² A noteworthy side effect is the alteration of CYP enzyme activity in the liver, which may result in prolongation of the effects of concurrently administered drugs that rely on CYP-mediated hepatic metabolism and elimination. Famotidine is the H₂-receptor antagonist least likely to cause this effect. Other side effects of H₂-receptor antagonists include decreased hepatic blood flow, leukopenia and thrombocytopenia, mental confusion, interstitial nephritis,

hepatitis, bradycardia, and hypotension.

The most effective antisecretory agents are the proton pump inhibitors, which are listed in [Table 33.8](#). Sucralfate, the aluminum salt of sulfated sucrose, not only binds to ulcers but also promotes thickening of the gastric mucous layer, thereby promoting healing processes. It has been shown to be equally efficacious when used with H₂-receptor antagonists and antacids, and is relatively devoid of side effects.

TABLE 33.8
Proton Pump Inhibitors

Generic Name	Trade Name	Adult Dosage Range
Esomeprazole	Nexium	20–40 mg daily
Lansoprazole	Prevacid	15–30 mg daily
Omeprazole	Prilosec	20–40 mg daily
Pantoprazole	Protonix, Protonix IV	40 mg daily 40 mg slow infusion
Rabeprazole	Aciphex	20 mg daily
Dexlansoprazole	Dexilant	30–60 mg daily

Misoprostol is a synthetic prostaglandin that may be used as a second line prophylactic agent to prevent ulcers in patients taking NSAIDs. *H. pylori* is a species of Gram-negative spiral bacteria sensitive to combination therapy with a variety of antibiotics. Approximately 80% of upper GI bleeds are self-limited. Laparoscopic repair is indicated when medical therapy is unsuccessful.

Gastric Ulcer Disease

Gastric ulcers develop as a result of the degeneration of the stomach's mucosal barrier against gastric acid. Gastric ulcers can occur anywhere in the stomach, and may or may not be associated with increased gastric acid secretion. Pain and anorexia predispose the patient to metabolic changes and weight loss. The most frequent complication of gastric ulceration is perforation. Most perforations occur along the anterior aspect of the lesser curvature. In general, older patients have increased rates of perforations, and larger ulcers are associated with more morbidity and higher mortality rates. Similar to duodenal ulcers, gastric outlet obstruction can also occur

in patients with type II or III gastric ulcers.⁵⁸ Surgery, consisting of antrectomy with pyloroplasty and vagotomy, is undertaken if the patient's condition does not respond to medical therapy.

Gastric Neoplastic Disease

Gastric cancer is the second most common type of cancer worldwide. In the United States, gastric cancer is the seventh most frequent cause of cancer-related death. Most gastric neoplasms are malignant. The incidence of these neoplasms according to type is adenocarcinoma, 95%; lymphoma, 4%; and leiomyosarcoma, 1%. The epigastric pain is similar to pain caused by benign ulcers, and may also mimic angina. Typically, however, the pain is constant, nonradiating, and unrelieved by food ingestion. More advanced disease may present with weight loss, anorexia, fatigue, or vomiting. Symptoms often reflect the site of origin of the tumor. Endoscopic mucosal resection has become the treatment of choice for early gastric cancer, and usually is performed in association with endoscopic ultrasonography for staging. Advanced adenocarcinoma is defined as a tumor that invades the gastric wall beyond the submucosa. Most patients are men (male:female ratio of 2 : 1) in their fifth to seventh decades of life. Clinically, symptoms include epigastric pain, dyspepsia, anemia, and weight loss. Hematemesis and symptoms of gastric outlet obstruction are not uncommon. Female patients may develop metastatic ovarian lesions (Krukenberg tumors) composed of diffuse-type cancer cells. Unfortunately, the majority of patients with gastric cancer in the United States are diagnosed at an advanced stage.⁶⁴

Surgical resection remains the primary curative treatment for gastric cancer, and represents the best chance for long-term survival. In addition, surgical resection often provides the most effective palliation of symptoms, particularly those of obstruction. In general, total gastrectomy is performed for proximal gastric tumors and diffuse gastric cancer, and partial gastrectomy is reserved for tumors in the distal stomach. Despite increased morbidity and mortality, arguments in favor of an extended lymphadenectomy include the fact that the removal of a larger number of lymph nodes results in more accurate pathologic staging, and that failure to remove these lymph nodes leaves tumor

cells behind in as many as one-third of patients.⁶⁴

Anesthetic Considerations in Gastric Disease

Despite advances in medical therapy designed to inhibit acid secretion and to eradicate *H. pylori*, surgery remains an important strategy for managing these patients. Patients undergoing surgery for gastric disease are generally either acutely ill and requiring emergency surgery, as in the case of a bleeding gastric ulcer, or stable and requiring elective surgical treatment of gastric carcinoma or intractable ulcer disease. Many procedures are performed laparoscopically. Limitations to the laparoscopic approach include the risk of developing peritonitis and the risk of forming dense adhesions. Acutely ill patients are more likely to be hemodynamically unstable and dehydrated. Elective surgical patients may exhibit varying degrees of debilitation and anemia. Aspiration precautions are warranted in both groups during anesthesia.

Hypovolemia should be corrected with the administration of appropriate colloid, crystalloid, or blood products before the induction of anesthesia. Suggested laboratory tests include complete blood count, electrolytes, blood urea nitrogen, glucose, magnesium, calcium, phosphate, PT, and PTT. Other tests are performed based on history and physical examination. Preparations for the perioperative transfusion of blood products must be undertaken before anesthesia and surgery. Expect a moderate fluid shift with moderate to large fluid losses. Two large-bore IV catheters (14- to 16-gauge) are indicated.

Clinical anemia and coagulopathy should be corrected with packed red blood cells and appropriate blood products (e.g., FFP, cryoprecipitate, platelets). The use of invasive monitoring (i.e., through the use of a pulmonary artery catheter, CVP line, or arterial line) is determined by the presence of preexisting, age-related, or acquired compromise in the function of other organ systems. Potential postoperative complications include hemorrhage, hypovolemia, hypothermia, atelectasis, and ileus. A postoperative stay in the intensive care unit may be necessary, especially in the case of fluid shifts caused by peritonitis and the need for large-volume fluid resuscitation.

The anesthetic technique used in gastrectomy may include preoperative epidural catheter placement as an intraoperative adjunct and for use in postoperative analgesia. Procedures other than total and partial gastrectomy performed for gastric disease include the following:

- Billroth I (gastroduodenostomy): resection of the distal stomach with reconstruction via end-to-end gastroduodenostomy
- Billroth II (gastrojejunostomy): resection of the distal stomach with reconstruction via end-to-side gastrojejunostomy
- Laparotomy with oversewing of the ulcer and application of an omental patch

Vagotomy is usually performed for gastric ulcer surgery to decrease gastric acid secretion and to allow ulcer healing. The vagus nerve can be transected at the main vagal trunks (truncal), which interrupts transmission to the top of the stomach and other abdominal viscera, or selectively, so that only the gastric vagal nerves are interrupted. The anesthetic technique is general or laparoscopic; esophageal dilators are used to facilitate traction on the stomach. An NG tube is placed after induction.

Gastrostomy

Gastrostomy is the surgical placement of a permanent or temporary artificial opening into the stomach that exits the skin of the abdominal wall, for the purpose of gastric decompression and nutritional support. Patients who require placement of a gastrostomy tube (permanent or temporary) are often neurologically incapacitated or otherwise markedly debilitated, and are likely to have compromised command of their airway reflexes. This, along with the need to insufflate the stomach, places the patient at greater risk for aspiration.

Gastrostomy placement is performed percutaneously at the bedside, in the endoscopy suite, or in the operating room. Endoscopic guidance is used with percutaneous placement of the gastrostomy tube. Any tube feedings should be stopped at least 8 hours prior to the procedure. A bite block should be used. As a primary procedure, gastrostomy placement is commonly undertaken with sedation and local anesthesia at the incisional site

and in the back of the throat. General endotracheal anesthesia is indicated in patients who require laparotomy in conjunction with endoscopic placement, and in those for whom percutaneous placement under local anesthesia with sedation may be contraindicated (e.g., the comatose patient). If general anesthesia is used, the ETT may need to be held as the surgeon inserts and withdraws the gastroscope.

Pancreatic Disease

Physiologic Overview

The pancreas is approximately 20 cm long; its head is tucked into the curve of the duodenum, and its tail touches the spleen. The body of the pancreas lies behind the stomach. The pancreas functions in both an exocrine digestive enzyme and endocrine hormonal capacity.

The exocrine functions of the pancreas include protein secretion and electrolyte secretion. The exocrine function of the pancreas is primarily the continuous transductal secretion of 2.5 L of clear, colorless, bicarbonate-rich (pH 8.3) pancreatic juice per day. The ionic composition consists largely of sodium, potassium, bicarbonate, and chloride, with smaller concentrations of phosphate, sulfate, zinc, and calcium. The principal function of pancreatic juice is duodenal alkalinization to promote the optimal activity of pancreatic enzymes.

The arrival of acidic chyme (partially digested gastric contents) into the duodenum and jejunum stimulates the release of the hormones cholecystokinin-pancreozymin (CCK-PZ) and secretin. Both hormones are produced in the duodenum, jejunum, and ileum. Secretin causes the pancreas to release bicarbonate and water, and CCK-PZ, released in response to the presence of fats and partially digested proteins in the duodenum, stimulates secretion of the pancreatic enzymes necessary for further intestinal digestive processes. Trypsinogen, which is produced by pancreatic cells, is converted to the active enzyme trypsin in response to the release of enterokinase by the gastric mucosa. Trypsin is responsible for the conversion of large ingested proteins into smaller peptides and amino acids in preparation for intestinal absorption.³⁵ The major pancreatic enzyme groups are listed in [Table 33.9](#).

TABLE 33.9

Major Pancreatic Enzyme Groups*

Enzyme Group	Enzyme, Proenzyme, or Precursor
--------------	---------------------------------

Proteolytic	Trypsinogen (trypsin), chymotrypsinogen (chymotrypsin), procarboxypeptidase A (carboxypeptidase A), procarboxypeptidase B (carboxypeptidase B), proaminopeptidase (aminopeptidase), proelastase (elastase)
Amylolytic	α -Amylase
Lipolytic	Lipase, phospholipase A ₂ (phospholipase A ₂), carboxylesterase lipase, procolipase (colipase)
Nucleolytic	Deoxyribonuclease, ribonuclease
Other	Trypsin inhibitor

*Precursor molecules are listed, with products in parentheses.

Secretion of the aqueous and enzymatic components of pancreatic juice is controlled by hormonal and parasympathetic stimuli. Administration of vagolytic agents (e.g., atropine, glycopyrrolate) or ganglionic blocking agents, along with physical interruption of the vagus nerve, may induce a decreased response to secretin. Vagotomy has also been shown to result in a decrease in the release of pancreatic bicarbonate in response to duodenal acidity.

The endocrine function of the pancreas consists primarily of regulation of plasma glucose levels through the release of glucagon and insulin. Pancreatic endocrine cells reside in the islets of Langerhans, and the adult human pancreatic islet contains multiple cell types: the A (alpha) cell secretes glucagon, the B (beta) cell secretes insulin, the D (delta) cell secretes somatostatin (growth hormone–releasing inhibitory factor, which is responsible for controlling plasma levels of insulin, glucagon, and gastrin), whereas the D₂ (delta-2) cell secretes vasoactive intestinal peptide (VIP), and the PP (or F) cell secretes pancreatic polypeptide (PP).⁶⁵ The chief physiologic function of the endocrine pancreas might be starkly summarized as regulation of body energy (a role largely achieved by hormonal control of carbohydrate metabolism). Simply stated, insulin is the hormone responsible for energy storage, and glucagon is the hormone responsible for energy release. Insulin promotes energy storage by decreasing blood glucose levels, increasing protein synthesis, decreasing glycogenolysis, decreasing lipolysis, and increasing glucose transport into cells (except for beta cells, hepatocytes, and central nervous system cells). Glucagon promotes energy release by increasing blood glucose levels through the stimulation of glycogenolysis, gluconeogenesis, and lipolysis.

α -Adrenergic sympathetic stimulation has been shown to inhibit insulin secretion. β -Adrenergic sympathetic and cholinergic

blockade are inhibitory to insulin secretion as well. Arterial hypoxemia, hypothermia, traumatic stress, and surgical stress all suppress insulin secretion through α -adrenergic stimulation. Insulin secretion is enhanced by parasympathetic vagal stimulation, β_2 -adrenergic sympathetic activation, and cholinergic drug administration.

Anesthetic considerations in patients with abnormalities in pancreatic endocrine function (such as diabetes mellitus) are outside the scope of this chapter. The present discussion is directed toward anesthetic considerations germane to patients with inflammatory or neoplastic disease of the pancreas.

Acute Pancreatitis

The cause of pancreatitis is multifactorial. Common causes include alcohol abuse, direct or indirect trauma to the pancreas, ulcerative penetration from adjacent structures (e.g., the duodenum), infectious processes, biliary tract disease, metabolic disorders (e.g., hyperlipidemia and hypercalcemia), vascular and autoimmune causes, toxic causes, and certain drugs (e.g., corticosteroids, furosemide, estrogens, and thiazide diuretics). In industrialized nations, 80% of acute pancreatitis cases are caused by alcohol abuse or gallstones. Although 35% to 40% of attacks are induced by gallstones, only 3% to 7% of patients with gallstones develop pancreatitis. The incidence of gallstone pancreatitis is increased in white females older than 60 and is highest among patients with small gallstones (less than 5 mm in diameter). Severe acute pancreatitis (SAP) is associated with organ failure, local complications, prolonged intensive care stay, and mortality rates greater than 25%. In patients with SAP, multiple organ dysfunction syndrome (MODS) is the main cause of death.⁶⁶

Patients who have undergone extensive surgery involving mobilization of the abdominal viscera are at risk of developing postoperative pancreatitis, as are patients who have undergone procedures involving cardiopulmonary bypass. Patients who have received large doses of calcium intraoperatively, particularly after cardiopulmonary bypass, have also been shown to be at risk of developing postoperative pancreatitis.^{67,68} Hypothetically, the

pathophysiologic mechanism for the development of postoperative pancreatitis may involve an induced autodigestion syndrome. In fact, acute pancreatitis is characterized as a severe chemical burn of the peritoneal cavity.

It is generally believed that acute pancreatitis is triggered by obstruction of the pancreatic duct, and that the injury begins within pancreatic acinar cells. That injury is believed to include, and possibly be the result of, intraacinar cell activation of digestive enzyme zymogens, including trypsinogen. The pathophysiology of acute pancreatitis can be divided into three phases. The first phase is characterized by the premature activation of trypsin in acinar cells. The second phase is the inflammatory response of the pancreas, which is disproportionate to the response of other organs to a similar insult. In the third phase, systemic activation of the immune system and remote organ dysfunctions occur.⁶⁶ Aberrant activation or release of pancreatic enzymes or injury to the acinar cells caused by one or more of the aforementioned etiologic factors results in hemorrhage, edema, and necrosis of the pancreas.

Enzymes implicated as major culprits in pancreatitis are those activated by trypsin, enterokinase, and bile acids. These enzymes are necessary for proteolysis, elastolysis, and lipolysis. The inappropriate production of these enzymes results in pancreatic inflammation, which is caused by vascular breakdown, coagulation necrosis, fat necrosis, and parenchymal necrosis. Cardiovascular complications of acute pancreatitis can lead to pericardial effusion, alterations in cardiac rhythmicity, signs and symptoms mimicking acute myocardial infarction, thrombophlebitis, and cardiac depression. Acute pancreatitis also predisposes patients to the development of acute respiratory distress syndrome (ARDS) and disseminated intravascular coagulopathy.⁶

The pain of pancreatitis may be severe and difficult to control. Most patients require narcotic medications. Pancreatic pain may radiate from the midepigastic to the periumbilical region, and may be more intense when the patient is in the supine position. Abdominal distention is often seen, and is largely attributable to the accumulation of intraperitoneal fluid and paralytic ileus. Nausea, vomiting, and fever are common symptoms. Hypotension is seen in 40% to 50% of patients, and is attributable to hypovolemia

secondary to the loss of plasma proteins into the retroperitoneal space. Acute renal failure secondary to dehydration and hypotension may occur.

Immediate circulatory and electrolyte resuscitation restores the microcirculation and represents one of the most powerful and effective interventions, especially in patients with SAP. Fluid losses can be enormous, and can lead to marked hemoconcentration, as well as hypovolemia. Inadequate fluid resuscitation during the early stages of pancreatitis can worsen the severity of an attack and lead to subsequent complications. The fluid depletion that occurs in pancreatitis results from the additive effects of losing fluid both externally and internally. The external fluid losses are caused by repeated episodes of vomiting, and are worsened by nausea, which limits fluid intake. Repeated vomiting can result in hypochloremic alkalosis. Internal fluid losses, which are usually even greater than the external losses, are caused by fluid sequestration in areas of inflammation (i.e., the peripancreatic retroperitoneum) and in the pulmonary parenchyma and soft tissues elsewhere in the body. These latter losses result from diffuse capillary leakage, which is triggered by the release of proinflammatory factors during pancreatitis. Total fluid losses may be so great that they lead to hypovolemia and hypoperfusion, and metabolic acidosis can develop as a result.⁶⁹

In patients with SAP, the magnitude of the proinflammatory response correlates with the severity and concomitant course of disease. A simple predictive tool is C-reactive protein (CRP) levels. A CRP level exceeding 150 mg/L (an arbitrarily chosen cutoff level) within the first 72 hours correlates with the occurrence of necrotizing pancreatitis and the degree of severity.⁷⁰

During the first several days of a severe attack, circulating levels of many proinflammatory factors, including cytokines and chemokines, are elevated. In many cases, this so-called cytokine storm triggers the systemic immune response syndrome, and as a result, the hemodynamic parameters of these patients may resemble those of patients with sepsis associated with other disease states. The heart rate (HR), CO, and cardiac index usually rise, and total peripheral resistance falls. Hypoxemia also can occur as a result of the combined effects of increased intrapulmonary shunting and

pancreatitis-associated lung injury that closely resembles that seen in other forms of ARDS. Fluid management, although critical, may be particularly difficult when hypovolemia is combined with ARDS-related respiratory failure.⁶⁹

Severely ill, malnourished patients are often given parenteral nutritional support. Pain is controlled with synthetic opioids, such as fentanyl, which are preferable to morphine. Morphine-induced spasms of the sphincter of Oddi may exacerbate bile obstruction and stasis. Normeperidine, the metabolite of meperidine, causes analeptic activity and makes meperidine unattractive for pain management in these patients. Epidural analgesia may be appropriate in select patients⁶⁹

Patients with gallstone pancreatitis can be divided into two groups: those who have or have had gallbladder-derived problems (cholecystitis or biliary colic) and those whose only problems are purely related to stones in the biliary ductal system (i.e., cholangitis and pancreatitis). Patients in the first group undergo cholecystectomy to prevent additional gallbladder attacks and eliminate the source of stones that might trigger another attack of pancreatitis. Patients in the second group, however, do not necessarily require cholecystectomy, because their problem relates only to ductal stones. Theoretically, they could be treated simply by endoscopic stone clearance combined with endoscopic sphincterotomy, so that future stones are passed without becoming impacted in the ampulla and triggering either pancreatitis or cholangitis. Indeed, for patients with high surgical risk, the endoscopic approach is generally recommended. Patients with low surgical risk are better managed by cholecystectomy.

The choice of anesthetic technique and the extent to which monitoring modalities are used are based on assessment of the patient's history, the severity of disease, and the degree of preexisting physical compensation. Special attention should be paid to correcting significant intravascular volume deficits. The presence of labile hemodynamics and altered hepatic function must also be discerned, and appropriate modifications made to the anesthetic plan, for example, by ensuring stable arterial pressure, using anesthetic agents and adjuvants that require minimal hepatic biotransformation, ensuring adequate oxygenation, and replacing

electrolytes and blood volume.

Chronic Pancreatitis

Chronic pancreatitis is traditionally defined as having permanent and irreversible damage to the pancreas, with histologic evidence of chronic inflammation, fibrosis, and destruction of exocrine (acinar cells) and endocrine (islets of Langerhans) tissue. Chronic pancreatitis is believed to reflect repeated episodes of subclinical acute pancreatitis with unrecognized pancreatic necrosis evolving into pancreatic fibrosis.

The most common etiology of chronic pancreatitis is alcohol use (70% of cases), with the risk increasing logarithmically with increasing alcohol use. Other causes include tobacco use (increased risk of pancreatic calcifications), genetic mutation, autoimmune disease, and obstruction of the main pancreatic duct by tumors, scars, stones, or duodenal wall cysts.⁷¹

Chronic pancreatitis is strongly suggested by the classic diagnostic triad of steatorrhea, pancreatic calcification (evidenced radiographically), and diabetes mellitus. Steatorrhea does not occur until pancreatic lipase secretion is less than 10% of the maximum output. The most common clinical problem in chronic pancreatitis is abdominal pain causing loss of appetite that results in weight loss and malnutrition. The clinical picture may also include hepatic disease, as evidenced by jaundice, ascites, esophageal varices, and abnormalities in coagulation factor, serum albumin, and transferase levels. A disturbance in pancreatic exocrine function, with consequent enzymatic insufficiency, results in malabsorption of fats and proteins in the intestine. Patients with chronic pancreatitis also have a predisposition for pericardial and pleural effusions.⁶⁹

Many patients with chronic pancreatitis are alcoholics who, even before the onset of pancreatitis, had hypoalbuminemia and hypomagnesemia. Those problems are exacerbated by pancreatitis. The measured values for serum albumin may decrease even further as fluid losses are treated with albumin-free crystalloid solutions. Although hypocalcemia is common, particularly during a severe attack, the low total serum calcium is usually attributable to the low levels of circulating albumin, and no treatment is needed when ionized calcium levels are normal. Occasionally, however, ionized

calcium levels also may be depressed, and tetany as well as carpopedal spasm can occur. This necessitates monitoring the ECG for cardiac rhythm disorders (e.g., lengthened QT interval with possible reentry dysrhythmias). When cardiac rhythm disorders are present, aggressive calcium replacement is indicated.⁶⁹

Endocrine insufficiency is another consequence of chronic pancreatitis, and is especially common after pancreatic resection. Approximately half of all patients with chronic pancreatitis develop insulin-dependent diabetes. Unlike in type I diabetes, in patients with insulin-dependent diabetes, insulin-producing beta cells and glucagon-producing alpha cells are injured, leading to an increased risk of prolonged and severe hypoglycemia with overzealous insulin treatment.⁷¹

Pancreatic abscesses develop from the peripancreatic collection of fluids that become infected. Abscesses are usually secondary manifestations of chronic pancreatitis, and warrant surgical drainage to prevent the spread of infectious contents to the subphrenic and pericolic spaces. Fistula formation is possible, particularly into the transverse colon. Severe intraabdominal hemorrhage is also possible, as a result of erosion into major proximal arteries.

Pancreatic Pseudocysts

Most pseudocysts communicate with the pancreatic ductal system, and contain a watery fluid that is rich in pancreatic digestive enzymes. Typically, patients with pseudocysts have persistent elevation of circulating pancreatic enzyme levels. Many pseudocysts eventually resolve without complications, and intervention is not mandatory in all cases, unless the pseudocysts are symptomatic, enlarging, or associated with complications. The likelihood that a pseudocyst will resolve spontaneously, however, is dependent on its size. Large pseudocysts (i.e., greater than 6 cm in diameter) are more likely to become symptomatic, either because they are tender or because of their mass effect on adjacent organs. Those that compress the stomach or duodenum may cause gastric outlet obstruction with nausea and vomiting. Those that reduce the capacity of the stomach frequently cause early satiety, whereas those impinging on the bile duct can cause obstructive jaundice.

Pancreatic pseudocysts that erode into a neighboring vessel can result in formation of a pseudoaneurysm with *hemorrhage pancreatica* and upper GI bleeding.

Most patients who develop symptomatic pseudocysts are best managed by pseudocyst drainage. Internal drainage can be accomplished either endoscopically (by transpapillary drainage, cystogastrostomy, or cystoduodenostomy) or surgically (by cystogastrostomy, cystoduodenostomy, or Roux-en-Y cystojejunostomy). The approach chosen depends primarily on the locally available expertise and the location of the pseudocyst, but endoscopic drainage may be preferable in patients with high surgical risk.

Surgical Therapy for Pancreatitis

Depending on the cause of the pancreatitis, several surgical approaches can be used. Endoscopic therapy is used to improve drainage of the pancreatic duct. This can be done through pancreatic duct sphincterotomy, stent placement, or pancreatic duct stone removal (including extracorporeal shock wave lithotripsy). Open surgical therapy in chronic pancreatitis is most often considered for intractable abdominal pain for which medical therapy has failed, complications involving adjacent organs, failure of endoscopic management of pseudocysts, and internal pancreatic fistulas.

Surgical drainage of a pancreatic pseudocyst is usually undertaken after a period of maturation of the cyst (usually 6 weeks with acute pancreatitis). Pseudocysts with chronic pancreatitis are generally mature at the time of diagnosis, and delay is not necessary to allow for maturation. The procedure consists of the formation of a cystogastrostomy, cystojejunostomy, cystoduodenostomy, or possibly distal pancreatectomy. The location of the pseudocyst dictates the extent and type of procedure used for providing drainage of cystic contents into the GI tract. Percutaneous external drainage guided by CT is reserved for cases in which the pseudocyst is particularly friable.⁷²

Pancreatic Tumors

Pancreatic cancer affects 25,000 to 30,000 people in the United States each year, occurs more often in men than in women, and is more common among blacks than in whites. The population most commonly associated with pancreatic cancer is between 60 and 80 years of age (80%), whereas less than 2% of cases occur in people younger than 40 years. Other risk factors include a family history of pancreatic cancer or a history of either hereditary or chronic pancreatitis, cigarette smoking, and occupational exposure to carcinogens. The incidence of diabetes mellitus is increased in patients with pancreatic cancer; some studies have indicated that diabetes is a risk factor for the development of pancreatic cancer, whereas others have argued that diabetes may be a manifestation of the cancer. Coffee drinking, which was once considered a risk factor, is no longer thought to play a role in the development of pancreatic cancer.⁶⁹

Eighty to ninety percent of all pancreatic tumors can be accounted for by ductal adenocarcinomas, and an even greater percentage of the malignant tumors are ductal adenocarcinomas. Most ductal cancers (70%) arise in the pancreatic head or in the uncinate process. They are generally resected by pancreaticoduodenectomy, with or without preservation of the pylorus and proximal duodenum. Ductal cancers originating in the body or tail of the pancreas are often larger, and are more likely to have spread before their presence is known.⁶⁹

Pancreatic cancers are insidious tumors that can be present for long periods and grow extensively before they produce symptoms. Once symptoms appear, they are determined by the location of the tumor in the pancreas. Those in the head or uncinate process of the pancreas cause bile duct, duodenal, or pancreatic duct obstruction. Because the head of the pancreas is most often the locus of the tumor, biliary obstruction is likely, resulting in progressive painless jaundice. The patient may have vague and nonspecific symptoms that include dull, aching, midepigastic or back pain. Anorexia and fatigue are often present, and are associated with weight loss. Other symptoms include unexplained episodes of pancreatitis, nausea, vomiting, and steatorrhea. If the tumor spreads beyond the pancreas, peripancreatic nerve plexuses may cause abdominal or back pain. In the presence of peritoneal carcinomatosis or portal

vein occlusion, ascites may occur. New-onset diabetes mellitus is occasionally the first symptom of an otherwise occult pancreatic cancer. Recent studies have suggested that this form of diabetes may be mediated by a factor released from the tumor that either inhibits insulin release from islets or induces peripheral insulin resistance. Unexplained migratory thrombophlebitis (Trousseau syndrome) may be associated with pancreatic cancer and other types of malignancy. It is probably a paraneoplastic phenomenon that results from a tumor-induced hypercoagulable state.⁶⁹

Laboratory studies usually show elevated bilirubin and alkaline phosphatase levels. Radiographic evidence is generally nonspecific; needle biopsy during CT is most helpful in making a diagnosis. Percutaneous transhepatic cholangiography and ERCP are useful diagnostic modalities. ERCP is the most useful modality for defining lesions in the body and tail of the pancreas, or in the duodenum or ampulla.⁷³

Insulinoma is the most common functioning tumor of the pancreas, and affected patients have a multitude of symptoms attributable to hypoglycemia, including seizures and coma (symptoms of catecholamine release), mental confusion and obtundation. . Hypersecretion of insulin is a major manifestation of this disease, and results in profound hypoglycemia. The diagnostic hallmark of the syndrome is the so-called Whipple triad, namely: hypoglycemia (catecholamine release), low blood glucose (40–50 mg/dL), and relief of symptoms after the IV administration of glucose.

Insulinoma is treated surgically, by either an open or a laparoscopic approach (except in patients with advanced metastatic disease), and involves distal pancreatectomy, subtotal pancreatectomy, or removal of all but a small portion of pancreatic tissue around the rim of the duodenum (Child procedure).⁷³

If neoplastic disease is determined to be respectable, that is, without involvement of mesenteric vessels or infiltration into the mesenteric arterial root or hepatobiliary structures, a pancreaticoduodenectomy (Whipple procedure) may be performed. This procedure involves excision of the head of the pancreas, the entire duodenum, the proximal portion of the jejunum, the distal third of the stomach, the gallbladder, and the distal half of the CBD.

A Whipple procedure also can be performed for malignancies of the CBD, traumatic injury to the pancreas, or benign obstructive chronic pancreatitis.⁷⁴

Zollinger-Ellison syndrome (ZES; gastrinoma), a neoplasm primarily arising from the duodenum, results in the release of overabundant quantities of gastrin, which leads to the secretion of massive quantities of hydrochloric acid from the parietal cells. This condition is associated with severe, intractable ulcer pain. If other endocrine neoplasias are present (i.e., thyroid or parathyroid adenoma, pituitary adenoma, insulinoma), the condition is referred to as *multiple endocrine neoplasia type I*.

Omeprazole therapy is so effective in these cases that surgery is performed only for tumor removal. Every patient with ZES is a candidate for a tumor removal operation until proved otherwise because of systemic illness or widespread metastases. Although gastrinomas have a high rate of malignancy, they are more apt to be cured than cancer of any other abdominal viscera. During anesthetic induction for gastrinoma excision, a rapid sequence technique is recommended because of the likelihood of a large volume of stagnant, acidic intragastric fluid. Electrolyte and intravascular volume abnormalities (e.g., from severe diarrhea) should be anticipated and corrected before surgery. Attention should also be given to intraoperative monitoring of electrolyte and fluid balances. Hypokalemia and metabolic alkalosis are likely to be present if the patient has been vomiting and is dehydrated. Furthermore, preparations for the treatment of patients with known or suspected abnormalities in endocrine function must be included in the anesthetic plan, to include blood glucose monitoring, vigilance for and timely correction of swings in vital signs and physiologic parameters, maintenance of normothermia and normocarbica, maintenance of an appropriately anesthetized state, and maintenance of renal function.³⁵

Gastrinoma is the second most common islet cell tumor, and is the most common symptomatic, malignant endocrine tumor of the pancreas. That being said, the current data indicate that gastrinomas are three to ten times more common in the duodenum than in the pancreas, and although up to 70% of duodenal gastrinomas have lymph node metastases, only 5% have liver

metastases. Although gastrinomas have a high rate of malignancy, they are more apt to be cured than cancer of any other abdominal viscera.

Anesthetic Considerations in Pancreatic Disease

The patient undergoing surgical treatment of pancreatic disease exhibits a variable clinical picture, from jaundiced and stable with a painless pancreatic mass to severely ill with multiorgan system involvement. Patients may have severe, acute abdominal pain with possible intestinal obstruction or ileus. Aspiration precautions should be in effect during induction of anesthesia and emergence from anesthesia, and an NG tube should be placed after induction. Because these patients are likely to be diabetic (secondary to beta-cell dysfunction) or hypoglycemic (as in the case of insulinoma), perioperative assessment of serum glucose and institution of appropriate control measures are warranted. Patients with pancreatitis are usually hypotensive and hypovolemic. As such, aggressive blood product and crystalloid resuscitation may be necessary throughout the perioperative period, and likely will necessitate placing invasive hemodynamic lines to guide therapy and monitor central pressures.

Severe electrolyte disorders may be present, and include hypocalcemia, hypomagnesemia, hypokalemia, and possibly hypochloremic metabolic alkalosis. The serum hematocrit value may be falsely increased secondary to hemoconcentration, or it may be decreased secondary to the presence of a bleeding diathesis. Coagulation parameters, including platelet count, PT, aPTT, and fibrinogen levels, should be assessed at regular intervals perioperatively. Preserving renal function mandates the preoperative assessment of blood urea nitrogen, serum creatinine, and 24-hour creatinine clearance (if possible); urinalysis also should be performed. Intraoperatively, a urine output of at least 0.5 to 1 mL/kg/hr should be maintained.

Thorough assessment of preexisting pulmonary status is vital. Pleural effusions, ventilation/perfusion (\dot{V}/\dot{Q}) mismatching, and atelectasis may occur, and can progress to respiratory failure. A

significant incidence of postoperative respiratory morbidity is associated with upper abdominal surgery, especially in association with a preoperative debilitated state and splinting secondary to pain. Pulmonary assessment includes arterial blood gas analysis, chest radiography, and pulmonary function tests, when appropriate.

Cardiovascular assessment should assimilate related findings from the assessment of other organ systems so that the degree to which functional hemodynamic impairment may need to be corrected is fully appreciated. Correction of preexisting hemodynamic disturbances entails restitution of plasma volume and the oxygen-carrying capacity of the blood. Ischemic changes noted on the ECG must be treated promptly. ECG changes mimicking myocardial ischemia are often seen in patients with pancreatitis.³⁵

The celiac plexus transmits visceral afferent impulses from the upper abdominal organs, including the pancreas. Celiac plexus block may be performed in patients with chronic pancreatitis, but its effects are short-lived. A combination of glucocorticoid and long-acting local anesthetic such as bupivacaine are commonly used. Celiac plexus neurolysis also may be performed by injecting absolute alcohol under CT or ultrasound guidance.⁷¹

Pancreatectomy

Pancreatectomy is performed for a variety of reasons, including ductal obstruction, pancreatic stones or cysts, trauma, benign or malignant tumors, chronic pancreatitis, and endocrine tumors. Complete surgical excision is the only definitive treatment of ductal pancreatic cancer.

In a partial pancreatectomy, part of the pancreas, the duodenum, the gallbladder, and part of the bile duct are removed. The tail of the pancreas is joined to a portion of the small bowel. In a total pancreatectomy, the distal portion of the stomach, the gallbladder, part of the bile duct, the spleen, and the surrounding lymph nodes are removed. The remaining distal portion of the stomach is reanastomosed to a portion of the small intestine.⁷⁴

General endotracheal anesthesia is preferred for pancreatectomy, and muscle relaxants are used. The presence of increased IAP

requires a rapid sequence induction. The use of nitrous oxide should be avoided, due to the expansion of air-filled spaces in the bowel. An epidural at the T9 to T10 level is advised for postoperative pain control, as it seems to improve the surgical outcome.⁷⁵ An even better choice may be the use of intrathecal morphine. One study also showed that the use of intrathecal morphine for major hepato-pancreato-biliary surgery is associated with a lower incidence of postoperative hypotension, reduced perioperative IV fluid requirement, and shorter hospital stays compared with thoracic epidural anesthesia.⁷⁶

Patients undergoing extensive pancreatic surgery often require postoperative ventilatory support and intensive care unit monitoring because of the magnitude and length of the procedure, as well as the their preexisting cardiopulmonary status.³⁵ Pancreatic transplants are discussed in detail in [Chapter 41](#).

Diseases of the Intestinal Tract

Anatomic and Physiologic Overview of the Small Intestine

The overall length of the small intestine is between 5 and 7 m long; it extends from the pylorus to the ileocecal valve. The small intestine is divided into three functional anatomic and physiologic segments. The first segment, the duodenum, begins at the pylorus and has a length of approximately 20 cm. The duodenum joins the second segment, the jejunum, which has a length of approximately 100 to 110 cm, at a suspensory ligament called the *ligament of Treitz*. The third and longest segment of the small intestine is the ileum, which has a length of approximately 150 to 160 cm and ends at the ileocecal valve. The jejunum has a larger lumen and is thicker than the ileum, with a less extensive blood supply (one or two vascular networks versus four or five in the ileum).⁷⁷

The mesentery, which is rich in lymphatic vessels and blood vessels, is a peritoneal membrane that tethers the ileum and jejunum to the posterior abdominal wall and facilitates intestinal motility. Branches of the superior mesenteric artery provide the primary arterial supply to the jejunum, the ileum, and the proximal transverse colon. Venous drainage is primarily furnished by the superior mesenteric vein. This vessel joins the splenic vein posterior to the pancreas, and empties into the portal circulation to the liver. Lymphatic drainage from the bowel wall originates from the central bowel wall lacteal, continues through the superior mesenteric nodes into the cisterna chyli and ultimately drains into the thoracic duct.

The wall of the small intestine is composed of the mucosa, the submucosa, the muscular layer (muscularis), and the serosa. The outermost serosal layer is composed of visceral peritoneum. This layer is formed in the jejunum, the ileum, and the anterior duodenum, and is analogous to the pericardium and pleura that surround the heart and lungs, respectively. There is a fluid-containing space between the visceral peritoneum and the parietal peritoneum that lubricates organ movement. The muscular layer is made up of an outer longitudinal layer and a thin circular layer of

smooth muscle, both of which are continuously present along the length of the small intestine. The Auerbach (myenteric) plexus, which primarily controls gross GI motility, lies between the two muscular layers. The strongest component of the bowel wall is the submucosa, which consists of fibroelastic connective tissue. Within it lies the Meissner plexus, which controls local blood flow and GI secretions. The innermost layer, the mucosa, is composed of transverse folds with millions of villi. These intraluminal projections are the functional units of the intestines, and greatly increase the absorptive surface.

The mucosa is further subdivided into three distinct layers:

1. *Muscularis mucosae*. The deepest layer, composed of a thin muscular sheet.
2. *Lamina propria*. A continuous connective tissue layer between the muscularis mucosae and the epithelium. This layer serves as a support epithelium and immunogenic barrier. Constituents of this layer include plasma cells (which produce immunoglobulins), macrophages, and lymphocytes.
3. *Epithelial layer*. Covers the villi and lines the Lieberkühn crypts. The functional units of the intestines, villi, contain goblet (mucus-secreting), absorptive, and endocrine cells. The villi also secrete enzymes that are necessary for digestion and useful for nutrient absorption. Cell turnover takes 3 to 7 days.

The intestinal mucosa provides a barrier to pathogen entry. The lamina propria provides a rich reservoir of IgA (the secretory immunoglobulin) and plasma cells (responsible for IgA synthesis). IgA antigen binding initiates mucus secretion, which prevents intestinal bacterial and viral uptake. Furthermore, IgA binds with, disables, and facilitates enzymatic destruction of bacteria. Binding with and preventing the entry of toxins is another role of IgA. Lymphocytes, which are instrumental in the elaboration of a specific antibody to a given antigen, are found in Peyer patches, which are located in the intestinal wall.⁷⁸

An additional function of the small intestinal mucosa is the production of a rich supply of hormones that regulate GI function

(Table 33.10).

TABLE 33.10
Gastrointestinal Hormones

Hormone	Location	Major Stimulants of Peptide Secretion	Primary Effects	Diagnostic and Therapeutic Uses
Gastrin	Antrum, duodenum (G cells)	Peptides, amino acids, antral distention, vagal and adrenergic stimulation, gastrin-releasing peptide (bombesin)	Stimulates gastric acid and pepsinogen secretion; stimulates gastric mucosal growth	Gastrin analog (pentagastrin) used to measure maximal gastric acid secretion
Cholecystokinin (CCK)	Duodenum, jejunum (I cells)	Fats, peptides, amino acids	Stimulates pancreatic enzyme secretion; stimulates gallbladder contraction; relaxes sphincter of Oddi; inhibits gastric emptying	Biliary imaging of gallbladder contraction
Secretin	Duodenum, jejunum (S cells)	Fatty acids, luminal acidity, bile salts	Stimulates release of water and bicarbonate from pancreatic ductal cells; stimulates bile flow and alkalinity; inhibits gastric acid secretion and motility and inhibits gastrin release	Provocative test for gastrinoma; measurement of maximal pancreatic secretion
Somatostatin	Pancreatic islet (D cells), antrum, duodenum	Gut: Fats, proteins, acid, other hormones (e.g., gastrin, CCK) Pancreas: Glucose, amino acids, CCK	Universal "off" switch; stimulates release of all GI secretion and motility; stimulates gastric acid secretion and release of antral gastrin; stimulates growth of intestinal mucosa and pancreas	Treatment of carcinoid diarrhea and flushing; decreases secretion from intestinal fistulas (particularly pancreatic fistulas); ameliorates symptoms associated with hormone-overproducing endocrine tumors; treatment of esophageal variceal bleeding
Gastrin-releasing peptide (mammalian equivalent of bombesin)	Small bowel	Vagal stimulation	Universal "on" switch; stimulates release of all GI hormones (except secretin); stimulates growth of intestinal mucosa and pancreas	
Gastric inhibitory polypeptide	Duodenum, jejunum (K cells)	Glucose, fats, protein adrenergic stimulation	Inhibits gastric acid and pepsin secretion; stimulates pancreatic insulin release in response to	

			hyperglycemia	
Motilin	Duodenum, jejunum	Gastric distention, fats	Stimulates upper GI tract motility; may initiate the migrating motor complex	
Vasoactive intestinal peptide	Neurons throughout the GI tract	Vagal stimulation	Primarily functions as a neuropeptide; potent vasodilator	
Neurotensin	Small bowel (N cells)	Fats	Stimulates pancreatic and intestinal secretion; inhibits gastric acid secretion; stimulates growth of small and large bowel mucosa	
Enteroglucagon	Small bowel (L cells)	Glucose, fats	Glucagon-like peptide-1: stimulates insulin release; inhibits pancreatic glucagon release; Glucagon-like peptide-2: potent enterotropic factor	
Peptide YY	Distal small bowel, colon	Fatty acids, CCK	Inhibits gastric and pancreatic secretions; inhibits gallbladder contraction	

CCK, Cholecystokinin; GI, gastrointestinal.

Both divisions of the autonomic nervous system innervate the small intestine, but innervation is primarily parasympathetic through the vagus nerve and celiac ganglia. Parasympathetic stimulation is responsible for pain sensation, increased motility, secretion, and intestinal reflexes (e.g., related to the LES). Splanchnic nerves from the celiac plexus provide sympathetic innervation; activation of these nerves inhibits motility and produces vasoconstriction. Sympathetic nerve tracts are also responsible for carrying afferent pain impulses. Intrinsic motor innervation is mediated by the myenteric plexus (Auerbach plexus) and the submucosal plexus (Meissner plexus). The enteric nervous system also plays an important role in the GI tract. The enteric nervous system is the network of neurons found within the walls of the GI tract, including neurons in the pancreas and gallbladder. The enteric nervous system contains as many nerve cells as the spinal cord, and is unique in its extraordinary degree of local autonomy. The high degree of local autonomy allows digestion and peristalsis to continue in the event of spinal cord transection or spinal

anesthesia. Spinal anesthetic inhibition of sympathetic preganglionic fibers from T8 through L3 yields a contracted small intestine that may afford superior surgical conditions.

The intestinal inhibitory reflex responds to abnormal distention by decreasing motility proximal to the locus of distention. This reflex may have significant indirect clinical implications (e.g., aspiration risk).⁷⁸ The arrival of chyme from the stomach stimulates intestinal movements that mix secretions from the liver, pancreas, and intestinal glands. A basic electrical rhythm in the longitudinal smooth muscle layer initiates action potentials in the circular muscular layers of the small intestine. This activates the muscular contractions that constitute small bowel motility. Segmental contractions mix chyme with digestive enzymes and expose it to the villi's absorptive surfaces, and peristaltic (propulsive) contractions move chyme toward the large intestine.

Malabsorption Syndromes

The two most important goals of the small intestine are to efficiently absorb nutrients and to maintain the movement of chyme and indigestible substances along the small intestine.

Approximately 85% to 90% of the water entering the GI tract is absorbed in the small intestine. Malabsorption syndromes interfere with nutrient absorption in the small intestine through mucosal disruption. Numerous disorders of the small intestine manifest as abnormalities in absorption. Primary clinical signs include unexplained weight loss, steatorrhea, and diarrhea. These disorders affect the absorption of the major constituents of ingested nutrients, including amino acids, carbohydrates, and fats.⁶

Fat malabsorption results in deficiencies in the uptake of fat-soluble vitamins (vitamins A, D, E, and K). Vitamin K deficiency manifests as hypoprothrombinemia. This condition is often evidenced through bleeding dyscrasias. Vitamin B₁₂ deficiency results in anemia (which may also be encountered in patients with impaired iron absorption), neuropathy, and glossitis. Protein malabsorption may result in the development of peripheral edema and ascites. Tetany, osteomalacia, and pathologic fractures result from calcium deficiency caused by vitamin D malabsorption and

calcium malabsorption because fatty acids bind calcium. In the setting of steatorrhea, pancreatic replacement enzymes are often effective in decreasing fat loss.⁵⁸

The cause of malabsorption syndromes is multifactorial. The basic underlying defect is either disruption of intestinal mucosal integrity, such as from a disease processes, or loss of absorptive surface area caused by extensive surgical resection of the small intestine (i.e., short gut syndrome). The particular part of the small bowel that is resected and the amount that is removed have a significant bearing on the degree to which deficiencies in minerals, vitamins, and electrolytes are clinically manifested, and are of particular concern to the anesthetist.

Maldigestion Syndromes

Maldigestion syndromes are generally caused by failure of the chemical digestive processes take place in the intestinal lumen or at the brush border of the intestinal mucosa. The most common causes include pancreatic deficiency, lactase deficiency, or bile salt deficiency. Diseases that are more likely to result in malabsorption syndromes (failure to absorb and transport digested nutrients) differ from those that are responsible for maldigestion (failure of the chemical digestive process). The hallmark of maldigestion is steatorrhea. Significant pancreatic disease is usually present when a maldigestion syndrome exists, because the pancreas has a large functional reserve in both normal and disease states. Chronic pancreatitis is the major and most common cause of pancreatic insufficiency. Cystic fibrosis, fistulas, gallstones, ischemic enteritis, and neoplastic disease processes, however, are also etiologic factors.⁷⁸

Anatomic and Physiologic Considerations of the Large Intestine

The large intestine is approximately 3 to 5 ft. long, consists of the cecum, appendix, colon, rectum, and anal canal, and may be recognized not only by its size and position, but also by the presence of three strips of longitudinal muscle called *teniae coli* and the numerous outpouchings (haustrations) formed by the circular

muscles of the colon. The arterial supply comprises the superior mesenteric artery (which perfuses the right side of the midtransverse colon), the inferior mesenteric artery (which perfuses the midtransverse colon to the superior rectum), and the internal iliac artery (which perfuses the middle and lower rectum). Venous drainage parallels arterial drainage, with the middle and superior veins contributing to the portal venous system. The myenteric plexus regulates motor and secretory activity independently of the extrinsic system. Sympathetic innervation is derived from T10 to T12 (right colon), L1 to L3 (left colon), and the presacral nerves arising within the preaortic plexuses (rectum). Parasympathetic innervation is primarily from the vagus nerve (right and transverse colon) and from nerve fibers arising from S2 to S4 (descending colon, sigmoid colon, and rectum). A rich endowment of lymphatics is present throughout the length of the colon and rectum.³⁵

The primary function of the large colon is to store and expel waste products. Approximately 500 to 700 mL of chyme are delivered from the ileum to the cecum each day. Another function performed largely in the right colon is the absorption of sodium and water. All but 100 to 200 mL of the 1 to 2 L of ileal effluent presented to the large colon per day is reabsorbed through diffusion and active transport.

Sodium absorption occurs through active transport against a gradient, and is enhanced by minerals, corticoids, glucocorticoids, and fatty acids that are produced by indigenous bacteria. Conservation of sodium is so efficient in the large colon that a normal individual may require only 5 mEq/day in order to maintain a sodium balance. However, a patient presenting with an ileostomy necessitates a greater intake of sodium (80–100 mEq/day) to approximate the high sodium content lost as ileal effluent. The loss of the normal colonic reabsorption of sodium chloride and water (e.g., after colectomy) may eventually exceed the small intestine's compensatory capacity to increase absorption, and clinical abnormalities in electrolyte balance follow.

Potassium is passively absorbed and secreted across the electrochemical gradient, whereas chloride is absorbed as the complementary ion to sodium and in exchange for bicarbonate.

Potassium is lost through passive diffusion in the colonic mucoid secretions. Significant potassium loss is likely to occur, therefore, in the presence of colitis and villous adenoma, two disease processes notable for mucoid stools.

Inflammatory Bowel Disease

In the United States, approximately 1.17 million individuals have inflammatory bowel disease, and approximately 30,000 new cases are diagnosed each year. The two major types of inflammatory bowel disease are Crohn's disease and ulcerative colitis (UC), which have different clinical features and manifestations (Table 33.11).

TABLE 33.11

Diagnosis of Crohn's Colitis Versus Ulcerative Colitis

Observation	Crohn's Colitis	Ulcerative Colitis
Symptoms and Signs		
Diarrhea	Common	Common
Rectal bleeding	Less common	Almost always
Abdominal pain (cramps)	Moderate to severe	Mild to moderate
Palpable mass	At times	No (except for large tumors)
Anal complaints	Frequent (> 50%)	Infrequent (< 20%)
Radiologic Findings		
Ileal disease	Common	Rare (backwash ileitis)
Nodularity, fuzziness	No	Yes
Distribution	Skips areas	Rectum, extending upward and continuously
Ulcers	Linear, cobblestone, fissures	Collar-button
Toxic dilation	Rare	Uncommon
Proctoscopic Findings		
Anal fissure, fistula, abscess	Common	Rare
Rectal sparing	Common (50%)	Rare (5%)
Granular mucosa	No	Yes
Ulceration	Linear, deep, scattered	Superficial, universal

Adapted from Mahmoud NN et al. Colon and rectum. In Townsend CM, et al., eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia: Elsevier; 2017.pg 1339.

Crohn's disease can involve any part of the GI tract from the mouth to the anus, but it most commonly affects the distal ileum and the proximal large colon. Th1-mediated inflammation with activation of leukocytes and cytokines causes injury. The involved leukocytes release proinflammatory substances including

prostaglandins, leukotrienes, proteases, and nitric oxide, with resulting injury. Progression of the disease leads to neutrophil infiltration of the crypts, with resulting abscess formation and crypt destruction. Symptoms of Crohn's disease may initially be described as irritable bowel. Abdominal pain and diarrhea are the most common signs (more than five stools per day), with passage of blood and mucus. If the ileum is involved, patients may have right lower quadrant tenderness, and individuals may be anemic due to decreased vitamin B₁₂ absorption.

The deeper layers of the intestinal mucosa are typically involved, a situation that leads to derangements in colonic absorption. Owing to the loss of functional absorptive surfaces in the large colon, patients with Crohn's disease are often deficient in magnesium, phosphorus, zinc, and potassium. They also have deficiencies secondary to the loss of absorptive capability in portions of the small intestine. Protein-losing enteropathy is often encountered, as is anemia resulting from occult blood loss and deficiencies in vitamin B₁₂ and folic acid. Disturbances in the enterohepatic circulation of bile in the terminal ileum are reflected in complex nutrient deficiencies, including deficiencies in proteins, zinc, magnesium, phosphorus, fat-soluble vitamins, calcium (leading to bone disease), and vitamin B₁₂. This state is typical of patients with chronic Crohn's disease. Folate deficiency may also be present in patients who receive sulfasalazine preparations.

Fistulas often develop between inflamed portions of the intestine and adjacent abdominal structures. There is a high incidence of abdominal and pelvic abscesses, rectocutaneous fistulas, and perirectal abscesses in these patients. Increased calcium oxalate absorption in the terminal ileum frequently occurs, resulting in a high rate of renal calculi and cholelithiasis.^{79,80} Medical therapy for Crohn's disease includes a variety of drugs, as shown in [Box 33.9](#).

Agents Used to Treat Crohn's Disease

5-Aminosalicylate Acids (5-ASAs)

- Sulfasalazine
- Sulfa-free (mesalamine, olsalazine, balsalazide)

Antibiotics

- Metronidazole
- Ciprofloxacin

Glucocorticoids

- Classic
- Novel (controlled ileal-release budesonide)

Immune Modulators

- 6-Mercaptopurine, azathioprine
- Methotrexate
- Cyclosporine

Biologic Response Modifiers

- Infliximab
- Adalimumab
- Certolizumab pegol
- Natalizumab

Adapted from Sands BE, Seigel CA. Crohn's disease. In Feldman M, et al., eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 10th ed. Philadelphia: Elsevier; 2016:2011-2012.

Surgery is performed when medical treatment fails or when complications supervene. Although effective in relieving complications, surgical resection of the diseased colon and ileum does not alter the progression of the disease. The primary goal of surgical management is to limit the operation to correcting the presenting complication, which could include bowel obstruction,

fistulas, abscesses, perforation, and symptoms that indicate widespread symptomatic disease (for which total colectomy and ileal resection may be warranted). Surgical resection of small intestinal segments can lead to short bowel syndrome, with accentuated complications of malabsorption, diarrhea, and nutritional deficiencies.

Most patients with Crohn's disease eventually undergo surgery, and a large number require repeat or continued procedures. The recurrence rate at 10 years after surgery is 50%. A high likelihood of repeat surgery involves areas of the remaining bowel proximal to the area of a previous anastomosis. Patients with a long history of Crohn's disease are also shown to have a higher risk of intestinal carcinoma.⁸¹

UC is a chronic inflammatory disease that causes ulceration of the colonic mucosa and extends proximally from the rectum into the colon. It is a disease characterized by remissions and exacerbations. UC is more prevalent in females and whites, and has a peak incidence between ages 20 and 40. It is speculated that there is a strong genetic predisposition to the disorder, but psychological factors have also been implicated. UC lesions are limited to the mucosa, and are not transmural. Inflammation begins at the crypt of Lieberkühn, with the infiltration and release of inflammatory cytokines from neutrophils, lymphocytes, plasma cells, macrophages, eosinophils, and mast cells.⁸²

Symptoms usually include abdominal pain, fever, and bloody diarrhea. Loss of absorptive mucosal surface and decreased colonic transit time can lead to large volumes of watery diarrhea. UC is typically chronic, with periods of remission and exacerbation. UC has relatively low-grade symptoms, such as bloody stools with purulent mucus, malaise, diarrhea, and pain. In approximately 15% of patients, however, UC with acute, fulminating characteristics may occur. These patients demonstrate continuous severe abdominal pain, profuse rectal hemorrhage, and high fever. Associated symptoms include nausea and vomiting, anorexia, and profound weakness. Physical signs usually include dehydration, pallor, and weight loss. Severe blood loss may result in hypotension and shock.

Associated with an acute onset of fulminating UC is toxic

megacolon, which is characterized by severe colonic distention that causes shock. In patients with this condition, the distended bowel lumen (greater than 5.5–6 cm on a supine abdominal film) provides an environment conducive to bacterial overgrowth. This condition, coupled with erosive intestinal inflammation and perforation, allows for the systemic release of bacterial toxins. Clinical signs and symptoms of toxic megacolon include fever, tachycardia, abdominal distention, pain, ileus, and dehydration. Electrolyte abnormalities, anemia, and hypoalbuminemia are also commonly present. If there is no significant improvement within a short period of medical treatment, patients arrive in the operating room for subtotal colectomy with an end ileostomy. Patients with toxic megacolon due to Crohn's disease undergo surgical treatment similar to those with toxic megacolon due to UC.⁸³

Patients with chronic UC are at increased risk for the development of left-sided carcinoma of the colon. An increased incidence of large-joint arthritis is seen in patients when the disease is clinically active. Concomitant liver disease, as evidenced by fatty infiltrates and pericholangitis, also may complicate the clinical picture. Other extracolonic manifestations of UC include iritis, erythema nodosum, and ankylosing spondylitis.

Therapy for UC is initially medical. As with Crohn's disease, sulfasalazine preparations, antidiarrheal agents, immunosuppressive agents, and corticosteroids are the cornerstones of medical therapy. Nicotine may have a protective effect in UC, but not in Crohn's disease. Both Crohn's disease and UC result in systemic disorders such as anemia and nutritional deficiencies, which are handled in the same supportive manner. In both diseases, surgical resection is reserved for patients with intractable complications. Whereas surgery for Crohn's disease is nondefinitive and complication-oriented, proctocolectomy with ileostomy is generally curative for UC, and eliminates the risk of malignancy and long-term steroid use.⁸⁴

Anesthetic Considerations in Inflammatory Bowel Disease

Anesthetic management of patients with inflammatory bowel

disease begins with optimization of the patient's medical status. Correction of anemia, fluid depletion, electrolyte and acid-base disorders, and performance of a nutritional assessment are mandatory. Possible extracolonic complications (e.g., sepsis, liver disease, coagulopathy, anemia, arthritis, hypoalbuminemia, and other metabolic abnormalities) must also be considered during planning and perioperative management.

Patients on long-term steroid therapy may require prophylactic steroid coverage. Nitrous oxide should be avoided due to the possibility of bowel distention associated with its prolonged intraoperative use. Many patients require total parenteral nutrition (TPN) and bowel rest, because eating may worsen symptoms. As such, the anesthetist should be aware of complications from parenteral nutritional therapy (e.g., hyperglycemia or hypoglycemia, increased carbon dioxide production, renal or hepatic dysfunction, nonketotic hyperosmolar hyperglycemic coma, and hyperchloremic metabolic acidosis). Any preexisting TPN infusion should be maintained throughout the perioperative period at the ordered infusion rate. Correction of fluid, electrolyte, and hematologic abnormalities may be necessary before surgery. Periodic laboratory assessment of metabolic status (i.e., serum glucose and electrolytes) should be performed and should guide corrective interventions. The severity of extracolonic influences on the function of other organ systems dictates appropriate technique and drug selection, as well as the extent to which invasive monitoring is used. The increased intraluminal pressure caused by the administration of anticholinesterases for neuromuscular blockade reversal has been shown to have no effect on colonic suture lines. No particular anesthetic technique is mandated; however, the use of a combined technique (epidural and general anesthesia) is attractive for both intraoperative use and postoperative analgesia needs. A combined spinal-epidural technique may be beneficial in fast-track cases and low anterior rectal resections.⁸⁵

Diverticulitis and Diverticulosis

Diverticulosis of the colon is characterized by the presence of numerous asymptomatic mucosal herniations or outpouchings in

the large colon, with the highest prevalence (65%) noted in the left (sigmoid) colon. The colonic mucosa herniates through the smooth muscle layers. Structural weakness of the colonic wall (usually where arteries penetrate the tunica muscularis to nourish the mucosal layer) and intraluminal hypertension are two mechanisms theorized to be responsible for the development of diverticulosis.

Diverticulitis is inflammation of the diverticula; this syndrome manifests as abdominal pain with ileus and other symptoms that indicate an acute abdomen, such as nausea, vomiting, diarrhea, rigid abdominal distention, and dehydration. Diverticulitis occurs in only 1% of patients with diverticulosis. Inflammation of the diverticula may be localized or more widespread, and may involve the mesentery and other abdominal organs. Progression of symptoms may lead to hypovolemia, hypokalemia, and shock. The presence of free intraperitoneal air, as evidenced on radiographic abdominal films, suggests perforation. Air in the retroperitoneum may be indicative of paracolic abscess. Both conditions require urgent surgical exploration. Abscess formation and visceral perforation indicate the need for urgent surgical intervention.⁷⁷

Surgical treatment of diverticulitis is reserved for severe symptoms that are refractory to aggressive medical therapy. IV corticosteroids, antibiotics, and fluid replacement are attempted initially. Exploratory laparotomy with colectomy may be necessary under emergent conditions of acute bleeding, recurrent bleeding that fails to cease spontaneously, or sepsis. The goals of surgical exploration include fecal diversion and abscess drainage, as well as resection of the diseased colon.³⁵

Complications of diverticulitis, which occur in up to 25% of patients, frequently necessitate surgical intervention. Such complications include bowel obstruction; fistulas between the sigmoid colon and the skin, bladder, vagina, or small intestine; abscesses; and peritonitis. Abscess formation after colonic obstruction and perforation is generally confined to the pelvis, and may involve such structures as the abdominal wall and the subdiaphragmatic spaces. More extensive abscess formation can include the deep pelvic organs and the hip and thigh. Patients with pelvic abscesses caused by diverticulitis have significant pain, fever, and leukocytosis.

Bleeding is uncommon in patients with diverticular disease, but when present, it is often difficult to locate by endoscopy and even laparotomy. Bleeding in diverticular disease may be either occult or massive, and is caused by erosion of the vessels adjacent to the diverticulum. Elective colon resection is usually considered in patients with recurrent episodes of acute diverticulitis. After a second attack of acute diverticulitis, the prevalence of complications associated with the disease approaches 50%, and the associated mortality rate is twice that of an initial attack. Diverticulitis, when present in the right colon or cecum, often mimics acute appendicitis. Surgery for appendectomy, therefore, may uncover the presence of an inflamed diverticulum or diverticulitis, necessitating extension of the procedure so that colonic resection can be performed.³⁵

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS) develops when there is abnormally high IAP (greater than 20 mm Hg) with associated organ dysfunction. Also known as *intraabdominal hypertension*, ACS can be diagnosed by measuring IAP with a bladder manometer. Normal IAP is less than 10 mm Hg. At pressures greater than 10 mm Hg, hepatic arterial blood flow significantly decreases. Cardiovascular perturbations occur at 15 mm Hg. Oliguria occurs at 15 to 20 mm Hg, and anuria at 40 mm Hg. Organ dysfunction develops if these increased pressures last longer than 6 hours. IAP greater than 20 to 30 mm Hg can result in organ failure and death.⁸⁶

ACS is associated with abdominal trauma, hemoperitoneum, mesenteric arterial thrombosis, acute pancreatitis, intestinal obstruction, visceral edema (as occurs in sepsis and shock), and massive fluid volume replacement. Causes of chronic ACS include ascites, pregnancy, and intraabdominal tumors. Resuscitative efforts and exposure of the abdomen induce mesenteric edema formation and bowel dilation. Under these conditions, additional ischemic injury to the abdominal viscera is avoided by delaying closure until the gross abdominal distention is resolved.

CO is decreased secondary to decreased cardiac preload (venous return), elevated systemic vascular resistance, and elevated intrathoracic pressure. Reflex tachycardia is a baroreceptor-mediated

response to decreased preload, with resultant diminished diastolic filling and coronary perfusion. Intracranial filling pressures are increased. Decreased thoracic compliance and decreased lung volumes result from impaired diaphragmatic descent. The outcome is an increased pulmonary shunt fraction, atelectasis, and pulmonary edema. Impairment in renal function results from compression of the kidney and diminished glomerular perfusion. The end consequence is multiple organ failure.

ACS is treated by urgent decompressive laparotomy, which may be performed at the bedside if the patient is too unstable to move. However, surgical decompression is ideally performed in the operating room. One study showed that overall mortality after surgical decompression was 46%, with preoperative renal failure, lower preoperative IAP, and late decompression being predictive of death. This underscores the point that once the diagnosis of ACS is made, prompt intervention is needed. If medical interventions are futile or judged to be inadequate, prompt decompression is mandatory.⁸⁷

Affected patients often have myriad medical problems that may significantly influence their outcome. The possibility of developing ACS subsequent to performing a resuscitative “damage-control” laparotomy in a traumatically injured patient is always a consideration. Under this circumstance, immediate life-threatening injuries are addressed, and the patient is then returned to the operating room from the intensive care unit at a later date, when hemodynamic stabilization has occurred.³⁵ Definitive repairs of associated, less life-threatening injuries are then undertaken, often in stages. During this time, the abdomen may be left open but packed and sealed with sterile dressings, along with a drainage appliance to resolve postresuscitation intraabdominal edema.³⁵ The patient may be returned repeatedly to the operating room for dressing changes until conditions are conducive for abdominal wound closure. Providing anesthesia care for these patients can be extremely challenging. Intraoperative monitoring is directed toward the maintenance of hemodynamic stability, and includes knowledge of the patient's preoperative hemodynamic profile. If the patient is still receiving mechanical ventilatory support, it is of utmost importance to provide intraoperative ventilation in a mode

as close as possible to that being administered in the intensive care unit. This is particularly vital in the patient with ARDS. This may require modification of the anesthesia delivery ventilator to approximate as closely as possible the minute ventilation, fraction of inspired oxygen (FiO_2), inspiratory/expiratory ratio, ventilatory rate, and level of positive end-expiratory pressure the patient has been receiving. This minimizes the potential for perioperative deterioration of previously accomplished improvement in the patient's ventilatory status. Invasive monitors brought with the patient, such as an arterial line, central venous catheter, and pulmonary artery catheter, should be used for perioperative management. Opioids and inhalation agents are used with discretion in accordance with patient tolerance. The induction of adequate muscle relaxation and amnesia with a benzodiazepine or with scopolamine assume priority in the pharmacologic anesthetic management of the physiologically labile patient. Other vasoactive agents are included as indicated for hemodynamic support. Best practice caveats for the anesthetic management of these patients are the provision of intraoperative stability and the preservation of preoperative homeostatic compensation.

One serious but rare complication of surgical decompression is the so-called "reperfusion syndrome," in which the patient develops severe hypotension and acidosis immediately after the abdomen is decompressed, as a result of the release of acidotic blood from the mesenteric beds.⁸⁷ Reperfusion washout of the by-products of anaerobic metabolism releases an array of cardiac depressants and vasodilatory mediators into the general circulation. Proper preparation is required, and includes optimization of intravascular volume, acid-base status, and arterial oxygenation.⁸⁸

The mortality rate in ACS approaches 42%, with most patients succumbing to secondary systemic inflammatory response syndrome, sepsis, and MODS. Other causes of death include respiratory failure (i.e., ARDS) and the consequences of added stress imposed on cardiac function in susceptible patients.⁸⁸

Anesthetic Considerations in Elective Surgery of the Colon

Using either a laparoscopic or anterior open approach, the surgeon mobilizes the colon and ligates the associated blood vessels. The diseased bowel is removed, and the remaining ends of the distal and proximal colon are anastomosed together; alternatively, a colostomy or ileostomy may be created. Preoperative elimination of fecal mass and bacterial flora are critical to avoid postoperative infection. The night before admission, the patient can lavage with isotonic and isosmotic solutions orally or by way of an NG tube. Cleansing enemas also may be ordered. These techniques are often used for elective procedures in conjunction with dietary changes that emphasize the intake of fluids and low-residue foodstuffs and culminate in the intake of only clear liquids for 24 to 48 hours before surgery. IV and oral antibiotics used for bowel cleansing commonly include drugs from the aminoglycoside family (e.g., neomycin, erythromycin) and/or a combination of the cephalosporins and metronidazole.

Awareness of this preoperative preparation in patients who undergo elective bowel surgery is critical, because aggressive preoperative bowel preparation predisposes a patient to water and electrolyte imbalances that may have a deleterious influence on perioperative cardiovascular function, hemodynamics, and systemic organ perfusion, particularly if the patient is elderly or debilitated. Depending on how chronic the disease process is, anemia resulting from frank or occult bleeding may be present. Malnutrition with hypoalbuminemia also may be present before surgery.

Preoperative NG drainage may be required if an adynamic colon or obstruction is present. This preoperative intervention may be superimposed on a dehydrated patient or one who is electrolyte-depleted, resulting in hypochloremic hypokalemic alkalosis. The resulting fluid and electrolyte abnormalities may be of sufficient magnitude to require postponement of the procedure until volume and electrolyte resuscitation has been accomplished.

Carcinoma of the Colon

Cancer of the colon is a highly treatable and often curable disease when it is localized to the bowel. It is the second most frequently diagnosed malignancy and the third most common cause of cancer

death in both men and women in the United States. Most colorectal cancers develop from adenomatous polyps. Surgery is the primary treatment and results in a cure in approximately 50% of patients. The location and amount of resection depends on the site of the cancer. If the rectum is involved, a permanent colostomy will be created. Recurrence after surgery is a major problem, and is often the ultimate cause of death. The prognosis of patients with colon cancer is clearly related to the degree of penetration of the tumor through the bowel wall and the presence or absence of nodal involvement. Carcinoma of the colon accounts for approximately 50,000 deaths annually, and more than 145,000 new cases are diagnosed in the United States each year.⁸³ The etiology is multifactorial, and includes a strong environmental correlation with diet (high red meat intake, low dietary fiber intake) and genetic predisposition. Inflammatory bowel disease is usually associated with a greater predisposition to colonic carcinoma. Stool testing for occult blood is a standard screening method. Rectal examination and colonoscopic examination with biopsy are important diagnostic modalities. Tests designed to detect genetic markers for colon cancer in stool and blood are being developed.

Right-sided colonic lesions grow along one wall of the cecum and ascending colon, and often cause symptoms including pain, a palpable mass in the lower right quadrant, anemia, and dark-colored blood mixed with the stool. Persistent blood loss and anemia with fatigue are common, and obstruction is unlikely because the feces are more liquid. Bleeding is usually less profuse than in patients with diverticular disease. Left-sided colonic lesions grow circumferentially, and symptoms include progressive abdominal distention, pain, vomiting, constipation, cramps, and bright red blood in the stool. Obstruction is common, but develops slowly.⁷⁷

Volvulus of the Colon

Volvulus is a twisting of the bowel on its mesenteric pedicle, resulting in an occlusion of the blood supply. This condition usually affects a freely mobile colonic segment and a fixed point or set of points about which the colon twists. Approximately 75% of cases of colonic volvulus affect the sigmoid colon. Colonic volvulus is often

associated with fibrous adhesions in the small intestines.⁷⁷

Although colonic volvulus is relatively rare in the United States, it is responsible for 5% of large bowel obstruction cases. Symptoms usually suggest the presence of acute or subacute bowel obstruction (e.g., sudden onset of acute, severe, colicky abdominal pain, vomiting, and distention). Acute strangulation of the bowel is suggested by generalized severe abdominal pain, hypovolemia, and fever. Initial therapy starts with appropriate resuscitation followed by decompression through the placement of a rectal tube through a proctoscope or the use of a colonoscope. This treatment has a high success rate (70% to 80%) and allows resection as an elective procedure, which can be accomplished with reduced morbidity and mortality. If detorsion of the volvulus cannot be accomplished with either a rectal tube or a colonoscope, laparotomy with resection of the sigmoid colon and the formation of an end colostomy and mucous fistula (Hartmann operation) is required.⁸³

Many patients with this condition are elderly (in their seventh to eighth decade) or debilitated, and are referred from long-term care facilities. Associated disease processes include Alzheimer disease, Parkinson disease, multiple sclerosis, paralysis, pseudobulbar palsy, chronic schizophrenia, and dementia. Medications taken on a long-term basis by these institutionalized patients may include psychotropic drugs, which are known to affect intestinal motility.

Ischemic Bowel Disease

Ischemic injury to the GI tract occurs whenever the oxygen or vascular supply cannot meet the metabolic demands of the tissue. GI ischemia has many causes, including inadequate perfusion, narrowing of blood vessels from any cause, bowel obstruction and distention, drug effects, and infections that can mimic ischemic damage. Most ischemic episodes result from nonocclusive ischemic bowel disease (low-flow states), and in these cases, no vascular lesion or specific cause for ischemia can be demonstrated on pathologic examination.⁸⁹ Surgical iatrogenic causes, such as interruption of the inferior mesenteric artery as a result of aortic cross-clamping during abdominal aortic surgery, are also responsible. Prolonged hemodynamic lability in patients with significant comorbidities such as advanced age, chronic diabetes,

hypertension, and atherosclerotic disease places them at even greater risk for the consequences of ischemic bowel disease. Any part or length of bowel can be affected, depending on the cause and duration of hypoxia and the state of the collateral circulation. The extent, severity, and prognosis of the syndrome of ischemic bowel disease are variable. Localized or segmental ischemia is often present. Differentiation of ischemic colitis from infectious processes, diverticulitis, or inflammatory bowel disease may be difficult. Definitive diagnosis depends on endoscopic examination with biopsy. Bowel perforation can be excluded in the differential diagnosis through radiographic or ultrasonographic examination of the abdomen for the presence of free air.

Patients with ischemic bowel disease are usually elderly. Symptoms of ischemic bowel disease typically include fever, vomiting, rectal bleeding, and abdominal cramping pain, and may be present for weeks or months. The development of sudden rectal bleeding associated with left-sided abdominal pain and peritoneal signs strongly suggests the presence of this disease process. Concomitant ischemic heart disease and peripheral vascular disease are often present in these patients.⁹⁰ Supportive measures are initially undertaken if bowel necrosis is not suspected. This includes antibiotic therapy and fluid resuscitation. In patients in whom perforation or necrosis is suspected, emergency laparotomy is indicated, with possible bowel resection and temporary or permanent colostomy. Stable patients may be candidates for vascular reconstructive procedures.⁶

Diseases of the Rectum and Anus

Diseases of the anorectal region may include neoplastic lesions. Rectal carcinomas are defined as tumors occurring up to 15 cm from the anal opening. If biopsy findings are consistent with localized adenocarcinoma, abdominal-perineal resection of the rectum and sigmoid colon with permanent colostomy may be curative. Squamous cell carcinomas of the rectum are effectively treated with chemotherapy and radiation, as well as local excision. Rectal carcinoma can spread through the rectal wall to nearby structures (the prostate and vagina), especially in the lower third of the rectum. Surgical proctectomy is another treatment option.

Other rectal diseases include rectal prolapse, which is characterized by full-thickness eversion of the rectal wall through the anus, and is repaired with rectosigmoidectomy or proctopexy. Rectal prolapse is seen most often in the elderly and in females. Another rectal disease is perirectal abscess, which requires drainage; this may be performed on either an inpatient or an outpatient basis.

Perirectal fistulas typically develop secondary to infectious disease processes that cause abscess formation. Four types are generally recognized: extrasphincteric, suprasphincteric, transsphincteric, and intersphincteric. Initial therapy is incision and drainage with delayed fistulectomy to facilitate healing of the abscess.³⁵

Hemorrhoids are a common affliction, and have been described and treated for more than 4000 years. The refined, low-fiber diet of Western nations makes hemorrhoids extremely common in the United States, where 1 in 25 to 30 individuals is afflicted. Hemorrhoids are composed of vascular, mucosal, and muscular tissue. Although frequently attributed to varicosities, all three elements compose the hemorrhoid. There are two types of hemorrhoids: internal and external. Internal hemorrhoids originate above the dentate line, are covered with mucosa, and lack sensory innervation. Internal hemorrhoidal prolapse may be painless. Gangrenous, strangulated, extruded, or thrombosed internal hemorrhoids, however, may be extremely painful. Treatment is usually by rubber band ligation or surgical excision. External hemorrhoids originate below the dentate line and are covered with squamous epithelium that makes them easily recognizable, because their covering matches the surrounding skin. The inferior rectal nerve innervates external hemorrhoids. A thrombosed external hemorrhoid appears as a bluish mass covered by epidermis. Acute thrombosis occurs suddenly, and is usually very painful. Significant bleeding is uncommon, but may occur in the case of spontaneous rupture. Increased pressures from straining or trauma from constipation or diarrhea may exacerbate external hemorrhoids. Distention and trauma predispose the hemorrhoidal venous plexus to stasis, with ensuing clot formation and edema.⁹¹ Surgical excision is the treatment of choice.

Anesthesia for most perirectal and perianal procedures may be effectively provided by regional techniques such as spinal subarachnoid block or epidural blockade, as well as by local anesthesia infiltration with sedation. A particularly useful technique is a saddle block with hypobaric bupivacaine. In some cases, general endotracheal anesthesia may be necessary. Anesthetic considerations must include the effect of the patient's position (e.g., prone, jackknife, or lithotomy position) on intraoperative cardiovascular and respiratory dynamics.

Radiation Enteritis

Radiation therapy is commonly used as adjuvant therapy for various abdominal and pelvic cancers. In addition to tumor cells, however, other rapidly dividing cells in the intestinal epithelial lining may be affected by radiation. Surrounding normal tissue such as the small intestinal epithelium may sustain severe, acute, and chronic deleterious effects. The amount of radiation used appears to correlate with the probability of developing radiation enteritis. Radiation damage tends to be acute and self-limiting, with symptoms consisting mainly of diarrhea, abdominal pain, and malabsorption. The late effects of radiation injury are the result of damage to the small submucosal blood vessels, and include progressive obliterative arteritis and submucosal fibrosis, eventually resulting in thrombosis and vascular insufficiency. Operative intervention may be required in a subgroup of patients who experience chronic effects of radiation enteritis. Indications for surgical intervention include obstruction, fistula formation, perforation, and bleeding, with obstruction being the most common presentation. Operative procedures include bypass or resection with reanastomosis, sometimes under emergent conditions. The presence of adhesions and the induced increased friability of the intestinal tissues predispose affected patients to increased intraoperative bleeding and tissue third spacing. Radiation enteritis can be a relentless disease process. Almost half of patients who survive their first laparotomy for radiation-induced bowel injury require further surgery for ongoing bowel damage. Up to 25% of these patients die of radiation enteritis and complications from its management.⁷⁸

Appendicitis

The appendix arises from the apex of the cecum. The length of the appendix varies from 2 to 20 cm, and the average length is 9 cm in adults. The appendiceal artery, a branch of the ileocolic artery, supplies blood to the appendix.⁹² The appendix may assume any of a number of positions that influence the quality of symptoms and the site of pain when inflammation occurs.

Appendicitis occurs most often in individuals between 10 and 30 years of age, and is the most common general surgical emergency. A slight prevalence for male patients over female patients exists. Obstruction of the appendiceal lumen is believed to be the major cause of appendicitis.

In the classic presentation of appendicitis, patients first note vague, poorly localized epigastric or periumbilical discomfort, which progresses to localized right lower quadrant tenderness in 80% of patients. Within 4 to 12 hours of the onset of pain, most patients also note nausea, vomiting, anorexia, or some combination of these three symptoms. If vomiting is the main symptom, the diagnosis should be questioned.⁹³ Patients point to localized pain at McBurney's point, which is midway between the iliac crest and umbilicus; rebound tenderness, muscle rigidity, and abdominal guarding are noted. In the pregnant patient, Alder's sign is used to differentiate between uterine and appendiceal pain: the pain is localized with the patient supine, and the patient then lies on her left side. If the area of pain shifts to the left, it is presumed to be uterine.

The major complication of untreated appendicitis is perforation, with resultant peritonitis, abscess, and portal pylephlebitis. The risk of perforation increases as the duration of the illness progresses, especially beyond 24 hours. Patients with perforation are more likely to have a higher fever, leukocytosis, and physical findings of peritonitis. The most severe complication of appendiceal perforation is septic thrombophlebitis of the portal vein, or portal pylephlebitis.

If the appendix perforates, abdominal pain becomes intense and more diffuse, and abdominal muscular spasm increases, producing rigidity. The HR rises, with an elevation of temperature above 39°C. Occasionally, pain may improve somewhat after rupture of the

appendix, although a true pain-free interval is uncommon.⁹²

The definitive treatment for appendicitis is appendectomy, which may be performed with general or regional anesthesia. The patient is frequently dehydrated, and may require a brief period of fluid resuscitation and antibiotics for enteric anaerobic Gram-negative bacilli before the induction of anesthesia. Laparoscopic procedures are the most common techniques used for simple presentations. If an open appendectomy is performed and regional anesthesia is chosen, the analgesia level should be maintained at the T6 to T8 level. If general anesthesia is selected, muscle relaxation is necessary, and aspiration precautions that include a rapid sequence induction should be considered. Local anesthesia with IV sedation may also be a useful technique.

Splenic Disease

Anatomic and Physiologic Overview

The spleen is located in the posterior left upper quadrant of the abdomen, and is surrounded by the fundus of the stomach (medially), the splenic flexure of the colon (inferiorly), the left kidney and adrenal gland (posteriorly), and the diaphragm (superiorly). Attachment to these organs via suspensory ligaments, which are vascular except for the gastrosplenic ligament, protects and supports this organ.³⁵

The normal spleen weighs less than 250 g, decreases in size with age, normally lies entirely within the rib cage, has a maximum cephalocaudal diameter of 13 cm by ultrasonography or maximum length of 12 cm and/or width of 7 cm by radionuclide scan, and is usually not palpable. In fact, palpability is the major physical sign of diseases affecting the spleen, and suggests enlargement of the organ.

The encapsulated spleen is divided into three zones by strands of connective tissue (trabeculae) that originate from the capsule. Each compartment contains masses of lymphoid tissue called *splenic pulp*. Each of the three splenic compartments is surrounded by a 1- to 2-mm capsule. These compartments are (1) the white pulp, which consists of lymphatic sheaths and contains lymphocytes, plasma cells, and macrophages; (2) the red pulp, which consists of large, thin-walled, highly distensible venous sinuses, also known as the *splenic sinusoids*, which ultimately form the splenic vein; and (3) the marginal zone, an ill-defined vascular space that interfaces between the white pulp and the red pulp.³⁵

Total splenic blood flow is approximately 300 mL/min, and comes from the splenic artery. The splenic artery is a tortuous vessel that arises from the descending aorta. The splenic artery divides into several branches within the splenorenal ligament before entering the splenic hilum, where they branch again into the trabeculae as they enter the splenic pulp. Splenic blood flow drains into the splenic vein and then contributes to portal venous blood flow.

The spleen functions in several physiologic capacities, including blood filtering, maintenance of normal erythrocyte morphology, and immune processing of blood-borne foreign antigens. The spleen is also involved in hematopoiesis in the fetus until the fifth month of gestation. In filtering blood, the splenic sinusoids remove nuclear remnants and excess cell membrane found in immature erythrocytes. Abnormal blood cells, such as those found in patients with sickle cell disease, thalassemia, and spherocytosis, are filtered and removed by macrophages and other cells of the reticuloendothelial system. This process can occasionally lead to worsening anemia, symptomatic splenomegaly, and occasionally splenic infarction. Aged red blood cells (older than 120 days) that have lost enzymatic activity and membrane elasticity are removed by the same processes.³⁵

The spleen plays an important role in specific and nonspecific immune responses. Macrophages and specialized histiocytes engulf and remove foreign cells, particularly those that have been bound by antibodies. The production of specific antibodies (immunoglobulin M) is facilitated in the white pulp through the processing of foreign antigens.³⁴ It is well-established that people lacking a spleen are at a significantly higher risk for overwhelming postsplenectomy infection with fulminant bacteremia, pneumonia, or meningitis, as compared with those with normal splenic function. Asplenic subjects have defective activation of complement by the alternative pathway, leaving them more susceptible to infection.⁹⁴ Kristinsson et al.⁹⁵ reviewed 8149 cancer-free splenectomized patients over 27 years and found these patients had a significantly increased risk of pneumococcal pneumonia, pneumonia not otherwise specified, meningitis, and septicemia. Splenectomized patients had a 1.58-fold and 3.02-fold increased risk of death from pneumonia and septicemia, respectively.

The spleen has a minor role as a reservoir of platelets. This function, however, is important in only a few pathologic conditions. The spleen is not a significant reservoir for red blood cells, but if there is a sudden decrease in BP, sympathetic nervous system activation can constrict the red pulp sinuses, contributing as much as 200 mL of blood to the venous circulation and increasing the hematocrit by as much as 4%.⁹⁶

Despite its important and myriad functions, the spleen is not essential for life. Splenectomy may be performed for benign hematologic conditions, including idiopathic thrombocytopenic purpura (ITP), thrombotic thrombocytopenic purpura, hereditary spherocytosis, hereditary hemolytic anemia, and hemoglobinopathies (e.g., thalassemia, sickle cell disease). Splenectomy also may be performed for malignancies such as Hodgkin or non-Hodgkin disease, lymphoma, certain leukemias, or for benign conditions such as splenic abscess, splenic cysts, the presence of an accessory spleen, wandering spleen, and splenomegaly (spleen greater than 20 cm longitudinally). The development of primary (having no identifiable underlying cause) or secondary (having a known cause) hypersplenism may warrant splenectomy. Hypersplenism and acute splenic sequestration are life-threatening disorders in children with sickle cell anemia and thalassemia. Symptoms of hypersplenism include fatigue, malaise, recurrent infection, and easy or prolonged bleeding. These symptoms occur from a hyperfunctional spleen that removes and destroys normal blood cells.⁹⁷

In portal hypertension, transmitted back pressure results in hypersplenism, which leads to congestive failure of splenic function. Treatment of the primary disease process usually relieves symptoms. Splenectomy, however, is often a necessary part of therapy, particularly with long-standing disorders. Splenectomy also offers a curative solution for patients with isolated splenic vein thrombosis and bleeding gastric varices.⁹⁸

Splenic Trauma

Angiographic embolization of hemorrhaging vessels in the spleen has reduced the need for open procedures. However, the spleen is the most frequently injured abdominal organ, being involved in 25% to 60% of adults with intraabdominal trauma. Damage to the spleen is important because it is the most vascular body organ, receiving 5% of the CO. Because blood loss from the spleen is mostly arterial, splenic injury can produce a lethal hemoperitoneum. Unlike the liver, hemorrhage from splenic trauma is always within the peritoneal cavity.⁹⁹ Rapid deceleration or puncture from an adjacent broken rib are common causes of

spleen injuries. Any patient who has sustained blunt abdominal trauma and who has left upper quadrant pain should be suspected of having sustained splenic injury. Conservative, nonoperative treatment (with avoidance of splenectomy) may be elected for minor splenic injury. The clearest indication for urgent operation is hemodynamic instability. Because there can be no standard criteria for hemodynamic instability, a general guideline is to operate for a systolic BP below 90 mm Hg or a pulse of more than 120 beats/min if there is no immediate response to 1 to 2 L of crystalloid resuscitation and when physical examination, ultrasound, or diagnostic peritoneal lavage indicates intraabdominal blood loss.⁹⁷ Splenectomy is generally avoided in children because of the importance of splenic function (i.e., immunologic function) in growth and development.^{100,101}

In hemodynamically stable patients with severe splenic damage and hemoperitoneum, the surgery can be performed laparoscopically with no related morbidity or mortality. Anesthesia concerns regarding the laparoscopic approach are related to respiratory distress, which can be exacerbated by the lateral decubitus position and by pneumoperitoneum, usually associated with multiple trauma and rib fractures. At least one study showed no negative outcomes for a laparoscopic approach, and in fact found that these patients exhibited improved postoperative respiratory compliance.¹⁰²

In the presence of impending shock, emergency exploratory laparotomy is carried out to diagnose and treat all injuries to the abdominal viscera, including the spleen. Anesthetic management in these cases is directed by considerations for all unstable patients undergoing emergency laparotomy, particularly hemodynamic stability and renal function. A paramount consideration is maintaining physiologic hemoglobin and hematocrit levels and arterial BP. Hemoglobin and hematocrit are decreased in the emergent setting, not only by hemorrhagic diathesis but also from dilution secondary to aggressive volume resuscitation with crystalloid solutions. These considerations assume an integral part in the decision to implement perioperative blood product transfusion.

Anesthetic Considerations in Elective Splenectomy

Anesthetic management for splenectomy is individualized based on the patient's medical condition. Patients who have received chemotherapy must be assessed for potential organ system complications.

Minimally invasive procedures have become standard for most splenectomies, and laparoscopy is now the procedure of choice. The spleen may be removed laparoscopically if the it is normal or close to normal in size. Although the operative time is significantly greater than for laparotomy, the postoperative recovery time, the risk of damage to the pancreas, the likelihood of developing subphrenic abscess and peritoneal adhesions postoperatively, and the nutritional and metabolic challenges to the patient are considerably reduced.¹⁰³

Patients with systemic disease may be chronically ill and have decreased cardiovascular reserve. Patients who have received doxorubicin (Adriamycin) may have a dose-dependent cardiotoxicity that can be worsened by radiation therapy. Manifestations include decreased QRS amplitude, congestive heart failure, pleural effusions, and dysrhythmia. Patients may have a degree of left lower lobe atelectasis and altered ventilation. In patients treated with bleomycin, pulmonary fibrosis may occur. Methotrexate, busulfan, mitomycin, cytarabine, and other chemotherapeutic agents may cause pulmonary toxicity. Neurologically, patients may exhibit deficits after the administration of chemotherapeutic agents. Vinblastine and cisplatin can cause peripheral neuropathies. Any evidence of neurologic dysfunction should be documented. Hematologically, patients are likely to have splenomegaly secondary to hematologic disease (e.g., Hodgkin disease, leukemia). Cytopenias are common. Some chemotherapeutic agents (e.g., methotrexate, 6-mercaptopurine) may be hepatotoxic. Evaluation of liver function tests should be considered in patients considered to be at risk. Renally, some chemotherapeutic drugs (e.g., methotrexate, cisplatin) are nephrotoxic. Patients exposed to such agents may have renal insufficiency.

Laboratory tests that should be performed as indicated by the patient history and physical examination include a complete blood count, PT, PTT, bleeding time, platelet count, electrolytes, blood urea nitrogen, creatinine, and urinalysis. Consider aspiration prophylaxis, and administer steroids (25–100 mg hydrocortisone) if the patient has received them as part of a chemotherapeutic or medical treatment.

Because of the potential for large blood loss, the patient should be typed and cross-matched, and the use of cell saver recovery system is appropriate. The ability to transfuse blood products when indicated should be accommodated with the insertion of at least two large-bore IV lines if a central line is not placed. The extent of monitoring modalities is dictated by the patient's preexisting condition and anticipated perioperative course.

General endotracheal anesthesia (GETA) with or without an epidural for postoperative analgesia is used. GETA induction should include consideration of rapid sequence intubation as indicated. Intravascular volume should be restored before anesthetic induction. If the patient is hemodynamically unstable, etomidate or ketamine should be considered. Nitrous oxide should be avoided to prevent bowel distention. Appropriate measures must also be implemented intraoperatively to prevent any further deterioration in preexisting function. These measures include positioning the patient carefully, administering appropriate IV fluids, maintaining adequate urine output, monitoring hemoglobin and hematocrit levels, and avoiding anesthetics and adjuvants that place an extra metabolic burden on the renal or hepatic system. An epidural catheter may be beneficial in postoperative pain control in the absence of ITP.

Carcinoid Tumors and Carcinoid Syndrome

Carcinoid tumors are slow-growing malignancies composed of enterochromaffin cells (Kulchitsky cells), and are most commonly found in the GI tract. They also may occur in the lung, pancreas, thymus, and liver.

Approximately two-thirds of carcinoids occur in the GI tract. Within the GI tract, most tumors occur in the appendix (45%), jejunioileum (28%), rectum (16%), and duodenum (4%). Carcinoid tumors are capable of metastasis, and are composed of multipotent cells with the ability to secrete numerous bioactive humoral agents, the most important of which are serotonin, histamine, and kinin peptides. In addition to these substances, carcinoid tumors have been found to secrete corticotropin, histamine, dopamine, neurotensin, prostaglandins, substance P, gastrin, somatostatin, pancreatic polypeptide, calcitonin, and neuron-specific enolase (Table 33.12).⁹²

TABLE 33.12

Secretory Products of Carcinoid Tumors

Amines	Tachykinins	Peptides	Other
Serotonin	Kallikrein	Pancreatic polypeptide (40%)	Prostaglandins
5-HIAA (88%)	Substance P (32%)	Chromogranins (100%)	
5-HTP	Neuropeptide K (67%)	Neurotensin (19%)	
Histamine		hCG α (28%)	
Dopamine		hCG β	
		Motilin (14%)	

hCG α , Human chorionic gonadotropin alpha subunit; hCG β , human chorionic gonadotropin beta subunit; 5-HIAA, 5-hydroxyindoleacetic acid; 5-HTP, 5-hydroxy-L-tryptophan.

From McKenzie S, Evers BM. Small intestine. In Townsend CM, et al., eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 19th ed. Philadelphia: Elsevier; 2012.PG 1259.

Adrenergic stimulation causes the release of serotonin into the circulation. Serotonin is metabolized by aldehyde dehydrogenase and monoamine oxidase to 5-hydroxyindoleacetic acid (5-HIAA),

which is excreted in the urine. Elevated levels of 5-HIAA in the urine are a marker of excess serotonin production and, therefore, the presence of a carcinoid tumor. Serotonin may cause vasoconstriction or vasodilation; thus, both hypertension and hypotension are possible. At normal concentrations, serotonin does not affect cardiac function; however, the elevated levels seen in carcinoid syndrome may cause both inotropic and chronotropic responses. This action is due in part to an indirect effect from the release of norepinephrine. Elevated serotonin levels also result in increased gut motility and the secretion of water, sodium, chloride, and potassium by the small intestine. Other effects attributed to elevated levels of serotonin are vomiting, bronchospasm, hyperglycemia, and prolonged drowsiness after emergence from anesthesia.¹⁰⁴

Histamine release is seen predominantly in patients with gastric or foregut carcinoids, and may be due to the presence of histidine decarboxylase in normal gastric mucosa. Histamine is probably responsible for the bronchospasm seen in some carcinoid patients, and it also may be the cause of flushing.¹⁰⁴

Other substances thought to be released by carcinoid tumors are the kinins, especially bradykinin. Kinins are produced by the action of proteolytic enzymes, called *kallikreins*, on the inactive kinin precursors.¹⁰⁴ Lysosomal kallikrein release is triggered mainly by sympathetic stimulation. When this occurs, the newly produced bradykinin is usually rapidly broken down and removed from the circulation by plasma aminopeptidases and kinases. When abnormally high amounts of bradykinin are released, the pathways become saturated, causing an exaggerated and prolonged effect from bradykinin. The bradykinins produce profound vasomotor relaxation, causing severe hypotension and flushing, probably via increased nitric oxide synthesis.^{105,106} Bradykinin also causes bronchospasm, especially in asthmatics and frequently in patients with cardiac disease.¹⁰⁶

Normally, the release of vasoactive substances causes few if any symptoms, because the liver is able to rapidly inactivate these substances. If these substances reach the systemic circulation without first being metabolized by the liver, they are capable of

Producing carcinoid syndrome ([Box 33.10](#)).

Signs and Symptoms of Carcinoid Syndrome

- Episodic cutaneous flushing, purple face and neck (kinins, histamine)
- Diarrhea (serotonin, prostaglandins E and F)
- Heart disease
- Tricuspid regurgitation, pulmonic stenosis
- Supraventricular tachydysrhythmias (serotonin)
- Bronchoconstriction (serotonin, bradykinin, substance P)
- Hypotension (kinins, histamine)
- Hypertension (serotonin)
- Abdominal pain (small bowel obstruction)
- Hepatomegaly (metastases)
- Hyperglycemia
- Hypoalbuminemia (pellagra-like skin lesions resulting from niacin deficiency)

Modified from Tantay H, Myslajek T. Diseases of the gastrointestinal system. Hines RL, Marschall KE, eds. In *Stoelting's Anesthesia and Co-Existing Disease*. 6th ed. Philadelphia: Elsevier; 2012 297.

Carcinoid syndrome may produce life-threatening perioperative hemodynamic instability. This syndrome most often occurs with primary tumors that do not drain into the portal system or with hepatic metastases (the most common site of metastasis). Although 25% of tumors actively secrete substances capable of causing symptoms, less than 10% of people with a carcinoid tumor develop the classic carcinoid syndrome.^{106,107} Symptoms related to carcinoid

syndrome include episodic cutaneous flushing (kinins, histamine), diarrhea (serotonin, prostaglandins E and F), heart disease, tricuspid regurgitation, pulmonic stenosis, supraventricular tachydysrhythmias (serotonin), bronchoconstriction (serotonin, bradykinin, substance P), hypotension (kinins, histamine), hypertension (serotonin), abdominal pain (small bowel obstruction), hepatomegaly (metastases), hyperglycemia, and hypoalbuminemia (pellagra-like skin lesions resulting from niacin deficiency).

Since the introduction of octreotide as a therapeutic option, the prognosis for patients with carcinoids has significantly improved. Nevertheless, carcinoid tumors may prove fatal for some patients. Death in these patients often results from pulmonary, cardiovascular, or hepatic involvement and dysfunction, rather than from carcinoid crisis. Overall survival is significantly worse for patients with cardiac involvement.

Carcinoid crisis, a life-threatening form of carcinoid syndrome, may be precipitated by physical manipulation of the tumor (including bedside palpation), chemical stimulation or tumor necrosis resulting from chemotherapy, and hepatic artery ligation or embolization.¹⁰⁸ It may occur spontaneously or during the induction of anesthesia. Clinical manifestations of carcinoid crisis include severe flushing with associated dramatic changes in BP, cardiac arrhythmias, bronchoconstriction, and mental status changes. Complete surgical excision of the tumor, often with partial bowel resection and mesenteric lymphadenectomy, is generally regarded as the most effective treatment for carcinoid tumors.¹⁰⁶ Other procedures associated with carcinoid syndrome include cardiac valve replacement and hepatic resection for metastatic disease.

Anesthetic Management

The primary goal during the perioperative period is to prevent the release of bioactive mediators, thereby avoiding carcinoid crisis. Caution should be exercised in the anesthetic management of patients with carcinoid tumors, because anesthesia may precipitate a carcinoid crisis characterized by hypotension, bronchospasm, flushing, and tachycardia predisposing to arrhythmias. Long-acting

synthetic analogues of somatostatin (octreotide and lanreotide) are now the drugs of choice for symptom control. Sustained release preparations of both drugs, octreotide LAR and lanreotide autogel, are widely used, as they are effective for 4–6 weeks. In patients with carcinoid crises, 150–200 mcg of octreotide is administered every 6–8 hours for 24–48 hours prior to surgery and continued throughout the procedure.¹⁰⁶

Many anesthetic techniques have been used successfully in the treatment of patients with carcinoid syndrome (Box 33.11). Most patients with carcinoid tumors undergo general anesthesia because of the need to avoid the sympathectomy associated with neuraxial anesthesia; however, both epidural and spinal anesthesia have been used successfully in these patients. Successful spinal anesthesia has been reported with the use of preoperative octreotide, fluids, and low-dose spinal anesthetic supplemented with low-dose intrathecal opioids.¹⁰⁶ Laboratory tests should include the standard chemistry, blood count, liver function panel, blood glucose concentration, and ECG, as well as urinary 5-HIAA measurements.¹⁰⁶ A low threshold for further cardiac workup should be used because the reported prevalence of cardiac involvement is as high as 50% to 60%.

Anesthetic Considerations in Carcinoid Syndrome

- The most common clinical signs are cutaneous flushing of the head, neck, and upper thorax, wheezing, blood pressure and heart rate changes, and diarrhea.
- Preoperative assessment should include complete blood count, measurement of electrolytes, liver function tests, measurement of blood glucose, electrocardiogram, and determination of urine 5-HIAA levels. Echocardiography should be performed to determine the extent of carcinoid heart disease.
- Confirmation: > 30 mg of 5-HIAA per 24-hour urine sample (normal = 3–15 mg/24 hr).
- Optimize fluid and electrolyte status and pretreat with octreotide as noted. Continue octreotide throughout the postoperative

period. Aprotinin (kallikrein inhibitor) may be used to treat hypotension refractory to octreotide. Interferon- α has shown success in controlling some symptoms.

- Both histamine-1 and histamine-2 receptor blockers must be used to fully counteract histamine effects.
- Perioperative blockade of serotonin receptors.
- Anxiolytics reduce stress-related serotonin release.
- Avoid histamine-releasing agents such as morphine and atracurium. Avoid sympathomimetic agents such as ketamine and ephedrine.
- Treat hypotension with an α -receptor agonist such as phenylephrine.
- General anesthesia is preferred over regional anesthesia. Patients with high serotonin levels may exhibit prolonged recovery; therefore, desflurane and sevoflurane, which have rapid recovery profiles, may be beneficial.
- Aggressively maintain normothermia to avoid catecholamine-induced vasoactive mediator release.
- Monitor intraoperative plasma glucose, because these patients are prone to hyperglycemia. Treat with insulin as is customary.
- Pay attention to procedures, treatments, and drugs that may stimulate the release of vasoactive substances from tumor cells. These include tumor-debulking surgery or hepatic artery embolization to reduce tumor size, and biotherapy (interferon for tumor shrinkage) or chemotherapy for systemic spread.

5-HIAA, 5-Hydroxyindoleacetic acid.

Adapted from Mancuso K, et al. Carcinoid syndrome and perioperative anesthetic considerations. *J Clin Anesth.* 2011;23(4):329–341; Dierdorf S. Carcinoid tumor and carcinoid syndrome. *Curr Opin Anaesthesiol.* 2003;16:343–347.

Rapid changes in BP are often seen in carcinoid patients; therefore, in addition to standard monitoring, invasive monitoring is typically required. Invasive monitors should be inserted before the induction of anesthesia, and their use should be continued postoperatively. The hypotension commonly associated with induction agents may trigger a carcinoid crisis, so the insertion of an arterial catheter is mandatory prior to the induction of anesthesia. Increased bleeding also may be encountered, because abdominal carcinoids often have a rich vascular supply, and metastases may involve vessel-rich organs such as the liver. CVP monitoring may be very useful in these patients, especially during abdominal surgery for tumor resection. CVP monitoring may help exclude hypovolemia as a cause of hypotension and allow better attention to and adjustment of fluid balance.

The release of catecholamines should be avoided. Propofol and etomidate have been used to induce anesthesia; however, propofol has a more profound effect in suppressing the sympathetic response to intubation and, as long as hypotension is avoided, may be the best induction agent in patients with carcinoid syndrome. Etomidate may have less effect on HR and BP, but may not suppress laryngeal reflexes. The use of histamine-releasing agents such as morphine, thiopental, pancuronium, and atracurium should be avoided.

Succinylcholine-induced increases in IAP from fasciculations may trigger mediator release; however, some researchers have not found any adverse effects with its use. Opioids that are associated with histamine release should not be used. Furthermore, only nondepolarizing neuromuscular blocking agents that do not cause histamine release should be used. Because of its cardiovascular stability, vecuronium is a good choice, and rocuronium is an effective alternative.

A balanced technique that incorporates positive pressure ventilation, an inhalation agent, a nondepolarizing neuromuscular blocking agent, and an opioid, most commonly fentanyl, may be the best choice in patients with carcinoid tumors. The use of propofol infusions has also been reported. Inhalation agents with low blood-gas solubility such as desflurane are preferred, although all available inhalation agents have been used. Nitrous oxide is also

safe. High-dose opioids may be indicated because volatile anesthetics may cause myocardial depression and hypotension, resulting in the release of tumor peptides. Because these patients often have chronic right ventricular (RV) valvular lesions and heart failure, anesthetic factors that increase RV work and may precipitate acute RV failure should be avoided. Factors that increase RV work include hypoxemia, hypercarbia, and a light anesthetic plane.¹⁰⁶ Hypotension should be treated with an α -receptor agonist such as Neo-Syneprine to avoid β -adrenergic activation.

Summary

Managing the anesthetic needs of patients with hepatobiliary and GI disorders requires a thorough understanding of the normal physiologic functions of the organ systems, as well as an appreciation for the systemic implications of the pathophysiologic abnormalities discussed in this chapter. Advances in anesthetic and surgical management of patients are resulting in improved outcomes, but ongoing inquiry by clinicians and researchers is still needed. The discussions in this chapter represent some of the most current evidence available in regard to providing quality anesthesia care for and management of the patient undergoing hepatobiliary and GI procedures.

Anesthesia for Laparoscopic Surgery

Nancy A. Moriber

The advent and expansion of laparoscopic surgical techniques over the past 30 years has transformed the way in which practitioners approach the care of patients during the perioperative period. Surgeons in gynecology, urology, and general surgery are using laparoscopy to perform increasingly more complex diagnostic and therapeutic procedures (Box 34.1). In fact, in some cases laparoscopic approaches have almost entirely replaced the traditional open laparotomy. These “minimally invasive” surgical procedures offer many advantages over “open” procedures, but **Box 34.1** have also created unique challenges for the anesthesia community.

Applications of Laparoscopy

General Surgery

- Diagnosis
- Evaluation of abdominal trauma
- Lysis of adhesions
- Cholecystectomy
- Gastrectomy
- Esophagectomy
- Nephrectomy
- Lymph node dissection

- Pancreatectomy
- Appendectomy
- Inguinal hernia repair
- Bowel resection
- Esophageal reflux surgery
- Colectomy
- Myotomy
- Splenectomy/Adrenalectomy
- Liver resection
- Hiatal hernia repair
- Bariatric surgeries of all types
- Telemedicine
- Stereo imaging

Gynecologic Surgery

- Diagnosis
- Lysis of adhesions
- Fallopian-tube surgery (sterilization, ectopic pregnancy surgery)
- Fulguration of endometriosis
- Ovarian cyst surgery
- Laparoscopic-assisted hysterectomy

Urologic Surgery

- Nephrectomy
- Varicocelectomy
- Prostatectomy

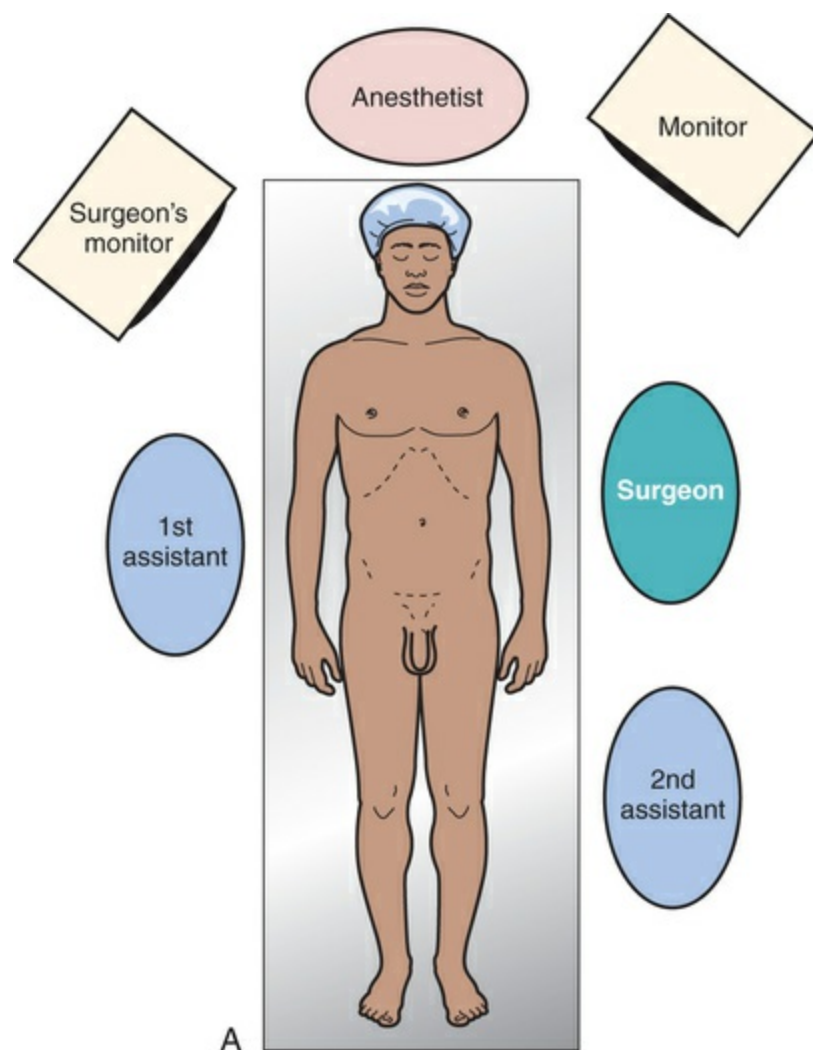

Orthopedic Surgery

- Shoulder procedures
- Knee procedures
- Ankle and wrist procedures

Although the explosion in laparoscopic surgical procedures is a relatively new phenomenon in health care, the origins of laparoscopic surgery date back over 100 years. In 1901 the first endoscopic examination of the peritoneal cavity, known at the time as *celioscopy*, was attempted by the German surgeon George Kelling to evaluate the effects of pneumoperitoneum on intraabdominal hemorrhage associated with such conditions as ectopic pregnancy and bleeding ulcers.¹⁻³ Over the next 70 years several surgeons used laparoscopic techniques, but because of technologic limitations and a high complication rate from bowel and cautery injuries and vascular perforation, few mainstream surgeons embraced the techniques.² With the development of the open entry Hasson trocar in 1971 and videoscopic imaging in the mid-1980s, the safety of laparoscopy improved dramatically. Finally, in 1988 the first videolaparoscopic cholecystectomy was performed by the French surgeon Philip Mouret and the technique soon spread worldwide as the health care community began to realize the true benefits of laparoscopy—a safer, less painful, minimally invasive alternative to open laparotomy with a faster recovery and return to normal function.^{2,4,5}

After the success of laparoscopic cholecystectomy, surgeons began to apply minimally invasive approaches to a vast array of complex intraabdominal procedures including herniorrhaphy, prostatectomy, hysterectomy, nephrectomy, splenectomy, hiatal hernia repair, as well as many others. These techniques are now

employed by many surgical specialties in patients across the life span and with significant coexisting disease. As a result, the challenges associated with laparoscopy, such as pneumoperitoneum and positioning, are coupled with increasingly critical patients, adding unique complexity to the anesthetic management for these procedures. In addition, many laparoscopic procedures are now being combined with robotic techniques, adding to the complexity of patient care (see [Chapter 35](#)). [Fig. 34.1](#) depicts a classic approach to a laparoscopic cholecystectomy.

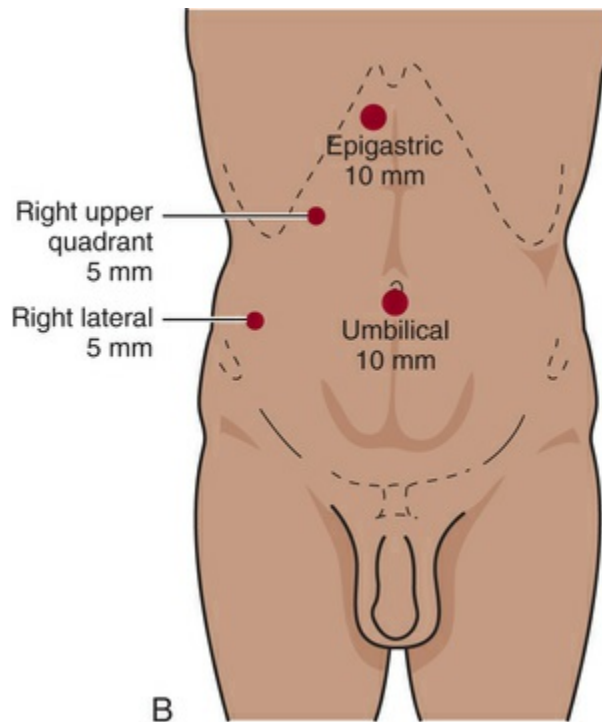

FIGURE 34.1 Laparoscopic cholecystectomy. **A**, Placement of personnel and monitors for gallbladder removal. **B**, Trocar placement for gallbladder removal. (From Phillips N: *Berry and Kohn's Operating Room Techniques*, ed 13, St. Louis, 2017, Elsevier.)

Creation of the Pneumoperitoneum

To perform laparoscopic procedures, it is necessary to create an environment in which the surgeon can clearly view all intraabdominal structures and successfully manipulate the instruments required for surgical dissection. This is accomplished through the creation of an artificial *pneumoperitoneum*—the installation of air or gas into the peritoneal cavity under controlled pressure. Although complications associated with laparoscopic surgery are rare, initial entry into the abdominal cavity and establishment of the pneumoperitoneum are responsible for a significant proportion of those that do occur.⁶⁻⁹ Large multicenter studies have demonstrated the pooled risk of severe vascular or bowel injury at the time of abdominal entry to be 0.2 and 0.4 per 1000, respectively.^{6,8} In addition to the risks caused by the placement of the surgical trocars, insufflation of gas into the peritoneal cavity produces significant physical stress on multiple organ systems. These physiologic effects are seen intraoperatively and can carry over into the immediate postoperative period, increasing the morbidity and mortality associated with these procedures.

Two entry methods are used most commonly for the establishment of the pneumoperitoneum during laparoscopic surgery—the closed technique or the open (Hasson) procedure.^{6,8} Other techniques are available but are used less often because little evidence exists to support their superiority in respect to preventing the complications associated with needle and trocar placement. These techniques include direct entry without prior establishment of the pneumoperitoneum and the use of optical entry trocars.¹⁰⁻¹² The choice of technique is determined by the surgeon; however, the evidence indicates that patients who are extremely thin, obese, or known to have abdominal adhesions are at increased risk for laparoscopic entry-related injuries at the umbilical entry point, and they may benefit from an alternative entry procedure such as the open (Hasson) or left upper-quadrant (Palmer's point) entry technique.^{6,13,14}

The closed technique involves the use of a spring-loaded needle

known as a *Veress needle* to pierce the abdominal wall at its thinnest point, either in the infraumbilical or intraumbilical region. Various different techniques have been used to test for proper placement of the Veress needle including attempted saline aspiration and hanging-drop techniques. However, a review of case control and cohort studies of women undergoing laparoscopic procedures has shown that an intraabdominal pressure of 10 mm Hg or less reliably indicates correct placement of an umbilically placed Veress needle.^{6,15-17} An appropriate nonflammable gas, usually carbon dioxide (CO₂), is then insufflated through the needle to increase the intraabdominal pressure, lift the abdominal wall, and create a space between it and the underlying organs. After insufflation of the abdomen, a trocar is inserted blindly or under direct vision to allow the surgeon to pass instruments into the abdominal cavity.^{6,7}

The open technique was developed by H. M. Hasson in 1970 in an attempt to combine the benefits of laparoscopy with the safety of open laparotomy.¹⁸ The technique involves the development of a 1- to 2.5-mm midline vertical incision that begins at the lower border of the umbilicus and extends through the subcutaneous tissue and underlying fascia.¹⁹ The surgeon is then able to directly separate the abdominal wall from the underlying tissues, minimizing the risk of damage to the bowel and vasculature. Once the surgeon has entered the abdominal cavity, a trocar can be placed under direct vision and sutured in place. Gas can then be insufflated directly through a side port in the Hasson trocar establishing the pneumoperitoneum.

Physiologic Effects of the Pneumoperitoneum

As the complexity of laparoscopic surgery and the severity of illnesses in patients undergoing these procedures increase, the need to have a comprehensive understanding of the physiologic effects of pneumoperitoneum becomes paramount. The magnitude of patient response to pneumoperitoneum depends upon multiple factors, including the degree of intraabdominal pressure generated during creation of the pneumoperitoneum, the length of surgery, patient position, patient age, perioperative volume status, and the presence of preexisting pulmonary and/or cardiovascular disease.^{9,20,21} The chemical and biophysiologic properties of the gas utilized also have an effect on the patient's response to pneumoperitoneum. Carbon dioxide has become the gas of choice in most instances because it is nontoxic, nonflammable, and readily absorbed into the blood stream with minimal risk of air embolization. In addition, it produces less hemodynamic effects when compared with other nonflammable gases such as argon, that have been utilized in laparoscopic procedures. Whereas clinical complications have not been demonstrated following transitory elevations in intraabdominal pressure, prolonged periods of high intraabdominal pressure and tension, such as those required for successful laparoscopy, may be associated with significant physiologic effects.^{9,22-24} These changes occur as a result of direct mechanical pressure and the stimulation of intrinsic neurocirculatory responses. When combined with surgery-specific conditions, unique patient positioning needs (i.e., steep Trendelenburg), and variations in anesthetic technique, the net effect of intraabdominal pressure on physiologic hemostasis may be unpredictable. Fortunately, long-term clinical complications are rare.

Cardiovascular Effects

Multiple studies demonstrate that the creation of a pneumoperitoneum is associated with significant changes in

hemodynamic and other physiologic parameters (Box 34.2). Similar hemodynamic changes have been demonstrated in the morbidly obese despite higher baseline intraabdominal pressures.²⁵

Consistently, increases in mean arterial pressure (MAP), systemic vascular resistance (SVR), and heart rate that are sustained over the duration of insufflation have been demonstrated.^{9,20,26,27}

Compression of the intraabdominal vessels and release of neuroendocrine hormones (i.e., vasopressin and renin) are implicated as causative factors in this hemodynamic response. The increases in MAP and SVR are observed regardless of whether the pneumoperitoneum is created under low pressure (12 mm Hg) or high pressure (20 mm Hg).⁹

Pneumoperitoneum Pressure Effects: 5, 10, 20, and 40 mm Hg

Effects	5 mm Hg	10 mm Hg	20 mm Hg	40 mm Hg
Cardiovascular				
Heart rate	↑	↑	↑	↓
Mean arterial pressure	↑	↑	↑	↑
Systemic vascular resistance	↑	↑	↑	↑
Venous return	→/↓	↓↑	↓↑	↓
Cardiac output	→/↓	→/↑	→/↓	↓
Renal				
Glomerular filtration rate	→	↓	↓↓	↓↓
Urine output	→	↓	↓↓	↓↓
Respiratory				
End-tidal CO ₂	→	→/↑	→/↑	↑
PCO ₂	→	↑	↑	↑
Arterial pH	→	→/↓	↓	↓

↑, increased; ↓, decreased, →, no change.

CO₂, carbon dioxide; Pco₂, partial pressure of carbon dioxide.

From Ordon M, et al. Fundamentals of Laparoscopic and Robotic Urologic Surgery. In Wein AJ, et al., eds. *Campbell-Walsh Urology*, 11th ed. Philadelphia: Elsevier; 2016:195–244.

Reports on the impact of abdominal insufflation on cardiac filling pressures are mixed. Several studies demonstrate increases in central pressures, whereas others show significant reductions.^{20,27–29} Confounding variables, such as the use of vasodilating anesthetics and perioperative fluid restrictions, can significantly alter preload. It is known that insufflation compresses abdominal vasculature, but the extent to which this impacts venous return is not fully

understood. Changes in position appear to have a greater effect on central pressures than does the pneumoperitoneum itself.^{20,27} Steep Trendelenburg produces significant increases in central venous pressure because it increases hydrostatic pressure at the level of the external auditory meatus.²⁰ In contrast, placing the patient in the head up or reverse Trendelenburg position reduces cardiac preload, which in turn will decrease cardiac index.²⁸

Uniformly, studies demonstrate that the creation of the pneumoperitoneum produces significant decreases in stroke volume.²⁷⁻³⁰ These changes appear to be secondary to decreases in venous return and not a result of changes in myocardial function. Russo et al.²⁷ demonstrated that in patients with healthy myocardium, left ventricular systolic function and ejection fraction as measured by transesophageal echocardiogram were preserved regardless of surgical position. Changes in stroke volume were associated with early diastolic impairment as a result of prolonged deceleration time and augmented isovolumetric relaxation time. The decreases in stroke volume caused by increased intraabdominal pressures can be offset through adequate perioperative hydration, changes in patient position, and the application of compression stockings because these interventions augment venous return.³⁰

Although it is clear that stroke volume decreases as a result of abdominal insufflation, the impact of pneumoperitoneum on cardiac output (CO) and cardiac index (CI) is variable because these parameters are influenced by a multitude of factors. In several studies, CO was maintained because reductions in stroke volume were offset by increases in heart rate and increases in venous return when patients were placed in the Trendelenburg position.^{27,29} Other researchers have observed significant reductions in CI after operative insufflation pressures are achieved.^{30,31} Healthy patients undergoing laparoscopic cholecystectomy have demonstrated 30% to 40% reductions in CO using a thermodilution technique.³⁰ In addition, significant reductions in left ventricular end-diastolic pressures have been demonstrated, which in turn negatively impact cardiac function if not accompanied by sufficient increases in heart rate.³¹ Despite the variability in findings, patients who have been adequately fluid loaded and who have received therapies to augment venous return (e.g., compression stockings) experience

significantly smaller reductions in CO as compared with control patients (20% versus 50%).²⁸

Finally, the pneumoperitoneum appears to have an effect on the cardiac conduction system, even in healthy patients. A study by Ekici et al.³² showed that high-pressure insufflation significantly prolonged QT dispersion (QTd) in patients undergoing laparoscopic cholecystectomy as compared with a low-pressure control group. The QTd reflects ventricular instability, and prolongation of this parameter is associated with an increased risk of arrhythmias and cardiac effects. Although these changes would not be expected to have clinical significance in healthy patients undergoing an elective laparoscopic procedure, they may produce significant hemodynamic effects in elderly patients with significant cardiac disease.

Hemodynamic Changes in the Elderly

Most research on the hemodynamic effects of abdominal insufflation has been conducted in young healthy patients. Therefore little is known about the impact of the pneumoperitoneum in the elderly population, who often present with significant comorbidities. When compared with healthy patients, patients with significant comorbidity have been shown to exhibit exaggerated hemodynamic responses to pneumoperitoneum.^{33,34} The cumulative effects of CO₂ in the pneumoperitoneum and the reverse Trendelenburg position can result in moderate decreases in CO, as well as significant increases in filling pressures and afterload in sick patients. In one study of patients undergoing laparoscopic colorectal surgery, elderly patients exhibited greater increases in central venous pressure (CVP) and decreases in MAP, as compared with younger, healthier patients.³⁴ In addition, the magnitude of these changes at different time intervals was also greater in the elderly population. These findings may reflect baseline physiologic differences in organ function and compensatory mechanisms in the elderly population.³⁴

Respiratory Effects

Although laparoscopic surgery is associated with a significant

decrease in postoperative respiratory complications, intraoperative pulmonary function is greatly impacted by both the mechanical effects of the pneumoperitoneum and introduction of CO₂ into the intraperitoneal cavity itself. Increases in intraabdominal pressure shift the end-expiratory position of the diaphragm cephalad decreasing forced vital capacity (FVC), forced expiratory volume in 1 second (FEV1), functional residual capacity (FRC), creating areas of atelectasis and making ventilation difficult.³⁵ In addition, CO₂ insufflation causes acid-base alterations that can have deleterious effects on multiple organ systems.³⁶

In the presence of fixed minute ventilation, CO₂ pneumoperitoneum is associated with increases in the partial pressure of arterial CO₂ (PaCO₂) and end-tidal CO₂ (ETCO₂) with or without acidosis.³⁶ The increases in PaCO₂ are primarily caused by CO₂ absorption through the peritoneal serosa secondary to the increased intraabdominal pressure caused by the pneumoperitoneum. The resultant acidosis is considered to be respiratory rather than metabolic in nature. Therefore increases in PaCO₂ must be offset by increased minute ventilation or CO₂ levels will continue to rise. Studies show that during laparoscopy, decreases in arterial pH are accompanied by a rise in partial pressure of carbon dioxide (PCO₂), but not by increases in lactate or decreases in the apparent strong ion difference.³⁶ These parameters return to baseline after discontinuation of CO₂ insufflation. Maximum absorption of CO₂ is noted with an intraabdominal pressure of 10 torr (mm Hg pressure). PaCO₂ levels are noted to reach a plateau approximately 40 minutes after the induction of the peritoneum.³⁶⁻³⁸

A major concern during the creation of the pneumoperitoneum involves the risk of subcutaneous tracking of CO₂ through misplaced trocars or rents in the peritoneum that develop during trocar placement. Compared with intraperitoneal insufflation of CO₂, extraperitoneal insufflation (subcutaneous absorption) has been associated with an unusually rapid increase in PaCO₂ and exceptionally high, sustained levels of CO₂.³⁹⁻⁴¹ Cases of pneumopericardium and severe emphysema of the orbit have been

documented after subcutaneous absorption of CO₂.^{39,40} Factors that increase the incidence and degree of subcutaneous emphysema during laparoscopy are listed in [Box 34.3](#).⁴²⁻⁴⁴ The anesthesia provider should suspect the development of subcutaneous emphysema if physiologic changes such as crepitus, hypercarbia, elevated end-tidal CO₂, decreased lung compliance, cardiac arrhythmias, and hypertension are observed. Management of [Box 34.3](#) subcutaneous emphysema is outlined in [Box 34.4](#).⁴³

Factors Leading to Subcutaneous Emphysema

- Insufflator (high gas flow and high gas pressure setting)
- Intraabdominal pressure > 15 mm Hg
- Multiple attempts at the abdominal entry
- Veress needle or cannula not placed in the peritoneal cavity
- Skin/fascial fit/seal around the cannulas is not snug
- Use of > 5 cannulas
- Laparoscope used as a lever
- Cannula acting as a fulcrum
- Long arm of the laparoscope is a force multiplier
- Tissue integrity compromised by repetitive movements
- Structural weakness caused by repetitive movements
- Improper cannula placement, causing stressed angulation
- Soft tissue dissection and fascial extension
- Gas dissection leading to more dissection
- Procedures lasting > 3.5 hours

- Positive end-tidal CO₂ > 50 mm Hg

From Ott DE. Subcutaneous Emphysema—Beyond the Pneumoperitoneum. *JSLs*. 2014;18(1):1–7.

Box 34.4

Management of Subcutaneous Emphysema

- Decrease intraabdominal pressure, if possible terminate pneumoperitoneum
- Discontinue nitrous oxide because it can increase subcutaneous emphysema volume
- Place on 100% FiO₂
- Evaluate for a pneumothorax
- Increase minute ventilation to treat hypercarbia
- Evaluate ET_{CO}₂ and Pa_{CO}₂
- Assess chest wall and lung compliance
- Assess airway to rule out compression prior to extubation

*ETCO*₂, End-tidal CO₂; *FiO*₂, fraction of inspired oxygen; *PaCO*₂, partial pressure of arterial CO₂.

The mechanical effects of peritoneal insufflation impair ventilation. Insufflation of the peritoneum displaces the diaphragm in a cephalad direction, decreases functional residual capacity, decreases vital capacity, and in turn induces collapse of the dependent regions of the lungs.^{35,45} Perfusion of these nonventilated alveoli causes the development of pulmonary shunt with impaired oxygenation and CO₂ elimination.^{35,45} The development of atelectasis is also associated with an increase in the arterial to end-tidal PCO₂ difference.³⁵ Therefore techniques such as transcutaneous

carbon dioxide ($P_T\text{CO}_2$) monitoring may serve as a better predictor of PaCO_2 levels than end-tidal PaCO_2 monitoring.⁴⁶ Increases in intraabdominal pressure also affect pulmonary compliance; in supine patients, pulmonary compliance has been observed to be reduced by 43%.^{20,33}

The impact of atelectasis on gas exchange has been shown to be offset by a redistribution of perfusion away from collapsed lung units when the pneumoperitoneum is established.^{45,46} Although the exact mechanism is not known, it appears to be the result of activation of the hypoxic pulmonary vasoconstriction (HPV) reflex.⁴⁵ Because many anesthetics attenuate or inhibit the HPV reflex, increases in ventilation/perfusion (V/Q) mismatching and changes in oxygenation during laparoscopic surgery may reflect the physiologic effects of the anesthetics used, rather than the impact of the pneumoperitoneum itself. This may have implications for the choice of anesthetics used during these procedures. Physiologic pulmonary changes associated with pneumoperitoneum are listed in [Box 34.5](#).

Pulmonary Function Changes Associated With Pneumoperitoneum

- Positive inspiratory pressure (PIP) ↑
- Pulmonary compliance dV/dP ↓
- Vital capacity ↓
- Functional residual capacity ↓
- Intrathoracic pressure ↑

↑, Increased; ↓, decreased; dV/dP , change in volume/change in pressure.

An additive effect is observed when general anesthesia, which in and of itself reduces FRC and pulmonary compliance, is combined with pneumoperitoneum.^{35,45} The surgical position employed to facilitate exposure can either aggravate or attenuate

pneumoperitoneum-induced pulmonary changes. The Trendelenburg position has been shown to increase the effects of pneumoperitoneum on pulmonary mechanics. During robotic laparoscopic prostatectomy in the steep Trendelenburg position, pulmonary compliance decreased approximately 50% and peak plateau pressures increased by 50%, and remained stable over the duration of the CO₂ insufflation.²⁰ In contrast, the reverse Trendelenburg position partially counteracts the effects of pneumoperitoneum on the diaphragm and improves diaphragmatic function.⁴⁷

Another impact of pneumoperitoneum is the potential for the development of endobronchial intubation as a result of a shortening of the distance from the tip of the endotracheal tube to the carina.⁴⁸⁻⁵⁰ Because the carina is attached to the lungs, cephalad displacement of the diaphragm compresses the lungs and shifts the position of the carina upward. Studies indicate that displacement of the tube occurs within 10 minutes of creation of the pneumoperitoneum; therefore the authors recommend reconfirmation of tracheal tube position after establishment of the pneumoperitoneum.^{49,50}

Controlled mechanical ventilation is necessary to maintain normocarbia in anesthetized patients undergoing laparoscopic surgery with CO₂ pneumoperitoneum. Studies of patients in the Trendelenburg position during pneumoperitoneum reveal that a 20% to 30% increase in minute ventilation is necessary to maintain prepneumoperitoneum levels and prevent respiratory acidosis.^{36,51} In these studies, increasing the minute ventilation by preferentially increasing tidal volume rather than increasing respiratory rate was the preferred method. In addition, the use of the pressure control (PC) modes appears to be more effective in maintaining arterial pH when compared with the volume control (VC) modes of ventilation.⁵² Patients ventilated using PC were also easier to ventilate, generating significantly lower maximum peak airway pressures and increased mean airway pressures. However, careful attention must be paid to changes in intraabdominal pressure as significant changes in tidal volume may occur with the release of the pneumoperitoneum.

There has been a push for the use of low tidal volume ventilation

strategies in patients undergoing major abdominal surgery by either the laparoscopic or open approach. It is well documented in the literature that high tidal volume ventilation is associated with the development of acute lung injury in the critically ill ventilator dependent patient as a result of the mechanical stress and strain placed on the lung parenchyma and the subsequent release of proinflammatory factors.⁵³ Lung protection strategies utilizing 6 to 8 mL/kg of predicted body weight, 6 to 8 cm H₂O positive end-expiratory pressure (PEEP), and intraoperative recruitment maneuvers every 30 minutes were associated with improved clinical outcomes including decreased postoperative pulmonary complications, as well as the need for postoperative intubation, and decreased length of stay.⁵⁴⁻⁵⁶

Patients with marginal cardiopulmonary function undergoing laparoscopic surgical procedures are at increased risk of decompensation when faced with the stress introduced by increases in intraabdominal pressure and CO₂ insufflation. Patients particularly vulnerable to the effects of exposure to prolonged CO₂ insufflation are those with increased metabolic rates (as in sepsis), large ventilatory dead space, and decreased cardiac output.²¹ Patients with chronic obstructive pulmonary disease (COPD) are at increased risk of developing postoperative complications after laparoscopic procedures.^{57,58} One study demonstrated the odds ratio for postoperative complication to be 1 : 63 in patients with significant COPD.⁵⁷ Studies also indicate that although healthy patients experience minor changes in PaCO₂ and ETCO₂ during CO₂ insufflation, patients with COPD show significantly higher levels of CO₂ retention and subsequent respiratory acidosis.⁵⁹ Although ETCO₂ is standard of care for all patients, careful intraoperative monitoring of CO₂ levels during laparoscopic surgery in these patients is essential. Because of the significant arterial to end-tidal PCO₂ gradient that develops during sustained pneumoperitoneum, and which is compounded in patients with chronic CO₂ retention, ETCO₂ may underestimate arterial CO₂. Therefore direct measurement of PaCO₂ via arterial blood gases or P_TCO₂ may be warranted.^{35,44} Studies show that P_TCO₂ is an accurate, noninvasive predictor of arterial carbon dioxide levels and can be used as a

proxy in patients with significant cardiopulmonary disease.⁴⁴

Mild pulmonary dysfunction after laparoscopic procedures has been shown to persist into the immediate postoperative period in patients recovering from laparoscopic surgery.⁵⁶ A slight restrictive breathing pattern in the postoperative period has been observed secondary to the residual effects of anesthesia, pain, and diaphragmatic dysfunction induced by stretching or reflex inhibition. In addition, after laparoscopic surgery, patients may still be subjected to an elevated CO₂ load secondary to systemic absorption and subcutaneous tracking of gas during the procedure.²⁵ Moreover, if surgery is prolonged and exposure to pneumoperitoneum is sustained for the majority of the procedure, CO₂ may be stored in skeletal muscle and bone. It may take hours for this excess CO₂ to be excreted from the patient.⁶⁰

Renal Effects

The effects of pneumoperitoneum on renal physiology primarily manifest as transient increases in creatinine clearance and decreases in urinary output.^{23,25,61,62} Oliguria has been reported but most commonly occurs only during periods of sustained high intraabdominal pressures.^{23,25,61,62} It is proposed that the high intraabdominal pressures created during the pneumoperitoneum cause transient renal injury by reducing renal blood flow and subsequently causing hypoperfusion of the renal cortex. High intraabdominal pressures (15 mm Hg or greater) create renal oxidative stress and the generation of tissue oxidases that promote tubular injury.²³ In addition, the neuroendocrine response to pneumoperitoneum results in the release of antidiuretic hormone (ADH), aldosterone and renin.²⁵ Elevated hormonal levels in the presence of a pneumoperitoneum induced respiratory acidosis induces a sympathetic response and renal vasoconstriction, which further diminishes renal blood flow.^{23,25,63,64}

Hepatic and Splanchnic Effects

There is conflicting evidence regarding the effects of increased intraabdominal pressure on hepatic and splanchnic blood flow. Several animal studies have demonstrated that abdominal

insufflation can cause marked decreases in splanchnic and liver perfusion, as well as intestinal ischemia secondary to the production of oxygen free radicals and bacterial translocation.^{65,66} This is further supported by the fact that approximately 50% of patients undergoing laparoscopic cholecystectomy demonstrate elevated liver enzymes.^{67,68} Other studies indicate that low-pressure insufflation of the abdomen either did not disrupt or improved hepatic and splanchnic perfusion, possibly secondary to the local vasodilatory effect of CO₂ on splanchnic vasculature.^{69,70}

Immunologic Effects

CO₂ pneumoperitoneum also may have a negative effect on the local immune response by altering the concentrations of certain cytokine levels with the peritoneum. Several studies have demonstrated that CO₂ pneumoperitoneum influences the growth of cultured human cancer cells, and that this effect is pressure dependent.^{71,72} In addition, patients receiving low insufflation pressures (6–8 mm Hg) showed statistically significant lower concentrations of C-reactive protein, interleukin-1B and interleukin-6 and other proinflammatory factors resulting in a reduction in the postoperative inflammatory response.⁷³ In contrast, other studies have shown no significant differences in levels of cytokines and other proinflammatory factors between low- and high-pressure insufflation.⁷⁴ Proinflammatory cytokines and angiogenic factors have been shown to influence neoangiogenesis, adhesion formation, and normal wound healing processes.

Complications of Laparoscopic Surgery

Although laparoscopy has revolutionized the way surgery is conducted today, it is not devoid of complications. Even though major complications are rare, when they do occur, they are usually associated with significant morbidity. More than 50% of all complications occur during entry into the abdomen and insertion of trocars.^{8,75} Entry-related complications involve intestinal, urinary tract, and vascular injuries, as well as carbon dioxide gas embolism.⁷⁵ The reported incidence of these injuries is between 0.3% and 1.0% of all laparoscopic procedures.^{75,76}

Unfortunately, approximately 30% to 50% of these injuries go undiagnosed intraoperatively, resulting in significant surgical mortality (3.5–5%).⁸ Rates as high as 30% have been reported when major bowel and vascular injuries occur.⁷⁷ Delayed diagnosis may occur because initial signs and symptoms may be confused with other conditions such as anaphylaxis, gas embolism, or perioperative cardiac events. Frequently, bleeding may be occult and confined to the retroperitoneal space, which can tamponade significant hemorrhage.

The potential for injury to intraabdominal structures during the creation of the pneumoperitoneum is easily understood when one considers the proximity of anatomic structures to the site of incision and infraumbilical puncture. The major abdominal vessels including inferior vena cava, aorta, and iliac arteries and veins, as well as the bladder, bowel, and uterus, lie in close proximity to the entry points. Factors that increase risk of injury include body habitus, anatomic anomalies, prior surgery, surgical skill, degree of abdominal elevation during trocar placement, patient position, and the volume of gas insufflation.^{6,75,76}

A prompt and coordinated response is required to prevent morbidity associated with vascular injury. Blood on aspiration of the Veress needle, free intraperitoneal blood, or unexplained hypotension and tachycardia should alert the operative team to a potential vascular injury.⁷⁵ Retroperitoneal hematomas are often

difficult to visualize during laparoscopy and may become apparent only when blood loss is significant. Temporary measures to control bleeding may be possible through the abdominal trocar while resuscitative measures are instituted, but definitive treatment is usually achieved via conversion to an open laparotomy.

Visceral injuries can occur at any time during laparoscopy and are associated with significant morbidity and mortality. Intestinal injuries occur in 0.3% to 0.5% of operative laparoscopies, and less than 50% of these are recognized at the time of surgery. Diagnosis is difficult because presenting symptoms vary significantly depending upon the location of injury and degree of peritoneal contamination. Early recognition and surgical repair is essential to prevent mortality from bowel injuries. Untreated patients may develop peritonitis, sepsis, respiratory distress, and multisystem organ failure.⁷⁶ Because of the seriousness of these complications, many practitioners advocate the use of the open (Hasson) entry laparoscopic technique, because it is believed to be associated with a lower incidence of unrecognized vascular and visceral injury.⁶

Injury to the urinary tract occurs in 0.5% to 8.3% of cases secondary to trauma from instrument manipulation, electrocautery, or laser.⁷⁸ These injuries are easily recognized by direct visualization of urine leakage from damaged structures. Therefore urinary bladder catheterization and instillation of methylene blue dye is often employed during these procedures when significant risk of damage to urinary structures is suspected.⁷⁵

To help decrease the incidence of major vascular and visceral injury during laparoscopic surgery, the Royal College of Obstetricians and Gynaecologists has established evidence-based practice guidelines for abdominal entry.⁶ Quality randomized controlled trials and systematic reviews consistently demonstrate that placement of the primary trocar under high pressure (25 mm Hg) creates the safest distance between the anterior abdominal wall and underlying abdominal contents in order to minimize injury from trocar insertion. In addition, in healthy patients these transitory, high intraperitoneal pressures appear to be well tolerated without significant adverse clinical effects.⁹

Another potentially life-threatening complication of laparoscopic surgery is gas embolism. Gas embolism is defined as the direct

entrainment of air and/or other medical gases, such as carbon dioxide, into the arterial or venous system.^{75,78} Significant gas embolism is rare, having a reported incidence of 0.001% to 0.59% and an associated mortality rate of up to 28.5%.⁷⁵ Massive and/or fatal gas embolisms have been reported during all types of laparoscopic procedures including laparoscopic cholecystectomy, liver resection, and hysterectomy.^{79,80} It can occur any time there are open vessels that have an intravascular pressure that is below intraabdominal pressure or with the erroneous placement of a Veress needle or trocar directly into the lumen of an intraabdominal vessel. However, studies that have evaluated methods of increasing CVP, such as the use of PEEP, in order to decrease the pressure gradient across vessels have not shown them to be effective in reducing the incidence of gas embolism.⁷⁹

Both animal and human studies using transesophageal echocardiography and monitoring of pulmonary artery pressure have shown that the actual incidence of gas embolism during laparoscopic procedures is between 65% and 100%.^{78,81,82} The majority of these embolisms, although minor, were still associated with respiratory and hemodynamic changes that usually resolved spontaneously. These studies raise concerns regarding best practices for appropriate monitoring during the perioperative period in patients undergoing laparoscopic procedures. Intravascular insufflation of large volumes of gas can travel to the right side of the heart where they enter the pulmonary circulation and lodge in the pulmonary outflow tract, causing increased pulmonary artery pressure, right ventricular failure, decreased pulmonary venous return with subsequent decreased left ventricular preload, decreased cardiac output, asystole, and cardiovascular collapse.⁷⁵

Other gases such as helium have been utilized for peritoneal insufflation in order to avoid the negative side effects of CO₂ insufflation including CO₂ accumulation, hypercarbia, acidosis, and sympathetic nervous system stimulation, particularly in patients with preexisting impairment in respiratory function (COPD, infancy). Although helium pneumoperitoneum is associated with a greater degree of cardiopulmonary stability, there appears to be a higher incidence of subcutaneous emphysema and life-threatening

gas embolism even with entrainment of small volumes.^{83,84}

Signs and symptoms of a significant gas embolism in the anesthetized patient include an acute decrease or loss of end-tidal partial pressure of carbon dioxide ($P_{ET}CO_2$), and an increase in end-tidal nitrogen, which is accompanied by hypotension and/or hypoxia that cannot be explained by deep anesthesia or hypovolemia. Dysrhythmias, severe hemodynamic instability, and cardiovascular collapse can occur when large volumes of gas are entrained, especially in patients with impaired cardiovascular function and minimal cardiac reserve.⁷⁸

Diagnosis of gas embolism depends upon recognition of the physiologic manifestations of gas emboli and/or visual detection of gas emboli in the right side of the heart and pulmonary outflow tract. Transesophageal echocardiography is the most sensitive diagnostic technique for the detection of gas emboli and can identify emboli as small as 0.02 mL/kg.⁸⁵ However, this technology is rarely used because these volumes of air are well tolerated and usually not associated with hemodynamic changes. Changes in Doppler sounds and increases in pulmonary artery pressures will occur with volumes of 0.5 mL/kg of gas. Unfortunately, when the “classic mill wheel murmur” is audible, gas volumes of 2 mL/kg or more have been entrained, and significant hemodynamic instability is present manifesting in tachycardia, hypotension, cardiac dysrhythmias, cyanosis, and electrocardiogram (ECG) changes indicative of right-sided heart strain.⁸⁶

Management of gas embolism includes halting the insufflation of gas, eliminating nitrous oxide (N_2O) from the anesthetic gases if it is being administered to prevent expansion of the embolism, releasing the pneumoperitoneum, flooding the field with normal saline to halt gas entrainment, placing the patient in left lateral decubitus position (Durant maneuver), aspirating the gas through a central venous catheter if in place, and supporting the hemodynamics with volume and pressors as required.⁸⁶ Low CVP increases the risk of venous gas embolism; therefore adequate hydration should be provided for the patient undergoing laparoscopy.⁸⁷ However, the decision to obtain central venous access during laparoscopic procedures is guided by the complexity of the surgical procedure and presenting comorbidities of the patient, rather than as a means

of managing perioperative gas embolism. [Box 34.6](#) lists the signs, symptoms, and treatment of venous gas embolism.

Gas Embolism

Signs and Symptoms

- $\downarrow P_{ET}CO_2$, \uparrow end-tidal nitrogen
- Oxygen saturation \downarrow
- Chest pain, dyspnea (spinal or epidural anesthesia)
- Increased pulmonary artery pressures
- Hypotension
- Dysrhythmias
- Cyanosis
- Hypoxia
- Pulmonary edema
- Wheezing, rales
- “Mill wheel” murmur
- Detection of air in the heart by transesophageal echocardiography or precordial Doppler ultrasound

Treatment

- Discontinue gas insufflation
- Discontinue nitrous oxide
- Administer 100% oxygen
- Release pneumoperitoneum

- Flood surgical field with normal saline
- Position patient in left lateral decubitus position
- Attempt to aspirate gas via central venous catheter
- Supportive measures to maintain hemodynamics

↑, Increased; ↓, decreased; $P_{ET}CO_2$, end-tidal pressure of carbon dioxide.

Another set of serious but rare complications related to the creation of pneumoperitoneum occur as a result of migration of gas into adjacent body cavities and include unilateral or bilateral pneumothorax, pneumomediastinum, and pneumopericardium. Gas may enter the thoracic cavity via congenital defects in the diaphragm, embryonic connections between the thoracic and abdominal cavities that may open under high pressure, or through perforations in the diaphragm or pleura during upper abdominal laparoscopic procedures, most commonly during laparoscopic esophageal surgery.⁸⁸⁻⁹⁰ A retrospective review of 968 cases revealed an incidence of pneumothorax or pneumomediastinum in 1.9% of patients.⁹¹ Another possible cause of pneumothorax is barotrauma secondary to increased airway pressures and decreased pulmonary compliance as a result of abdominal insufflation.⁹² Pneumothorax caused by CO₂ insufflation may rapidly resolve spontaneously without intervention.⁹³ However, pneumothorax that results from barotrauma, such as a ruptured bleb, requires surgical decompression and chest tube placement.⁹² Risk factors associated with the development of pneumothorax during laparoscopy include procedures involving laparoscopic mobilization of the esophagus, operative times over 200 minutes, end-tidal CO₂ greater than 50 mm Hg, and operator inexperience.⁹⁰

Mild to severe localized or generalized subcutaneous emphysema is a frequent manifestation of pneumoperitoneum that occurs as a result of gas entry into the subcutaneous tissues. As previously discussed, it can be the result of trocar or Veress needle misplacement in subcutaneous tissue or the result of high

intraabdominal pressure and movement of gas through defects in the peritoneum.³⁸⁻⁴⁰ However, the incidence of extraperitoneal insufflation appears to be the same regardless of the laparoscopic entry technique utilized.⁹⁴ Most cases of subcutaneous emphysema are clinically insignificant; however, it has been associated with the development of severe hypercarbia, decreased chest compliance, and hemodynamic instability.^{20,42} Most cases resolve spontaneously.

The ideal gas for the creation and maintenance of pneumoperitoneum would demonstrate several properties, including colorlessness, lack of flammability in the presence of electrocautery, physiologic inertness, and excretion via a pulmonary route.⁸³ Several gases have been investigated in an attempt to find an alternative to CO₂ that is devoid of hemodynamic and respiratory effects.⁸³ Both N₂O and air support combustion and could not be used in the presence of electrocautery, which is essential for successful laparoscopy.⁶⁰ Inert gases such as helium have been evaluated for use in abdominal insufflation, but helium is not highly insoluble and raises issues about safety in the presence of a significant gas embolism.^{83,95}

Despite efforts to identify other gases suitable for the development of the pneumoperitoneum, CO₂ has proven to be closest to an "ideal" gas for abdominal insufflation. CO₂ is readily available and inexpensive, does not support combustion, and is rapidly absorbed from the vascular space and is readily excreted by the respiratory system. However, when used in a pneumoperitoneum, prolonged CO₂ absorption can cause hypercarbia and respiratory acidosis.⁸⁰ It is also a known peritoneal and diaphragmatic irritant, which has been implicated as a causative factor in the development of postoperative shoulder pain.⁹⁶

Anesthetic Management

Laparoscopic procedures have been performed using local, regional, and general anesthetic techniques. The choice of anesthetic technique is dependent upon the specifics of the surgical procedure, method of insufflation utilized and patient preference.

Local anesthesia with sedation has been used successfully in the United States for patients undergoing minor gynecologic laparoscopic surgical procedures such as diagnostic laparoscopy or sterilization since 1971.⁹⁷ Gasless laparoscopy has been shown to be useful in the emergency department for the diagnosis of acute abdomen and the management of hemodynamically stable patients with penetrating abdominal injury. The use of local anesthesia is facilitated by surgical techniques such as the use of single-port techniques, low-pressure pneumoperitoneum, and port and small-diameter laparoscopes.^{98–100} Research indicates that compared with patients who received general anesthetics, patients who received local anesthesia had shorter hospital stays and a reduction in overall hospital and anesthesia costs.^{97,100} In addition, they demonstrated a faster recovery, decreased incidence of postoperative nausea and vomiting, and fewer hemodynamic changes.^{97,100,101} However, use of this anesthetic technique requires a cooperative patient and gentle surgical manipulation. When heavy sedation is required, the combination with pneumoperitoneum can result in hypoventilation and arterial oxygen desaturation.

Regional anesthesia techniques, including spinal and epidural anesthesia, have also been used successfully for laparoscopic procedures, including cholecystectomy, without significant ventilatory compromise.¹⁰² Regional techniques are associated with a reduction in the stress response, early ambulation with a lower incidence of deep vein thrombosis and effective postoperative analgesia.¹⁰² However, significantly high sensory levels are required for these procedures, which may result in significant patient discomfort and hypotension due to sympathetic blockade. In addition, there is a high incidence of shoulder pain reported (27%–47%) secondary to diaphragmatic irritation from insufflated carbon dioxide that is not well managed by means of regional

techniques.^{103,104}

General anesthesia is the most common anesthetic technique used during diagnostic and surgical laparoscopy. General anesthesia allows for control of ventilation and facilitates management of patient discomfort associated with the creation of the pneumoperitoneum and changes in intraoperative position such as steep Trendelenburg.

Most often the airway is secured with a cuffed endotracheal tube to facilitate ventilation and prevent aspiration of gastric contents. Minute ventilation is increased by approximately 15% to 35% to offset CO₂ absorption and maintain P_{ET}CO₂ between 35 and 45 mm Hg. This is most effectively performed using pressure-controlled versus volume-controlled ventilation.⁵² Intraoperative recruitment maneuvers, the application of PEEP, and the use of innovative ventilator modes have all been successful in improving lung compliance, oxygenation, and ventilation.¹⁰⁵⁻¹⁰⁷ Studies show that recruitment maneuvers that use the combination of PEEP 10 cm H₂O and intermittent positive airway pressure (40 cm H₂O) for 40 seconds was most effective in improving end-expiratory lung volumes, lung compliance, and arterial oxygenation in both healthy weight and obese patients than either intervention alone.^{106,107}

The use of laryngeal mask airway (LMA) and other supraglottic airway devices in patients receiving general anesthesia for laparoscopic surgery remains controversial. Several authors have expressed concerns that the increased intraabdominal and intrathoracic pressures characteristic of pneumoperitoneum place the patient at increased risk of gastroesophageal reflux and pulmonary aspiration. In addition, the classic LMA does not secure the airway and the low seal pressures preclude the use of high airway inflation pressures without causing gastric distention.¹⁰⁸

The barrier pressure (BrP) quantifies resistance to gastroesophageal reflux and is defined as the difference between the lower esophageal sphincter pressure and the gastric pressure.¹⁰⁹ To prevent aspiration, the gradient needs to remain positive because this will help prevent the lower esophageal sphincter from opening. A study examining the effect of induction, intubation, anesthesia, and pneumoperitoneum on barrier pressure in nonobese patients undergoing laparoscopy and obese patients

undergoing laparoscopic gastric bypass showed that BrP decreased in both groups but at all times remained positive.¹⁰⁹ The obese patients, however, had lower BrP at all points when compared with the nonobese patients, suggesting that they may be at increased risk for aspiration. In addition, Rabey et al.,¹¹⁰ in a study of general and orthopedic surgery patients, demonstrated reductions in lower esophageal sphincter pressures when an LMA was used as an airway in general anesthesia.

Researchers have conducted studies to evaluate the safety and efficacy of LMAs in a variety of laparoscopic procedures. A meta-analysis by Brimacombe and Berry¹¹¹ of 547 LMA publications, which used multiple anesthetic techniques, found the incidence of pulmonary aspiration to be two in 10,000 or 0.02%. Most of these patients demonstrated preexisting risk factors for pulmonary aspiration. A meta-analysis by Beleña et al.,¹¹² of 704 patients undergoing laparoscopic cholecystectomy demonstrated a similar incidence of aspiration (0.4%). In all of these studies optimal ventilation was provided in approximately 99.5% of cases.^{111,112}

Several studies have also examined the efficacy of several types of supraglottic airway devices for the management of ventilation during laparoscopic procedures. A study comparing the ProSeal LMA and Laryngeal Tube Suction demonstrated that both devices were able to provide a secure airway under conditions of elevated intragastric pressure and positive pressure ventilation, without evidence of pulmonary aspiration.¹¹³ In addition, both devices allow for decompression of the stomach so that continuous gastric decompression can be accomplished.¹¹² The efficacy of the LMA supreme versus the i-gel was also evaluated in approximately 100 patients undergoing laparoscopic surgery in the Trendelenburg position.¹¹⁴ Again, both devices provided an adequate seal during controlled ventilation and allowed for decompression of the stomach throughout the procedures. Similar findings were demonstrated in a randomized prospective study evaluating the Cobra Perilaryngeal Airway and the LMA classic.¹¹⁵ Finally, the efficacy of the ProSeal LMA was also compared to the LMA Supreme in elective cholecystectomy in order to examine ease of insertion and oropharyngeal leak pressure (OLP).¹¹⁶ Whereas the LMA supreme was easier to insert and demonstrated higher

success rates for first-time insertion, the OLP was much higher with the ProSeal LMA, which allowed for the delivery of greater tidal volumes and more effective ventilation. These studies suggest that the LMA ProSeal may offer some advantages when concerns for the adequacy of ventilation exist.

The evidence suggests that under certain circumstances, the use of the LMA and other supraglottic devices may be appropriate during laparoscopy, but no general consensus exists to date.^{112,117} Many clinicians feel that the risk of airway difficulties is too high to warrant their use. With the development of newer supraglottic devices that allow for decompression of the stomach and adequate high-pressure ventilation, the issue may become clearer. Recommendations for clinicians using supraglottic airways for laparoscopic procedures are presented in [Box 34.7](#).

Guidelines for Use of the Laryngeal Mask Airway During Laparoscopy

- Ensure that clinician is an experienced LMA user.
- Select patients carefully (e.g., fasted, not obese).
- Use correct size of LMA.
- Use LMA that allows for gastric drainage (i.e. LMA Proseal).
- Make surgeon aware of the use of LMA.
- Use total IV anesthetic technique or volatile agent.
- Use low-pressure insufflation.
- Avoid steep Trendelenburg position.
- Avoid inadequate anesthesia during surgery.
- Avoid disturbance of the patient during emergence.

The airway in day surgery. *Minerva Anesthesiol.* 2010;76(1):38–44.

There is no one specific anesthetic technique that is best for laparoscopic surgery. The choice is dictated by a combination of factors including the surgical procedure, postoperative disposition of the patient (ambulatory or in-patient) and the presence of coexisting disease processes. However, the use of N₂O in laparoscopic surgery has been a source of controversy because of beliefs that N₂O contributes to bowel distention and increases the incidence of postoperative nausea and vomiting (PONV). Based upon the evidence, the jury is still out.

The effect of N₂O on the incidence of PONV has been evaluated in several studies. A randomized controlled trial (2008) in three groups of patients undergoing gynecologic laparoscopy showed that N₂O increases the incidence and severity of PONV in a dose-dependent manner.¹¹⁸ Patients who received 70% N₂O had a statistically significant greater incidence of nausea than patients who received no N₂O or 50% N₂O. However, a similar study showed that the elimination of N₂O from a propofol-based anesthetic for ambulatory gynecologic surgery had no effect on readiness to discharge and did not increase the incidence of adverse postoperative events including PONV.¹¹⁹

The effect of N₂O on bowel distention has been examined in two studies. In a randomized controlled trial involving 28 patients undergoing laparoscopic donor nephrectomy, the use of N₂O caused bowel distention in 50% of patients.¹²⁰ In 25%, the distention was severe enough to interfere with the progress of the surgery and as a result needed to be discontinued. In contrast, a randomized controlled trial examined the use of N₂O in 50 morbidly obese patients undergoing laparoscopic bariatric surgery.¹²¹ Half of the patients received N₂O as part of the anesthetic and the other half did not. The surgeons, unaware of anesthetic technique, were unable to detect any differences in bowel distention between the

groups over a 90-minute time period.

There is also controversy surrounding the use of muscle relaxants for laparoscopic surgical procedures. It has been hypothesized that deep neuromuscular blockade as demonstrated by a train-of-four (TOF) count of zero but a post-tetanic count of 1 or more, would allow for better surgical operating conditions at lower insufflation pressures.¹²² However, studies from 2013 have demonstrated no differences in operating conditions or long-term benefits during laparoscopic gynecologic procedures under varying levels of neuromuscular blockade.^{123,124} In addition, deep blockade does not appear to allow for the use of lower insufflation pressures and may be associated with inadequate reversal and postoperative respiratory depression.^{122,125}

Postoperative Concerns

Postoperative nausea and vomiting is a major concern for patients undergoing laparoscopic surgical procedures. In fact, patients report that they are more worried that they will experience nausea and vomiting after surgery than they are about experiencing postoperative pain.¹²⁶ The incidence of PONV in the laparoscopic population has been reported to be as high as 72% and is known to be associated with significant postoperative complications such as surgical wound dehiscence, aspiration, and unanticipated hospital admission.^{127,128} Because the etiology of PONV is multifactorial, multimodal therapy using antiemetics that target different receptors has become standard of care.^{128,129} The use of total intravenous anesthesia (TIVA) and a combination of antiemetics has been reported to decrease the incidence of PONV to less than 10%. A randomized controlled trial compared TIVA and multimodal therapy with inhalation anesthesia plus multimodal therapy or propofol anesthesia alone.¹³⁰ The study showed that patients who received TIVA and multimodal therapy had a 90% response rate versus 63% and 66% in the other two groups. In addition, multimodal therapy was associated with a greater degree of patient satisfaction.

Although the development of laparoscopic surgical procedures has reduced the overall need for analgesia both intraoperatively and postoperatively, pain still continues to be a concern in the postoperative period. Pain after laparoscopy is comprised of three components; incisional pain (parietal pain), deep intraabdominal pain (visceral pain), and shoulder pain, which is believed to be referred visceral pain.¹³¹ However, the majority of postoperative pain after laparoscopic surgery is typically of a visceral quality on the day of surgery, with shoulder pain predominating on the first postoperative day.¹³² The creation of the pneumoperitoneum is associated with distention of the peritoneum and abdominal wall, and in conjunction with visceral dissection and resection activates nociceptors via the enteric nervous system.⁹⁶ The enteric nervous system is a complex system that functions to some extent independent of the central nervous system.⁹⁶ The peritoneum and

viscera convey unpleasant sensations and autonomic reactions to injury via the vagus nerve giving rise to both painful and nonpainful sensations.^{133,134} In addition, intraabdominal CO₂ contributes to postoperative pain by decreasing intraperitoneal pH and causing irritation of the phrenic nerve.¹³⁵

Management of postoperative pain in laparoscopy patients is complex and involves a multimodal approach that includes opioids, nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, and local anesthetics. The multimodal approach has been found to improve patient satisfaction, decrease opioid requirements, and decrease the incidence of postoperative complications including PONV and unplanned hospital admission.^{96,136}

NSAIDs have proven to be of value in managing postoperative laparoscopic pain. Several types of NSAIDs have been used including the cyclooxygenase-2 (COX-2) inhibitor celecoxib, ketorolac, and acetaminophen, and their efficacy has been repeatedly studied. Although NSAIDs are not potent enough as a sole analgesic for managing laparoscopic pain, they have been shown to act synergistically leading to decreased opioid use. A double-blinded, placebo-controlled, randomized study of 80 American Society of Anesthesiologists (ASA) class I to III patients undergoing out-patient laparoscopy showed that short-term use of celecoxib decreased postoperative pain and postoperative opioid-containing analgesic requirements, while improving the quality of recovery.¹³⁷ In addition, multiple NSAIDs are being combined to optimize their effectiveness. A retrospective comparative study examining the efficacy of preemptive administration of pregabalin, acetaminophen, and celecoxib for the management of perioperative pain after robotic-assisted laparoscopic radical prostatectomy showed a decrease in both intraoperative and postoperative opioid use.¹³⁸ The efficacy and utility of celecoxib for use in the management of postoperative pain was confirmed in a 2015 Cochrane report.¹³⁹

Glucocorticoids also have been used successfully for the management of post-laparoscopy pain. In addition to possessing antiemetic properties, glucocorticoids have antiinflammatory and analgesic properties that make them useful in the management of visceral pain. The exact mechanism is not fully understood, but it is

known that glucocorticoids reduce prostaglandin synthesis by inhibiting phospholipase enzyme and cyclooxygenase type II. In addition, they modulate the inflammatory response by inhibiting major cytokines including C-reactive protein, tumor necrosis factor, and several interleukins.¹⁴⁰ In a randomized controlled trial, the efficacy of dexamethasone administration in decreasing perioperative opioid consumption was evaluated.¹⁴¹ The study showed that preemptive administration of glucocorticoids decreased total opioid consumption in the first 24 hours after laparoscopic hysterectomy. In addition, it was not associated with an increase in adverse effects.

The effectiveness of peripherally administered local anesthetics in the management of postoperative laparoscopy pain is a complicated question because research evidence remains mixed. A systematic review of postoperative pain management strategies demonstrated that infiltration of surgical incisions at the end of procedures was effective in the management of postoperative pain.¹⁴² In addition, intravenous lidocaine infusions were shown to be useful for rescue therapy. However, neuraxial techniques are not necessary because of a high risk:benefit ratio. Evaluation of studies of intraperitoneal local anesthesia injection showed that the technique improved overall pain scores but questioned the clinical significance of the treatment effect. In contrast, a 2011 meta-analysis of five randomized trials evaluated the efficacy of intraperitoneal local anesthetic for pain reduction after laparoscopic gastric procedures.⁹⁶ The analysis revealed an overall reduction in abdominal pain intensity, reduced incidence of shoulder pain, and decreased opioid use without adverse effects in patients managed using the block. Other techniques, such as ultrasound-guided transversus abdominus sheath block, are also proving to be effective in the management of post-laparoscopy pain by blocking the terminal branches of the lower intercostal nerves in a T8 to L1 dermatomal distribution.¹⁴³⁻¹⁴⁵

The Future of Laparoscopic Surgery

Minimally invasive surgery has become the norm over the last 20 years, prompting major advances in laparoscopic techniques. Innovations in technology include the development of robotic-assisted surgical systems such as the DaVinci Surgical System, which provide for greater surgical precision, decreased postoperative pain, and shorter lengths of hospital stay^{146,147} (see [Chapter 35](#)). In addition, efforts have been made to eliminate the need for pneumoperitoneum through the development of “gasless” laparoscopic systems. The gasless laparoscopy technique creates a working space for the surgeon by inserting a fan-shaped device into the abdomen to lift the abdominal wall away from the viscera, eliminating the need for CO₂ insufflation. Current research shows much promise for this technique. Compared with conventional laparoscopy, gasless laparoscopy was associated with lower intraoperative blood loss, decreased postoperative pain, and less postoperative inflammation.¹⁴⁸⁻¹⁵⁰

The development of robotic-assisted laparoscopic surgery has allowed surgeons to overcome some of the limitations imposed by standard laparoscopic technology.^{146,147} A surgeon using robotic-assisted technology controls surgical instruments from a control console that may be immediately adjacent to the patient, within the operative suite, or at a site hundreds of miles away from the operating room. An important advantage of robotic technology is the incorporation of three-dimensional (stereoptic) imaging, which permits superior depth perception. Robotic-assisted surgery offers the surgeon improved ergonomics, superior dexterity, and the ability to use traditional open surgical skills for laparoscopic operations. Robotic-assisted surgical techniques have been used in all types of procedures—cardiac, general, gynecologic, and urologic surgical specialties. The anesthetic management of these procedures is discussed in [Chapter 35](#).

Summary

As technology advances, laparoscopic surgical techniques will be employed in increasingly more complicated procedures and patient populations. Providing safe and effective anesthetic care demands that the anesthesia care provider understand the unique challenges of laparoscopic surgery, with particular attention to the physiologic effects of carbon dioxide insufflation and pneumoperitoneum.

Anesthesia for Robotic Surgery

Nancy A. Moriber

Robotic surgical techniques have evolved as an offshoot of the minimally invasive surgical phenomenon. Robotic systems provide surgeons with improved dexterity that translates into greater stability of surgical instruments and greater surgical precision.¹ As a result, robotic procedures have been shown to benefit both the patient and the hospital system, demonstrating improved outcomes including decreased length of stay, decreased postoperative pain, decreased infection risk, and improved overall patient satisfaction.^{1,2} Minimally invasive robotic-assisted surgery has been utilized in a vast array of surgical specialties, including general surgery, urology, gynecology, cardiac surgery, and otolaryngology. However, these advances in surgical technique have created unique challenges for the anesthetic management of patients undergoing robotic procedures in order to assure patient safety and hemodynamic stability.

History of Robotic Surgery

Whereas science has seen the development of robots over the past 75 years, the first conceptualizations as an adjunct for use in surgery began in the mid- to late-1980s at the National Aeronautics and Space Administration (NASA) Ames Research Center in Palo Alto, CA.³ This work marked the beginning of the development of “virtual reality”, which made it possible to interact with three-dimensional space. The NASA-Ames team took the concept of virtual reality to engineers at the Stanford Research Institute with expertise in human interface technology in order to develop an extremely dexterous telemanipulator that would revolutionize vascular and nerve anastomoses for hand surgery by providing surgeons with the sense that the surgical field was directly in front of them, even when operating at a distance.

While the NASA-Ames group was working on their robotic system, the laparoscopic cholecystectomy was developed in France.³ As a result of the widespread implementation of this procedure, it became apparent that it created enormous challenges for the surgeon, including degradation of the sense of touch, loss of natural three-dimensional visualization, and impairment of dexterity as a result of the fulcrum effect, which could be resolved by the integration of robotic systems.^{4,5} The fulcrum effect is a nonintuitive motion of laparoscopic instrument tips around a fixed point, which in laparoscopic procedures is considered to be the skin insertion site.

The earliest robotic surgical device was created in 1992 for use in hip replacement surgery. The RoboDoc (Integrated Surgical Systems) was developed to precisely core out the femoral shaft with 96% precision, far exceeding the 75% accuracy of manual approaches.³ However, despite the accuracy of the instrument, it would be many years before it would be approved by the Food and Drug Administration (FDA). At the same time, the military became interested in developing remote surgical technologies that would enable surgeons, through telepresence, to stabilize soldiers who would otherwise die on the battlefield.⁶ Although these systems have never been implemented for use on the battlefield, they

provided the technology that supports many of the systems in use today.

The first robotic system approved by the FDA was the Automated Endoscopic System for Optimal Positioning (AESOP), which allowed for precise control of the camera in laparoscopic procedures and launched the era of robotic general surgery.⁷ AESOP would then evolve into the Zeus Robotic Surgical System (Computer Motion, Inc.). Simultaneously, the Stanford Research Institute developed the first master-slave manipulator for medical use. This system was unique in that it was capable of offering four degrees of freedom in instrumentation motion. In 1994, the rights to this robotic system were purchased by Intuitive Surgical (Mountainview, CA), and after extensive redesign, the da Vinci surgical system, which offered greater dexterity and six degrees of freedom, was introduced.⁸ The da Vinci system displayed an image just above the surgeon's hands, giving the appearance that the surgical instruments operated as an extension of the hands. In April 1997, the first da Vinci robotic surgical procedure was performed in Brussels, Belgium.⁹ The FDA approved the da Vinci System in 2000. Finally, in 2003, Computer Motion and Intuitive Surgical merged, combining their technology to become the da Vinci systems in use today.

Over the past 10 years, there has been a dramatic increase in the number of robotic procedures performed as a result of major advances in technology. In 2014 alone, an estimated 570,000 robotic procedures were performed worldwide, the majority of which were hysterectomies and prostatectomies.¹⁰ Today, robotic techniques are employed in all surgical specialties, including colorectal surgery, cardiac surgery, gynecology, urology, and otolaryngology.

Robotic Systems

Robotics systems are classified according to the degree of “hands on” control required from the operator. Assist devices such as AESOP are used to guide and control the location of surgical instruments, but require the input of specific cues from the operator. They are not autonomous and cannot operate on their own. In contrast, telemanipulators, such as the da Vinci surgical system, require continuous hands-on control from the operator so that the movement of the instruments exactly replicates the motion of the operator. Currently, the da Vinci system is the only FDA-approved robotically-assisted surgical system in the United States.

The da Vinci system consists of three components: the vision system, the surgeon console, and the patient-side cart (Fig. 35.1).¹¹ The vision system is comprised of the endoscope, the cameras, and all the equipment necessary to produce a three-dimensional image of the operative field. The patient side-cart contains three to four robotic arms, which are designed to hold the endoscope and the EndoWrist surgical instruments.¹¹ The EndoWrist instruments mimic the motions of the human hand and wrist in three-dimensional space. The current EndoWrist instruments possess seven degrees of freedom, including three arm motions (in-out, up-down, side-to-side), three wrist motions (side-to-side, left, and right yaw), pitch, and rotation, allowing for greater rotation and pivoting. Once the instruments are properly positioned at the surgical field, they are docked in place by the patient side-cart.

FIGURE 35.1 Surgeon operates while seated at the robotic console. (Courtesy of Intuitive Surgical Inc., Sunnyvale, CA.)

The surgeon console stands several feet away from the operating room table and serves as an operating station from which the surgeon can manipulate the robotic arms and attached instruments within the surgical field. The surgeon's fingers are inserted into rings on the console's levers, which allows him or her to finely control the movement of the surgical instruments. The image displayed on the console is transmitted via two separate channels to create the virtual three-dimensional image visualized by the operator. The surgeon's head must be placed in the viewer, or the system will lock automatically and remain motionless until it senses the presence of the surgeon's head once again. In order to assure the sterility and safety of the surgical field, a second surgeon is always present to ensure that institutional protocols are followed and to adjust the camera and docked instruments as needed.

General Anesthetic Considerations

Minimally invasive robotic surgery is associated with improved patient outcomes, including decreased length of stay, faster recovery, reduced perioperative blood loss, and reduced postoperative pain.^{1,12} However, the transition to robotic surgery has created challenges for anesthetic management that are unique to patients undergoing these procedures. Additional factors must be taken into consideration, depending upon the surgical specialty involved. Regardless of the procedure, however, the anesthetic plan must take into consideration the following factors: (1) prolonged surgical times; (2) spatial restrictions associated with use of the robot; (3) inability to alter patient position after docking of the robot; (3) physiologic changes associated with extreme positioning; (4) risk of postoperative visual loss (POVL); (5) physiologic consequences associated with the creation of pneumoperitoneum (see [Chapter 34](#)); and (6) implementation of Enhanced Recovery after Surgery (ERAS) protocols.^{12,13}

Surgical Time, Spatial Restrictions, and Mobility Issues

Robotic surgery is associated with significantly longer operative times but shorter hospital stays as compared with traditional surgical techniques.¹² Factors influencing surgical time are out of the control of the anesthesia care provider, and include operator experience, surgical complexity, and the time requirements associated with patient positioning and docking/undocking of the robot. In addition, the bulkiness and proximity of the equipment in relation to the operative field limits the accessibility of the anesthesia care provider to the patient after the start of the surgical procedure. In order to accommodate the robot, the patient's extremities are frequently tucked at their sides and inaccessible for the remainder of the procedure. This is compounded by the fact that once the robot is docked, rapid access to the patient and emergent positional changes are difficult to achieve. Therefore complications of robotic surgery, when they arise, can have

catastrophic implications for the patient.¹⁴

There is limited access to patients for prolonged periods of time during robotic procedures, and therefore it is imperative the patient be adequately prepared for surgery. A minimum of two large-bore intravenous lines should be placed and an arterial line inserted if rapid blood loss or the need for serial lab tests is anticipated. Additional invasive monitoring should be dictated by the patient's underlying comorbidities. The patient should be typed and cross-matched for a minimum of four units of blood as indicated by the surgical procedure. It is also essential that the members of the perioperative team be trained to quickly undock the robot in order to allow for rapid intervention during times of crisis. Operating rooms should have established emergency undocking protocols in place to handle these situations. These protocols should clearly define the responsibilities of the surgeon at the console the bedside assistant(s), surgical scrub nurse, circulating nurse, and anesthetists(s).¹⁵ Operating room personnel should be provided with adequate time in a simulated environment to practice these procedures in order to improve performance and ensure positive patient outcomes.

The proximity of the fixed robotic arms and attached surgical instruments to the patient also creates the potential for constant compression of underlying structures, including the face and chest. The anesthetist needs to assure that adequate padding is placed between the robotic arms/instruments and the patient. Because extreme surgical positions may be employed during robotic procedures, there is the risk that patients could move as a result of gravitational forces. Patients must be appropriately secured on the operating room table to prevent inadvertent movement and the creation of pressure points. Therefore it is essential that the surgical position be assessed at regular intervals (at least every 15 minutes) throughout the procedure or when changes in the position of the patient, robot, or operating room table occur.

Physiologic Changes Associated With Extreme Positioning

In order to facilitate surgical exposure for many robotic procedures,

the steep Trendelenburg position is commonly used. Steep Trendelenburg position is defined as a 40- to 45-degree head-down tilt of the operating room table.^{16,17} Patients are frequently placed in this position for several hours, resulting in significant and potentially adverse cardiovascular, respiratory, and neurophysiologic changes, which are compounded by the simultaneous creation of the pneumoperitoneum. It is difficult at times to separate the positional effects from those caused by the pneumoperitoneum, as both are frequently instituted simultaneously. The physiologic changes associated with steep Trendelenburg are summarized in [Box 35.1](#).

Physiologic Changes Associated With the Steep Trendelenburg Position

Cardiovascular Changes

- Increased:
 - Mean arterial Pressure (MAP)
 - Central Venous Pressure (CVP)
 - Pulmonary Capillary Wedge Pressure (PCWP)
 - Systemic Vascular Resistance (SVR)
- Unchanged:
 - Heart rate (HR)
 - Stroke Volume (SV)
 - Mixed Venous Oxygen Saturation

Respiratory Changes

- Increased:
- Airway Resistance
- Peak pressure
- Plateau pressure
- End-tidal carbon dioxide (ETCO₂)
- Upper airway edema
- Decreased:
- Lung compliance
- Vital capacity (VC)
- Forced Expiratory Volume in 1 second (FEV1)

Cerebrovascular Changes:

- Increased:
- Intracranial pressure
- Hydrostatic pressure gradient
- Cerebral vascular resistance
- Decreased:
- Cerebral venous drainage

- Unchanged:
- Regional cerebral oxygenation
- Cerebral perfusion pressure

Pneumoperitoneum and steep Trendelenburg create significant changes in cardiovascular parameters in both healthy patients and those with preexisting cardiovascular disease.¹⁷⁻²⁰ Mean arterial pressure (MAP), central venous pressure (CVP), and pulmonary capillary wedge pressure (PCWP) increase dramatically. Lestar et al.¹⁷ demonstrated a threefold increase in CVP and a twofold increase in PCWP as compared to initial supine values. In addition, MAP increases by as much as 35%. The overall effect of increased filling pressure and systemic vascular resistance is a prolongation in isovolemic relaxation time. However, despite the changes in MAP and cardiac filling pressures, heart rate, stroke volume, and mixed venous oxygen saturation remain relatively unchanged.^{17,19} Once the patient assumes the horizontal position and the pneumoperitoneum is released, cardiac parameters return to baseline.

The steep Trendelenburg position has significant effects on ventilation, gas exchange, and the ventilation-perfusion distribution.^{17,19-21} There is a decrease in lung compliance and an increase in airway resistance as a result of increased intraabdominal pressure and gravitational forces, which restrict descent of the diaphragm.^{17,19,20} Both peak and plateau pressures rise and continue to increase with the creation of the pneumoperitoneum.¹⁷ As a result, end-tidal carbon dioxide (ETCO₂) levels increase, which is associated with a widening of the arterial partial pressure of carbon dioxide (PaCO₂)-ETCO₂ gradient.^{17,19} In the presence of controlled ventilation, the arterial blood acid-base balance is relatively well-maintained; however, significant abnormalities can develop in the spontaneously breathing patient without ventilatory assistance.¹⁷ The steep Trendelenburg position can also lead to the development of significant upper airway edema and increased risk of upper airway obstruction following extubation.^{21,22} Finally, the creation of

the pneumoperitoneum in the steep Trendelenburg position has been shown to shorten the distance from the vocal cords to the carina, which could potentially displace the endotracheal tube, resulting in an endobronchial intubation.²³ It is therefore imperative to reconfirm bilateral breath sounds after positioning and following abdominal insufflation.

The physiologic effects of steep Trendelenburg position on airway resistance, compliance, and lung volumes persist after emergence from anesthesia, and are magnified in patients with preexisting chronic obstructive pulmonary disease (COPD). In the steep Trendelenburg position, the ratio of maximal expiratory flow to maximal inspiratory flow at 50% of vital capacity (MEF50/MIF50) increases significantly in patients with and without COPD and returns to baseline within 24 hours. There are also significant reductions in both vital capacity and forced expiratory volume in 1 second (FEV1), leading to lung atelectasis, which can persist for more than 5 days postoperatively in patients with COPD. Many of the prolonged changes can be attributed to the development of airway edema as a direct result of positional effects.²¹

The steep Trendelenburg position also impacts cerebral homeostasis because of its effects on cerebral perfusion and intracranial pressure (ICP). The head-down position causes a simultaneous increase in both MAP and CVP that impairs venous drainage from the head, increasing the hydrostatic pressure gradient in the cerebral vasculature.^{16,24} The net effect is an increase in ICP, cerebral edema, and cerebral vascular resistance, which could potentially impair cerebral blood flow.^{16,25} In fact, ICP rises to more than 20 mm Hg in the steep Trendelenburg position.²⁵ This increase is directly associated with elevations in MAP. Regional cerebral oxygenation and cerebral perfusion pressures appear to be well-maintained despite these physiologic changes, as a result of local cerebral autoregulation.^{16,21,24} It is prudent to limit the time spent in the steep Trendelenburg position, as these hemodynamic perturbations have implications for the development of POVL.

Postoperative Visual Loss

Postoperative visual loss is a rare but devastating complication following surgery. It has been documented after cardiac, spine,

head and neck procedures, and, most recently, robotic surgical procedures performed in the steep Trendelenburg position.^{26,27} The major causes of POVL include anterior ischemic optic neuropathy (AION), posterior ischemic optic neuropathy (PION), central retinal artery occlusion (CRAO), and cortical blindness.^{26,27} AION is caused by occlusion or hypoperfusion of the anterior optic nerve and is most common following cardiac, major vascular, and spine procedures.^{26,28} In contrast, PION results from infarction of the optic nerve posterior to the lamina cribrosa, usually as a result of elevated venous pressures, increased intraocular pressures, and interstitial edema, which compromise blood flow to the eye, as seen in prone and steep Trendelenburg positions.^{26,27,29} AION and PION present with sudden onset of painless visual loss and visual field deficits, and are usually discovered upon emergence from anesthesia. CRAO and cortical blindness are usually associated with procedures in which there is a high likelihood of high embolic load, severe hypotension, or direct global compression.²⁶

A large multicenter case-control study conducted by the Postoperative Visual Loss Study Group in 2012 examined risk factors associated with the development of ischemic optic neuropathy (ION) following spine surgery in the prone position.³⁰ This study concluded that male gender, obesity, prolonged anesthetic duration, greater estimated blood loss, and a lower percentage of colloid in nonblood replacement were independent risk factors for the development of POVL. Because prolonged surgical time in positions associated with venous congestion and rising intraocular pressures are common in robotic surgery, it has been postulated that similar risk factors would be seen in this surgical population.²⁶ Although the reported incidence of POVL in robotic surgery is currently low, it is recommended that efforts to reduce the degree of venous congestion and interstitial edema in the head during robotic procedures should be implemented.

Prevention of POVL should include risk-modification strategies that are aimed at minimizing surgical time, minimizing estimated blood loss, and decreasing venous congestion. The American Society of Anesthesiologists (ASA) and the Anesthesia Patient Safety Foundation (APSF) recommend consideration of staged surgical procedures to reduce operative time, keeping the head at

or above the level of the heart when possible, and including colloid in nonblood replacement strategies.^{29–32} In addition, they highly encourage the anesthesia care provider to include a discussion of risk factors associated with POVL and the current understanding of interventions available to reduce the risk as part of the informed consent process in high-risk patients. Finally, several researchers have attempted to identify pharmacologic agents that might be effective in reducing venous congestion through a reduction in intraocular pressure.^{29,33} They examined the effect of topical β -adrenergic blockers and carbonic anhydrase inhibitors (dorzolamide-timolol, betaxolol) in patients undergoing procedures in the steep Trendelenburg position, and found that these agents significantly reduce IOP and that these effects are sustained over time. Whereas a causative relationship between elevated IOP and POVL has not been found, it may be prudent to manage IOP during these procedures. A further discussion of POVL can be found in [Chapters 23](#) and [45](#).

Enhanced Recovery After Surgery (ERAS)

The goal of minimally invasive robotic procedures is to improve surgical outcomes and allow patients to return to normal activity as quickly as possible. Enhanced recovery management pathways have been developed to facilitate this process. The ERAS program is an international, multimodal approach to perioperative care that aims to achieve early recovery following major surgery.^{34–36} It was first designed for application in patients undergoing gastrointestinal procedures, but has been applied across surgical specialties including gynecology, general surgery, and orthopedics.

The ERAS protocol is a multidisciplinary, evidence-based list of recommendations for the care of patients during the preoperative, intraoperative, and postoperative periods in an attempt to modify the stress response to surgery so as to improve surgical outcomes.³⁷ The protocol is comprised of approximately 20 elements that have been shown to decrease hospitalization and perioperative complications ([Box 35.2](#)).³⁴ Preoperative guidelines focus on prevention of the catabolic state associated with long periods of fasting and fluid restriction. Intraoperative and postoperative recommendations are designed to fast-track patients in order to

promote early ambulation and feeding following surgery. A Cochrane review of four randomized controlled trials (237 patients) demonstrated a significant decrease in length of stay, a reduction in major perioperative complications, and similar rates of readmission in patients receiving ERAS-based versus conventional care.³⁸ In addition, ERAS programs are associated with attenuation of the stress response, as evidenced by reduced levels of stress hormones including cortisol, tumor necrosis factor, interleukins, and interferon.³⁷ This leads to faster return of gastrointestinal function and accelerated postoperative recovery. Anesthesia clinicians are in a unique position to control many aspects of care related to the **Box 35-2** successful implementation of the ERAS protocol.

Enhanced Recovery After Surgery (ERAS) Protocol Recommendations

- Preoperative
- Preadmission counseling re: ERAS protocol
- Fluid and carbohydrate loading
- Elimination of NPO status
- No/selective bowel preparation
- Antibiotic and thromboembolism prophylaxis
- Eliminate routine use of premedication
- Intraoperative
- Use of short-acting anesthetic agents only
- Midthoracic epidural anesthesia/analgesia as

appropriate

- Avoidance of surgical drains
- Avoidance of salt/water overload (goal-directed fluid therapy)
- Maintenance of normothermia
- Postoperative
- Midthoracic epidural anesthesia/analgesia as appropriate
- Avoidance of postoperative nasogastric tubes
- Aggressive PONV prophylaxis
- Avoidance of salt/water overload (goal-directed fluid therapy)
- Early ambulation
- Early oral nutrition/stimulation gut motility
- Early catheter removal
- Audit of ERAS compliance and patient outcome

NPO, Nil per os; *PONV*, postoperative nausea and vomiting.

From ERAS Protocol (EP). Accessed at <http://www.erassociety.org>.

Guidelines for perioperative fluid management are a main component of the ERAS protocol. Perioperative fluid overload is associated with increased morbidity, postoperative ileus, and delayed hospital discharge. In addition, hypoproteinemia associated with large crystalloid loads has been shown to cause delayed gastric emptying, increased small bowel transit time, and postoperative ileus.³⁹ Studies have long demonstrated that the avoidance of perioperative fluid overload, independent of the amount of fluid administered preoperatively or postoperatively, decreases the rate of postoperative complications and improves outcomes following major gastrointestinal and thoracic surgery.^{40,41} Therefore, the overarching goal of fluid management during implementation of the ERAS protocol is maintenance of the euvolemic state.

During the preoperative period, patients are “fed” in order to reduce the hemodynamic effects associated with induction of anesthesia as a result of hypovolemia.⁴² Current guidelines recommend the avoidance of preoperative fasting and intentional carbohydrate loading prior to surgery.³⁹ Patients are permitted to consume clear fluids up to 2 hours before anesthesia in order to prevent dehydration. Research evidence has shown that patients who consume clear liquids up to 2 hours before surgery have lower gastric volumes than patients following conventional fasting guidelines, and are at no greater risk for pulmonary aspiration. In addition, 100 g (800 mL) of a 12.5% maltodextrin carbohydrate drink is administered the night before surgery, followed by an additional 50 g (400 mL) 2 to 3 hours before induction of anesthesia in order to reduce the catabolic state induced by preoperative fasting.⁴³ Overnight fasting inhibits insulin secretion and promotes the release of catabolic hormones (including cortisol and glucagon), leading to insulin resistance, glycogen depletion, and protein breakdown in the postoperative period.^{43,44} Intraoperatively, the goal of fluid therapy is to achieve a “zero” fluid balance at the end of surgery.^{39,43}

Intraoperative fluid requirements should be met with a basal infusion of isotonic crystalloid solutions such as lactated Ringer's at a 3 ± 2 mL/kg per hour.⁴³ Additional volume therapy is administered by bolus based on objective measures of hypovolemia

such as changes in stroke volume measured through minimally invasive techniques as heart rate, blood pressure, urine output, and CVP are not reliable measures of volume status. Normal saline (0.9%) should be avoided because of the potential for developing hyperchloremic metabolic acidosis, which has been associated with reductions in gastric blood flow and pH, as well as changes in renal perfusion.⁴⁵ Postoperatively, resumption of oral intake should be encouraged as soon as possible in order to maintain a euvolemic state, reduce the risk of infection, and decrease length of stay.⁴⁶ Intravenous fluids should be discontinued unless there is a clinical indication.³⁹

The choice of anesthetic technique for implementation of the ERAS protocol must consider the need to minimize the impact of anesthetics on organ systems and facilitate rapid awakening following surgery in order to speed recovery of gastrointestinal and motor function. Whereas several different techniques can be utilized to achieve this goal, short-acting agents with minimal side effects are recommended in all cases. Aggressive postoperative nausea and vomiting (PONV) prophylaxis using a multimodal approach should be included in all ERAS protocols.⁴³ This includes the use of antiemetics and total intravenous anesthesia (TIVA) with propofol rather than inhalational agents. All patients with one to two risk factors (female gender, history of motion sickness/PONV, nonsmoking status, and use of perioperative narcotics) should receive a combination of two antiemetics, whereas patients with three to four risk factors should receive two to three antiemetics in addition to TIVA and opioid-sparing strategies.⁴⁷ In addition, to minimize the use of perioperative opioids, pain management should be achieved with the use of nonsteroidal anti-inflammatory drugs and regional anesthetic techniques. Epidural anesthesia/analgesia has been recommended for complex and open procedures. Transversus abdominis plane (TAP) blocks have also been used safely in patients undergoing gynecologic robotic procedures, but have not been shown to significantly decrease overall opioid consumption in the first 24 hours after surgery.⁴⁸ Neuromuscular blockade should be accomplished with short-acting agents and adequate recovery demonstrated to minimize the risk of postoperative respiratory depression. Finally, normothermia should

be maintained throughout the perioperative period with the use of active warming devices.⁴³ A further discussion of ERAS techniques can be found in [Chapter 21](#).

Considerations for Surgical Subspecialties

Cardiac Procedures

Minimally invasive robotic surgical techniques have been performed successfully for many cardiac procedures. The first successful internal mammary artery harvest was performed via thoracoscopy in 1997.⁴⁹ This was followed by the first totally endoscopic coronary artery bypass surgery (TECAB) in 1998.⁵⁰ Since then, robotic techniques have been applied in such procedures as mitral valve repair, repair of atrial septal defects, and ablation of atrial arrhythmias. The challenge for anesthesia care providers is the need for expertise in both cardiac and thoracic anesthesia, as one-lung ventilation (OLV) is required to successfully perform these procedures. All members of the perioperative team must be ready for conversion to an open procedure should it become necessary. Preoperative preparation involves assessment of both cardiac and pulmonary function. The presence of significant pulmonary disease and poor preoperative lung function may be a contraindication to the performance of robotic cardiac procedures, even in patients who are deemed suitable from a cardiac perspective.⁵¹ Evaluation of pulmonary function should include pulmonary function testing, preoperative chest x-ray, room air arterial blood gas analysis, and assessment of functional capacity (≥ 4 metabolic equivalent of task [METs]).⁵¹ Patients are also evaluated for the presence of significant peripheral vascular disease and atherosclerosis, which would create excessive risk for perfusion peripheral to the site of endovascular cannulation.

Box 35.3 Contraindications to TECAB are listed in [Box 35.3](#).

Contraindications to Totally Endoscopic Coronary Artery Bypass Surgery (TECAB)

- Morbid obesity
- Presence of anatomic abnormalities

- Pleural adhesions
- Previous cardiac or thoracic surgery
- Narrow intercostal spaces
- Severe cardiomegaly
- Valvular heart disease
- Severe aortic insufficiency
- Severe valvular stenosis of any kind
- Severe peripheral vascular disease and atherosclerosis
- Inability to tolerate one-lung ventilation

From Deshpande SP, et al. Anesthetic management of robotically assisted totally endoscopic coronary artery bypass surgery (TECAB). *J Cardiothor Vasc An.* 2013;27(3):586–599.

Robotically Assisted Totally Endoscopic Coronary Artery Bypass Surgery

TECAB surgical techniques are currently used in patients requiring up to quadruple-vessel bypass using either on-pump (arrested heart) or off-pump (beating heart) techniques, with results comparable to conventional techniques.⁵²⁻⁵⁴ Arrested heart TECAB procedures provide more optimal conditions for performing distal arterial anastomoses. Aortic cross-clamping is accomplished through the left femoral insertion of an endoaortic occlusion balloon catheter (EAOBC), through which antegrade cardioplegia can be delivered.⁵¹ The da Vinci instruments and endoscope are inserted through ports placed in third through seventh left intercostal spaces to allow harvesting of both the right and left internal mammary arteries as needed. Beating heart TECAB is most

often performed in patients who are not candidates for endovascular balloon insertion, and can be performed off-pump or with cardiopulmonary bypass (CPB) support in order to improve visualization.⁵¹ CPB may be required in the presence of intraoperative hemodynamic instability, ventricular arrhythmias, or in the patient who fails to tolerate OLV strategies.

Choice of anesthetic technique is dependent upon the patient's underlying comorbidities. General anesthesia can be accomplished with the use of intravenous induction agents and maintained with inhalational anesthetics and intravenous opioids as needed. Adequate muscle relaxation is essential as long as da Vinci surgical instruments are in situ in order to prevent damage or perforation of underlying mediastinal and thoracic structures. The patient is positioned supine with elevation of the operative hemithorax at 30 degrees. Intraoperative monitoring includes the use of transesophageal echocardiography (TEE) to monitor cardiac function and determine catheter placement, bilateral arterial lines to detect migration of the EAIBC, and pulmonary artery catheter placement as indicated. Near-infrared cerebral oximetry has also been used as an adjunct to monitor EAIBC position, as a decline in left-sided readings may be indicative of left common carotid artery occlusion.⁵¹

One-lung ventilation is initiated once full cannulation is completed in preparation for CPB. Lung isolation can be achieved with the use of a standard double lumen tube or bronchial blocker and managed in the traditional manner (Box 35.4). In patients unable to tolerate OLV, high frequency jet ventilation with a single-lumen endotracheal tube has been shown to be an effective method of ventilation for TECAB procedures.⁵⁵ Once the left lung is allowed to collapse, the chest is insufflated with 10 to 12 mm Hg carbon dioxide (CO₂) to create a capnothorax, in order to improve surgical exposure.⁵¹ The instruments are then inserted into the thoracic cavity, the internal mammary arteries are harvested, and CPB is instituted, so that revascularization of the coronaries can be

Box 35.4
Completed.

Management of One-Lung Ventilation for Totally Endoscopic Coronary Artery

Bypass (TECAB) Surgery Procedures to Prevent Hypoxia and Hypercarbia

- 100% FiO₂
- Pressure control ventilation
- Peak plateau pressure < 30 cm H₂O
- Respiratory rate to maintain PaCO₂ at 35–40 mm Hg, as assessed by arterial blood gas
- CPAP to nonventilated lung
- PEEP to ventilated lung

CPAP, Continuous positive airway pressure; *FiO₂*, fraction of inspired oxygen; *PaCO₂*, partial pressure of arterial carbon dioxide; *PEEP*, positive end expiratory pressure.

From Deshpande SP, et al. Anesthetic management of robotically assisted totally endoscopic coronary artery bypass surgery (TECAB). *J Cardiothor Vasc An.* 2013;27(3):586–599.

The creation of the capnothorax may be accompanied by significant hemodynamic and respiratory changes. These are the result of elevated intrathoracic pressures (>10 mm Hg) that result in proportional increases in CVP, pulmonary artery pressures, PCWP and peak airway pressures.^{51,56,57} These increases may be accompanied by increases in heart rate and decreases in cardiac index and MAP.^{56,57} Hypovolemic patients and patients with preexisting left ventricular dysfunction are more likely to develop hemodynamic instability, even with low insufflation pressures.⁵⁸ Hemodynamic instability may be prevented with the administration of fluid boluses in order to raise the CVP to approximately 10 mm Hg prior to creation of the capnothorax. In addition, the capnothorax can be created slowly with the

implementation of 2 mm Hg incremental increases in intrathoracic pressure. Vasopressors and inotropic agents may be required in the presence of significant increased right and left afterload and ventricular dysfunction.

TECAB procedures also present unique challenges with respect to temperature management in the perioperative period, which is dependent upon the total number of anastomoses planned and the technique employed (arrested heart vs. beating heart). The closed chest procedure is associated with a decrease in radiant heat loss, so active systemic cooling is required for myocardial protection while on bypass.⁵¹ For one-vessel arrested heart procedures, the temperature will be allowed to drift down to 34–35°C. However, for two- or more vessel procedures, active cooling to as low as 28°C may be required. In beating heart procedures, mild hypothermia may be desired for brain protection. At the completion of TECAB, patients should be rewarmed to establish normothermia in order to prevent shivering and increased myocardial demand in the immediate postoperative period.

Mitral Valve Procedures

Minimally invasive mitral valve procedures can be performed using a variety of surgical techniques, with the ultimate goal of decreasing surgical trauma, cardiac manipulation, and length of hospital stay. Minimally invasive mitral valve repairs can be performed through either a minithoracotomy or closed chest technique, whereas mitral valve replacement requires the latter in order to allow placement of the prosthetic valve. In the United States, the first robot-assisted mitral repair was performed at East Carolina University in 2000.⁵⁹ The current trend is towards the performance of more complex, multiple valve procedures. Patients undergoing minimally invasive robotic procedures demonstrate shorter stays in the intensive care unit, decreased blood transfusions, lower incidence of renal failure, and reduced in-hospital mortality.⁶⁰

Robotically-assisted mitral valve procedures are most often performed through a 2 to 3 cm inframammary incision in the right fourth or fifth intercostal space.⁶¹ Additional trocars are inserted around the primary incision to place the robotic arms/instruments,

allow insufflation of CO₂, and facilitate transthoracic aortic cross-clamping if required. The patient is positioned in a modified left lateral position with a support placed under the right upper back and shoulder so as to form a 25- to 30-degree angle with the operating table.⁶¹ The pelvis is kept flat on the table. The surgeon may request a left lateral tilt in order to further elevate the chest, but care must be taken not to put stress on the brachial plexus. Monitoring approaches are similar to those utilized for TECAB procedures, and TEE is the standard of care to evaluate valvular function and to assess for residual mitral regurgitation before terminating CPB. Transcutaneous defibrillation/pacing pads are placed for intraoperative cardioversion and defibrillation, because placement of internal paddles is not possible. OLV and thoracic insufflation are required, except in this case, the right lung is collapsed and the right chest is insufflated. Hemodynamic instability is a concern with moderate to high insufflation pressures. Recommendations are to limit the rate of CO₂ insufflation to 2–3 L/min, and to maintain intrathoracic pressures within the right hemithorax at less than 10 mm Hg to avoid hemodynamic changes and prevent the development of a tension pneumothorax.^{62,63}

The choice of anesthetic for robotically-assisted mitral valve procedures is similar to TECAB and dependent upon the patient's presentation. Intraoperative and postoperative analgesia can be achieved through the use of parenteral techniques or a combination of regional and opioid-based techniques, including intercostal and paravertebral approaches.⁶¹ The use of neuraxial analgesia remains controversial in light of full intraoperative anticoagulation; however, in select patients, the placement of epidural catheters in the postoperative period may be warranted.

Thoracic Procedures

Video-assisted thoracoscopic surgery (VATS) is a well-established technique for the resection of thoracic tumors, because it is associated with less trauma, decreased pain, shorter duration of chest tube drainage, and decreased length of hospital stay.⁶⁴ Since 2013, robotic-assisted surgical techniques have been successfully developed for several types of resections, including lung,

mediastinal, and esophageal resection, despite significant increases in cost.⁶⁴⁻⁶⁶ When compared to traditional VATS procedures, minimally invasive robotic procedures are associated with similar lengths of stay and perioperative morbidity. In addition, these procedures are not only easier for the surgeon to perform, but they are associated with a shorter learning curve as a result of the three-dimensional visual field created by the da Vinci system.⁶⁴

Robotically-assisted thoracic procedures create unique challenges for the anesthetist. Patient positioning and subsequent physiologic changes are determined by the specific surgical procedure and location of pathology. Mediastinal procedures are most commonly performed in the supine position with a slight lateral tilt (30 degrees, right side up). Hilar or lung procedures will employ a 90-degree lateral decubitus position.^{65,66} CO₂ insufflation and creation of a capnothorax is necessary in order to achieve adequate surgical exposure by compressing thoracic structures away from the operative field. However, as discussed in the management of robotic cardiac procedures, it is associated with significant hemodynamic instability and respiratory compromise. Hemodynamic instability may once again be prevented by the administration of fluid boluses in order to raise the CVP to approximately 10 mm Hg prior to creation of the capnothorax. In addition, the capnothorax can be established with the implementation of 2 mm Hg incremental increases in intrathoracic pressure. Vasopressors and inotropic agents may be necessary if significant increases in right and left afterload or ventricular dysfunction occur.

Although robotic video-assisted thoracic surgery (RVATS) may offer some advantages, it is not without its potential risks. When compared with a standard VATS approach, patients undergoing RVATS procedures had increased rates of chylothorax and recurrent laryngeal nerve injury.⁶⁷ This may be due to several factors, including the use of more aggressive surgical lymph node dissection and increased use of electrocautery. Meticulous airway manipulation and assessment of vocal cord motion is necessary following these procedures. A comparison of a VATS and robotic lobectomy techniques is shown in [Fig. 35.2](#).

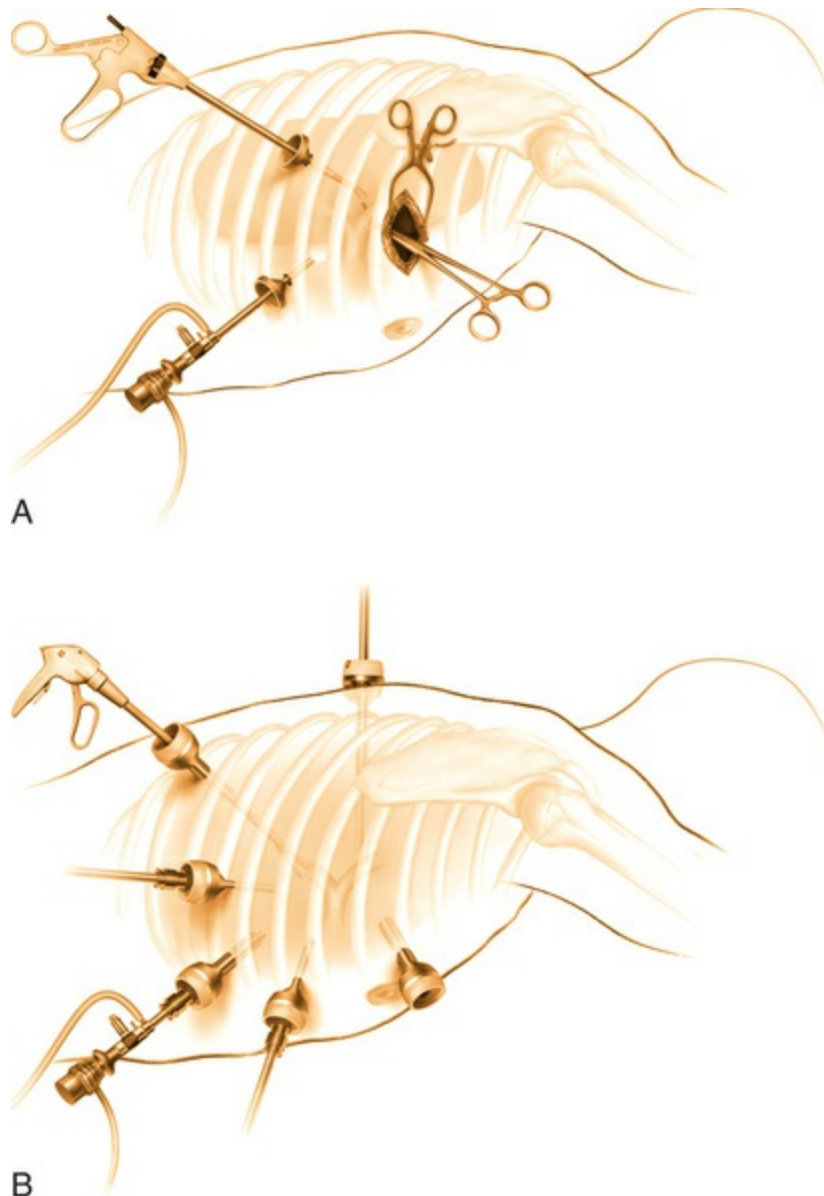

FIGURE 35.2 Comparison of video-assisted thoracic surgery (VATS) lobectomy to robotic lobectomy. The two patients shown are undergoing hilar dissection. **A**, VATS resection. Three incisions are shown: one for the videoscope and the other two for the right-angle clamp and stapler. The manipulation of the instrumentation and the arcs of rotation occur outside of the chest. The fulcrum of the instrumentation occurs at the chest wall, compressing and distending the intercostal nerves. **B**, Robotic resection. The arcs of rotation and management of the instrumentation for dissection are within the chest, allowing surgical dissection to occur in small spaces. (From Kernstine

KH, et al. Robotic lobectomy. *Op Tech Thorac Cardiovasc Surg.*

2009;13(3):204.e1–e23.)

General Surgical Procedures

Robotic surgical techniques have been employed in general surgery since the introduction of the earliest robotic systems. Currently, almost all gastrointestinal procedures can be successfully completed utilizing robotic techniques, including cholecystectomy, gastrectomy, and colon resection. Advocates of general surgical robotic procedures cite improvements in three-dimensional imaging and easier surgical manipulation, resulting in smaller surgical incisions with minimal activation of the stress response.⁶⁸ However, studies evaluating the efficacy of these procedures do not demonstrate improved patient outcomes.^{69,70} When compared with traditional laparoscopic approaches, robotic general surgical techniques are not associated with a lower incidence of major or minor morbidity. However, they are associated with significantly longer operative times and significantly higher total costs. There are also no demonstrable differences in estimated blood loss, rates of conversion to open techniques, or overall length of hospital stay. These results may be a deterrent to the long-term viability of these procedures in the general surgical population.

Anesthetic management for robotic general surgery must take into consideration the impact of patient positioning and pneumoperitoneum on hemodynamics and ventilation (see [general anesthetic considerations](#)). Patients should have adequate intravenous access. As in most surgical cases, both arms are tucked to their respective left and right side and may restrict access. It is prudent to have a second large-bore (minimum 18G) intravenous line in place, should fluid resuscitation become necessary. The decision to use invasive hemodynamic monitoring is made on a case-by-case basis and depends on the patient's underlying comorbidities. An orogastric tube is placed to decompress the stomach, and a Foley catheter is usually inserted to monitor urinary output if the procedure will last longer than 2 hours. Maintenance of normothermia is achieved utilizing standard techniques.

Gynecologic Procedures

Robotic techniques are increasingly employed in gynecological laparoscopic surgery, because these procedures are performed in an

extremely confined space (the female pelvis). With traditional laparoscopic techniques, complex surgical tasks can be difficult to perform, due to limited freedom of movement and dexterity. The enhanced dexterity of the seven degrees of freedom provided by the current da Vinci system allows the surgeon to perform finer dissection, removal, and/or repair of these tissues.¹² Despite the perceived improvement in surgical technique, there is little evidence to demonstrate the superiority of robotic procedures over traditional laparoscopic techniques in this patient population.^{71,72} Robotic gynecologic procedures take significantly longer at a significantly increased cost, but do not demonstrate a statistically significant difference in estimated blood loss or length of hospital stay. In addition, both techniques are associated with few major complications, similar postoperative pain scores, and similar time to resumption of normal daily activities compared to open techniques, which may not justify the increased cost associated with these procedures. Anesthetic management of patients undergoing these procedures is similar to the general surgical population. Careful attention must be paid to the effects of steep Trendelenburg position and CO₂ insufflation on hemodynamics and ventilation. Because a large proportion of patients undergoing robotic gynecologic procedures suffer from morbid obesity, TAP blocks have been used successfully to decrease postoperative pain and minimize opioid consumption.⁷³

Urologic Procedures

One of the earliest specialties to successfully employ robotically-assisted surgical techniques was urology. Wolfram et al.⁷⁴ demonstrated the safety and efficacy of this procedure in 2000. Since then, the robotically-assisted laparoscopic prostatectomy (RALP) has become one of the most common robotic procedures performed worldwide. Evidence suggests that RALP is associated with less blood loss and shorter length of stay, but a higher cost, when compared with open procedures.⁷⁵ However, the data regarding the superiority of the procedure in reducing urinary incontinence and impotency are conflicting.

The anesthetic management for patients undergoing RALP is

similar to the open or laparoscopic procedures, and takes into consideration the potential for significant blood loss, use of pneumoperitoneum, and hemodynamic/ventilatory changes associated with the utilization of steep Trendelenburg position (see [general anesthetic considerations](#)). Prior to the start of the procedure, two large-bore peripheral venous lines should be started in anticipation of blood loss. Because both arms will be tucked to the side and inaccessible once the robot is docked, an arterial line should be inserted (if warranted) to allow for continuous blood sampling and beat-to-beat blood pressure measurement.

Robotically-assisted laparoscopic prostatectomy is performed in the steep Trendelenburg lithotomy position with both arms tucked in order to maximize surgical exposure. This position creates the potential for the patient to slide cephalad on the operating table, causing dermal injury and altering the position of the extremities, which can result in peripheral nerve damage.⁷⁶ In addition, there is a risk of damage to abdominal wall and intraabdominal structures, because the fixed robotic arms can put unintended traction on underlying tissues. Therefore patients should be appropriately padded, and an appropriately-sized lithotomy bean bag should be placed under the patient. The patient's position should be checked frequently and adjusted as needed. Whereas shoulder restraints or braces may appear to be a desirable option to prevent movement, their use has been associated with the development of brachial plexus injury and is not recommended.⁷⁷

As noted earlier, the utilization of the steep Trendelenburg position in conjunction with the creation of the pneumoperitoneum also creates challenges for management of ventilation and hemodynamics. Pneumoperitoneum is associated with an increase in intraabdominal pressure, which can create significant hemodynamic changes that can be compounded if excessive perioperative bleeding occurs (see [Chapter 34](#)). Systemic absorption of CO₂ results in the development of hypercarbia, requiring compensatory increased minute ventilation. This can be accomplished successfully using either volume-controlled or pressure-controlled ventilation. The choice is dependent on the patient's underlying physiology and practitioner preference. Patients undergoing RALP are also at increased risk for the

development of venous air embolism if insufflation pressures exceed venous pressures in the presence of active bleeding. Evidence of subclinical gas embolism has been reported in 17% of patients undergoing RALP.⁷⁸ Finally, prolonged steep Trendelenburg and abdominal insufflation can result in increases in ICP, placing the patient at risk for ocular complications, including visual defects and POVL.

Head and Neck Procedures

As in all other surgical subspecialties, there has been a trend to employ robotic techniques in head and neck (HEENT) surgery in order to minimize surgical morbidity and improve cosmetic results. Robotic systems have been successfully used in transoral, transaxillary, and retroauricular approaches to head and neck pathology to perform tonsillectomy, thyroidectomy, radical neck dissection, and resection of early stage squamous cell cancers. Several studies have shown comparable outcomes, similar rates of complications, and higher cosmetic satisfaction in patients undergoing robotic versus traditional head, ears, eyes, nose and throat surgical procedures.⁷⁹⁻⁸¹ Anesthetic management for patients undergoing these procedures is similar to the traditional approaches and is guided by the patient's underlying pathophysiology, considerations of a shared airway, and the need for perioperative nerve monitoring.

Orthopedic Procedures

The utilization of robotic systems in orthopedic surgery is in its infancy. Currently, the MAKO Tactile Guidance System (TGS; MAKO Surgical Corporation, Fort Lauderdale, FL) is used in many operating rooms to facilitate robotically-assisted arthroplasty. This system requires active participation of the surgeon and relies upon preoperative computed tomography scan imaging to create a three-dimensional model of the knee for use by the surgeon in planning the placement of prosthetic components. These techniques have the advantage of increased surgical accuracy, optimization of component positioning, and improved functional outcomes.^{82,83} The anesthetic management of robotically-assisted orthopedic

procedures does not differ from the conventional approach.

Summary

Robotic technology continues to improve exponentially, and as a result it can be expected to be used in an increasing number and type of surgical procedures. Whereas the outcome data to date do not demonstrate a clear advantage of robotic procedures over traditional approaches, this may change with improved accuracy, decreased operative time, and reduced costs. Providing safe and effective anesthesia care requires the anesthetist to understand the challenges associated with robotic surgical techniques and to develop a plan of care that maximizes patient outcomes.

Musculoskeletal System Anatomy, Physiology, Pathophysiology, and Anesthesia Management

Mary C. Karlet

Somatic musculature is broadly classified into three compartments —skeletal, cardiac, or smooth—based on the muscles' anatomic and functional roles. Force generated by all these muscle types depends on the transient elevation of intracellular calcium (Ca^{2+}) and activation of actin and myosin filaments. Skeletal muscle is under voluntary control and is striated in appearance. Smooth muscle is found in most internal organs (except the heart), is under involuntary autonomic control, and is nonstriated. Cardiac muscle is striated in appearance and under control of an intrinsic pacemaker modulated by the autonomic nervous system.¹ The focus of this chapter is skeletal muscle, its function, and its neurologic control.

Skeletal muscle tissue includes muscles of the tongue and the soft palate, the extrinsic eye muscles, the muscles that move the scalp, all muscles attached to the skeleton, and the muscles in the pharynx and the upper third of the esophagus. Some skeletal muscles, such as those of the lips and the anus, serve as sphincters. Skeletal muscle is innervated by myelinated efferent motor nerve fibers called *alpha* (α) *motor neurons*. These fast-conducting somatic fibers arise from cell bodies located in the ventral horn of the spinal cord gray matter (Fig. 36.1).²

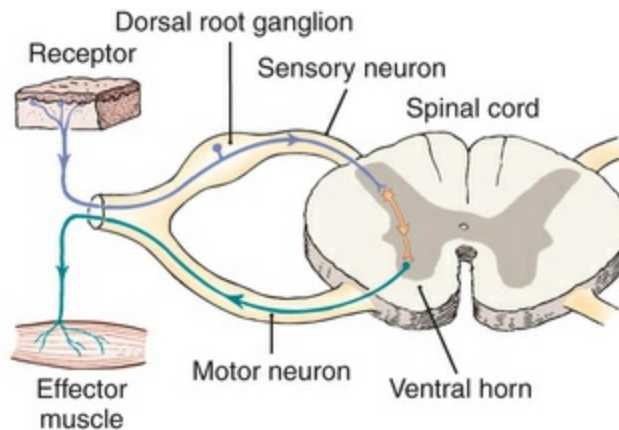

FIGURE 36.1 Spinal reflex arc. Sensory information from the skin is relayed to the motor neuron in the ventral horn of the spinal cord gray matter.

The motor nerve axon exits through the spinal cord ventral root and travels uninterrupted to the muscle through a mixed peripheral nerve. Inputs to the ventral horn motor nerve cell body are both excitatory and inhibitory. The inputs include neurons from the brain, neurons from other spinal cord segments, and afferent neurons from various sensory receptors. A motor neuron fires an action potential when the sum of the excitatory and inhibitory inputs depolarizes the nerve cell body to its critical threshold potential, leading to depolarization and action potential propagation down the axon.

At the muscle, each motor nerve divides into branches that enter the muscle and end on individual muscle cells called *muscle fibers*. A single motor neuron and all the muscle fibers it innervates are collectively called a *motor unit* (Fig. 36.2). When a motor nerve fires, all the fibers within a single motor unit contract simultaneously.

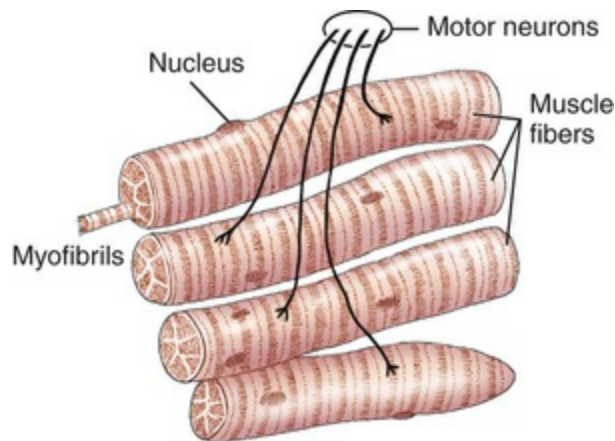

FIGURE 36.2 A motor unit. One motor neuron can synapse with several muscle fibers, which contract as a unit.

Each motor unit usually contains between 100 to 200 muscle fibers. However, the motor unit may contain as few as two muscle fibers for fine, delicate movements or as many as a thousand for coarse movements.^{1,2}

The strength of a muscle contraction is determined in large part by the number of motor units stimulated and the frequency of the stimulation. A minimal stimulus applied to a muscle may cause only a few muscle units to contract, with a weak overall response. As the stimulus is increased, more units are recruited, and a greater contraction of the muscle occurs.

Overview of Neuromuscular Transmission

Skeletal muscles are normally relaxed and do not contract without nervous stimulation. At rest, the electrical potential difference across the muscle membrane is approximately -90 mV (inside negative). There is a high potassium ion (K^+) concentration inside the muscle cell and a high sodium ion (Na^+) concentration outside the cell.

The process of muscle contraction begins when the electrical activity of a presynaptic motor neuron communicates across a junctional cleft, or synaptic gap, to postsynaptic skeletal muscle fibers. The specialized conduction area, or synapse, where the axon of a motor neuron ends on a skeletal muscle fiber, is called the *neuromuscular junction (NMJ)*, or *myoneural junction*. Each skeletal muscle fiber usually has only one NMJ. The mediator substance that chemically transduces the axon's electrical message across the synaptic gap to the muscle is the neurotransmitter acetylcholine (ACh).¹⁻³

Muscle contraction develops when the propagated action potential of the presynaptic motor neuron induces release of the chemical mediator ACh into the junctional cleft. ACh binds to specialized receptors on the postsynaptic muscle membrane. If released from the axon nerve ending in sufficient quantity, ACh-receptor (AChR) occupation induces a transient change in the electrical property of the skeletal muscle membrane, and an action potential and muscle contraction follow.¹⁻³

In the overall process of neuromuscular transmission, an action potential in the motor neuron induces the release of ACh into the junctional cleft, which evokes an action potential in the muscle. As described in greater detail in the following sections, the end result of muscle membrane depolarization is muscle contraction.

Neuromuscular Junction

Motor nerve endings develop in intimate and precise proximity to skeletal muscle fibers, forming a highly efficient communication

unit.^{4,5} The motor axon terminal is separated from the muscle cell it innervates by a synaptic gap of approximately 50 nm.² The demyelinated distal portion of the motor axon is essentially surrounded by a terminal Schwann cell that reinforces the connection of nerve and muscle.⁶ This anatomic alliance increases the likelihood for prompt receptor activation after transmitter release.⁶⁻⁸

The synaptic gap is contiguous with the extracellular fluid, which provides a route for drugs or toxins to gain access to the NMJ. Botulinum toxin, for example, gains access to the junction through the extracellular fluid and produces its depressive neuromuscular effects by inhibiting ACh release from the nerve ending.^{2,9,10}

Both sides of the NMJ, the presynaptic motor axon and the postsynaptic muscle cell, serve specialized functions. As it nears the NMJ, the motor nerve axon loses its myelin sheath and divides into many smaller nerve fibers, which terminate as end-feet or terminal boutons.

The motor nerve end-foot is distinct from the rest of the nerve. It is rich in mitochondria and the materials and support structures necessary for the synthesis, storage, mobilization, and release of the neurotransmitter ACh. Small vesicles or quanta of concentrated ACh are particularly numerous in the part of the nerve ending closest to the junctional gap.² ACh is concentrated in the vesicles by an ACh-H⁺ exchange pump. The ACh vesicles converge along the junctional surface of the nerve end-feet in areas called *active zones*.^{9,11-13}

At the NMJ, each motor nerve ending closely approximates with a thickened and highly convoluted portion of the postsynaptic membrane called the *motor end plate*. The motor end plate is physically and functionally demarcated from the surrounding muscle membrane. The many membrane convolutions at the end plate are known as *junctional folds* or *junctional clefts*.^{2,6} ACh receptors are concentrated near the shoulders of the junctional folds, lying near the ACh release sites. The close approximation of ACh release site and target receptor site ensures little transmitter waste and direct coupling of nerve signal and muscle response.^{2,6}

Fig. 36.3 summarizes the anatomy and dynamic function of the NMJ.

FIGURE 36.3 Vertebrate neuromuscular junction or motor end plate. A motor neuron, with its cell body in the ventral horn of the spinal cord, sends out an axon that progressively bifurcates to innervate several muscle fibers (a motor unit). The neuron contacts a muscle fiber at exactly one spot, called a neuromuscular junction or motor end plate. The end plate consists of an arborization of the nerve into many presynaptic terminals, or boutons, as well as the specializations of the postsynaptic membrane. A high-magnification view of a bouton shows that the synaptic vesicles containing the neurotransmitter ACh cluster and line up at the active zone of the presynaptic membrane. The active zones on the presynaptic membrane are directly opposite the secondary postsynaptic clefts that are created by infoldings of the postsynaptic membrane (postjunctional folds). Depolarization of the bouton causes the vesicles to fuse

with the presynaptic membrane and to release their contents into the synaptic cleft. The ACh molecules must diffuse at least 50 nm before reaching nicotinic AChRs.

Note the high density of AChRs at the crests of the postjunctional folds. The activity of the released ACh is terminated mainly by an AChE. The bouton reloads its discharged synaptic vesicles by resynthesizing ACh and transporting this ACh into the vesicle via an ACh-H

exchanger. *ACh*, Acetylcholine; *AChE*, acetylcholinesterase; *AChR*, ACh-receptor; *CoA*, coenzyme A. (From Boron WF, Boulpaep EL. *Medical Physiology*, 3rd ed. Philadelphia: Elsevier; 2017:208.)

The clustering of the ACh receptors at the motor end plate near the ACh “active zones” is the result of the interaction of synaptogenic factors such as agrin, muscle-specific tyrosine kinase (MuSK), and low-density lipoprotein receptor-related protein-4 (Lrp4).⁵ As will be described later in this chapter, defects in these synaptogenic factors are responsible for some forms of myasthenia gravis (MG).¹²

Acetylcholine Release

Physiologic transmission of the nerve message to the muscle begins with Ca^{2+} -dependent ACh release from the nerve terminal. When a nerve impulse arrives at a motor nerve ending, the action potential causes a transient increase in Ca^{2+} conductance across the nerve membrane by activating voltage-gated Ca^{2+} channels. It is primarily the fast (P/Q-type) Ca^{2+} channels that are involved in depolarization-induced transmitter release.^{2,9} Calcium enters the nerve terminal, diffusing down its electrochemical gradient. The influx of Ca^{2+} causes ACh vesicles to fuse with the nerve plasma membrane and then expel their content into the synaptic cleft.^{6,9,14} The amount of ACh released is influenced by the amount of Ca^{2+} that enters the nerve terminal during nerve stimulation. The more Ca^{2+} that enters the nerve terminal, the greater the amount of ACh released.

Approximately 150 to 300 ACh vesicles or quanta, are released with each nerve impulse. Each individual quantum in turn contains approximately 10,000 ACh molecules of the neurotransmitter.^{3,13,15} This amount of ACh and the normal abundance of postjunctional

receptors at each NMJ readily ensure muscle activation. A tenfold safety margin typically exists in normal synaptic transmission. With each nerve impulse, excess ACh is released, and excess ACh receptors are available for occupation.^{2,15}

Small concentrations of other divalent cations can compete with and limit Ca^{2+} influx into the nerve ending, decreasing ACh release and impairing neuromuscular transmission. When administered intravenously, magnesium sulfate, for example, can interfere with Ca^{2+} influx and produce muscle weakness by inhibiting ACh release. Aminoglycoside antibiotics also inhibit voltage-gated Ca^{2+} channels and ACh release at the NMJ and can enhance neuromuscular blockade when administered concomitant with clinical dosages of neuromuscular blocking agents.³

Calcium channel–blocking drugs used for the treatment of dysrhythmias and hypertension block Ca^{2+} conductance through so-called “slow” (L-type) channels. Their primary action is on the slow Ca^{2+} channels of the heart and blood vessels, but they can inhibit NMJ prejunctional Ca^{2+} influx. The large safety margin inherent in normal neuromuscular transmission obscures any clinically detectable effect these drugs may have on neuromuscular transmission. However, with disorders associated with impaired neuromuscular transmission, such as Lambert–Eaton myasthenic syndrome (LEMS), the Ca^{2+} channel blocker's prejunctional attenuation of ACh release may be unmasked, and neuromuscular transmission may be further weakened.^{3,14,16}

Acetylcholine Synthesis

Neurons that release the neurotransmitter ACh are called *cholinergic neurons*. Active cholinergic motor neurons replenish their ACh stores by continually resynthesizing the neurotransmitter. Many enzymes and other proteins needed by the nerve ending to synthesize, store, and release ACh are made in the motor nerve cell body and are transported distally to the nerve ending by a process called *axonal transport*.

In the axoplasm of the motor nerve ending, the enzyme choline acetyltransferase (CAT) catalyzes the reaction of two substrates, acetyl coenzyme A (acetyl CoA) and choline to form ACh, as seen in the following equation.

Choline is obtained locally by a Na^+ -linked uptake into the cholinergic nerve ending. Acetyl CoA is synthesized from pyruvate in neuronal mitochondria. Mitochondria and other metabolic machinery used to synthesize ACh are abundant in the nerve ending (Fig. 36.4).

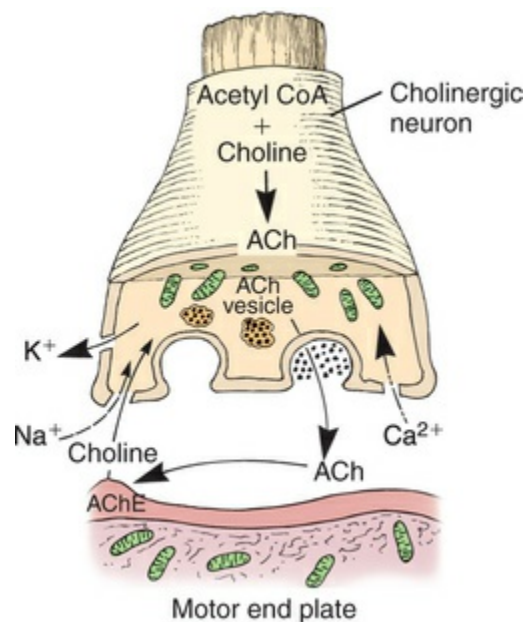

FIGURE 36.4 Acetylcholine (ACh) synthesis from choline and acetyl coenzyme A (acetyl CoA) in the motor nerve ending. Calcium ion entry into the nerve ending causes the ACh vesicles to release their contents. Acetylcholinesterase (AChE) on the postjunctional membrane destroys ACh. Choline is recycled into the nerve ending by a sodium ion–linked transport mechanism.

Each nerve ending contains more than 100,000 ACh vesicles.^{2,6} A small percentage of these vesicles are positioned for rapid release, whereas a more substantial amount is a reserve pool that is released more slowly. The ACh vesicles are released through exocytosis in response to action potential stimulation, but only a small fraction of the available vesicles is used to send each signal.^{2,6}

Postjunctional End Plate

ACh receptors that are present at the postjunctional motor end plate

are cation channels. There is a distinction between the postjunctional ACh receptor cation channels of the muscle end plate and other cation channels of nerve and muscle membranes. Motor end plate ACh channels are ligand-gated, that is, they are opened or closed by the action of a chemical, ACh. Cation channels of the remaining muscle membrane, on the other hand, are voltage-gated or voltage-activated; that is, they open or close in response to electrical changes in the membrane.³

The binding of ACh molecules to postsynaptic receptors causes a transient increase in conductance in the ligand (ACh)-gated cation channels at the postjunctional motor end plate. The cation flow allows an outward current of K^+ and an inward Na^+ current. The Na^+ current predominates because it is attracted to the negative charge inside the cell. As a result, the previously polarized end-plate membrane becomes transiently depolarized. The resulting postjunctional membrane voltage change is called a *generator potential* or the *end-plate potential* (EPP).³

EPPs vary in strength according to the quantity of ACh released. The more ACh released, the greater the postsynaptic end-plate voltage change. In other words, EPPs do not adhere to the “all-or-none” principle. EPPs can be summed, and their magnitude depends on the strength of the summed stimuli of ACh molecules.

The postjunctional end-plate membrane does not fire action potentials. After it is depolarized by ACh-receptor occupation, the current sink created by the local EPP depolarizes the adjacent muscle membrane.³ If the depolarizing input is great enough and reaches threshold potential, action potentials are fired from either side of the end plate in both directions along the muscle fiber (Fig. 36.5).

FIGURE 36.5 Depiction of the depolarization characteristics (the end-plate potential) at the postsynaptic membrane in response to acetylcholine (ACh) and the depolarization and action-potential response at the adjacent, electrically excitable muscle membrane. *TP*, Threshold potential.

The transition zone where the potential developed at the end plate is converted to an action potential is called the *perijunctional area*. A demarcation exists between the chemically sensitive AChR channels of the end plate and the chemically insensitive but electrically sensitive Na^+ channels in the perijunctional area of the muscle membrane.

With a typical motor neuron's action potential, the EPP produced at the muscle end plate is usually sufficient to create an action potential at the muscle membrane, and muscle contraction is regularly produced.

Acetylcholine Receptor

Postjunctional neuromuscular ACh receptors have been extensively purified and their complex architecture studied in detail.^{6,7,12,13,17} Approximately 30 million tightly packed nicotinic AChRs are at each NMJ.³

In fetal muscle, the ACh nicotinic receptor is a protein composed of five polypeptide subunits: two identical alpha (α) subunits, a beta (β) subunit, a gamma (γ) subunit, and a delta (δ) subunit, all surrounding a central cation channel (Fig. 36.6). As described later in this chapter, the fetal subunit composition ($\alpha_2\beta\gamma\delta$) is also present at nonjunctional regions of denervated adult skeletal muscle.⁶

FIGURE 36.6 **A**, The receptor consists of $(\alpha)_2$, β , γ and δ subunits in the fetal form, and **B**, $(\alpha)_2$, β , δ and ϵ subunits in the adult form. (From Shamley D. *Pathophysiology*. Philadelphia: Butterworth-Heinemann; 2005.)

In adults, the AChR protein structure is similar, except that the fetal γ subunit is replaced by an epsilon (ϵ) subunit^{6,7,17} (see Fig. 36.6). The change produces an adult cholinergic postjunctional AChR ($\alpha_2\beta\epsilon\delta$) that has an increased cation conductance, a shortened open time, and higher density at the NMJ.¹⁸

As noted earlier, the ACh receptors are clustered at the crests of the motor end-plate junctional folds, which directly align with nerve terminal release sites. In active adults, only the end-plate region of the muscle contains ACh receptors.¹³ As little as 200 μm away from the end plate, the muscle membrane becomes practically devoid of receptors.

The ACh receptors are synthesized in the muscle cells and then incorporated into the end-plate membrane as integral membrane proteins. The extracellular, or junctional, face of the receptor protrudes from the surface of the end-plate membrane, whereas the cytoplasmic surface of the receptor is more flush to the plasma membrane surface.

Activation of the postjunctional AChR and opening of the cation channel requires simultaneous ACh occupation at each of the two α -receptor subunits. The binding of two ACh molecules causes a conformational change in the α polypeptides, and the protein conformational change causes the central ion channel to open.^{6,7,17} If only one α subunit site is occupied by the agonist, the channel remains closed. As described earlier, the open channel increases the conductance to positively charged ions, particularly Na^+ , an effect that produces the net depolarizing potential, the EPP. When even

one ACh molecule leaves an α subunit, the channel snaps shut and the current stops. The opening and closing events are extremely fast, enabling rapid initiation and termination of the postsynaptic response.¹³

When ACh is present on the α -receptor subunit for an extended period (greater than approximately 20 ms), the ACh receptor may convert to a desensitized or nonconducting state.^{7,13} Desensitization is of little consequence for normal neuromuscular transmission, but this property may contribute to the neuromuscular blocking effects of the depolarizing muscle relaxant succinylcholine, as described in [Chapter 12](#).^{6,19}

The α subunits are sites of competition between the cholinergic agonist ACh and receptor antagonists, such as nondepolarizing neuromuscular blocking agents. The outcome of the competition, neuromuscular transmission or neuromuscular blockade, depends on the concentration of ACh and the relative concentration and binding properties of the antagonist involved. Nondepolarizing muscle relaxants produce neuromuscular blockade, in part because they bind to one or both α subunit sites and, in so doing, prevent ACh from binding to both sites and opening the channel.

Prejunctional Receptors

Cholinergic receptors are also present at the prejunctional motor nerve ending. In addition to mediating nerve transmission at postjunctional receptor sites, ACh also acts on prejunctional receptors to enhance transmitter mobilization and release. Prejunctional cholinergic receptors are structurally different to adult junctional receptors, containing three α subunits, and two β subunits. Stimulation of the prejunctional receptors are believed to transform the motor nerve ACh pool from a reserve store to a readily releasable store so that transmitter output can keep pace with transmitter demand.¹⁴

All the nondepolarizing muscle relaxants used in anesthesia practice compete with ACh for postjunctional cholinergic receptor sites to produce neuromuscular blockade. Receptor antagonist effects at prejunctional receptors may augment nondepolarizing blockade by diminishing ACh output as well. Herein also lies an explanation for the fade that is observed with neuromuscular

blockade monitoring of nondepolarizing muscle relaxants. Fade of tetanic and train-of-four (TOF) stimulation may reflect the blockade of presynaptic ACh receptors by the muscle relaxant and failure of ACh release to keep pace with rapid stimulation.^{19,20}

Acetylcholinesterase

As noted earlier, the combination of ACh with its muscle end-plate receptor causes a transitory depolarization of the end plate. The EPP is short lived because soon after binding, ACh is rapidly destroyed by hydrolysis, and its depolarizing action halts.³ Paradoxically, the rapid destruction and removal of ACh from the junctional cleft is critical for continued muscle contractile response. The ACh molecule must be off the muscle end-plate receptor for the perijunctional muscle membrane to repolarize, or reset, in anticipation of further activation.

The hydrolysis of ACh to choline and acetate is rapid and efficient. Most ACh is destroyed within a few milliseconds after it is released into the junctional cleft.² The enzyme acetylcholinesterase (AChE), also known as *true* or *tissue cholinesterase*, catalyzes the hydrolysis.

Much of the choline byproduct released by hydrolysis is efficiently drawn back within the presynaptic nerve terminal for use in the synthesis of new ACh. AChE is present in high concentrations on the external surface of the postsynaptic muscle membranes.

Without AChE, the concentration of ACh would become extremely high in the junctional cleft. Under these circumstances, ACh would maintain the muscle end plate in a state of persistent depolarization, yet the muscle itself would be paralyzed.^{6,19} The reason for this seemingly illogical behavior (ACh-receptor occupation, end-plate depolarization, yet no muscle contraction) is that in the face of persistent end-plate depolarization, the Na⁺ channels of the perijunctional muscle membrane do not reactivate or reset; these voltage-gated ion channels remain closed, impeding

further muscle membrane depolarization. Thus, even with persistent end-plate depolarization, muscle contraction is prevented, and clinical weakness follows. A cyclic muscle membrane depolarization/repolarization sequence is necessary for normal muscle contraction to occur.

The mechanism of depolarizing muscle relaxants may, at least in part, be explained by a similar mechanism. Depolarizing muscle relaxants, such as succinylcholine, activate the muscle end plate in a manner similar to that of ACh, but they have a more protracted end-plate depolarizing response because they are less rapidly metabolized. AChR occupation by a depolarizing muscle relaxant causes a prolonged depolarization of the end plate, prohibits activation of perijunctional channels, and produces a depolarizing block.^{6,19}

Reversal of a nondepolarizing neuromuscular block may be accomplished by the use of cholinesterase inhibitors. Anticholinesterase agents inhibit the breakdown of ACh and, in so doing, increase the amount of ACh at the NMJ. The abundance of ACh in the synaptic gap changes the agonist-antagonist ratio and enables the agonist (ACh) to bind to the ACh receptor with greater frequency than the antagonist (nondepolarizing muscle relaxant). Hence, a higher ACh concentration can overcome the receptor occupation by the muscle relaxant, and neuromuscular transmission can be restored.

Various other esterases, in addition to AChE, are present throughout the body. One that is found in the plasma is *pseudocholinesterase*, or *nonspecific cholinesterase*. Like AChE, pseudocholinesterase is capable of hydrolyzing ACh, but it also has properties separate from those of AChE. One distinction particularly relevant to anesthesia practice is the ability of pseudocholinesterase to metabolize ester local anesthetics and the depolarizing muscle relaxant succinylcholine. [Table 12.6](#) lists some common anesthesia-related drugs that undergo hydrolysis.

Extrajunctional Receptors

In utero, before muscle innervation occurs, the muscle cells of a fetus synthesize what are termed *immature, fetal, or extrajunctional receptors*. These fetal receptors (γ AChRs) are inserted over the entire

length of the muscle cell. As the fetal NMJ develops, increasing motor nerve activity has a trophic effect in restricting the ACh receptors specifically to the NMJ.⁷ By the age of 2 years, the nerve-muscle contact is fully mature and active, and the extrajunctional receptors disappear from the peripheral part of the muscle. If neural activity is reduced or abolished and the neural trophic influence is lost, the muscle resorts to fetal-like synthesis of γ AChRs.^{9,20,21}

Several situations, including stroke, spinal cord transection, thermal trauma, direct muscle damage, and prolonged immobility, have been associated with the accelerated spread of γ AChRs to large areas of the skeletal muscle membrane.^{9,10,21-23} These so-called denervation injuries result in an abnormal excitability of the muscle and an increase in muscle sensitivity to ACh, a condition that is called *denervation hypersensitivity*.^{1,24} The extrajunctional receptors may develop within 24 to 48 hours after diminution of nerve activity. Eventually, the number of aberrant receptors per muscle fiber may increase 5- to 32-fold.²⁴ These receptors disappear and muscle sensitivity returns to normal if neural input is reestablished. Extrajunctional and end-plate cholinergic receptors are similar in many ways, but an important distinction pertinent to anesthesia practice is their differing response to receptor agonists and antagonists.

Clinically, extrajunctional receptors demonstrate a resistance to nondepolarizing muscle relaxants. Hence, larger doses of nondepolarizing relaxants may be necessary to induce neuromuscular blockade, for example, in an immobilized limb or in parts of the body affected by a stroke.^{3,21} Monitoring a nondepolarizing neuromuscular block with a peripheral nerve stimulator in a paretic limb may result in underestimating the magnitude of neuromuscular blockade in nonparetic muscles.²⁵

Conversely, extrajunctional receptors are more easily activated by agonists (e.g., ACh, succinylcholine) than junctional receptors. Moreover, each extrajunctional channel stays open approximately four times longer than junctional receptors, allowing more ions to flow (primarily Na^+ into the muscle cell and K^+ out) in response to agonist-induced depolarization.

The clinical significance of denervation injuries and the

proliferation of extrajunctional receptors becomes evident with the administration of succinylcholine, which can produce alarmingly high levels of plasma K^+ in these patients.^{21,23} Succinylcholine-induced hyperkalemia reflects the extensive proliferation of extrajunctional receptors along the entire muscle membrane and their prolonged and exaggerated depolarization response to agonists. Succinylcholine stimulates the aberrant cholinergic receptors and triggers a protracted opening of the cation channels, allowing excess Na^+ movement into the cell and excess K^+ movement out, down their respective gradients.

Dangerous levels of succinylcholine-induced hyperkalemia have been observed within 4 days of denervation injury with doses of succinylcholine as low as 20 mg.²¹ The pronounced release of K^+ in response to succinylcholine cannot be circumvented by the prior administration of nonparalyzing doses of nondepolarizing muscle relaxants.

Muscle Physiology

Skeletal muscle constitutes the greatest mass of somatic musculature. Skeletal muscle is composed of bundles of multinucleated, long, cylindrical cells. Muscle fibers typically extend the entire length of a muscle.²⁶ Because their length is much greater than their width, these cells are called *muscle fibers*. Each muscle fiber is a single cell surrounded by an electrically polarized cell membrane called the *sarcolemma*. The sarcolemma separates the extracellular space from the myoplasm, the muscle-fiber intracellular space. Dystrophin is a large, rodlike protein that is located on the intracellular side of the sarcolemma and serves to stabilize the muscle membrane during contraction.¹ As will be discussed later in this chapter, disruption of dystrophin and its important structural features can result in different muscular dystrophies.²⁶

Individual skeletal muscle cells are parallel to the muscle body and have no anatomic or functional bridges between them. The parallel arrangement helps maximize shortening capacity and velocity. The cells function independently so that the force of contraction of the total muscle is equal to the sum of individual fibers. This contrasts with smooth and cardiac muscle, in which the muscle cells are interdependent and are mechanically coupled to adjacent cells.^{1,8}

Bundles of cylindrical filaments called *myofibrils* run along the axis of the muscle fiber. Each skeletal muscle fiber contains several hundred to several thousand myofibrils. The myofibrils are composed of contractile proteins that impart a striking, repetitive, light-and-dark banding pattern along the entire fiber length. The repeating unit, called a *sarcomere*, is the basic contractile unit of skeletal muscle. The alternating light-and-dark banding pattern is responsible for the classification called *striated muscle*. Cardiac muscle is also classified as striated muscle because it too has the repetitive pattern of light and dark bands.^{1,8} The arrangement of the muscle fibers, myofibrils, and sarcomeres is shown in [Fig. 36.7](#).

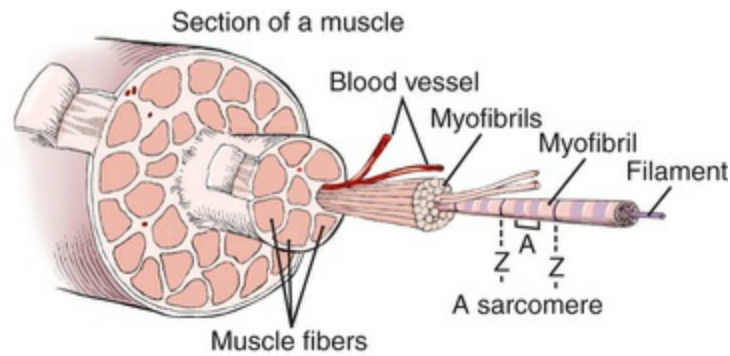

FIGURE 36.7 The structural arrangement and organization at each level of the muscle assembly. The skeletal muscle is composed of muscle fibers that contain long, cylindrical myofibrils. Each myofibril is made up of precisely arranged thick and thin filaments that form repeating dark and light bands called *sarcomeres*.

Most skeletal muscles bridge two skeletal attachment points and are recruited to generate force and movement in voluntary actions ranging from chewing to walking. A muscle contraction that involves shortening of the muscle length to perform work is called an *isotonic contraction*. A muscle contraction that produces increased tension but no appreciable decrease in length is called an *isometric contraction*.

Structure of the Contractile Apparatus

The repeating, striated arrangement of the myofibril arises from the contractile filaments that compose the sarcomere: the thick filaments and the thin filaments. The thick filaments, which are composed primarily of the protein myosin, are in the central region of the sarcomere. The thin filaments are approximately half the diameter of the thick filaments and are composed of the proteins actin, troponin, and tropomyosin. Myosin and actin filaments are responsible for the actual muscle contraction⁸ (Fig. 36.8).

FIGURE 36.8 Longitudinal diagram of a sarcomere showing the arrangement of the thick filaments (myosin) and the thin filaments (primarily actin) within the myofibril.

Cross sections of the myofibril reveal that each thick filament is surrounded by a hexagonal arrangement of thin filaments. The thick and thin filaments are arranged to slide over one another, overlap, and create shortening of the sarcomere.⁸ With muscle contraction, force is generated by interaction and overlap of thick and thin filaments (Fig. 36.9).

FIGURE 36.9 Actin filament sliding over myosin filament during muscle contraction.

Cross-Bridge Interaction and Cycling

Sliding Filament Mechanism

Physiologic contraction of striated muscle occurs when muscle fibers are depolarized to a threshold for action-potential formation. The depolarizing wave initiated by AChR occupation at the motor

end plate is carried along the muscle membrane surface from one Na^+ channel to the next. Action potential depolarization of the sarcolemma spreads rapidly to the muscle cell's interior through a reticular network of intracellular tubules that are, in essence, internal extensions of the cell membrane.

This network, composed of transverse tubules, or T tubules, forms a grid around the intracellular myofibrils and closely associates with the intracellular sarcoplasmic reticular membranes. The T tubules provide a path for the rapid transmission of the action potential from the sarcolemma to the myoplasm.²⁶

The sarcoplasmic reticulum is an irregular, closed membrane structure that weaves throughout the myoplasm of the muscle cell and contains large amounts of Ca^{2+} . The sarcoplasmic reticular membrane is active in sequestering Ca^{2+} by way of numerous high-affinity Ca^{2+} active-transport carriers in its membrane. These pumps maintain a high sarcoplasmic reticular store of Ca^{2+} and a very low resting myoplasmic Ca^{2+} concentration.^{8,26}

The transit of an action potential along the sarcolemma and into the T-tubule system is detected by intracellular dihydropyridine voltage sensors. The voltage sensors are linked to calcium release channels in the sarcoplasmic reticulum. Voltage sensor activation triggers Ca^{2+} efflux from the sarcoplasmic reticular stores. The major Ca^{2+} release channel located on the sarcoplasmic reticulum is called the *ryanodine receptor*. These channels are commonly called *receptors* because they bind the alkaloid ryanodine¹ (Fig. 36.10). As we will discuss later in this chapter, defects in the ryanodine receptor are a major factor contributing to malignant hyperthermia (MH).

FIGURE 36.10 Cellular components of excitation–contraction (E–C) coupling and relaxation in skeletal muscle. An action potential (AP) initiated at the neuromuscular junction is normally the first event in E–C coupling. The AP rapidly propagates over the sarcolemma and into the T-tubules. When the T-tubule is depolarized, the voltage sensors (\oplus) in the dihydropyridine receptors (DHPRs) move and open the ryanodine receptors (RyRs), thus permitting Ca^{2+} to flow out of the sarcoplasmic reticulum (SR) into the cytosol to trigger contraction. The Ca^{2+} released from the SR is subsequently returned to the SR by sarco/endoplasmic reticulum calcium-ATPase (SERCA) to relax the muscle. (From Blaustein MP, et al. *Cellular Physiology and Neurophysiology*. 2nd ed. Philadelphia: Elsevier; 2012: 237.)

In response to action potential stimulation, the myoplasmic Ca^{2+} concentration rises severalfold. The overall effect is the discharge of Ca^{2+} from the sarcoplasmic reticulum into the myoplasm by the transit of an action potential into the muscle cell.²

The Ca^{2+} released into the myoplasm acts as a switch to expose myosin binding sites on actin. Myosin reacts by binding to the surrounding exposed thin filament sites, and forms a reversible complex with actin, which is called the *actomyosin complex*. The process of myosin-actin binding in response to elevated

myoplasmic Ca^{2+} is termed *cross-bridge formation*.

When myosin binds to the actin site, it uses energy to drag the actin filaments towards the center of the sarcomere. The pull of the actin filaments accentuates the overlap of the thick and thin filaments, causing shortening of the sarcomere and culminating in muscle contraction. Cross-bridge cycling and the associated movement of actin is called the *sliding filament mechanism*.

If the intracellular Ca^{2+} concentration remains sufficiently high, which mainly depends on the frequency of incoming action potentials, the cycle begins again: myosin links to actin, slides the filament, detaches, and reconnects at the next actin site.

A single sliding cycle, or myosin power stroke, shortens the length of the sarcomere by approximately 1%. The sliding cycle has to be repeated approximately 50 times for full shortening of the muscle. The cycle continues until it is interrupted by the active removal of Ca^{2+} from the myoplasm or until adenosine triphosphate (ATP) is exhausted. Active Ca^{2+} removal from the cytoplasm back into the sarcoplasmic reticulum causes return to a configuration that prohibits myosin-actin binding and the muscle relaxes.

The overall process by which depolarization of the muscle fiber causes Ca^{2+} release from the sarcoplasmic reticulum into the myoplasm to cause cross-bridge cycling and muscle contraction is called excitation-contraction coupling² (Fig. 36.11).

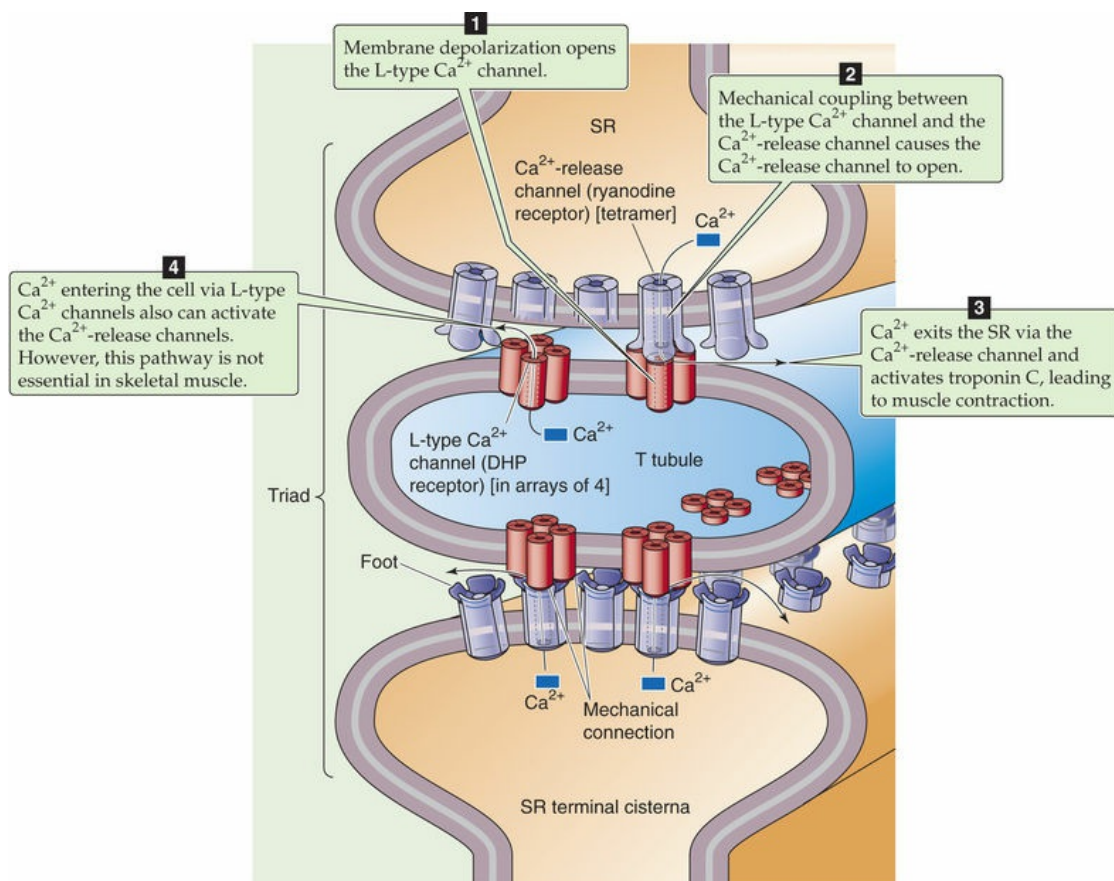

FIGURE 36.11 Excitation–contraction (E–C) coupling in skeletal muscle. A tetrad of four L-type Ca²⁺ channels on the T tubules faces a single Ca²⁺-release channel of the sarcoplasmic reticulum (SR), so that each L-type Ca²⁺ channel interacts with the foot of one of the four subunits of the Ca²⁺-release channel. Note that half of the Ca²⁺-release channels lack associations with L-type Ca²⁺ channels. *DHP*, dihydropyridine. (From Boron WF, Boulpaep EL. *Medical Physiology*. 3rd ed. Philadelphia: Elsevier; 2017: 230.)

Box 36.1 summarizes the excitation-contraction coupling events. Box 36.2 summarizes the events leading to skeletal muscle relaxation.

Steps of Neurohumoral Transmission and Excitation-Contraction Coupling

1. An action potential reaches the motor nerve ending.
2. Ca²⁺ enters the motor nerve ending; ACh is released into the synaptic cleft.

3. ACh binds to a postsynaptic cholinergic receptor at the motor end plate.
4. The motor end-plate membrane depolarizes (the EPP).
5. An action potential is generated at the perijunctional muscle membrane.
6. The action potential spreads along the muscle membrane and inward to the transverse tubules.
7. Depolarization of the T tubules causes Ca^{2+} release from the sarcoplasmic reticulum.
8. Ca^{2+} triggers actomyosin complex cross-bridge formation; the sarcomere shortens; the muscle contracts.

ACh, Acetylcholine; *T*, transverse.

Box 36.2

Steps of Skeletal Muscle Relaxation

1. ACh is hydrolyzed by AChE in the synaptic cleft.
2. The end plate and muscle membrane repolarize to their resting potentials.
3. Ca^{2+} is actively pumped back into the sarcoplasmic reticulum.
4. Myoplasmic Ca^{2+} concentration returns to a normal low level.
5. The muscle relaxes.

ACh, Acetylcholine; *AChE*, acetylcholinesterase

Grading Contractile Force

Two major mechanisms grade skeletal muscle contractile force. One determining factor of muscle force is the number of motor units activated or recruited. With increasing voluntary effort, more and

more motor units are recruited, and an increasing muscle force develops.

The other mechanism by which skeletal muscle tension is graded is by varying the frequency of the action potential discharge to the muscle. A single action potential invariably liberates sufficient Ca^{2+} ions to activate skeletal muscle contraction. However, the Ca^{2+} ions are rapidly transported back into the sarcoplasmic reticulum before the muscle has time to develop maximal tension. The brief contraction that results from transit of a single action potential is called a *twitch*.²⁶

Unlike cardiac muscle, skeletal muscle does not have a refractory period. Because of this property, rapidly repeated electrical impulses can cause summation of contractions and greatly increase the muscle tension. Repetitive action potentials maintain a high Ca^{2+} concentration in the myoplasm. The greater the myoplasmic Ca^{2+} concentration, the more cross-bridge sites are exposed, and the stronger the force of the contraction. Maximal and sustained muscle tension without relaxation—produced by the fusion and summation of successive twitch responses—is called *tetanus*.²

Fig. 36.12 shows the time course and relationship between a single action potential, the myoplasmic Ca^{2+} rise, and the resulting twitch response. The action potential lasts approximately 2 to 4 msec. The twitch begins approximately 2 msec after the start of the muscle membrane depolarization. The duration of the twitch varies with the type of muscle stimulated.

FIGURE 36.12 The electrical, ionic, and mechanical responses of a skeletal muscle to a single maximal stimulus. *AP*, Action potential.

Slow Versus Fast Muscle

Skeletal muscle fibers are classified as type I (slow twitch fibers) or

type II (fast twitch fibers), based on different myosin isoenzymes that distinguish the two types. The two fiber types differ in their metabolic demands, their myosin ATPase activity, and their cross-bridge cycling rates. Muscles usually contain a mixture of both types of fibers, but one type often predominates.^{1,27,28}

Slow twitch (type I) muscle fibers are adapted for sustained movements, such as maintaining posture, and are resistant to fatigue. They have slow twitch durations, depend on oxidative metabolism for energy, have extensive blood supplies, and have rich concentrations of mitochondria.^{1,27,28}

An example of a type I muscle is the soleus muscle of the leg, an important muscle used for maintaining posture and walking. Type I muscle is called *red muscle* because its high myoglobin content imparts a dark, rubrous color.

Fast twitch (type II) muscle fibers usually predominate in white muscle and are primarily concerned with rapid or powerful movement. They have short twitch durations, depend on glycolytic pathways for energy, and are easily fatigued.^{1,28} Muscles specialized for fine, skilled movement, such as extraocular muscles, and some muscles of the hand are in this category.

The diaphragm is engaged in continuous rhythmic activity and so the muscle fibers must be resistant to fatigue. Infants have a greater tendency toward respiratory failure in part because at birth only 25% of their diaphragm is composed of type I fatigue-resistant fibers, compared with 55% in the adult. Before 27 weeks' gestational age, type I slow fibers make up less than 10% of the total diaphragm muscle content.²⁷

Energy Sources for Skeletal Muscle

Muscle contraction requires a continual supply of energy at a rate proportionate to its energy consumption. The energy consumed by skeletal muscle is used for (1) cross-bridge cycling during muscle contraction, (2) sarcoplasmic reticular resequestration of Ca^{2+} during muscle relaxation, (3) rephosphorylation of creatine to replenish creatine phosphate energy stores, (4) activation of the Na^+/K^+ pump to restore proper membrane polarization, and (5) resynthesis of muscle glycogen.⁸

The amount of ATP present in the muscles is sufficient to sustain

maximal muscle power for only approximately 3 seconds. For this reason, actively contracting muscles must continually form new ATP. There are three metabolic systems that provide a continuous supply of ATP in muscle cells: (1) the phosphocreatine–creatine system, (2) the glycogen–lactic acid system, and (3) the aerobic system.²⁸

Phosphocreatine—Creatine System

The energy-rich phosphate bonds in muscle phosphocreatine (also called *creatine phosphate*) supply a limited amount of energy to produce ATP in skeletal muscle. The hydrolysis of creatine phosphate to creatine and phosphate is an extremely rapid reaction that releases large amounts of energy for the conversion of adenosine diphosphate (ADP) to ATP. Creatine phosphate provides a stored source of energy that is used for short bursts of muscle power or for use at the very beginning of muscle contraction while other, more sustainable, energy-regenerating systems are being turned on.⁸

Glycogen—Lactic Acid System

Skeletal muscle stores glucose as energy-rich glycogen. With brief, intense muscle exertion, muscles meet their energy demands from the breakdown of glycogen to glucose (glycogenolysis) and the metabolism of glucose to pyruvate and lactate (glycolysis). Glycolysis occurs without the consumption of oxygen in the cytoplasm of the muscle cell. The energy released from the breakdown of glucose to pyruvate or lactate is used to convert ADP to ATP for very short periods of muscle contraction.²⁸

Aerobic System

When oxygen is plentiful, the skeletal muscle takes up products of the glycolytic pathway and other substrates, such as amino acids, fatty acids, or ketone bodies, and efficiently oxidizes them to CO₂ and water in the muscle fiber mitochondria. This energy-yielding process is called *oxidative metabolism*. The oxidation of products of the glycolytic pathway and free fatty acids is a slow process, but it

is usually sufficient to meet the continual but more modest energy demands of more than 95% of skeletal muscle. The aerobic system is the primary source of energy for muscle cells during prolonged exercise and for steady-state requirements.²⁸

Musculoskeletal Pathophysiology and Anesthesia

Musculoskeletal diseases have a wide variety of causes, ranging from autoimmune destruction of tissue, to genetically determined defects in muscle membrane proteins, to pharmacologically induced alterations in Ca^{2+} metabolism. Musculoskeletal defects may reside in the NMJ, the muscle infrastructure, or the skeletal support structures.

Myasthenia Gravis

MG is a chronic disease of the NMJ, manifested by skeletal muscle weakness, fatigability on effort, and at least partial restoration of function after rest.^{29,30}

Epidemiology

MG occurs in 25 to 125 of every 1 million people worldwide and studies indicate that the prevalence is increasing.³⁰⁻³² In individuals younger than 50 years, there is a predominance of female cases (60–70%); however, in those older than 50 years, the disease is equally distributed between the sexes.³⁰ MG can begin spontaneously at any age, but it occurs most often in women between the ages of 30 and 40 years and in men between the ages of 50 and 60 years.^{15,33} The onset may be abrupt or insidious, and the course is fluctuating, marked by periods of exacerbation and remission.³⁴ Spontaneous remissions that do occur sometimes persist for years.

Pathophysiology

MG is a heterogeneous autoimmune disease, characterized by autoantibodies directed against different proteins of the NMJ.^{29,35-37} The complexity of MG is augmented by the presence of at least three distinct IgE antibodies and three distinct postsynaptic target proteins; NMJ dysfunction is the common feature.^{29,30,35} The postsynaptic lesion appears to be caused by immune-mediated

destruction or inactivation of the nicotinic acetylcholine receptor at the NMJ. The end result is a NMJ with a decreased number of functional postsynaptic ACh receptors (Fig. 36.13).

FIGURE 36.13 Myasthenia gravis and Lambert–Eaton myasthenic syndrome (LEMS). In myasthenia, there are antibodies to the acetylcholine receptors on the postsynaptic membrane which block conduction across the neuromuscular junction (NMJ). Myasthenic symptoms can be transiently improved by inhibition of acetylcholinesterase (e.g., with Tensilon [edrophonium bromide]) which normally removes the acetylcholine. A cell-mediated immune response produces simplification of the postsynaptic membrane, further impairing the safety factor of neuromuscular conduction. In LEMS, antibodies to the presynaptic voltage calcium channels impair release of acetylcholine from the motor nerve ending; calcium is required for the acetylcholine-containing vesicle to fuse with the presynaptic membrane for release into the NMJ. (From Walker BR, et al. *Davidson's Principles and Practice of Medicine*. 22nd ed. London: Elsevier; 2014:1227.)

In 85% of the patients with MG, circulating antibodies react directly with the nicotinic AChR, leading to varying degrees of dysfunction. This is the most prevalent subtype of MG and is

termed *AChR-MG*. The α subunits of the AChR channel appear to be the primary immunogenic target.^{30,38} Although antibodies are detected in the sera, the antibody level does not correlate with the severity of the disease.³⁹⁻⁴²

Another distinct subgroup of MG involves antibodies against MuSK, a protein involved in the development of the NMJ and acetylcholine receptor clustering at the motor end plate.³⁰ Patients with MuSK-MG have a distribution of muscle weakness typically involving the neck and respiratory muscles; an atrophied tongue is often seen.³⁵ Patients have more bulbar muscle involvement and are at increased risk for aspiration. Up to 50% of these patients are likely to experience respiratory crisis requiring mechanical ventilation.³⁹⁻⁴³ Serum concentration of MuSK-MG correlates with severity of symptoms.³⁹ Evidence from case series have demonstrated increased prevalence of MuSK-MG in people living closer to the equator.^{40,44}

A third and small subset of patients with MG involves antibodies against Lrp4, found at the motor end plate of the NMJ. As mentioned previously in this chapter, Lrp4 works with agrin, a glycoprotein released from the motor nerve terminal, and with MuSK to promote NMJ maturation and AChR clustering at the end plate.³⁵⁻³⁷

The initiating stimulus for the production of IgE antibodies against NMJ proteins (AChR, MuSK, and Lrp4) is enigmatic. A genetic predisposition, age, sex, and various environmental and infectious etiologies have been suggested as MG triggers.^{30,38} The thymus gland seems to play a central role in the pathogenesis of AChR-MG, but not MuSK-MG.^{15,35,38,41} In the majority of patients, the thymus is a recognized trigger for MG by producing autoantibodies against the AChR at the NMJ.^{30,35,45-47} The thymus is hyperplastic or abnormal in approximately 75% of patients with MG. Thymomas are present in an additional 10% of patients.³⁸

The effect of pregnancy on MG varies substantially from woman to woman.^{48,49} Pregnancy exacerbates the symptoms of MG in 33% of pregnant women with the disease; however, other patients with the disease experience remission or no change in symptoms during pregnancy.⁴⁹ Disease exacerbations are more likely to occur in the first trimester or puerperium.⁴⁸ Magnesium sulfate should be

avoided in the parturient with MG, either for tocolysis or treatment of preeclampsia.^{48,50} Anti-AChR antibodies that pass across the placenta may produce transitory symptoms of weakness in 15% to 20% of infants born to mothers with MG. Neonatal MG signs of weakness (difficulty with swallowing, sucking and breathing, ptosis, facial weakness) in the affected infant are usually present within the first few hours after birth. Spontaneous remission usually occurs within 2 to 4 weeks as the maternal antibodies are cleared from the neonate's circulation.⁴⁸ Neonatal MG has been linked to both AChR and MuSK antibodies.⁴⁰

MG is generally classified according to the profile of the autoantibodies, the age of onset of symptoms, the location of affected muscles (ocular versus generalized) and thymic abnormalities.²⁹ The Osserman staging system is widely used to categorize the severity of the disease (Table 36.1).

TABLE 36.1

Clinical Classification of Myasthenia Gravis; Osserman Score System

Stage	Clinical Status
I	Only ocular involvement
IIa	Generalized muscle weakness
IIb	Generalized moderate muscle weakness and/or bulbar involvement
III	Acute, fulminant presentation and/or respiratory depression
IV	Severe, generalized myasthenia

Clinical Manifestations

The clinical hallmarks of MG include generalized muscle weakness that improves with rest, and an inability to sustain or repeat muscular contractions. Enhanced effort produces enhanced weakness. The severity of MG can range from mild (slight ptosis only) to severe respiratory muscle weakness (termed *myasthenic crisis*). Environmental, physical, and emotional factors seem to affect the disease process, although unpredictably.¹⁵

Proximal limb and shoulder girdle musculature are often affected in patients with generalized disease. Oropharyngeal weakness may cause difficulties in articulation, chewing and swallowing.³⁷ Visual symptoms (ptosis and diplopia) from extraocular muscle weakness

occur in the majority of patients, especially at disease onset.^{37,40,51} The disease is restricted to the extraocular muscles (ocular myasthenia) in 20% of patients.²⁹ Sensation and cognition are not affected by the disease process.

Other autoimmune disorders, such as thyroid disease, collagen vascular diseases, polymyositis, and rheumatoid arthritis, occur more often in patients with MG.^{3,37}

Myocarditis may complicate MG, especially in patients with thymomas. The myocardial inflammation produces dysrhythmias, particularly atrial fibrillation and atrioventricular block.^{37,52}

Treatment

Therapy for patients with MG is directed toward improving neuromuscular transmission and includes cholinesterase inhibitors, corticosteroids and other immunosuppressants, plasmapheresis, intravenous immunoglobulin, and thymectomy.^{53–55} Additional immunomodulatory drugs are emerging.⁵⁶

Treatment with cholinesterase inhibitors can dramatically reduce the symptoms of MG in most patients by inhibiting the hydrolysis of ACh and therefore raising the neurotransmitter's concentration at the NMJ.³⁶ Increasing the synaptic concentration of ACh enhances the possibility of postsynaptic AChR occupation, which is critical for the production of a threshold-reaching EPP for muscle contraction.³⁶ The administration of AChE inhibitors improves muscular strength for several hours, but does not affect the course of the disease.³⁷ Anticholinesterase treatment is particularly successful in patients with milder disease and the subtype AChR MG.^{15,55} The most commonly used anticholinesterase agent in the United States is oral pyridostigmine.^{37,55} An oral dose of 60 mg pyridostigmine lasts 3 to 6 hours and is equivalent to an intramuscular or intravenous dose of 2 mg pyridostigmine.⁵⁷ The dosage is patient dependent with the average dose of 600 mg daily. Increased bronchial and oral secretions can be a serious problem in patients with swallowing or respiratory insufficiency.³⁷

Titration of the anticholinesterase dose is challenging. Underdosing does not sufficiently retard the muscle weakness and can result in myasthenic crisis, which is a severe exacerbation of myasthenic symptoms resulting in respiratory distress. Emotional

stress, pulmonary infection, and surgery can promote myasthenic crisis.⁴⁵ Overmedicating with a cholinesterase inhibitor can produce a surplus of ACh at the myoneural junction, causing a depolarizing-like block. This situation is called *cholinergic crisis* and like myasthenic crisis, it can augment muscle weakness, requiring respiratory support. Muscarinic side effects (e.g., abdominal cramping, diarrhea, bradycardia, excess bronchial and oral secretions, urinary urgency, and miosis) predominate in a cholinergic crisis.

Symptomatic treatment with AChE inhibitors is usually combined with immunosuppressive therapy.³⁷ Corticosteroid therapy produces an 80% remission rate in patients with MG, in part by reducing AChR antibody levels.^{36,55} Although corticosteroid treatment is highly effective, it is limited by the side effects (e.g., osteoporosis, gastrointestinal bleeding, suppression of endogenous cortisol release, cataracts, increased susceptibility to acute infections, hypertension, and glucose intolerance) observed with long-term administration.

In patients with more debilitating, widespread disease, immunosuppressive drugs such as azathioprine may induce remission by interfering with the production of AChR antibodies. Side effects of azathioprine include severe hemopoietic depression and liver dysfunction. Alternative immunosuppressive options include cyclosporine, cyclophosphamide, tacrolimus, and methotrexate.^{15,36,37,53,58} The monoclonal antibody rituximab is promising for severe generalized MG resulting in good therapeutic effect.³⁷

Excision of the thymus gland is recommended for adults with generalized disease and for patients with thymomas, thymus gland hyperplasia, or drug-resistant MG.¹⁵ Thymectomy effectively arrests or reverses the myasthenic process by removing a major source of antibody production and is generally a safe and viable treatment option.^{15,37,45,47} Clinical improvement of myasthenic symptoms is seen in 85% of patients within weeks to months after surgery; almost 35% of these patients go into remission requiring no medications.¹⁵ Early evidence suggests that MuSK-MG patients respond less well to thymectomy.^{15,37,55} Trans-sternal and endoscopic approaches have been used for surgical excision of the

thymus. The video-assisted thoracoscopic extended thymectomy requires one-lung ventilation and obligatory muscle paralysis.

Plasmapheresis (plasma exchange) and intravenous immunoglobulin (IVIg) arrest acute exacerbations of MG by reducing the concentration of circulating antibodies. These treatments are used primarily as short-term treatments because the improvement that they produce in symptoms is generally short lived.^{37,53,59} Plasmapheresis or IVIg may be used preoperatively to stabilize a patient before emergency surgery or for crisis intervention to temporarily improve muscle strength.^{15,53,55,59,60}

Anesthetic Implications

Several days before the operation and again immediately prior to surgery, the surgical candidate with MG should be evaluated for disease control and medical treatment. Ideally, the patient with MG should be scheduled for elective surgery during a stable phase when the patient is minimally medicated. Routine premedication with sedatives or opioids may result in exaggerated respiratory depression.^{31,60}

The continuation of the daily dose of anticholinesterase medication in the immediate preoperative period is debatable, and depends to a large degree on the patient's reliance on the drug for control of symptoms.^{31,54,61,62} Anticholinesterase therapy continued into the morning of surgery may be particularly important for patients with severe disease who depend on this therapy for their well-being. However, the presence of cholinesterase inhibitors may potentiate vagal responses, necessitate higher doses of nondepolarizing muscle relaxants and cloud the differential diagnosis and treatment of postoperative muscle weakness. Discontinuing or tapering pyridostigmine before surgery may avoid complicating the anesthetic management. Patients with mild MG can usually tolerate the temporary disruption in treatment.^{54,62}

Aminoglycoside antibiotics or electrolyte imbalances (hypokalemia, hypermagnesemia) may aggravate the disease.⁴⁵ Pharyngeal and laryngeal muscle weakness, difficulty in eliminating oral secretions, and the risk of pulmonary aspiration should be considered in the anesthesia plan of care.^{45,54} Swallowing and respiratory muscle dysfunction account for much of the

morbidity and potential mortality in patients with MG.^{54,63}

Regional and local anesthesia have important utility for the surgical patient with MG in that they not only minimize or eliminate the need for intraoperative neuromuscular blockade, but also improve postoperative analgesia and respiratory function.^{31,45,64} Amide local anesthetics are preferred, as ester local anesthetics rely on pseudocholinesterase for metabolism and their duration may be prolonged in patients taking cholinesterase inhibitors. Patients are more vulnerable to any respiratory depressant complications associated with upper extremity blockade and high neuraxial anesthesia levels.^{31,61,64,65} Sedation should be administered cautiously to avoid respiratory depression.⁶⁴ Despite the touted advantages of regional anesthesia over general anesthesia (GA) and neuromuscular blockade, perioperative monitoring for weakness in patients with MG is highly imperative.⁶⁴

Neuraxial anesthesia is preferred in myasthenic parturients, for both cesarean and vaginal delivery. Furthermore, early neuraxial analgesia for labor pain may circumvent fatigue, weakness, and stress.^{48,50,64}

When GA is indicated for surgical patients with MG, the respiratory depressant effects of sedatives, narcotics, and volatile anesthetic agents, compounded by the presence of an already weakened respiratory system, must be carefully considered.^{31,54,64,66,67} Nonopioid analgesics can be suitable options for the patient with MG, to reduce opioid dose.³¹

In many patients, the relaxant effects of a volatile anesthetic in combination with the patient's preexisting skeletal muscle weakness are sufficient to facilitate intubation of the trachea.^{62,66,68} Enhanced muscle relaxation may be seen with the administration of all the potent volatile anesthetics.^{31,54,64,66,67}

Small doses of succinylcholine may be used to facilitate tracheal intubation, but the response may be unpredictable.⁵⁷ Untreated patients with MG appear to be two to three times more resistant to succinylcholine. Normal dosages of succinylcholine may not effectively depolarize the end plate because of the deficiency of viable AChRs. For rapid-sequence induction using succinylcholine, the dose should be increased to 1.5 to 2 mg/kg.⁵⁴ Conversely, patients treated with cholinesterase inhibitors exhibit a normal or

prolonged response to succinylcholine. Cholinesterase inhibitors block the effects of plasma cholinesterase, as well as those of true cholinesterase; hence, succinylcholine and other medications metabolized by plasma cholinesterase may have a delayed hydrolysis and a prolonged duration of action.^{31,62} Ester hydrolysis of atracurium and cisatracurium is independent of plasma cholinesterase activity.

The deficient number of functioning AChRs in patients with MG produces an extraordinary sensitivity to nondepolarizing muscle relaxants. Small doses of nondepolarizing agents can produce a profound block with a prolonged effect, even in patients being treated with cholinergic drugs.^{31,54,60}

Muscle relaxant requirements can be variable in patients with MG, a characteristic that makes neuromuscular blockade monitoring an essential and integral part of anesthetic management. Monitoring only one muscle group may overestimate or underestimate the degree of muscle relaxation in patients with MG.^{69,70} Monitoring the neuromuscular blockade in more than one muscle group is a prudent choice to ensure safe recovery at the end of surgery.

A conservative and individualized approach to muscle paralysis is advised. The use of smaller doses (one-half the normal dose) of shorter-acting nondepolarizing relaxants makes sense.^{31,45,57,54} Patients with severe disease may require no nondepolarizing relaxants at all for surgical muscle relaxation.^{67,68,71,72} Airway management with a laryngeal mask airway can help avoid the use of muscle relaxants for some procedures.⁷³

Reversal of neuromuscular blockade with an AChE inhibitor should be performed cautiously in patients with MG. Overtreatment with an anticholinesterase agent can precipitate a cholinergic crisis and aggravate rather than reverse the muscle weakness. In many circumstances, the neuromuscular block can be titrated to allow complete spontaneous recovery, avoiding the use of reversal.⁶⁰ Case reports have described effective use of sugammadex for reversal of rocuronium neuromuscular blockade in MG patients.⁷⁴⁻⁷⁶ Its use needs to be examined further in MG patients.

Complete, sustained return of muscle strength (TOF ratio > 90%),

resumption of spontaneous ventilation, and intact upper airway reflexes must be present before extubation. The patient should be informed that postoperative tracheal intubation and ventilatory support may be required. Several studies have attempted to determine the perioperative factors that predict a higher likelihood for myasthenic crisis and the need for postoperative ventilation, especially following thymectomy.³¹ Study results have differed, but some of the factors cited for predicting the need for postoperative mechanical ventilation include: body mass index greater than 28, duration of the disease longer than 2 to 6 years, a daily pyridostigmine dose greater than 750 mg/day, positivity for acetylcholine receptor antibodies, the presence of respiratory disease, bulbar symptoms, a previous history of myasthenic crisis, a preoperative forced vital capacity (FVC) less than 2.7 L, and severity of muscle weakness.⁷⁷⁻⁸¹

Skeletal muscle strength may appear to be adequate shortly after surgery but may deteriorate a few hours later. All patients, whether they receive regional anesthesia or GA, must be monitored assiduously for weakness in the postoperative period. [Box 36.3](#) outlines important anesthesia considerations for the patient with

Box 36.3

Anesthesia Considerations for the Patient with Myasthenia Gravis

- Assess the patient for disease control and medical treatment several days before surgery and again immediately prior to surgery
- Avoid routine premedication with sedatives or opioids
- If anticholinesterase medication is continued on the morning of surgery, consider muscarinic and nicotinic effects of the agent
- Take into account pharyngeal muscle weakness, difficulty eliminating oral secretions, and the risk of pulmonary aspiration in the anesthesia plan of care
- Opt for local or regional anesthesia if appropriate; in myasthenic

parturients, neuraxial anesthesia is preferred for both cesarean and vaginal delivery

- For general anesthesia, use smaller doses of short-acting nondepolarizing muscle relaxants; volatile anesthetics may provide sufficient relaxation for some patients; monitor neuromuscular blockade in more than one muscle group; consider sugammadex for reversal of neuromuscular blockade
- Consider the respiratory depressant effects of sedatives, narcotics, and volatile anesthetic agents on an already weakened respiratory system
- Anticipate an unpredictable response to succinylcholine; untreated patients are resistant to effects of depolarizing muscle relaxants; patients taking cholinesterase inhibitors agents may have prolonged response due to inhibition of plasma cholinesterase
- Ensure full return of respiratory strength prior to extubation; closely monitor muscle strength in the postoperative period regardless of anesthesia technique

Lambert-Eaton Myasthenic Syndrome

Incidence

LEMS is an autoimmune disease that classically occurs in patients with malignant disease, particularly small-cell carcinoma of the bronchi. LEMS often precedes the diagnosis of cancer by months to years.⁸² One-third to one-half of patients, however, have no evidence of carcinoma.^{14,82,83} LEMS is a rare disease with an annual incidence one-tenth that of MG.⁸² Most patients with LEMS are men, with a history of cigarette smoking, between the ages of 50 and 70 years, although cases do occur in children.⁸²

Pathophysiology

The predominant defect associated with LEMS appears to be an autoantibody-mediated derangement in presynaptic P/Q-type

voltage-gated Ca^{2+} channels leading to a reduction in Ca^{2+} -mediated exocytosis of ACh at neuromuscular and autonomic nerve terminals.^{3,14,83-87} Calcium channel antibodies are present in 80% to 90% of patients with LEMS.⁸² The decreased release of ACh from the motor nerve ending produces a reduced postjunctional response. Unlike MG, the number and quality of postjunctional AChRs remain unaltered, and the end-plate sensitivity is normal. The NMJ abnormality of LEMS is similar in location to the effects of aminoglycoside antibiotics and magnesium sulfate in which impairment of presynaptic voltage-gated channels results in attenuated ACh release.^{3,82}

Clinical Manifestations and Treatment

Weak and often tender proximal muscles (hips, shoulders), fatigue, and hyporeflexia are dominant features of LEMS. Autonomic nervous system dysfunction occurs in 75% to 80% of patients and is manifested as constipation, dry mouth, orthostatic hypotension, and urinary retention. Autonomic dysfunction is not seen with MG.⁸²

Patients with LEMS experience a brief increase in muscle strength with voluntary contraction, distinguishing it from MG where increased effort produces increased weakness.

There is no cure for LEMS. Treatment is aimed at improving muscle strength and reversing autonomic deficits.^{15,88} If there is evidence of an underlying malignancy, treating the cancer often improves symptoms.⁸² 3,4-Diaminopyridine improves muscle strength by promoting activation of presynaptic voltage-gated Ca^{2+} channels and should be continued preoperatively.

Immunosuppressive treatment with corticosteroids (prednisolone) and azathioprine can also be used to control symptoms.

Plasmapheresis and IVIG can provide short-term improvement. In most patients with LEMS, pyridostigmine does not provide improvement, again differentiating it from MG.⁸⁸

Anesthetic Implications

An index of suspicion for LEMS should be maintained in surgical patients with a history of muscle weakness and suspected or

diagnosed carcinoma of the lung. Patients with LEMS are extremely sensitive to the relaxant effects of both depolarizing and nondepolarizing muscle relaxants. Inhalational anesthetics alone may provide adequate relaxation, but if muscle relaxants are required, their dosages should be reduced and the neuromuscular blockade closely monitored.^{60,62,89} Neuromuscular reversal with an anticholinesterase agent may be used. Patients are at risk for postoperative respiratory failure and close monitoring is required. Prolonged ventilatory assistance may be required postoperatively. [Box 36.4](#) summarizes anesthesia considerations for patients with

BOX 36.4

Anesthesia Considerations for the Patient with Lambert-Eaton Myasthenic Syndrome

- Maintain an index of suspicion for LEMS in surgical patients with a history of muscle weakness and suspected or diagnosed carcinoma of the lung
- Continue 3,4-diaminopyridine preoperatively
- Adjust muscle relaxant dose recognizing extreme sensitivity to both depolarizing and nondepolarizing muscle relaxants; assess neuromuscular blockade closely
- Monitor closely for postoperative respiratory failure regardless of anesthesia technique

Duchenne Muscular Dystrophy

Muscular dystrophy is a heterogeneous set of diseases that includes facioscapulohumeral dystrophy, Emery–Dreifuss muscular dystrophy, limb-girdle dystrophy, Becker muscular dystrophy, Duchenne muscular dystrophy (DMD), and others. DMD is the most common of these and has the most severe clinical course.⁹⁰

Incidence

DMD, described by the French neurologist G.B. Duchenne in 1861, is an inherited, sex-linked, recessive disease that presents in early

childhood between 3 and 5 years of age. It is clinically evident in males and has an incidence of approximately 1 in 3500 live male births.⁹¹ Females are generally unaffected but are carriers of the disorder. Cognitive and behavioral difficulties occur in approximately 30% of patients with DMD.^{91,92} There is no cure for the disease. Corticosteroid therapy preserves skeletal muscle strength, reduces the risk of scoliosis, delays cardiomyopathy onset, and stabilizes pulmonary function in many patients.⁹³⁻⁹⁷ Patients with DMD are now living longer than ever before, most likely due to advances in supportive care and steroid therapy.^{98,99} However, despite improvements in survival, death often occurs in early adulthood and is usually caused by progressive cardiomyopathy or pneumonia.^{90,91,97}

Pathophysiology

Patients with DMD experience an infiltration of fibrous and fatty tissue into the muscle, followed by a progressive degeneration and necrosis of muscle fibers. The disease affects skeletal muscle, cardiac muscle, and smooth muscle. Muscle weakness ends with muscle destruction.

In 1987 the abnormal gene responsible for DMD was identified. This gene is located on the X chromosome and is errant in coding for the vital muscle protein dystrophin. Dystrophin is part of a large, tightly associated complex of glycoproteins that serve as structural components of the muscle fiber sarcolemma.^{100,101} The dystrophin-associated protein complex stabilizes the sarcolemma during muscle contraction and relaxation.¹⁰² Patients with DMD have a complete absence or a severe deficiency of the dystrophin protein, which alters sarcolemma integrity, stability and signaling.^{90,95,101,102} The dystrophin protein is present in low amounts or is structurally altered in Becker muscular dystrophy, a similar but rarer disorder that follows a milder and less progressive course than the Duchenne type.^{90,102}

In the early stages of DMD, increased permeability of the sarcolemma and skeletal muscle necrosis are mirrored by elevated serum levels of the enzyme creatine kinase (CK).⁹⁰ Serum CK levels are greater than 50 to 100 times normal levels, but as muscle is lost to the destructive process, CK levels decline.^{91,102}

Clinical Manifestations

DMD is characterized by an unremitting weakness and a steady deterioration of muscle groups. Proximal muscles of the lower extremities are usually affected first. The child exhibits a clumsy, waddling gait, difficulty with climbing stairs and jumping, and frequent falls. Weakness of the pelvic girdle leads to the classic finding of Gowers sign, in which patients use their hands to climb up their legs to arise from the floor.⁹⁰ Neck flexor weakness occurs at all stages of the disease; when supine, a child with DMD is not able to lift his head against gravity.⁹⁰ Loss of strength is relentless and the steady deterioration of muscle strength forces most of these boys to be wheelchair bound by the ages of 11 to 13 years.^{90,91,102}

Skeletal muscle atrophy is usually preceded by fat and fibrous tissue infiltration, resulting in pseudohypertrophy. The infiltrative process is most apparent in the calf muscles, which become particularly enlarged.

Degeneration of respiratory muscles (diaphragm, intercostal, accessory muscles) occurs and leads to a restrictive type of ventilatory impairment. Particularly in nonambulating patients, paraspinal muscle weakness predisposes patients to kyphoscoliosis, which further decreases the pulmonary reserve. Decreasing muscle strength also results in ineffective coughing, impaired swallowing, and inability to mobilize secretions.^{90,95,103,104}

As the disease progresses, it affects not only skeletal muscle but also smooth muscle of the alimentary tract and cardiac muscle. Alimentary tract involvement can lead to intestinal hypomotility, delayed gastric emptying, and gastric dilation.¹⁰⁵

Myocardial involvement occurs in almost all patients with progressive disease and includes dilated cardiomyopathy, ventricular dysrhythmias, and mitral regurgitation.^{90,91,93,97,106-108} Preclinical cardiac involvement can be detected in up to 62% of boys between the ages of 6 and 10 years. Cardiomyopathy is present in nearly all patients by the age of 18 years.^{97,107,108} The cardiomyopathy primarily involves the left ventricle (LV) and is characterized by myocyte fibrosis, thinning of the LV wall, and decreased contractility. Oral corticosteroids have been shown to slow the deterioration of cardiac function.⁹⁷ Electrocardiographic (ECG) changes occur at a young age and include sinus tachycardia,

tall R waves in V1 and deep Q waves in the left precordial leads.^{90,91}

Although often severe, compromised cardiac and respiratory conditions may be masked by the limited activity imposed by the patient's skeletal myopathy. Added stress, such as that produced by surgery, may suddenly increase cardiorespiratory demand and uncover the weakened cardiac and respiratory states.^{95,109,110}

Anesthetic Implications

Patients with DMD are susceptible to untoward anesthesia-related complications. Careful preoperative evaluation by a cardiologist, pulmonologist, and neuromuscular specialist is suggested before any surgical procedure.^{90,110,111} When possible, local or regional anesthesia should be considered.¹¹⁰

For the patient on long-term corticosteroid treatment, potential side effects, including peptic ulcers, glucose intolerance, and adrenal suppression, should be considered.⁹⁰ Patients with DMD have decreased bone density due to limited mobility. Osteoporosis associated with steroid use compounds the bone fragility and increases risk for fractures. Particular care must be addressed with positioning these patients for surgery.⁹⁰ Consideration also needs to be given to surgical stress-dose steroid coverage for the patient on long-term glucocorticoid therapy.

Generalized muscle weakness, especially in the advanced stages of DMD, makes these patients exquisitely sensitive to the respiratory depressant properties of opioids, sedatives, and general anesthetic agents. Preoperative sedation should be omitted or minimal, and the smallest possible amounts of anesthetic agents should be used.

Preoperative and postoperative respiratory therapy can help maximize the patient's pulmonary condition.¹¹⁰ In patients with more advanced disease, arterial blood gas determinations and preoperative pulmonary function studies may elucidate the extent of respiratory involvement and the amount of respiratory reserve. A preoperative FVC less than 50% of predicted places the patient at increased risk for respiratory complications when undergoing GA or procedural sedation. Patients with a FVC less than 35% of predicted have a high risk for pulmonary complications.¹¹⁰ In one series, aggressive preoperative chest physiotherapy and

incorporation of postoperative noninvasive positive pressure ventilation (NPPV) enabled patients with preoperative FVC levels of 30% and below to successfully undergo corrective spinal surgery.¹¹² Extubation directly to NPPV should be considered for DMD patients with baseline FVC less than 50% of predicted and is strongly recommended for patients with a FVC less than 30% of predicted.^{110,111,113} Assiduous attention to respiratory function must be continued into the postoperative period. Delayed pulmonary insufficiency, as late as 36 hours after surgery, has been reported.¹⁰⁵

The effects of nondepolarizing muscle relaxants must be scrupulously monitored. There is enhanced muscle relaxant sensitivity, and recovery may be prolonged three to six times the normal duration in patients with DMD.¹¹⁴ If surgical muscle relaxation is required, a short-acting nondepolarizing muscle relaxant that is carefully titrated with the use of blockade monitoring is recommended.

Cardiomyopathy and decreased cardiac reserve makes these patients sensitive to the myocardial depressant effects of general anesthetic agents, sedatives, and narcotics.^{115,116} Echocardiography and cardiology consultation is recommended for operative patients to evaluate LV function.^{93,110,117} A carefully titrated intravenous “balanced” technique may help provide a smoother cardiovascular course. Ketamine has been used successfully for anesthesia during diagnostic muscle biopsy in patients with DMD. Judicious administration of IV fluids is warranted. The sudden occurrence of hypotension and tachycardia during anesthesia may herald heart failure.¹⁰⁹

The potential for delayed gastric emptying, plus the presence of weak laryngeal reflexes, dictates that the anesthesia plan of care includes measures for guarding against aspiration of stomach contents. Gastrokinetic agents and the prophylactic use of a nasogastric tube are recommended for patients with gastrointestinal dysmotility.¹¹⁰

Succinylcholine is contraindicated in patients with DMD.^{93,111} The altered sarcolemma can lead to rhabdomyolysis and myoglobin efflux with succinylcholine administration. The resultant massive breakdown of the diseased muscle fibers produces a profound hyperkalemia that requires extensive and tenacious treatment with

hyperventilation, calcium chloride, sodium bicarbonate, and glucose and insulin. Ventricular fibrillation and intractable cardiac arrest have been associated with succinylcholine administration to patients with diagnosed and undiagnosed muscular dystrophy.^{115,118,119}

Rhabdomyolysis, hyperkalemia, hyperthermia, unexplained tachycardia, and cardiac arrest have also been reported after the administration of potent inhalation anesthetics to patients with DMD without the use of succinylcholine.^{115,116,120–122} These malignant hyperthermia (MH)-like reactions may be due to the destabilizing effect of inhalational agents on an already unstable and frail muscle membrane resulting in anesthesia-induced rhabdomyolysis.¹²³

Given the availabilities of safe anesthesia alternatives, the anesthetist should consider a regional anesthetic or a trigger-free total IV anesthesia for patients with DMD.^{93,110,113,122–124} In addition to the strict contraindication of succinylcholine, this includes, when feasible, avoiding potent volatile inhalational agents.^{113,123}

Despite the increased risk for MH-like events in patients with DMD, MH and DMD are genetically distinct diseases. Current evidence indicates that DMD and Becker muscular dystrophy are not among the myopathies that are genetically associated with MH and that patients with DMD and Becker muscular dystrophy do not have an increased risk of MH.^{110,124} **Box 36.5** outlines important

Box 36.5 Anesthesia considerations for the patient with DMD.

Anesthesia Considerations for the Patient with Duchenne Muscular Dystrophy

- Obtain preoperative consultation from pulmonologist, cardiologist, and neuromuscular specialist
- When possible, consider local or regional anesthesia for surgical procedure
- Carefully position the patient considering bone fragility imposed by limited mobility and glucocorticoid use
- Appreciate extreme sensitivity to the respiratory depressant properties of opioids, sedatives, and general anesthetic agents;

preoperative sedation should be omitted or minimal; the smallest possible amounts of anesthetic agents should be used

- Consider potential for delayed gastric emptying; administer gastrokinetic agents and use nasogastric tube
- Monitor cardiovascular course, considering decreased cardiac reserve and potential sensitivity to the myocardial depressant effects of general anesthetic agents, sedatives, and narcotics
- Implement preoperative and postoperative respiratory therapy; extubation directly to noninvasive positive pressure ventilation (NPPV) recommended for patients with FVC < 50% of predicted
- If general anesthesia is selected, implement “trigger free” total intravenous anesthetic; succinylcholine is contraindicated; when feasible, avoid potent volatile inhalational agent
- Monitor patient closely in postoperative period for weakness

Malignant Hyperthermia

MH is an uncommon, life-threatening, hypermetabolic disorder of skeletal muscle, triggered in susceptible individuals by potent inhalation agents, including sevoflurane, desflurane, halothane, enflurane, ether, and isoflurane, and the depolarizing muscle relaxant succinylcholine.^{125,126} There is mounting evidence that MH may also be triggered in some patients by stressors such as vigorous exercise and heat.^{127,128}

Epidemiology/Incidence

The exact incidence of MH is unknown, but estimates range from 1 in 3,000 to 1 in 50,000 general anesthetics.¹²⁵ The highest incidence of MH is in young people. Children under 15 years of age comprise approximately 52% of all reactions.¹²⁶ A review of MH cases in New York state reported the prevalence of MH in males to be 2.5 to 4.5 times the rate for females.¹²⁹ All ethnic groups are affected in all parts of the world.¹²⁶

Susceptibility to MH is inherited as an autosomal-dominant

pattern. If a parent is identified as MH-susceptible (MHS), then each of the parent's siblings have a 50% chance of also being MHS.^{125,126} MH has been associated with at least 34 genetic mutations, and in many cases, the genetic defects have not been established.¹³⁰

The first formal case report of MH was of an Australian family, described by Denborough et al., over 50 years ago in the journal *The Lancet*.¹³¹ Since that time, a great deal has been learned about the biochemical and physiologic components of the disease. Nonetheless, many questions remain regarding the pathophysiology, genetics, diagnosis, and significance of some clinical manifestations.

Pathophysiology

Although the cause(s) of MH are not yet known with certainty, it is generally agreed that MH is an inherited disorder of skeletal muscle. In most susceptible patients, a defect in calcium regulation is expressed by exposure to specific anesthetic triggers, the volatile inhalational anesthetic agents, or succinylcholine. An uncontrolled rise in myoplasmic calcium results.

To date, two genetic mutations have been unequivocally identified as predisposing a patient to MH^{126,132}:

- RYR1 encodes the ryanodine receptor, the major calcium release channel of the sarcoplasmic reticulum.
- CACNA1S encodes a subunit of a dihydropyridine calcium channel located in skeletal muscle T-tubules.

Both these proteins are involved in muscle calcium release by the sarcoplasmic reticulum. Mutation of RYR1 and a defective ryanodine channel appear to underlie approximately 70% of reported cases, whereas approximately 1% of cases result from mutation of CACA1S.^{125,133}

MH is typically initiated in MHS patients when specific anesthetic-triggering agents induce enhanced calcium release from the sarcoplasmic reticulum in myocytes. The defect involves skeletal muscle, and there is no evidence for a primary defect in cardiac or smooth muscle cells. The enhanced intracellular calcium results in muscle contraction and abnormal muscle metabolism.

Energy-dependent reuptake mechanisms attempt to remove excess calcium from the myoplasm, increasing muscle metabolism two- to threefold. The accelerated cellular processes increase oxygen consumption, augment carbon dioxide and heat production, deplete ATP stores, and generate lactic acid.¹²⁵ Acidosis, hyperthermia, and ATP depletion cause sarcolemma destruction, producing a marked egress of potassium, myoglobin, and CK to the extracellular fluid.¹³⁰ Skeletal muscle constitutes 40% to 50% of our body mass, so relatively small changes in muscle metabolism may produce the dramatic systemic biochemical changes observed with MH.

Clinical Manifestations

Not all cases of MH are fulminant, but rather there is a spectrum or continuum of severity, ranging from an insidious onset with mild complications to an explosive response with pronounced rigidity, temperature rise, arrhythmias, and death.^{125,134}

All anesthetic inhalational agents except nitrous oxide are triggers for MH. Succinylcholine is a trigger. No other anesthetic agents appear to trigger MH.

Although MH may present in several ways, a typical MH episode begins while the patient is under GA with a volatile anesthetic. Succinylcholine may or may not precede the MH episode. The onset of MH symptoms may occur immediately after induction of anesthesia or several hours into the surgery.¹³⁴ MH risk may increase when succinylcholine is used in combination with volatile anesthetics.¹³⁵ Succinylcholine also appears to accelerate the onset and increase the severity of the MH episode.^{125,126} In some cases, but not all, desflurane and sevoflurane have been associated with delayed onset of MH, as long as 6 hours after induction of anesthesia.¹³⁶⁻¹³⁸ Although an uncommon event, MH can occur in the recovery room or the intensive care unit, usually within 1 hour after GA.¹³⁹⁻¹⁴¹

The clinical features of MH are not uniform and the time course between onset of initial signs and fulminant MH is variable. Overall, clinical manifestations of MH reflect increased intracellular muscle Ca^{2+} concentration and greatly increased body metabolism (Box 36.6). Tachycardia and an unanticipated increase in end-tidal

carbon dioxide (ETCO₂) levels (>55 mm Hg) out of proportion to minute ventilation are early diagnostic clues.^{125,126} Other common signs of MH include tachypnea, skin mottling, and total body or jaw muscle rigidity. Muscle rigidity is clinically apparent in 75% of cases. Hyperthermia, which may climb at a rate of 1°C to 2°C every 5 minutes and averages 39.3°C (102.7°F), may occur early or late in the course. Cyanosis is pathognomonic and is a confirming sign of MH.^{125,142}

Clinical Events and Laboratory Findings During Malignant Hyperthermia

- Unexplained, sudden rise in end-tidal CO₂ (greater than 55 mm Hg)
- Unexplained tachycardia or arrhythmias
- Tachypnea
- Labile blood pressure
- Masseter muscle or generalized muscle rigidity
- Rising patient temperature
- Cola-colored urine (myoglobinuria)
- Mottled, cyanotic skin
- Decreased SaO₂

Laboratory Findings Consistent with MH

- Arterial blood gases: respiratory and metabolic acidosis
- Serum potassium greater than 6 mEq/L
- Creatine kinase greater than 20,000 units/L
- Serum myoglobin greater than 170 mcg/L

- Urine myoglobin greater than 60 mcg/L

SaO_2 , % of oxygen saturation.

Acidosis, hyperkalemia, and hyperthermia lead to cardiac irritability, a labile blood pressure, and arrhythmias that can rapidly progress to cardiac arrest. Laboratory findings mirror the muscle breakdown and include increased serum potassium, myoglobin, and CK levels. Myoglobin appears in the urine and places the patient at risk for tubular obstruction and renal failure. Arterial and venous blood gas analysis reveals mixed metabolic and respiratory acidosis. Death may result unless the individual is promptly treated.¹²⁵ Even with treatment, the individual is at risk for complications including cerebral edema, consumptive coagulopathy, myoglobinuric renal failure, compartment syndrome, hepatic dysfunction, and pulmonary edema.^{125,126}

The variable time course and nonspecific clinical features and laboratory findings can make the diagnosis of MH difficult. Insufficient anesthetic depth, hypoxia, neuroleptic malignant syndrome, thyrotoxicosis, pheochromocytoma, and sepsis can share several characteristics with MH, making the clinical picture ambiguous and the differential diagnosis challenging to even the most experienced practitioner^{125,143,144} (Box 36.7). Surgical procedures performed of necessity in a darkened operating room **Box 36.7** further compromise the practitioner's diagnostic acumen.

Signs and Symptoms Shared by Malignant Hyperthermia and Other Clinical Occurrences

Tachycardia

- Hypoxia
- Hypercarbia
- Hypovolemia
- Insufficient anesthetic depth

- Anticholinergics, sympathomimetics, cocaine, amphetamine
- Hypermetabolic states (sepsis, thyroid storm, pheochromocytoma)

Hyperpyrexia

- Heatstroke
- Blood transfusion reaction
- Infection
- Drug reaction
- Neuroleptic malignant syndrome
- Serotonin syndrome
- Hypermetabolic states (sepsis, thyroid storm, pheochromocytoma)
- Iatrogenic overheating

Tachypnea, Hypercapnia

- Congestive heart failure, pulmonary edema
- Hypermetabolic states (sepsis, thyroid storm, pheochromocytoma)
- Intraoperative carbon dioxide insufflation
- Airway obstruction, pneumothorax
- Excess dead space, low minute volume

Masseter Muscle Rigidity

- Insufficient neuromuscular blockade

- Temporomandibular joint syndrome
- Neuroleptic malignant syndrome
- Myotonia

Preoperative Assessment and Prevention

Patients who are MHS are usually phenotypically normal, otherwise healthy, and completely unaware of their risk until exposed to a triggering anesthetic.^{125,145} Furthermore, not everyone who has the MH gene develops an MH episode upon each exposure to triggering anesthetics. An MHS patient may be anesthetized multiple times before experiencing an MH event. Although MH susceptibility cannot be ruled out by history alone, every surgical patient should be questioned about:

- Family history of unexpected intraoperative complications or deaths
- Family or personal history of MH, muscle rigidity/stiffness, and/or high fever under anesthesia
- Personal history of dark or cola colored urine after surgery or exercise
- Personal history or family history of high temperature or death during exercise

Because MH is an inherited disorder, all members of a family in which MH has occurred must be considered MHS unless proven otherwise.¹³⁰ Moreover, the absence of a positive family history does not preclude MH susceptibility.

Patients with neuromuscular disease may exhibit one or more clinical features of MH in the perioperative period. There are a limited number of relatively rare disease entities that have a strong clinical and/or genetic link to MH susceptibility. These include Central Core disease, King Denborough syndrome, and Multi-minicore disease.^{130,146–148} There is no risk for MH over the general population in patients with Duchenne or Becker muscular dystrophy, neuroleptic malignant syndrome, myotonia congenita, and myotonic dystrophy.^{126,147}

Over 50% of patients with unexplained CK elevation test positive

for MH on biopsy. However, as a screening test for MH, CK levels are imprecise and nonspecific.¹⁴⁹

Heat stroke and strenuous exercise have been implicated as causal factors of MH in some patients.¹⁵⁰ However, there is no clear consensus whether or how these factors cause, exacerbate, or have no effect on MH triggering.^{127,128,151,152} It may be advisable to provide a trigger-free anesthetic to patients with previously unexplained exertional heat illness or exertional rhabdomyolysis until definitive MH testing can be performed.¹⁵¹

Management of an MH Episode

Enhanced patient monitoring, earlier diagnosis and treatment, and the introduction of dantrolene are responsible for the dramatic decrease in mortality from nearly 80% 30 years ago to less than 5% today.¹²⁵

In 1979, dantrolene sodium was introduced as a treatment for MH. Since that time, dantrolene has contributed greatly to the dramatic decline in death and disability associated with MH. It remains the only drug known to specifically treat MH. Dantrolene is a unique muscle relaxant that does not work at the NMJ as do standard neuromuscular blocking drugs. Rather, it works by binding to the ryanodine calcium channel and reducing calcium efflux from the sarcoplasmic reticulum, counteracting the abnormal intracellular calcium levels accompanying MH.^{126,153,154} At clinical concentrations, dantrolene does not render the muscle totally flaccid and without tone, but it may cause significant muscle weakness and respiratory insufficiency, especially in patients with preexisting muscle disease. Dantrolene may also be efficacious in treating neuroleptic malignant syndrome.

Calcium channel blockers should not be administered with dantrolene, as they may induce life-threatening myocardial depression and hyperkalemia.^{126,154}

All patients given GA for more than 30 minutes should have core temperature monitoring.¹²⁵ Pulmonary artery, distal esophageal, nasopharyngeal, and tympanic membrane temperature monitors are the gold standards for core temperature measurement.¹⁵⁵ Skin temperature does not accurately reflect core temperature during an MH event.¹³⁰ Larach et al. showed that the risk of dying from an

MH episode was 9.7 times greater when only skin temperature was being used, and the relative risk of dying was 13.8 times higher when no temperature monitors were used compared to core temperature monitoring.¹⁴²

Early recognition of an impending MH crisis and prompt emergency response is critical for a patient's survival.¹⁵⁶ An increase in the time interval between the first clinical signs of MH and the administration of dantrolene has been associated with increased complication rates.¹⁵⁷ Once MH is recognized, it is important to discontinue triggering agents, administer dantrolene, hyperventilate with 100% O₂, cool the patient, and treat symptoms.¹²⁶ The Malignant Hyperthermia Association of the United States (MHAUS) provides an *Emergency Therapy for MH* poster that can be posted in every surgical site. The following treatment sequence is recommended for an acute MH episode¹⁵⁸:

- Immediately discontinue the volatile anesthetic and succinylcholine.
- Call for help and alert the surgeon to conclude the procedure promptly.
- Prepare and administer 2.5 mg/kg dantrolene IV bolus and repeat as necessary every 5 to 10 minutes until symptoms abate. Occasionally, a total dose greater than 10 mg/kg may be needed, but if greater than 10 mg/kg is given without reversal of symptoms, the diagnosis should be reassessed. The alkaline solution is highly irritating to vessels and should be administered through the largest vein possible.¹⁵⁴
- Hyperventilate with 100% oxygen at high flows (at least 10 L/min) to improve tissue oxygenation and eliminate CO₂. If available, apply activated charcoal filters (Vapor-Clean, Dynasthetics, Salt Lake City, UT) to each limb of the anesthesia circuit and replace after each hour of use. Even though the volatile anesthetic agent is discontinued when MH is first suspected, activated charcoal filters may become saturated after one hour.^{159,160}
- If fever is present, initiate cooling by lavage (orogastric, bladder, open cavities), administration of chilled intravenous normal saline, and surface cooling (e.g., hypothermia blanket, ice packs to the groin, axilla, and neck). Stop cooling measures at core body

temperature of 38.5°C to avoid hypothermia.

- Dysrhythmias will usually respond to treatment of acidosis or hyperkalemia. Treat persistent or life-threatening arrhythmias with standard antiarrhythmic agents. Do not administer calcium channel blockers with dantrolene.
- Check arterial blood gases, serum electrolytes, and blood glucose until the syndrome stabilizes. Correct severe metabolic acidosis with sodium bicarbonate, 1 to 2 mEq/kg, guided by pH and base deficit. Coagulation profile, CK, blood and urine myoglobin, and liver enzyme levels should be established.
- Treat hyperkalemia with hyperventilation, bicarbonate, and IV insulin and glucose. For refractory hyperkalemia, consider albuterol (or other β -agonist), kayexelate, dialysis, or extracorporeal membrane oxygenation (ECMO) if patient is in cardiac arrest.
- Maintain urine output greater than 1 mL/kg per hr with hydration, furosemide (0.5 to 1.0 mg/kg), and mannitol as needed. Large losses of intravascular volume should be anticipated. Evaluate need for invasive hemodynamic monitoring.

A full complement of dantrolene, along with other drugs and equipment necessary to treat an MH crisis, must be available at all facilities, including ambulatory surgical centers and offices, where MH triggering anesthetics or depolarizing muscle relaxants are administered or stocked.¹⁶¹ The cart should be kept in or very close to the operating room so it is available immediately if MH occurs.¹²⁶ MHAUS recommends that dantrolene be available to administer within 10 minutes of the decision to treat for MH.¹⁶² In addition to promoting patient safety, stocking dantrolene for the treatment of MH in an ambulatory surgical setting has been shown to be cost-effective.¹⁶³

There are two preparations of dantrolene available. The original preparation of dantrolene (Dantium/Revonto) is packaged as a 20-mg vial that must be reconstituted with 60 mL of sterile water for injection. There are 3 g of mannitol in each 20-mg vial of Dantium/Revonto. With this preparation, the initial dantrolene dose (2.5 mg/kg) equates to 8 to 10 vials of Dantium/Revonto for an average adult patient. The poor water solubility of Dantium

and, to a lesser degree, Revonto, makes it time consuming to mix and administer the requisite doses during an MH emergency.¹³⁰

A newer alternative formulation of dantrolene (Ryanodex) is easier to reconstitute, available as 250 mg per vial, and only requires 5 mL of sterile water diluent. Therefore, with Ryanodex, the initial dantrolene treatment can be more expeditiously achieved with administration of one vial. The provider should note that there is only 0.125 g of mannitol in each 250-mg vial of Ryanodex.

Documentation of an MH episode should include patient responses, personnel involved, medications administered, interventions, and patient outcomes.

Anesthesia for Malignant Hyperthermia–Susceptible Patients

Patients known or suspected of having MH should be assessed well before their date of surgery so that anesthesia records and MH testing center reports (if available) can be collected to corroborate the history.

Standard intraoperative monitoring for the MHS surgical patient includes blood pressure, ECG, pulse oximetry, capnography, and continuous measurement of core body temperature. A cooling water mattress should be placed under the MHS patient at the start of the procedure. Dantrolene pretreatment for the MHS surgical patient is not routine.¹⁵⁴

If the surgical site permits, a regional or local anesthetic technique is preferable for the MHS patient. Local anesthetics (both amide and ester) are nontriggering drugs. Preoperative administration of anxiolytics followed by a nontriggering general anesthetic can also be administered safely in concert with close monitoring of appropriate vital functions. The list of nontriggering anesthetic agents is comprehensive enough to meet most anesthetic requirements (Box 36.8). All volatile halogenated inhalation agents and succinylcholine are MH triggers and should be avoided when **Box 36.8** for the MHS patient.

Malignant Hyperthermia: Triggering and Nontriggering Agents

Triggering Agents

- All volatile inhalation anesthetics (desflurane, isoflurane, sevoflurane, halothane)
- Succinylcholine

Nontriggering Agents

- Local anesthetics
- Opioids
- Nitrous oxide
- Barbiturates, propofol, ketamine, etomidate
- Benzodiazepines
- Nondepolarizing skeletal muscle relaxants (vecuronium, atracurium, cisatracurium, pancuronium, rocuronium)
- Digoxin, tricyclic antidepressants, magnesium
- Anticholinesterase agents
- Anticholinergic agents

Not all drugs have been thoroughly screened as potential MH triggers, but it is clear that the vast majority of prescription and nonprescription drugs are safe, including antibiotics, antihypertensive agents, and drugs used in the treatment of gastrointestinal disorders.

Keys to successful perioperative outcome for the surgical patient who is MHS include the following:

- Perform preoperative care in a relaxed and quiet environment with premedication/analgesia as appropriate.
- Avoid MH-triggering medications.
- Remove trace anesthesia gas from the anesthesia machine.

Change the carbon dioxide absorbent. Ensure that anesthetic vaporizers are disabled by removing, or taping in the “OFF” position. Flush the anesthesia machine and ventilators with oxygen set at ≥ 10 L/min by attaching a new breathing circuit and reservoir bag to the Y-piece of the circle system and setting the ventilator to inflate the bag periodically. Preparation of modern anesthesia workstations is complex, as they have variability in their components and contain silicone parts that absorb inhalational agents and result in prolonged release of agent. The provider should review specific anesthesia machine instructions on preparation for an MH patient. Older anesthesia machines require only 20 minutes of oxygen flush for adequate preparation. Newer anesthesia machines may require up to 104 minutes for the anesthesia machine to be “cleaned” of volatile agents with oxygen flush. During the case, fresh gas flow should be kept at 10 L/min to avoid “rebound phenomenon” (increased release of residual volatile anesthetic agent when fresh gas flow is reduced after a set period of flushing).^{126,159,160,164–167}

- Activated charcoal filters placed on the inspiratory and expiratory proximal limbs of the anesthesia circuit decrease inhalational anesthetics to safe levels within several minutes. For both new and older machines, adding activated charcoal filters to the circuit will remove anesthetic gases and obviate the need for purging the system as described previously. However, the anesthesia machine will still need to be flushed with high fresh gas flows (≥ 10 L/min) for 90 seconds prior to placing the activated charcoal filters on *both* the inspiratory and expiratory ports. Adding activated charcoal filters to the airway circuit is effective in keeping anesthetic agent concentration below 5 ppm for up to 12 hours with fresh gas flows of at least 3 L/min.^{160,164,168,169}
- Other alternatives include the use of a dedicated “vapor free” machine for MHS patients or, if appropriate to the institution, the use of an intensive care unit (ICU) ventilator that has never been exposed to volatile anesthetic agents.
- An MH kit or cart that contains dantrolene along with other drugs and equipment necessary to treat an MH crisis should be placed in the OR. A full complement of Dantrium/Revonto is 36 vials and a full complement of Ryanodex is three vials.¹⁶¹

- Ice and the ability to crush it and at least 3000 mL of cold IV solution should be readily available.
- The patient should be observed for signs of MH, including continuous intraoperative monitoring of the patient's ETCO₂, arterial oxygen saturation, and core temperature.
- All perioperative medical personnel should be informed of the preestablished treatment protocol.

Surgery in an ambulatory surgical center can be safely performed for the MHS patient with appropriate planning and if the previously mentioned safety precautions are regarded.¹⁷⁰ A preoperative evaluation and consultation with the surgeon will help determine the best location to perform the needed surgery.

For the MHS patient who has undergone an uneventful surgical course, assiduous monitoring should continue in the postanesthesia care unit as MH can first manifest in the recovery room after uneventful surgery and anesthesia. Standard postoperative monitoring times (a minimum of 60 minutes in the postanesthesia care unit and a further 60 minutes in a step-down facility) are safe and appropriate for MHS patients as long as no problems relating to MH are encountered and the anesthetic has been uneventful.^{171,172} Patients undergoing outpatient procedures with an uneventful course may be discharged home the same day. It is important to provide discharge instructions with clear guidance on signs, symptoms, and instruction on how to manage complications.

Diagnostic Testing

The most accurate and commonly accepted test available for determining MH susceptibility is the caffeine halothane contracture test (CHCT). This test involves taking a biopsy of skeletal muscle from the patient and measuring its contractile response to caffeine, halothane, or both. Normal muscle contracts in response to caffeine or halothane, but this is augmented in the patient with MH. The test is available at four medical centers in North America.¹²⁶ Because the test must be completed within hours after muscle biopsy, the patient must travel to the testing site. Patients who have survived an unequivocal episode of MH are considered MHS. The CHCT is indicated for family members of an MHS patient or for patients

who have had a previous suspicious but undiagnosed reaction to anesthesia.

An alternative to CHCT for confirmation of MH susceptibility is genetic testing and DNA-based mutation analysis. Intensive investigations have focused on identifying the gene or genes responsible for MH. Most of the focus has been on searching for mutations in genes that encode the ryanodine receptor (RYR1), the dihydropyridine receptor, and associated proteins on chromosome 19. To date, most genetic studies link MH susceptibility to RYR1.¹⁷³⁻¹⁷⁷ For other MHS patients, the molecular genetic basis for MH, and possible related disorders such as exertional heat stroke, may be more heterogeneous, involving mutations at various sites on different chromosomes.^{176,177}

Postoperative Care After an MH Episode

The patient who has experienced an acute MH episode should be admitted to and monitored in an ICU for at least 36 hours.¹²⁶ For surgery performed outside a hospital setting, a transfer protocol to a facility that has inpatient capabilities to care for a patient in an MH crisis should be in place.¹⁷⁸ Intravenous dantrolene should be continued for a minimum of 24 hours, at approximately 1 mg/kg every 4 to 6 hours as a bolus dose or 0.25 mg/kg per hr by continuous infusion.^{130,179} Recrudescence of an intraoperative episode may occur in up to 25% of cases with a mean time from the initial reaction to recrudescence of 13 hours.^{125,180-182}

Masseter Muscle Rigidity

Masseter muscle rigidity (MMR), or trismus, is a sustained and forceful contracture of the masseter muscle. The contracture may be severe enough to make opening the jaw impossible (“jaws of steel”). A mild increase in masseter muscle tone or incomplete jaw relaxation after succinylcholine administration is fairly common and may be a normal response, but MMR presages MH in 20% to 30% of cases.^{125,130} Because MMR after succinylcholine administration may be a harbinger of MH, if a patient has received succinylcholine and his/her jaw cannot be opened or the patient has peripheral muscle rigidity, it is advisable to discontinue the trigger anesthetic, assume it is an MH event and immediately begin MH

treatment.^{125,126,130,183}

Information Resources

The MHAUS provides educational and technical information to patients and health care providers. Information is available at <http://www.mhaus.org>. An MH hotline may be accessed for MH emergencies 24 hours a day at 1-800-MH-HYPER (1-800-644-9737). Health care providers are encouraged to report MH episodes to the North American MH Registry of MHAUS.

Myotonic Dystrophy

The myotonias are a group of hereditary skeletal muscle diseases that include myotonic dystrophy, myotonia congenita, myotonia fluctuans, and paramyotonia congenita. A symptom common to all myotonias is the inability of skeletal muscles to relax after contraction or electrical stimulation. The molecular basis for the aberrant muscle contraction of myotonic dystrophy is not fully clear, but appears to be due to reduced conductance of chloride ions in the sarcolemma and other channelopathies.¹⁸⁴

Myotonic dystrophy (dystrophia myotonica) (DM) is composed of two recognized forms, type 1 (DM1 or Steinert disease) and type 2 (DM2), with overlapping phenotypes and distinct genetic defects.¹⁸⁵ DM1 and DM2 are characterized by skeletal muscles that are hypoplastic, dystrophic, and weak, yet prone to persistent contraction. Both disorders have multisystem features, including premature ocular cataracts, cardiac conduction problems and endocrine disorders.^{186,187} Of the two types of myotonic dystrophies, DM1 is more severe and roughly five times more common than DM2.¹⁸⁴⁻¹⁸⁷ The discussion in this chapter will focus primarily on DM1.

Incidence

Myotonic dystrophy type 1 is the most common and severe inherited muscular dystrophy in adults, with an estimated prevalence of 1 in 8000 to 1 in 20,000 depending on the geographic area.^{60,84,184,186} In most cases, an affected person has one affected

parent. The onset of symptoms can occur at any age, but approximately 75% of patients develop symptoms in the second, third, or fourth decade.^{184,187} A slow, progressive deterioration of skeletal, cardiac, and smooth muscle occurs, resulting in death by the sixth decade in most patients. Death is due to respiratory failure, pneumonia, fatal arrhythmias, or cardiac failure.^{186,188,189} Particularly with DM1, the severity of clinical symptoms increases with transmission to subsequent generations (genetic anticipation).¹⁸⁵

Clinical Manifestations

The name myotonic dystrophy aptly identifies two prominent aspects of the disorder, myotonia and muscular dystrophy; however, the disease is multisystem with involvement of almost all organ systems in the body.^{184,185} Frontal balding, premature ocular cataracts, and testicular atrophy in males form a frequently recognized triad of characteristics. Endocrine abnormalities, such as insulin resistance, occur with a greater frequency than in the general population.¹⁸⁷

Muscle stiffness and delayed muscle relaxation after contraction (myotonia) occurs in almost all patients with DM1 and is the most common initial symptom.^{184,187} Myotonic symptoms involving the hands, jaw, and tongue usually precede atrophy and weakness.¹⁸⁷

Muscle weakness most commonly affects facial, sternocleidomastoid, and distal limb muscles. The neck flexor muscles are affected early. Dysarthria and dysphagia are frequent problems. Distal limb weakness causes severe muscle debility in the later stages of the disease.^{185,186,188}

Cardiac disturbances occur in most patients with myotonic dystrophy, often manifesting as intraventricular and atrioventricular conduction defects and arrhythmias.^{91,185,186,190,191} Approximately 65% of patients with DM1 have ECG abnormalities, the most common being prolongation of the PR interval and the QRS duration.^{187,190,192} Arrhythmias include sinus bradycardia, atrial tachycardia, flutter or fibrillation, and ventricular tachyarrhythmias.^{91,184,191–193} Conduction defects are progressive and are an important cause of premature death in these patients.¹⁹⁰ Sudden death may result from asystole after complete heart block

or from ventricular tachycardia or fibrillation.^{91,190,192}

Recommendations include a cardiac pacemaker for DM1 patients with clinically significant cardiac conduction abnormalities and an implantable cardiac defibrillator for patients with cardiac tachyarrhythmia. In a study of 406 adult patients with DM1, patients were characterized as being at risk for sudden cardiac death if the ECG had at least one of the following features: rhythm other than sinus, PR interval of 240 msec or more, QRS duration of 120 msec or more, or second-degree or third-degree atrioventricular block.¹⁹² Although cardiac contractility is relatively preserved, LV systolic dysfunction and cardiomyopathy may occur at later stages.^{187,194}

Weakening of the thoracic muscles, including the diaphragm and intercostal muscles, reduces the respiratory reserve and the vital capacity. In addition, central and obstructive sleep apneas and hypersomnolence are reported in nearly 90% of patients with DM1 and can coexist with decreased ventilatory response to hypoxia and hypercarbia.^{184,185}

Gastrointestinal symptoms are common in patients with DM1 and may reflect involvement of smooth muscle. Gastric and intestinal dysmotility produces symptoms of bowel urgency alternating with constipation.^{195,196}

Treatment

There is currently no known cure for myotonic dystrophy and treatment is directed at symptom management.^{184,185,187} Sodium channel blockers are the main therapeutic agents for targeting myotonia. These agents delay the return of membrane excitation by blocking rapid Na⁺ influx into muscle cells. Mexiletine is currently regarded as the first-choice sodium channel blocker for treatment.¹⁹⁷ Other agents used to treat the myotonic contractures include a variety of antiarrhythmic drugs and anticonvulsants (phenytoin, carbamazepine, flecainide, and propafenone).^{184,198} Nondepolarizing muscle relaxants do not prevent or relieve recalcitrant contraction that may occur during airway management or following surgical stimulation or electrocautery.¹⁹⁹

Anesthetic Implications

Preoperative evaluation of the patient with myotonic dystrophy should focus on the degree of functional muscle involvement, cardiopulmonary function, and extramuscular manifestations of the disease.¹⁹⁹

Any drug that has the potential to depolarize skeletal muscle may produce an exaggerated contraction in patients with myotonic dystrophy. Succinylcholine is avoided, because administration can produce an intense generalized myotonic contracture for several minutes, making ventilation and intubation difficult or impossible.¹⁹⁹ Agents associated with myoclonus such as etomidate have the potential to produce similar effects.

Nondepolarizing muscle relaxants may be used in these patients, as long as the degree of muscle wasting and weakness is appreciated. The dose of the nondepolarizer should be reduced according to the degree of muscle impairment. Neuromuscular blockade monitoring should be assessed carefully as peripheral nerve stimulation could induce myotonia that is misinterpreted as sustained tetanus even when significant neuromuscular blockade still exists.

It is difficult to predict the reaction to reversal of neuromuscular blockade with anticholinesterase agents as they potentially can result in aggravation of myotonia. Shorter-acting, nondepolarizing muscle relaxants have the obvious advantage of being less likely to require reversal. Alternatively, sugammadex has been used successfully to reverse rocuronium-induced muscle blockade in patients with myotonic dystrophy.^{200,201} Extubation should occur only after the patient is awake with full return of muscle strength.

An abnormal swallowing mechanism resulting from oropharyngeal muscle involvement and gastrointestinal hypomotility renders these patients vulnerable to pulmonary aspiration of gastric contents.^{196,199,201}

The severity of respiratory compromise in patients with DM1 should not be underestimated. Pulmonary function test results may serve as useful baselines in the patient with advanced disease. The respiratory depressant effects of hypnotics, sedatives, opioids, and volatile anesthetics may compromise already weakened respiratory musculature and lead to unexpected decompensation.¹⁹⁹ The ultra-

short acting opioid remifentanyl may be an appropriate choice to provide intraoperative analgesia. In the patient with a history of hypersomnolence, even small doses of short-acting anesthetic agents may be associated with an exaggerated and prolonged anesthetic effect. Speedy²⁰² reported on a typical case in which a 31-year-old man with myotonic dystrophy remained unconscious and unable to maintain a patent airway for 4 hours after receiving an anesthetic that consisted of 50 mg of propofol, 0.5% isoflurane, and 50% nitrous oxide in oxygen.

Inhalational agents can be safely used in patients with myotonia dystrophy, but close monitoring of cardiac and respiratory function is indicated. Strict monitoring of the patient's cardiorespiratory status should continue into the postoperative period, especially if the patient received sedative or opioids.¹⁹⁹ Completely uneventful responses to GA in myotonic patients have also been reported.

Regional anesthesia and peripheral nerve blocks using ultrasound guidance may be prudent choices for anesthesia and a successful way to provide intra- and postoperative analgesia with no or minimal doses of opioids.¹⁹⁹

The patient should be questioned preoperatively about syncope, dizziness, and palpitations, and the ECG examined for advanced conduction blocks. It may be wise to assume that even asymptomatic patients have some degree of cardiac involvement. Diligent monitoring of cardiovascular parameters should be maintained intraoperatively and postoperatively. Conduction blocks may require access to pacemaker equipment.⁶²

Pregnancy may exacerbate the symptoms of myotonic dystrophy. Uterine atony, postpartum hemorrhage, and retained placenta have been reported.²⁰³ Magnesium sulfate can result in respiratory compromise in pregnant women with even mild DM1.²⁰⁴

Although the gene for DM1 is localized on chromosome 19, the risk for MH is no greater than in the general population.²⁰⁵ **Box 36.9** outlines important anesthesia considerations for the patient with **Box 36.9** myotonic dystrophy type 1.

Anesthesia Considerations for the Patient with Myotonic Dystrophy Type 1

- Consider pharyngeal muscle involvement and aspiration risk in plan of care; modified rapid sequence induction for intubation or a supraglottic airway equipped with a gastric tube
- Avoid succinylcholine as potential trigger of myotonia
- Titrate shorter-acting non-depolarizing muscle relaxant agents judiciously based on preexisting muscle weakness
- Use anticholinesterase agents cautiously to reverse muscle blockade; sugammadex has been used uneventfully in patients with DM1
- Be aware that peripheral nerve stimulation could induce myotonia that is misinterpreted as sustained tetanus even when significant neuromuscular blockade still exists
- Question patients preoperatively about syncope, dizziness and palpitations; monitor the EKG closely for conduction blocks; advanced conduction blocks may require access to pacemaker equipment
- Maintain normothermia to prevent shivering, which can precipitate myotonia
- Administer barbiturates, opioids, benzodiazepines, and propofol judiciously, considering the exaggerated effects in patients with preexisting respiratory muscle weakness, central and obstructive sleep apneas and hypersomnolence
- Consider regional anesthesia and peripheral nerve blocks using ultrasound guidance
- Anticipate slow awakening and continue close observation in the recovery area with pulse oximetry and nasal capnography

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, inflammatory polyarthropathy with extraarticular involvement. The disease is

multifactorial and the clinical picture varies widely in severity, extent of involvement, and symptoms. The capricious course of the disease may be persistent and debilitating or relapsing and remitting.²⁰⁶ With each successive exacerbation, new joints may become involved.

Incidence

Rheumatoid arthritis is the most common form of inflammatory arthritis, affecting 20 to 50 individuals per 100,000.²⁰⁶ The onset of RA can occur at any age, but most cases are diagnosed in patients between the ages of 25 and 55 years. RA is two to three times more likely to develop in women than in men.²⁰⁷ The life expectancy of patients with RA may be reduced by 3 to 7 years.^{206,208} Because patients with RA are living longer, one-third of patients with RA are older than 60 years.^{206,208,209}

Etiology

The exact cause of RA remains elusive, but it appears to involve a complex interplay among genetic factors, environmental triggers, and chance. Impaired immunity, stress, infection, smoking, and other environmental factors may precipitate or aggravate the disease.²⁰⁷

A viral or a bacterial infection that alters the immune system in a genetically susceptible host may play a role in the etiology.^{206,207} The invading microbe may produce a protein similar to those in the body's own tissue, particularly joint tissue (molecular mimicry).²⁰⁷ To destroy the antigen, the immune system may mount an autoimmune response and mistakenly direct its attack against its own tissue. Circulating autoantibodies, rheumatoid factors and anticitrullinated protein antibodies (ACPA) are detectable in up to 90% of patients with RA.^{207,208}

Clinical Manifestations

Joint Involvement.

Inflammation and destruction of synovial tissues are responsible for

most of the symptoms and chronic disability associated with RA. Contributors to the inflammatory process are proinflammatory cytokines (tumor necrosis factor [TNF], interleukin (IL)-1), synovial-like fibroblasts, osteoclasts, and macrophages.^{206,207} Joint involvement progresses in three main stages: (1) inflammation of the joint synovial membrane and infiltration by polymorphonuclear leukocytes; (2) rapid division and growth of cells in the joint (synovial proliferation and pannus formation); and (3) liberation of cytokines, osteolytic enzymes, proteases, and collagenases, which damage small blood vessels, cartilage, ligaments, tendons, and bones. Collapse of normal cortical and medullary architecture leads to erosion and dislocation of bone that is contiguous with the inflammatory cell mass.²⁰⁶

The onset of symptoms is most often insidious, evolving over a period of weeks to months. The most common sites of onset are the hands, wrists, and feet. There is often symmetric joint involvement. Swelling, warmth, and pain in the affected joints are caused by the inflammatory process. Weight loss and fatigue are noted early in the disease course.

Dissolution of bone and disuse atrophy of bone (osteoporosis) are found in all seriously affected areas. Inflammation and erosion of bone and tissue may permanently limit the joint's full range of motion. Later stages of the disease are characterized by severe pain, joint instability, loss of physical function, and crippling deformities.²⁰⁶

Nerve entrapment may occur at any site where peripheral nerves pass near the inflamed joint. Carpal tunnel syndrome is a common peripheral neuropathy.

Synovitis in the temporomandibular joint (TMJ) may limit jaw motion. An estimated 45% to 75% of patients with RA have involvement of the TMJ. As the disease progresses, flexion contractures and soft-tissue swelling may lead to a marked limitation in the patient's ability to open the jaw.

Although the thoracic and lumbar spines are usually spared, involvement of the cervical spine is common and includes atlantoaxial subluxation and instability, subaxial instability, and basilar invagination.²¹⁰⁻²¹⁴ The cervical spine is affected in up to 80% of patients with RA and the incidence of cervical spine instability

may exceed 40%.²¹⁴⁻²¹⁶ A common site of cervical involvement is C1-C2 (Fig. 36.14). Atlantoaxial (C1-C2) instability occurs from erosion and collapse of bone and destruction of supporting cervical ligaments. Cervical vertebrae subluxation may exert pressure on the spinal cord (Fig. 36.15) or impair blood flow through the vertebral arteries²¹⁷⁻²¹⁹ (Fig. 36.16). Cervical spine involvement may also lead to limited movement of the neck, odontoid prolapse into the foramen magnum, and severe laryngeal deviation.^{206,211,212,218}

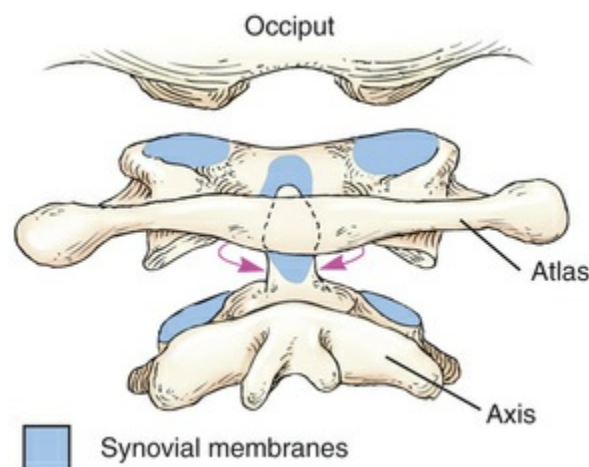

FIGURE 36.14 The relationship between the occiput, the atlas (C1), and the axis (C2). The atlas supports the head and rotates about the odontoid process of the axis. The occipitoatlantoaxial articulations are lined by synovial membranes and are firmly supported by surrounding ligaments (not shown).

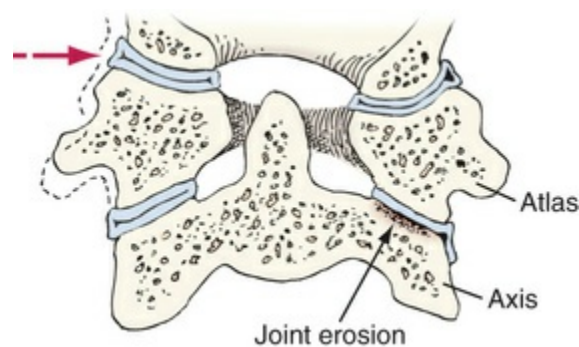

FIGURE 36.15 Erosion and collapse of C1 and C2 articular surfaces can lead to a shifting of the atlas over the axis. If the subluxation is pronounced, spinal cord compression may occur.

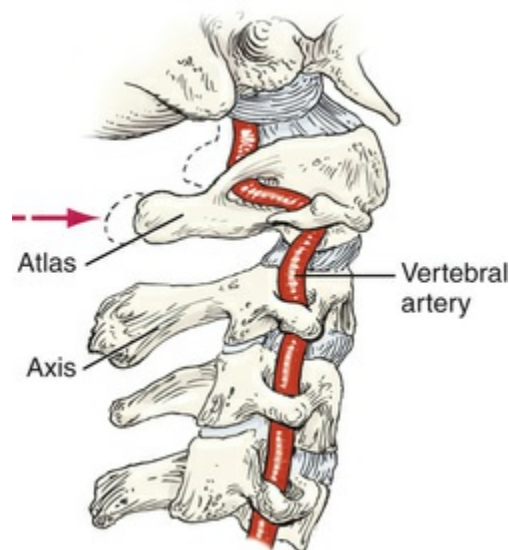

FIGURE 36.16 Vertebral artery compression may result from atlantoaxial subluxation.

Arthritis extends to the cricoarytenoid joint of the larynx in 26% to 86% of patients with severe RA.^{220,221} The joint may become swollen, inflamed, and fixed in a position that obstructs airflow. Vocal cord nodules and polyps also may be present. Symptoms of cricoarytenoid arthritis include tenderness over the larynx, hoarseness, pain on swallowing, with radiation to the ear, and dyspnea or stridor. Patients with no overt clinical symptoms may also have significant laryngeal disease.^{206,208}

Systemic Involvement.

Although the effects of RA are most clearly seen in joints, the disease is systemic. The immune-mediated inflammatory process produces extraarticular features, including cardiovascular and lung disease, anemia, myositis, and Sjögren syndrome.²⁰⁷ The occurrence of extraarticular manifestations is usually associated with more active, erosive articular disease.

Firm, painless subcutaneous nodules occur in approximately 30% to 40% of patients with RA.²⁰⁶ The nodules usually occur over pressure points, such as the occiput, the sacrum, the ulna, or the Achilles tendon, and may be associated with pressure ulcerations.

Patients with RA have a higher risk of atherosclerosis,

myocardial infarction, and stroke.²¹⁷ Pericarditis and pericardial effusion may accompany severe progressive RA and impair cardiac performance.

Pulmonary involvement manifests as pleural effusion, pneumonitis, pulmonary nodules, or interstitial fibrosis.^{206,208,222} Decreased lung volume, diffusion capacity, and vital capacity may result from the lung alterations. Ventilation-perfusion mismatch results in decreased arterial oxygenation.

Rheumatoid myositis, which is characterized by muscle weakness and eventual muscle necrosis and atrophy, may accompany RA. Inflamed, painful, and underused joints contribute to the skeletal muscle atrophy.

Lacrimal duct and salivary gland destruction may result in dryness of the eyes and the mouth (Sjögren syndrome) in approximately 14% of patients with rheumatoid arthritis.²²³

Treatment

Medical therapy for RA is directed toward relief of pain, nonspecific suppression of the inflammatory process, immunosuppression, prevention and correction of deformity, and control of systemic involvement.

The introduction of disease-modifying antirheumatic drugs (DMARDs) has dramatically improved long-term outcomes and quality of life for patients with RA. DMARDs used to manage RA include methotrexate, leflunomide, azathioprine, hydroxychloroquine, and biologic response modifiers (biologics) that inhibit TNF and IL-1. Biologics can arrest the underlying disease process and slow the progression of the disease.^{208,209}

The antimetabolite methotrexate is generally the initial DMARD of choice for patients with mild, moderate or severe RA.²²⁴ Oral ulcerations, bone marrow suppression, pneumonitis, and hepatic damage are potential side effects of methotrexate.²⁰⁸ Because of the efficacy of methotrexate, nonsteroidal antiinflammatory drugs (NSAIDs) are now used mainly as bridge drugs for relief of symptoms.

Biologic DMARDs are generally reserved for patients with moderate to severe RA.²²⁴ They limit joint destruction by blocking cytokines and cell-surface molecules involved in the inflammatory

response. Drugs such as etanercept (Enbrel), adalimumab (Humira), and infliximab (Remicade) work by interfering with the proinflammatory cytokine, TNF, and produce significant improvement in functional ability.^{208,224–226}

Other biologic agents are used to treat patients who do not respond to methotrexate or TNF inhibitor treatment alone. Rituximab (Rituxan) is a monoclonal antibody against CD20, a B-cell surface antigen. Abatacept (Orencia) alters T-cell activation. Tocilizumab (Actemra) is a monoclonal antibody that inhibits the binding of the proinflammatory cytokine IL-6 to its receptor.

Leflunomide (Arava, and generics) is a DMARD that inhibits the proliferation of T lymphocytes and slows disease progression. The major side effect of leflunomide is hepatotoxicity.^{206,224} The immunosuppressive drug azathioprine (Imuran, and others) is generally reserved for more refractory cases.

Glucocorticoids are potent antiinflammatory drugs that effectively suppress many aspects of the RA disease process. Because of their significant side effects (impaired wound healing, infection, hyperglycemia, osteoporosis), the risk-benefit ratio calls for limiting their use to isolated flares of the disease, low to medium dosage regimens, and adjunctive rather than primary treatment.^{224,227}

Surgical interventions for relief of pain or correction or prevention of deformities include total joint replacement, synovectomy, and tenolysis.

Anesthetic Management

Complications associated with RA, as well as medications used in therapy, can impact multiple organ systems beyond the joints.²¹⁵ Preoperative examination of an individual patient's disease course, comorbidities, and medication history are likely to reveal specific features that affect the choice of anesthetic agent or mode of anesthesia.

A thorough preoperative assessment of the airway is essential. Particular attention should be directed to the TMJs, cervical spine, and cricoarytenoid joints.

Range of motion of the TMJ must be assessed before anesthesia is induced. Patients with severe TMJ involvement may be unable to

open their mouths more than 1 to 2 cm. In such cases, the use of a flexible fiberoptic bronchoscope or other optically guided instruments for tracheal intubation are of proven value.

Neck pain and paresthesias are early symptoms of cervical spine instability, but history and exam alone cannot be relied upon to identify cervical spine disease.^{215,228} Cervical myelopathy can mimic other rheumatoid complications (neuropathy, arthralgia) and make the extent of cervical involvement underappreciated.^{212,229}

Compression on the vertebral arteries, with interruption of vertebral artery blood flow, may cause nausea, dysphagia, blurred vision, loss of consciousness, or stroke. However, the absence of preoperative symptoms does not guarantee cervical spine stability or safety, as some patients with significant radiographic evidence of atlantoaxial or subaxial instability are entirely asymptomatic.^{206,215,219,228,230} Preoperative imaging studies (radiography, computed tomography [CT], magnetic resonance imaging [MRI]) may be indicated if the degree of cervical involvement is unknown.^{228,230}

Cervical spine instability, cricoarytenoid and TMJ involvement, and laryngeal deviation can make intubation of the trachea an extreme challenge. Deviation of the larynx caused by cervical spine involvement can be detected preoperatively by palpating the location of the larynx in relation to the sternal notch. Flexion, extension, and rotation of the neck must be avoided in the presence of cervical instability. Regional anesthesia is often a safe choice for the patient with RA in order to avoid manipulation of the neck. If GA is required, airway management should minimize neck manipulation and may include use of videolaryngoscopy or fiberoptic-guided intubation of the trachea.²¹²

Hoarseness in a patient with RA should alert the anesthetist to possible cricoarytenoid joint involvement. Narrowing of the glottic opening may call for a smaller endotracheal tube. The vocal cords may be edematous and erythematous. Involvement of the laryngeal cartilages and cervical spine can predispose to difficult airway management. When intubation is required for GA, videolaryngoscopy is a valuable tool for visualizing the airway while maintaining neutral head position.^{231,232} The patient should be observed closely for signs of acute airway obstruction after

extubation.

The anesthetist should be aware that the spread of sensory spinal anesthesia may be higher in the patient with spinal block. Epidural nodules and synovitis in the thoracolumbar spine may cause narrowing of the subarachnoid space and decrease the cerebrospinal fluid volume. The reduced dilution of the local anesthetic may contribute to the sensory effect, averaging 1.5 dermatomes higher in an RA patient.²³³

Generalized demineralization of bone increases the risk of fractures in patients with RA. Glucocorticoid therapy aggravates the osteopenia. Careful patient positioning and padding of pressure points, as well as maintaining the natural position of the deformed joints, can help prevent nerve palsies, skin ulcerations, and further structural damage to the joints.²³²

TNF inhibitors and other immunosuppressive agents are important components of treating RA, but because of their mechanisms of action, they substantially increase the risk for serious infections.^{225,226,234,235} Clinical guidelines vary, but holding biologic therapy is generally advised at least 1 week before and after surgery, with adjustments made depending on the pharmacokinetics of the individual agent.^{210,215,217,234–238} Continuation of methotrexate preoperatively does not increase infection risk, therefore most recommendations support the safety of methotrexate in the perioperative period.^{210,215,217}

Patients receiving long-term glucocorticoid therapy may be at risk for hypophyseal-pituitary axis suppression and require perioperative stress dose steroid supplementation. However, glucocorticoid use is also a risk factor for infection and impaired wound healing in patients with RA.²¹⁵ Perioperatively, glucocorticoid supplementation may be tailored to prevent acute adrenal insufficiency, yet tapered in 1 to 2 days to minimize the risk of impaired wound healing and infection.^{215,217,238} **Box 36.10**

summarizes anesthesia implications for the patient with
Box 36.10 Rheumatoid arthritis.

Anesthesia Considerations for the Patient with Rheumatoid Arthritis

- Perform a thorough preoperative assessment of the airway, especially assessing temporomandibular joints, cervical spine, and cricoarytenoid joints; preoperative imaging studies (radiography, CT, MRI) may be indicated if the degree of cervical involvement is unknown.
- Consider local or regional anesthesia to avoid manipulation of the neck; the spread of sensory spinal anesthesia may be higher in the patient receiving subarachnoid block, due to epidural nodules and synovitis in the thoracolumbar spine.
- If general anesthesia is required, airway management should minimize neck manipulation and may include use of videolaryngoscopy or fiberoptic-guided intubation of the trachea.
- Avoid flexion, extension, and rotation of the neck in the presence of cervical instability.
- Carefully position the patient considering skin and bone fragility imposed by deformed joints, limited mobility, and possible glucocorticoid use.
- Avoid antisialagogues for patients with a history of dry mouth or dry eyes (Sjögren syndrome).
- TNF inhibitors and other therapy for RA suppress the immune response and increase the risk for serious infections; holding biologic therapy is generally advised at least 1 week before and after surgery.

Summary

Understanding the pathophysiologic characteristics, clinical presentation, and supporting studies of patients with musculoskeletal abnormalities is essential for safe and effective anesthetic management. A thorough preoperative assessment of this patient helps determine the extent of muscle, respiratory, and cardiac reserve and aids in anesthetic selection and planning for postoperative care.

Management of cases involving musculoskeletal pathology must take into account preoperative drug therapy for the disease and the potential effect drug therapy may have on anesthetic agents and muscle relaxants. An anesthetic agent's margin of safety is often reduced in such patients; therefore fixed dosage regimens should be avoided.

The Endocrine System and Anesthesia

Mary C. Karlet

General Principles of Endocrine Physiology

Body homeostasis is controlled by two major regulating systems: the nervous system and the endocrine or hormonal system.^{1,2} Both these systems communicate, integrate, and organize the body's response to a changing internal or external environment.^{1,3}

Organs that secrete hormones are called *endocrine glands*; collectively, these glands make up the endocrine system. The purpose of the endocrine system is regulation of behavior, growth, metabolism, fluid and electrolyte status, development, and reproduction. To accomplish these complex processes, multiple hormones interact to produce precise biochemical and physiologic responses.

Endocrine glands secrete their hormone products directly into the surrounding extracellular fluid. This distinguishes them from exocrine glands, such as salivary or sweat glands, whose products are discharged through ducts. Important endocrine glands include the pituitary gland, thyroid gland, parathyroid glands, adrenal glands, pancreas, ovaries and testes, and placenta.

Hormones

Endocrine function is mediated by hormones. Hormones are the signaling molecules or chemical messengers that transport information from one set of cells (endocrine cells) to another (target cells). Hormones are released from endocrine glands into body fluids in minute quantities, but they exert powerful control over most metabolic functions.^{1,2,4}

Transmission of a hormonal signal through the bloodstream to a distant target cell (e.g., pituitary gland to the adrenal gland) is called an *endocrine function*. If a hormone signal acts on a neighboring cell of a different type (e.g., pancreas α cells to pancreas β cells), the interaction is termed a *paracrine function*. If the secreted hormone acts on the producer cell itself, the interaction is called an *autocrine function*.⁴

Types of Hormones

Hormones can be classified into three major categories: (1) proteins or peptides, (2) tyrosine amino acid derivatives, and (3) steroids.

Table 37.1 outlines common endocrine glands, hormones, their functions, and their structures.

TABLE 37.1

Common Endocrine Glands, Hormones, Their Functions, and Structures

Gland/Tissue	Hormones	Major Functions	Chemical Structure
Hypothalamus	Thyrotropin-releasing hormone	Stimulates secretion of thyroid-stimulating hormone and prolactin	Peptide
	Corticotropin-releasing hormone	Causes release of adrenocorticotrophic hormone	Peptide
	Growth hormone-releasing hormone	Causes release of growth hormone	Peptide
	Growth hormone inhibitory hormone (somatostatin)	Inhibits release of growth hormone	Peptide
	Gonadotropin-releasing hormone	Causes release of luteinizing hormone and follicle-stimulating hormone	
	Dopamine or prolactin-inhibiting factor	Inhibits release of prolactin	Amine
Anterior pituitary	Growth hormone	Stimulates protein synthesis and overall growth of most cells and tissues	Peptide
	Thyroid-stimulating hormone	Stimulates synthesis and secretion of thyroid hormones (thyroxine and triiodothyronine)	Peptide
	Adrenocorticotrophic hormone	Stimulates synthesis and secretion of adrenocortical hormones (cortisol, androgens, and aldosterone)	Peptide
	Prolactin	Promotes development of the female breasts and secretion of milk	Peptide
	Follicle-stimulating hormone	Causes growth of follicles in the ovaries and sperm maturation in Sertoli cells of testes	Peptide
	Luteinizing hormone	Stimulates testosterone synthesis in Leydig cells of testes; stimulates ovulation, formation of corpus luteum, and estrogen and progesterone synthesis in ovaries	Peptide
Posterior pituitary	Antidiuretic hormone (also called vasopressin)	Increases water reabsorption by the kidneys and causes vasoconstriction and increased blood pressure	Peptide
	Oxytocin	Stimulates milk ejection from breasts and uterine contractions	Peptide
Thyroid	Thyroxine (T ₄) and triiodothyronine (T ₃)	Increases the rates of chemical reactions in most cells, thus increasing body metabolic rate	Amine
	Calcitonin	Promotes deposition of calcium in the bones and decreases extracellular fluid calcium ion concentration	Peptide
Adrenal cortex	Cortisol	Has multiple metabolic functions for controlling metabolism of proteins, carbohydrates, and fats;	Steroid

		also has anti-inflammatory effects	
	Aldosterone	Increases renal sodium reabsorption, potassium secretion, and hydrogen ion secretion	Steroid
Adrenal medulla	Norepinephrine, epinephrine	Same effects as sympathetic stimulation	Amine
Pancreas	Insulin (β cells)	Promotes glucose entry in many cells, and in this way controls carbohydrate metabolism	Peptide
	Glucagon (α cells)	Increases synthesis and release of glucose from the liver into the body fluids	Peptide
Parathyroid	Parathyroid hormone	Controls serum calcium ion concentration by increasing calcium absorption by the gut and kidneys and releasing calcium from bones	Peptide
Testes	Testosterone	Promotes development of male reproductive system and male secondary sexual characteristics	Steroid
Ovaries	Estrogens	Promotes growth and development of female reproductive system, female breasts, and female secondary sexual characteristics	Steroid
	Progesterone	Stimulates secretion of "uterine milk" by the uterine endometrial glands and promotes development of secretory apparatus of breasts	Steroid
Placenta	Human chorionic gonadotropin	Promotes growth of corpus luteum and secretion of estrogens and progesterone by corpus luteum	Peptide
	Human somatomammotropin	Probably helps promote development of some fetal tissues, as well as the mother's breasts	Peptide
	Estrogens	See actions of estrogens from ovaries	Steroid
	Progesterone	See actions of progesterone from ovaries	Steroid
Kidney	Renin	Catalyzes conversion of angiotensinogen to angiotensin I (acts as an enzyme)	Peptide
	1,25-Dihydroxycholecalciferol	Increases intestinal absorption of calcium and bone mineralization	Steroid
	Erythropoietin	Increases erythrocyte production	Peptide
Heart	Atrial natriuretic peptide	Increases sodium excretion by kidneys, reduces blood pressure	Peptide
Stomach	Gastrin	Stimulates hydrogen chloride secretion by parietal cells	Peptide
Small intestine	Secretin	Stimulates pancreatic acinar cells to release bicarbonate and water	Peptide
	Cholecystikinin	Stimulates gallbladder contraction and release of pancreatic enzymes	Peptide
Adipocytes	Leptin	Inhibits appetite, stimulates thermogenesis	Peptide

From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:927.

Peptide or Protein Hormones.

Most hormones in the body have a peptide or protein structure. This group of hormones includes insulin, growth hormone (GH), vasopressin (antidiuretic hormone [ADH]), angiotensin, prolactin, erythropoietin, calcitonin, somatostatin, adrenocorticotrophic hormone (ACTH), oxytocin, glucagon, and parathyroid hormone. Peptide hormones are synthesized in endocrine cells as prehormones and prohormones. They are processed by the cell and stored in secretory granules within the endocrine gland.^{1,2,4} The

proper stimulus to secretion causes exocytosis of the peptide or protein hormone into the extracellular fluid.

Protein hormones, such as insulin, erythropoietin, and GH, can now be synthesized for therapeutic purposes by recombinant deoxyribonucleic acid (DNA) techniques.

Tyrosine Amino Acid Derivative Hormones.

Thyroid hormones (thyroxine and triiodothyronine) and catecholamine hormones (dopamine, epinephrine, and norepinephrine) are derived from the amino acid tyrosine. Thyroid hormones are stored in the thyroid gland and catecholamine hormones stored in the adrenal medulla; they are released by the appropriate stimulation.⁴

Steroid Hormones.

All steroid hormones are lipid soluble and derived from cholesterol or have a chemical structure similar to that of cholesterol.⁴ Common steroid hormones include hormones of the adrenal cortex (cortisol, aldosterone) and reproductive hormones (estrogen, progesterone, testosterone). Active metabolites of vitamin D are also steroid hormones.¹ In contrast to most other hormones, steroid hormones are not stored in discrete secretory granules but are compartmentalized within the endocrine cell and released into the extracellular fluid by simple diffusion through the cell membrane into the blood.¹

Transport of Hormones

Once released into the circulation, steroid and thyroid hormones are bound to transport proteins. Circulating catecholamine hormones and most protein hormones are not bound to carriers. Plasma protein binding protects hormones from metabolism and renal clearance.² The circulating half-life of steroid and thyroid hormones is therefore typically much longer than that of peptide and catecholamine hormones. For example, the thyroid hormone thyroxine, which is over 99% protein bound, has a plasma half-life of 6 to 7 days, whereas insulin, which has essentially no plasma protein binding, has a half-life of approximately 7 minutes.¹

The major sites of hormone degradation and elimination are the liver and the kidneys, respectively. Some hormone degradation also occurs at target-cell sites.^{1,2,4}

Hormone Receptors

Binding to a specific target-cell receptor is the primary event that initiates a hormone response.² The hormone receptor displays high specificity and affinity for the proper hormone ligand, and the location of the receptor directs the hormone to the specific target organ or target-cell site.³ Some hormones, such as insulin and GH, act on widespread target sites; others, such as thyroid-stimulating hormone (TSH), act on one target tissue. After binding, the hormone-receptor complex induces a cascade of intracellular events that produce specific physiologic responses in the target cell.²

Hormone Receptor Activation.

Hormone receptors are located (1) on the surface of the target cell membrane, (2) in the target cell cytoplasm, or (3) in the target cell nucleus.⁴ Receptors for protein, peptide, and catecholamine hormones are located in or on the surface of the target-cell membrane. Hormone binding to a cell membrane receptor triggers a response by activating enzyme systems in or near the plasma membrane bilayer. The activated enzymes generate intracellular signals, called *second messengers*, which carry the hormone's message within the intracellular space.

Several different second-messenger systems operate in response to cell membrane receptor-hormone binding. Probably the most widely described second-messenger system is the cyclic adenosine monophosphate (cAMP) system. This transduction mechanism is initiated when hormone-receptor occupation activates the plasma membrane enzyme adenylyl cyclase. The membrane-bound adenylyl cyclase then catalyzes the intracellular conversion of adenosine triphosphate to cAMP; cAMP in turn becomes the hormone's intracellular messenger, activating intracellular enzymes, modifying cell-membrane permeability or transport, and altering cellular gene expression¹ (Fig. 37.1). The enzyme phosphodiesterase catalyzes the hydrolysis of cAMP and terminates its intracellular

actions. Hormones that use cAMP as their second messenger include TSH, vasopressin (V2 receptor), parathyroid hormone, glucagon, catecholamines (β -receptors), follicle-stimulating hormone (FSH), and luteinizing hormone (LH).

FIGURE 37.1 Mechanism of action of a G-protein receptor. *cAMP*, Cyclic adenosine monophosphate; *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate.
 (From O'Neill R, Murphy R. *Crash Course: Endocrinology: Updated*. 4th ed. Philadelphia: Elsevier; 2015:7.)

Other intracellular second messengers include calcium, diacylglycerol, inositol triphosphate, and cyclic guanosine monophosphate. The primary intracellular messenger has not been identified for many hormones.

In contrast to peptide and catecholamine hormones, thyroid and steroid hormones produce the desired target-cell response chiefly by interacting with specific intracellular hormone receptors.¹ Thyroid and steroid hormones are small, lipophilic molecules that

enter target cells by simple diffusion or by special transport mechanisms. Once within the cell, these hormones occupy specific intracellular receptors.² In combination with their receptors, the hormones interact with DNA in the cell nucleus to enhance or suppress gene transcription or translation.² Thyroid and steroid hormones cause target cells to synthesize proteins that function as enzymes and transport either proteins or structural proteins.

Every hormone has a specific onset and duration of action. Hormones that act by binding to cell membrane receptors (peptide, protein, and catecholamine hormones) usually generate a hormonal effect in seconds to minutes. Hormones that bind to intracellular receptors and activate the transcription processes of specific genes (thyroid and steroid hormones) may require several hours or even days to generate a hormonal response.^{1,4}

Hormone Receptor Regulation.

Each target cell that is stimulated by a hormone has 2000 to 100,000 receptors specific to that hormone. These receptors are dynamic molecules that are constantly being destroyed and replaced, changing from day to day.⁴ The receptor for insulin, for example, has a normal half-life of only approximately 7 hours.² Regulation of receptor turnover, and thus hormone receptor number, is a mechanism by which hormone activity can be precisely modulated. Hormone receptor destruction may be part of a normal endocrine response or part of an acquired or genetic disease state.

In many instances, the hormone receptor number is inversely related to the concentration of the circulating hormone. A sustained elevation of the plasma level of a given hormone may cause the target site to decrease the number of receptors per cell. This down-regulation of receptor number serves to decrease the responsiveness of a target cell to hormone excess.¹ The insulin resistance observed in obesity and type 2 diabetes mellitus (DM) may be partly explained by down-regulation of the insulin receptors in response to chronically high levels of circulating insulin.²

Conversely, a low circulating hormone concentration may cause the target gland to increase the number of hormone receptors per cell. This up-regulation of hormone receptor number amplifies the

cell's sensitivity to hormone stimulation.^{1,2}

Regulation of Hormone Secretion.

The synthesis and secretion of hormones by endocrine glands are regulated by three general control mechanisms: neural controls, biorhythms, and feedback mechanisms.

Neural controls can evoke or suppress hormone secretion. Pain, emotion, smell, touch, injury, stress, sight, and taste can alter hormone release through neural mechanisms.⁵ Glucagon, cortisol, ADH, and catecholamines, for example, are all stimulated by the stress response to surgery and trauma. Deep general anesthesia or regional anesthesia blunts this stress response, but does not eliminate it.

The secretion of other hormones is governed by genetically encoded or acquired biorhythms. These intrinsic hormonal oscillations may be circadian (e.g., the daily variability in glucocorticoid secretion), weekly (e.g., the menstrual cycle), or seasonal (e.g., thyroxine production).^{3,5} The biorhythms also may vary at different stages of development and life (e.g., GH secretion).⁶

Feedback control is another sophisticated mechanism through which a hormonal response is controlled. Many endocrine disorders arise from the breakdown of feedback loops.^{1,2} Negative feedback acts to limit or terminate the production and secretion of a given hormone once the appropriate response has occurred. Negative feedback of a target-cell product to the hormone producer (the endocrine gland) limits or prevents hormone excess. When concentrations of the product are low, feedback inhibition to the endocrine gland is lessened and hormone secretion enhanced.

Virtually all hormones are controlled by some type of negative feedback mechanism.^{3,6} For example, parathyroid hormone is controlled by calcium, insulin and glucagon are controlled by glucose, and vasopressin is controlled by serum osmolarity.⁵ The negative feedback mechanism is a very important system for the regulation of hormones of the hypothalamus and pituitary gland. Hypothalamic hormones stimulate the release of pituitary hormones from the pituitary gland. The pituitary hormones in turn may stimulate an output of product from peripheral target cells.

Product from peripheral target tissues may then initiate feedback to the pituitary gland or the hypothalamus to inhibit pituitary or hypothalamic hormone synthesis and discharge.² Fig. 37.2 shows negative feedback control of the hypothalamic-pituitary axis.

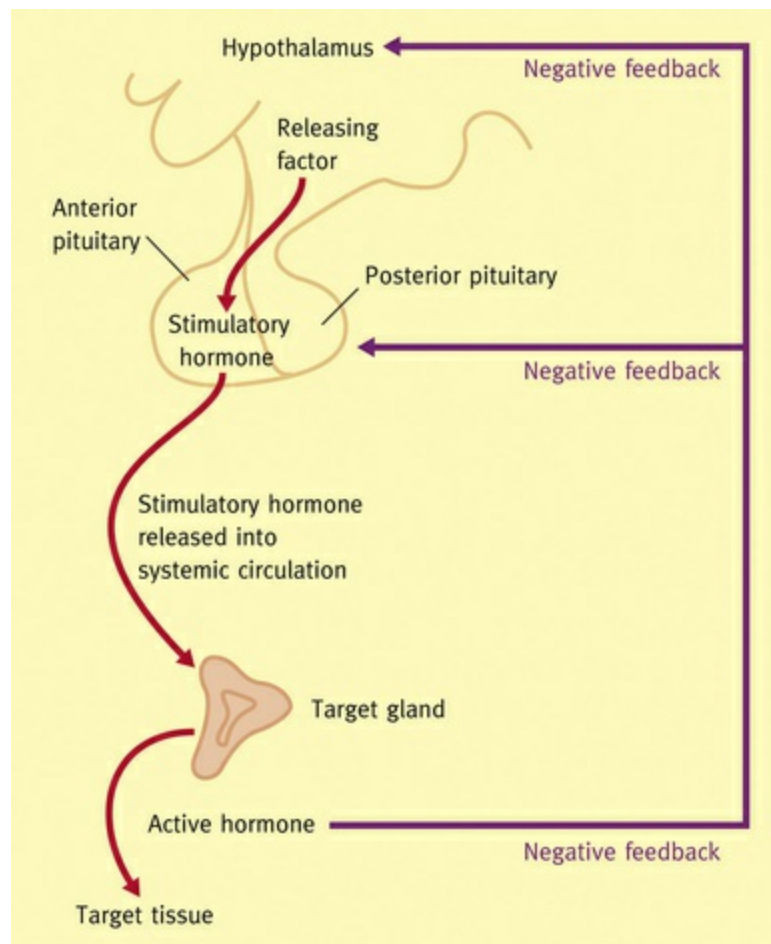

FIGURE 37.2 Negative feedback control of hypothalamic-pituitary axis. (From Nicholson G, Hall GM. Hypothalamic-pituitary-adrenal function: anaesthetic implications. *Anaesth Int Care Med.* 2014;15(10):473–476.)

Positive feedback is a less common hormone-regulating mechanism in which a given hormone response initiates signals amplifying hormone release. The surge in LH that precedes ovulation is stimulated by LH; this is an example of positive feedback.²

Pituitary Gland

Relationship Between Pituitary Gland and Hypothalamus

The pituitary gland, or hypophysis, is known as the *master endocrine gland*.⁷ It secretes hormones that have far-reaching effects on various homeostatic, developmental, metabolic, and reproductive functions of the body. The pituitary is a small endocrine gland (only 500–1000 mg in weight and approximately the size of a pea) centrally located at the base of the brain. It is enclosed within a bony cavity of the sphenoid bone called the *sella turcica*.^{5,6} The pituitary gland is connected to the overlying hypothalamus by the hypophysial stalk (pituitary stalk). The hypothalamus is located below the thalamus, behind the optic chiasm and between the optic tracts. The pituitary, hypothalamus, and some of the surrounding structures are shown in [Fig. 37.3](#).

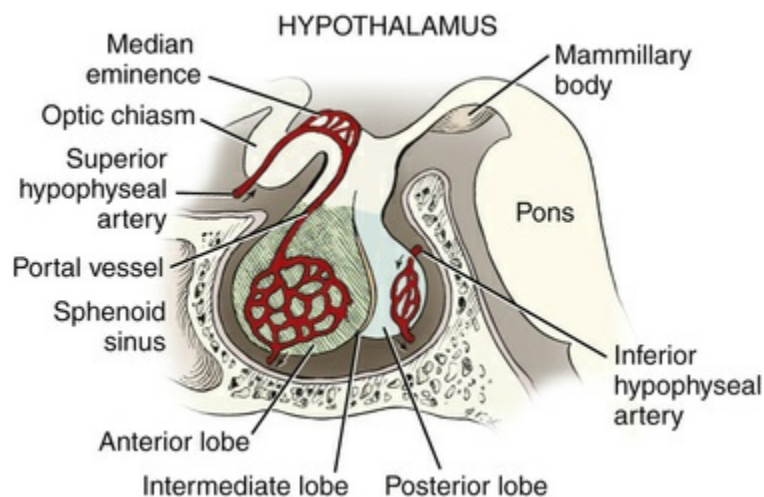

FIGURE 37.3 The pituitary gland is located at the base of the brain. It is connected to the overlying hypothalamus by the pituitary or hypophysial stalk.

The brain, via the hypothalamus, is an important regulator of pituitary gland secretion. The hypothalamus collects and integrates information (e.g., pain, emotions, energy needs, water balance, olfactory sensations, electrolyte concentrations) from almost all

parts of the body and uses this information to control the secretion of vital pituitary hormones.^{5,6} Pituitary hormone secretion also is regulated by feedback control from peripheral target-organ hormones or other target-organ products. The pituitary gland and hypothalamus have virtually no blood-brain barrier, allowing feedback products to exert potent effects.^{8,9}

Functionally and histologically, the pituitary gland is divided into two distinct portions: the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis).^{5,6} The anterior pituitary lobe is embryologically derived from an upward invagination of pharyngeal epithelial cells (Rathke pouch). The posterior pituitary lobe develops from a downward outpouching of ectoderm from the brain.

Anterior Pituitary Lobe

The anterior pituitary lobe, which constitutes approximately 80% of the pituitary gland by weight, secretes six major peptide hormones.⁶ Target sites for the anterior pituitary hormones are shown in [Fig. 37.4](#). In addition to secreting the six “classic” hormones, the pituitary also secretes other hormones, including melanocyte stimulating hormone, beta-endorphins, substance P, and others.

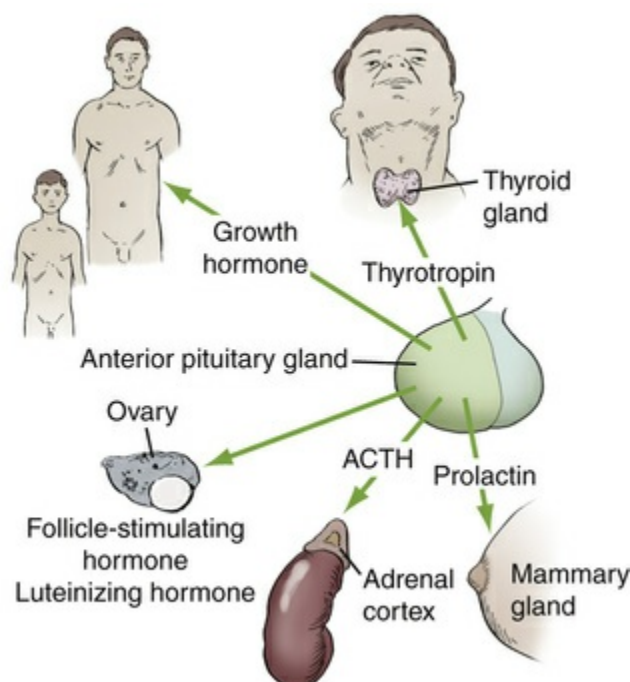

FIGURE 37.4 Major target sites for anterior pituitary hormones. *ACH*, Adrenocorticotrophic hormone.

1. Growth hormone (GH, somatotropin) promotes skeletal development and body growth, stimulates insulin-like growth factor-1 (IGF-1), and inhibits action of insulin on carbohydrate and fat metabolism.
2. Corticotropin or adrenocorticotrophic hormone (ACTH) regulates the growth of the adrenal cortex and the release of cortisol and androgenic hormones from the adrenal gland. ACTH possesses mild melanocyte-stimulating properties, resulting in skin pigmentation at high levels.
3. Thyroid-stimulating hormone (thyrotropin or TSH) controls the growth and metabolism of the thyroid gland and the secretion of thyroid hormones (thyroxine and triiodothyronine), which regulate intracellular metabolic activity in virtually all cells of the body.⁶
4. Follicle-stimulating hormone (FSH) stimulates ovarian follicle development in females and spermatogenesis in males.
5. Luteinizing hormone (LH) induces ovulation and corpus luteum development in females and stimulates the testes to produce testosterone in males.
6. Prolactin promotes mammary gland development and milk production (lactogenesis) by the breasts. Prolactin also exerts an effect on reproductive function by inhibiting the synthesis and secretion of LH and FSH. Prolactin synthesis is markedly increased during pregnancy.

Anterior pituitary hormones are synthesized and secreted by five distinct endocrine cell types within the gland: somatotrophs synthesize GH; gonadotrophs synthesize the two gonadotropic hormones, LH and FSH; thyrotrophs synthesize TSH; corticotrophs synthesize ACTH; and lactotrophs (mammotrophs) synthesize prolactin. Approximately 30% to 40% of the anterior pituitary cells are somatotrophs and approximately 20% are corticotrophs.⁶

Control of Anterior Pituitary Hormone Secretion

Synthesis of anterior pituitary hormones is controlled by signals from the hypothalamus. Neurosecretory cells in various hypothalamic nuclei respond to input from the body by synthesizing specific neurohormones that have corresponding anterior pituitary target-cell types.⁶

Hypothalamic neurohormones are released into a capillary bed of the hypothalamus in an area called the *median eminence*. The hypothalamic hormones travel from the capillary plexus of the median eminence, down the pituitary stalk, in a specialized vascular system called the *hypothalamic-hypophysial portal vessels* (Fig. 37.5). At the anterior pituitary lobe, the hypothalamic hormones are released in high concentrations into capillary sinuses located among the glandular cells.⁶ The hypothalamic hormones then locate and bind to their specific target-cell type.

FIGURE 37.5 Neuroendocrine organization of the hypothalamus and pituitary gland. The posterior pituitary is fed by the inferior hypophyseal artery and the hypothalamus by the superior hypophyseal artery, both branches of the internal carotid artery. Most of the blood supply to the anterior pituitary is venous by way of the long portal vessels, which connect the portal capillary beds in the median eminence to the venous sinusoids in the anterior pituitary. Hypophysiotropic neuron 3 in the parvocellular division of the paraventricular nucleus and

neuron 2 in the arcuate nucleus are shown to terminate in the median eminence on portal capillaries. These neurons of the tuberoinfundibular system secrete hypothalamic releasing and inhibiting hormones into the portal veins for conveyance to the anterior pituitary gland. Neuron 2 is innervated by monoaminergic neurons. Note that the multiple inputs to such neurons, using neuron 2 as an example, can be stimulatory, inhibitory, or neuromodulatory, in which another neuron may affect neurotransmitter release. Neuron 1 represents a peptidergic neuron originating in the magnocellular division of the paraventricular nucleus or supraoptic nucleus and projecting directly to the posterior pituitary by way of the hypothalamic-neurohypophyseal tract. (In Goldman L, Schafer AI. *Goldman-Cecil Medicine*. 25th ed. Philadelphia: Elsevier; 2016:1473. From Gay VL. The hypothalamus: physiology and clinical use of releasing factors. *Fertil Steril*. 1972;23:50–63, with permission of the American Society for Reproductive Medicine.)

Specific hypothalamic hormones have either an inhibitory or a stimulatory effect on their corresponding anterior pituitary target cells. Synthesis and release of most anterior pituitary hormones depend on a positive stimulatory signal from a given hypothalamic hormone. Some anterior pituitary cells are subject to both inhibitory and stimulatory control by more than one hypothalamic neurohormone.⁵

Synthesis of prolactin from anterior pituitary lactotroph cells is unique in that it is tonically restrained by inhibitory hormonal signals (dopamine) from the hypothalamus. In essence, these inhibitory signals serve as a “physiologic brake” for lactotroph growth and prolactin synthesis. The inhibitory effect of dopamine agonists, such as bromocriptine or cabergoline, is exploited therapeutically for suppressing pathologic production of prolactin from pituitary tumors.^{5,7} [Table 37.2](#) outlines the major hypothalamic releasing or inhibiting hormones and their corresponding anterior pituitary target sites.

TABLE 37.2**Hypothalamic Hormones and Corresponding Anterior Pituitary Hormones**

Hypothalamic Releasing/Inhibiting Hormones	Anterior Pituitary Target-Cell Type	Anterior Pituitary Hormone Produced	Hormone Target Site	Primary Peripheral Hormone Involved in Negative Feedback
Thyrotropin-releasing hormone	Thyrotroph	Thyroid-stimulating hormone (TSH, thyrotropin)	Thyroid gland	Triiodothyronine (T ₃)
Corticotropin-releasing hormone	Corticotroph	Adrenocorticotrophic hormone (ACTH, corticotropin)	Zona fasciculata and zona reticularis of adrenal cortex	Cortisol
Gonadotropin-releasing hormone	Gonadotroph	Follicle-stimulating hormone Luteinizing hormone	Gonads (testes, ovaries)	Estrogen, progesterone, testosterone
Prolactin-inhibitory factor (dopamine, PIF)	Lactotroph	Inhibits prolactin		None
Growth hormone-releasing hormone	Somatotroph	Growth hormone	All tissues	Growth hormone, insulin growth factor-1
Growth hormone-inhibitory factor (somatostatin)	Somatotroph	Inhibits growth hormone		Growth hormone, insulin growth factor-1

Anterior Pituitary Disorders

Disorders involving the anterior pituitary system may be due to a defect at the peripheral endocrine gland (primary disorder), the pituitary gland (secondary disorder), or the hypothalamus (tertiary disorder).⁵ Pituitary tumors account for approximately 15% of all intracranial tumors.¹⁰ Most pituitary tumors, both functional, secreting tumors and nonfunctional, nonsecreting tumors, are benign adenomas. Pituitary carcinoma is exceedingly rare.^{7,10}

Hyposecretion.

Anterior pituitary hormone deficiency states may occur when large nonfunctional pituitary tumors (e.g., chromophobe adenoma, craniopharyngioma, Rathke pouch cysts) compress and destroy normal anterior pituitary cells. Postpartum hemorrhagic shock causing pituitary apoplexy (Sheehan syndrome), irradiation, trauma, and infiltrative disorders (e.g., sarcoidosis, amyloidosis) are less common causes of pituitary hyposecretion. Generalized pituitary hypofunction (panhypopituitarism) is more common than reduced output of a single anterior pituitary hormone.^{7,11}

Important effects of panhypopituitarism include a decrease in thyroid function due to reduction in levels of TSH, depression of glucocorticoid production by the adrenal cortex due to the lowering

of ACTH levels, and suppression of sexual development and reproductive function due to deficient gonadotropic hormone secretion.⁶ In addition, large pituitary tumors (macroadenomas greater than 1 cm) may extend into or compress the surrounding brain tissue, producing diplopia, visual loss, facial numbness, facial pain, or seizures.¹²

Surgical intervention may be implemented for decompression or removal of the pituitary tumor or to control bleeding. Surgical patients with hypopituitary disorders will require glucocorticoid coverage in the perioperative period.¹³ Because of the possibility of diabetes insipidus after removal of the tumor, vasopressin should also be available.

Hypersecretion.

Most pituitary tumors are benign hypersecreting pituitary adenomas.¹² The three most common hypersecreting pituitary tumors are those that produce prolactin, ACTH, or GH. Tumors that secrete gonadotropin and thyrotropin hormones are rare. Pituitary tumors may also be inherited as part of multiple endocrine neoplasia (MEN) type 1.^{10,14}

Preparation of the patient awaiting pituitary surgery is guided in part by the results of preoperative endocrine tests. Hypersecreting pituitary tumors may become so large that they compress and destroy normal anterior pituitary cells, producing a deficiency in some anterior pituitary hormones.

Prolactin-secreting tumors commonly produce symptoms of galactorrhea, amenorrhea, and infertility in women, and decreased libido and impotence in men.¹² Dopamine agonists (cabergoline, bromocriptine) are used to control prolactin levels, decrease tumor size, and restore normal gonadal function. Patients who have a suboptimal response to medical therapy benefit from microsurgical removal of the pituitary tumor.¹²

Specific anesthetic management implications for patients with excess ACTH (Cushing disease) and excess GH (acromegaly) are described in this chapter.

Growth Hormone

GH (somatotropin) is synthesized and secreted by somatotroph cells of the anterior pituitary lobe and is under dual control by the hypothalamus.⁶ GH-releasing hormone stimulates GH release, and GH-inhibiting hormone (somatostatin) is a powerful inhibitor of GH release.

Pulsatile fluctuations of the hypothalamic releasing and inhibiting hormones regulate somatotroph activity throughout the day.⁵ In addition, GH secretion is stimulated by stress, trauma, hypoglycemia, exercise, and deep sleep.^{5,6} The GH secretion rate is generally increased in childhood, followed by a further increase in adolescence, a plateau in adulthood, and declining values in old age. The normal physical decline associated with aging may be due, in part, to the age-related decline in GH production.^{5,6}

Unlike the other anterior pituitary hormones, GH does not exert its principal effects through a specific target gland but functions through all or almost all tissues of the body; it promotes the growth and development of most tissues capable of growing.⁶ A major target of GH is the liver, where it stimulates the production of somatomedin C (also called IGF-1). Somatomedin C and other somatomedins mediate many of GH's effects.^{6,10} Skeletal muscle, the heart, skin, and visceral organs undergo hypertrophy and hyperplasia in response to GH and somatomedins.^{6,10,15}

The most obvious effect of GH is on the skeletal frame. It produces linear bone growth by stimulating the epiphyseal cartilage or growth plate at the ends of long bones. Throughout childhood, under the influence of GH, bone forming cells, called *osteoblasts* are stimulated. Bones elongate at the epiphyseal plate, and the skeletal frame enlarges. After puberty, the growth plates unite with the shaft of the bone, bone lengthening stops, and GH has no further capacity to increase bone length.⁶

GH and IGF-1 support growth by increasing amino acid transport into cells and enhancing protein synthesis in the cell. GH also decreases the catabolism of existing proteins by stimulating lipolysis and mobilizing free fatty acids for energy use, a protein-sparing effect. In addition to its growth-promoting activities, GH is said to be a "diabetogenic hormone." It increases blood glucose levels by decreasing the sensitivity of cells to insulin (promoting insulin resistance) and inhibiting glucose uptake into cells.^{6,15}

As is true of other anterior pituitary hormones, GH secretion is subject to negative feedback control. GH, as well as IGF-1, exert negative feedback control on the pituitary and hypothalamus. GH release is also inhibited by hyperglycemia and increased plasma free fatty acids.⁵

Hyposecretion.

Deficient GH production in childhood can result in insufficient bone maturation and short stature, a condition known as *dwarfism*. Mild obesity, decreased lean body mass, and hypoglycemia are common in GH-deficient dwarfs. Puberty is usually delayed. Symptoms of GH deficiency may be the result of hypothalamic dysfunction, pituitary disease, failure to generate normal insulin growth factor hormones, or GH-receptor defects.^{6,7}

The biosynthesis of human GH by recombinant DNA techniques has enhanced the outlook for patients with GH deficiency. Treatment of these patients with GH leads to a positive nitrogen balance, accretion of lean body mass, and an improvement in metabolic homeostasis.⁷

Hypersecretion.

Hypersecretion of GH, usually caused by a GH-secreting pituitary adenoma (99% of cases), can produce a highly distinctive syndrome in adults called *acromegaly*. Acromegaly is produced by the excessive action of GH and IGF-1 after adolescence, leading to anatomical changes and metabolic dysfunction.^{12,15,16} If hypersecretion of GH occurs before puberty, that is, before closure of the growth plates, all body tissues grow and the individual grows very tall (8 to 9 feet), an extremely rare condition known as *gigantism*.

Because growth plates close with adolescence, the excessive production of GH associated with acromegaly does not induce bone lengthening but rather enhances the growth of periosteal bone by the stimulatory effects of GH on bone osteoblasts. Periosteal growth causes new bone to be deposited on the surface of existing bone.⁶ The unrestrained bone growth in patients with acromegaly produces bones that are massive in size and thickness. Bones of the hands and feet (acral) become particularly large, almost twice

normal size.

Soft-tissue changes are also prominent with GH hypersecretion. The patient develops coarsened facial features (acromegalic facies) that include a large, bulbous nose, supraorbital ridge overgrowth, dental malocclusion, and a prominent prognathic mandible.¹⁰ The changes in appearance are insidious, and many patients do not seek treatment until the diagnosis is obvious and the disease course advanced.^{10,17}

Overgrowth of internal organs is less apparent clinically but no less serious. The liver, heart, spleen, and kidneys become enlarged. Pulmonary function tests are consistent with increased lung volumes, but gas exchange is usually not grossly abnormal.¹⁰ Exercise tolerance may be limited due to increased body mass and skeletal muscle weakness.

Cardiomyopathy and hypertension in patients with acromegaly can lead to symptomatic cardiac disease (e.g., diastolic dysfunction, heart failure).^{17,18} Hypertension occurs in more than 40% of patients and evidence of left ventricular hypertrophy is common.^{12,15} Baseline echocardiography is indicated.¹⁵

The insulin-antagonistic effect of GH produces glucose intolerance in most patients and frank diabetes in up to 25% of patients with acromegaly.⁷

Clinical manifestations resulting from the local effects of the expanding tumor may include headaches, papilledema, and visual field defects. Significant increases in intracranial pressure are uncommon. Compression or destruction of normal pituitary tissue by the tumor may eventually lead to panhypopituitarism.⁷

Box 37.1 features of acromegaly are summarized in [Box 37.1](#).

Common Features of Acromegaly

- Skeletal overgrowth (enlarged hands and feet, prominent prognathic mandible)
- Soft-tissue overgrowth (enlarged lips, tongue, and epiglottis; distortion of facial features)
- Visceromegaly

- Hypertension
- Osteoarthritis
- Glucose intolerance
- Peripheral neuropathy
- Skeletal muscle weakness
- Extrasellar tumor extension (headache, visual field defects)

Acromegaly is associated with decreased life expectancy, with cardiac and respiratory complications being the most common cause of death.^{10,15} Hormonal control has a definite impact on survival. Lowering serum GH levels results in reduction of the mortality rate to levels comparable with the general population.^{19,20}

Treatment for acromegaly is aimed at restoring normal GH levels through surgical, pharmacological, and radiotherapeutic approaches.¹⁶ The preferred initial therapy, especially for small, well-circumscribed adenomas, is microsurgical removal of the pituitary tumor, with preservation of the gland.¹² Surgery achieves biochemical cure in approximately 70% to 90% of microadenomas (less than 1 cm). Cure rates for macroadenomas by surgery are lower (approximately 50%).^{7,10,21}

The surgical approach to the pituitary tumor is most often via the endonasal transsphenoidal route, and this route is generally well tolerated by most patients^{10,13,22} (see [Fig. 31.19](#)). A transcranial approach may be used for very large tumors with suprasellar extension.¹³

For transsphenoidal pituitary surgery, the head of the bed is typically elevated 15 degrees to improve venous drainage. Venous air embolism is usually not a concern, unless there is cavernous sinus invasion by the tumor and the patient is positioned in a steep head-up tilt. The approach and exposure of the tumor is not usually associated with significant blood loss.^{10,22} The use of submucosal injection of epinephrine-containing solutions or topical vasoconstrictors to assist in hemostasis may result in blood pressure increases.²³ An anesthetic technique that incorporates muscle

relaxation and allows for smooth extubation and rapid neurologic assessment is desirable.^{10,22} The patient should be prepared preoperatively for awakening with nasal packing. Surgical complications are not common, but may include epistaxis, transient diabetes insipidus, cranial nerve damage, hyponatremia, and cerebral spinal fluid leaks.¹⁷ Surgical ablation is usually successful in rapidly reducing tumor size, inhibiting GH secretion, and alleviating some symptoms.^{7,17,22}

Administration of octreotide or lanreotide (somatostatin receptor ligands), cabergoline (a dopamine agonist), pegvisomant (a GH-receptor antagonist), and gland irradiation are adjunctive treatments for tumor regression or treatment options for patients who are not surgical candidates.^{10,16,21} A further discussion of anesthesia for pituitary surgery can be found in [Chapter 31](#).

Anesthetic Implications of Acromegaly.

Preanesthetic assessment of patients with acromegaly should include a careful examination of the airway. Facial deformities and the large nose may hamper adequate fitting of an anesthesia mask. Endotracheal intubation may be a challenge because of the patient's large and thick tongue (macroglossia), prognathism, enlarged thyroid gland, hypertrophy and distortion of the epiglottis, and general soft-tissue overgrowth in the upper airway.^{12,17,24-27}

Subglottic narrowing and vocal-cord enlargement may dictate the use of a smaller-diameter endotracheal tube. Nasotracheal intubation should be approached cautiously because of possible turbinate enlargement.¹¹ The occurrence of Mallampati III and IV grades is higher in patients with acromegaly, and the incidence of difficult intubations may be four to five times higher than patients without acromegaly.^{24,26} Preoperative dyspnea, stridor, or hoarseness should alert the anesthetist to airway involvement.¹¹

Indirect laryngoscopy and computed tomography (CT) of the neck may be performed for thorough assessment. Airway adjuncts should be readily available during induction of anesthesia. If difficulties in maintaining an adequate airway are anticipated, optically-guided intubation or fiberoptic-guided intubation in an awake patient is of proven value.^{12,13,17} Equipment for tracheostomy should be available if airway changes are advanced.¹² The

endotracheal tube should remain in place until the patient is fully awake and has total return of reflexes.

Arthropathy affects approximately 75% of acromegaly patients.¹⁵ Overgrowth of vertebrae may cause kyphosis and osteoarthritis and may make central neuraxial anesthesia a challenge.

Up to 70% of patients with acromegaly have a history of sleep apnea.^{13,15,17} The predisposition to airway obstruction in these patients makes assiduous perioperative monitoring of the patient's respiratory status an absolute precaution.^{12,15,17}

The frequent occurrence of cardiomyopathy, coronary artery disease, and hypertension in acromegalic patients warrants a thorough preanesthetic cardiac evaluation. Hyperglycemia may complicate the perioperative period, mandating careful perioperative monitoring of blood glucose and electrolyte levels.^{15,17}

Stress-level glucocorticoid therapy is often administered to address any impairment of the adrenal axis.¹² Entrapment neuropathies, such as carpal tunnel syndrome, are common in patients with acromegaly. Hypertrophy of the carpal ligament may cause inadequate ulnar artery flow, which should be considered in the decision to place a radial arterial catheter.^{7,11}

Posterior Pituitary Lobe

The posterior pituitary lobe secretes two important peptide hormones: antidiuretic hormone (vasopressin or ADH) and oxytocin. Oxytocin and ADH are almost identical structurally, but they have quite different actions. ADH controls water excretion and reabsorption in the kidney and is a major regulator of serum osmolarity. Oxytocin stimulates contraction of myoepithelial cells of the breast for milk ejection during lactation. It also powerfully stimulates uterine smooth muscle contraction during delivery of the baby at the end of gestation.⁵ Oxytocin and its derivatives are used clinically for inducing labor and decreasing postpartum bleeding.

In contrast to the anterior pituitary lobe, which communicates with the hypothalamus via a vascular system, the posterior pituitary lobe communicates with the hypothalamus through a neural pathway. Unlike anterior pituitary hormones, posterior pituitary hormones are not synthesized within the pituitary gland itself but rather within two large nuclei of the hypothalamus, the

supraoptic nucleus and the paraventricular nucleus. ADH is chiefly synthesized in the supraoptic nucleus and oxytocin in the paraventricular nucleus.^{5,6,28} As shown in Fig. 37.6, nerve fibers arising from these hypothalamic nuclei transport ADH and oxytocin down the pituitary stalk by axoplasmic flow to the posterior pituitary lobe. There, the hormones are stored in secretory granules at the nerve terminals. With proper excitation, nerve impulses originating in the cell bodies of the supraoptic or paraventricular nucleus are transmitted down the pituitary stalk and stimulate the release of ADH or oxytocin from the posterior pituitary lobe. The hormones then diffuse into nearby blood vessels and are transported to their distant target sites.

FIGURE 37.6 Nerve fibers arising from the supraoptic nucleus and the paraventricular nucleus transport antidiuretic hormone and oxytocin to the posterior pituitary.

Three major types of vasopressin receptors have been identified: V1, V2 (subtype 1a and 1b), and V3. Activation of the V1 receptor mediates vasoconstriction. V2 receptors mediate water reabsorption in the renal collecting ducts. V3 receptors are found within the central nervous system and their stimulation modulates corticotrophin secretion.^{9,29}

Antidiuretic Hormone

ADH is the body's principal preserver of water balance. It acts on V2 receptors on renal collecting ducts to increase the absorption of

solute-free water through water channels called *aquaporins*. The integrated role of thirst, vasopressin, and renal response conserves water in the body and supports normal body-fluid osmolarity. Plasma osmolarity is physiologically controlled within a small range (285 to 290 mOsm/L).⁹ Without ADH, the collecting ducts are impermeable to water reabsorption; in this setting, water loss in the urine is excessive, and serious dehydration and hypernatremia is provoked.⁶

ADH acts primarily to increase urine osmolarity, decrease serum osmolarity, and increase blood volume.⁶ Additionally, high levels of ADH stimulate V1 receptors and cause potent systemic vasoconstriction, especially in splanchnic and renal vascular beds. ADH-induced vasoconstriction of vascular beds has been exploited therapeutically for control of catecholamine-resistant vasodilatory shock, hemorrhage, and sepsis.^{9,30,31} The recommended infusion rate for vasopressin in the treatment of shock in adults is 0.01–0.04 units/min. Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]), a synthetic arginine analog of ADH, increases circulating levels of von Willebrand factor and factor VIII. In addition to treating ADH deficiency, DDAVP is used to reverse coagulopathy associated with platelet adhesion defects, including the coagulopathy of renal failure.⁹

Consonant with its role of maintaining normal fluid homeostasis, ADH is secreted in response to an increase in plasma osmolarity or plasma sodium ion concentration, a decrease in blood volume, or a decrease in blood pressure.⁶

The osmolarity of body fluids is the main variable controlling ADH secretion. Serum osmolarity changes are sensed by hypothalamic osmoreceptors, which in turn alter ADH synthesis and secretion.⁵ The plasma osmotic threshold for ADH release is only 1% to 4% higher than normal plasma osmolarity.^{5,28} Therefore, when the plasma tonicity increases even subtly, healthy individuals release ADH into the blood. The interplay between ADH and water is controlled by a delicate negative feedback loop. Water deprivation (increased plasma osmolarity) initiates signals in the hypothalamic osmoreceptors that cause ADH release from the pituitary gland to increase three- to fivefold. ADH, in turn, enhances renal tubular water reabsorption, dilutes the extracellular

fluid, and restores normal osmotic composition.⁶ Conversely, water ingestion (decreased plasma osmolarity) suppresses the osmoreceptor signal for ADH release. Thirst provides a second line of defense of water balance. The thirst threshold is set approximately 5% higher than the osmotic threshold for ADH.^{6,28}

A 15% to 25% decrease in blood volume or blood pressure also provokes ADH release.²⁸ Changes in blood volume are sensed in peripheral baroreceptors (especially the great veins and pulmonary vessels) and atrial stretch receptors. When these baroreceptors sense underfilling (volume depletion), they transmit afferent signals through vagal and glossopharyngeal nerves to the hypothalamus.^{5,28} The hypothalamus responds by increasing ADH synthesis and stimulating ADH release, sometimes as high as 50-times normal rate.⁶

The perioperative period is characterized by enhanced ADH secretion.^{31,32} Pain, emotional stress, nausea, hemorrhage, and various drugs can be potent stimuli to ADH release. Positive-pressure ventilation enhances ADH release by reducing central blood volume.⁸ The mild hyponatremia sometimes observed postoperatively may be at least partly explained on the basis of ADH action.³³ **Box 37.2** lists factors that stimulate ADH release or **Box 37.2** describe the action of ADH at the renal tubules.¹¹

Stimulators of Antidiuretic Hormone Action or Release

- Increased plasma sodium ion concentration
- Increased serum osmolarity
- Decreased blood volume
- Decreased blood pressure
- Smoking (nicotine)
- Stress
- Pain

- Nausea
- Vasovagal reaction
- Various medications (chlorpropamide, clofibrate, thiazide diuretics, carbamazepine, nicotine, cyclophosphamide, vincristine, morphine, high-dose oxytocin)
- Angiotensin II
- Positive-pressure ventilation

Deficient Antidiuretic Hormone and Anesthetic Implications.

Inadequate ADH secretion from the posterior pituitary lobe or the inability of renal collecting duct receptors to respond to ADH (impaired receptor sensitivity) results in a disorder called *diabetes insipidus (DI)*. Decreased ADH release from the posterior pituitary produces neurogenic or central DI. Renal tubular resistance to vasopressin is termed *nephrogenic DI*.^{28,34}

Common causes of neurogenic DI include head trauma, neurosurgical procedures (e.g., pituitary surgery), meningitis/encephalitis, infiltrating pituitary lesions, and brain neoplasms.^{28,34,35} Neurogenic DI that develops after pituitary surgery is usually transient and often resolves in 5 to 7 days.^{8,13}

Nephrogenic DI may be due to genetic mutations or acquired in association with hypercalcemia, hypokalemia, and medication-induced nephrotoxicity.^{28,36} Ethanol, demeclocycline, temozolomide, phenytoin, chlorpromazine, and lithium all inhibit the action of ADH or its release.⁸

The hallmark of DI is the excretion of abnormally large volumes of dilute urine (polyuria). The inability to produce a concentrated urine results in dehydration and hypernatremia.^{34,35} The syndrome is characterized by low urine osmolarity (< 300 mOsm/L), urine specific gravity less than 1.010, and urine volumes greater than 2 mL/kg per hr.²⁸ The tremendous urinary water loss produces serum osmolarities greater than 290 mOsm/L and serum sodium concentrations greater than 145 mEq/L. Neurologic symptoms of hypernatremia reflect neuronal dehydration and include hyperreflexia, weakness, lethargy, seizures, and coma.²⁸

The thirst mechanism assumes a primary role in maintaining water balance in awake patients with DI, preventing serious hyperosmolarity and life-threatening dehydration.⁸ In the unconscious patient, intravascular volume and serum sodium concentrations are restored slowly to avoid consequences of overrapid correction such as pulmonary and cerebral edema.³⁵

Treatment protocols for DI depend on the degree of ADH deficiency. Most patients have incomplete DI and retain some capacity to concentrate their urine and conserve water. Treatment in general is enhanced by restricting sodium intake. In patients with central DI, DDAVP, a selective V2 agonist, is often a preferred agent. It has less vasopressor (V1) activity than vasopressin, a prolonged duration of action, and enhanced antidiuretic properties.^{9,28,34} DDAVP may be administered nasally, intravenously, subcutaneously, and orally.

Other treatment options for DI include medications that either augment the release of ADH or increase the receptor response to ADH. Drugs may include chlorpropamide (sulfonylurea hypoglycemic agent), carbamazepine (anticonvulsant), and thiazide diuretics.

Preoperative assessment of the patient with DI includes careful appraisal of plasma electrolytes (especially serum sodium), hydration status, renal function, and plasma osmolarity. Dehydration will make these patients especially sensitive to the hypotensive effects of anesthesia agents. Plasma osmolarity, urine output, and serum sodium concentration should be measured hourly during surgery and in the immediate postoperative period.⁸ Isotonic fluids can generally be administered safely during the intraoperative period.⁸

Perioperative administration of vasopressin is usually not necessary in the patient with partial DI, because the stress of surgery causes enhanced ADH release.^{8,32} The surgical patient with complete DI may be treated with aqueous vasopressin (5–10 units intramuscular [IM]/subcutaneously every 8–12 hr) or desmopressin (1 to 2 mcg IV/subcutaneously every 12 hr or 5–40 mcg spray intranasally twice a day).³⁴ Caution is advised when administering aqueous vasopressin to patients with coronary artery disease or hypertension because of the arterial constrictive action.²⁸

Hypersecretion of Antidiuretic Hormone and Anesthetic Implications.

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is a disorder characterized by high circulating vasopressin levels relative to plasma osmolarity and serum sodium concentration. With SIADH, the kidneys, under ADH stimulation, continue to reabsorb water from the renal tubules despite the presence of hyponatremia and plasma hypotonicity.⁸ Hormone-induced water reabsorption causes expansion of intracellular and extracellular fluid volumes, hemodilution, and weight gain. The urine is hypertonic relative to the plasma, and urine output is typically low.

Clinical features of severe SIADH reflect water intoxication, dilutional hyponatremia, and brain edema.²⁸ The swelling of brain cells may cause lethargy, headache, nausea, mental confusion, seizures, and coma. Typically, hypertension and peripheral edema are not common. The severity of symptoms is related to the degree of hyponatremia and the rate of decrease of serum sodium.^{33,35,37} Furthermore, acute hyponatremia leads to a greater mortality than chronic hyponatremia.³⁵

Inappropriate hypersecretion of ADH can result from various pathologic processes, including hypothyroidism, pulmonary infection, carcinoma, head trauma, intracranial tumors, and following pituitary surgery.¹¹ Secretion of ADH by neoplasms, especially small-cell carcinomas of the lung, is a common cause of SIADH.⁸ The ectopic ADH produced by these tumors is identical to the ADH of hypothalamic origin. Certain drugs are associated with enhanced ADH secretion or response; these include carbamazepine, tricyclic antidepressants, chlorpropamide, cyclophosphamide, oxytocin, nicotine, and clofibrate.²⁸

The patient with mild SIADH not associated with symptoms of hyponatremia is often managed effectively with fluid restriction of 800 to 1000 mL/day with 0.9% normal saline.^{13,35} Patients with severe hyponatremia (plasma $\text{Na}^+ < 115\text{--}120$ mEq/L) may require more aggressive treatment with an IV infusion of hypertonic (3%) saline, with or without furosemide.^{28,35,37} To prevent acute loss of brain water and possible permanent neurologic damage (central pontine demyelination syndrome), the plasma sodium

concentration must be corrected slowly. Many investigators recommend that acute hyponatremia be corrected at a rate not to exceed 1 to 2 mEq/L per hr or 6 to 12 mEq/L in 24 hours.^{11,35,38} Serum sodium levels should be measured at least every 2 hours during treatment.²⁸ Definitive treatment for SIADH is directed at the underlying disorder.

Clinical assessment of the patient's volume status is an essential part of the preoperative evaluation. Perioperative fluid management of the surgical patient with SIADH can usually be accomplished with fluid restriction that involves the use of isotonic solutions.⁸ Estimating central volume status on the basis of central venous pressure measurements can help guide fluid replacement. Frequent determinations of urine output, urine osmolarity, and plasma osmolarity also can help direct fluid management. Nausea should be prevented, because it is a potent stimulus of ADH release.²⁸ [Table 37.3](#) compares SIADH and DI.

TABLE 37.3

Syndrome of Inappropriate Antidiuretic Hormone (SIADH) and Diabetes Insipidus (DI)

	SIADH	DI
Serum osmolarity	Less than 270 mOsm/L	Greater than 290 mOsm/L
Serum sodium	Less than 130 mEq/L	Greater than 145 mEq/L
Urine volume	Low	High (greater than 2 mL/kg per hr)
Urine osmolarity	Hypertonic urine relative to plasma	Hypotonic urine relative to plasma
Treatment	Fluid restriction; if patient symptomatic or serum Na ⁺ less than 115–120 mEq/L, consider hypertonic saline	DDAVP or vasopressin

DDAVP, 1-Deamino-8-D-arginine vasopressin.

Parathyroid Gland

The parathyroid glands are small (approximately $3 \times 6 \times 2$ mm) oval bodies located on the posterior surface of the thyroid gland. Most individuals have four parathyroid glands, one on each pole of the thyroid, but some individuals have five glands and some have only three.³⁹

Calcium Regulation

The adult human body contains approximately 1 to 2 kg of the divalent cation calcium. Approximately 99% of the calcium exists in the bony skeleton, and only approximately 1% is in the extracellular space and soft tissues.³⁹⁻⁴¹ Bone therefore serves as a large reservoir that can store or release calcium as needed.

The concentration of the total serum calcium is tightly regulated within a range of approximately 8.5 to 10.5 mg/dL.^{42,43} Serum calcium exists in three different forms (Fig. 37.7):

FIGURE 37.7 Serum calcium exists in three different forms: ionized, bound to serum proteins, and bound to diffusible anions. Only the ionized form of calcium exerts physiologic effects. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016:1001.)

1. Approximately 9% exists complexed to anions such as citrate, bicarbonate, and phosphate and is diffusible across capillaries membranes.
2. Approximately 41% is combined with plasma proteins (primarily albumin) and is not diffusible across capillary membranes.
3. Approximately 50% exists in an ionized and diffusible form (normal level 4.7 to 5.2 mg/dL).

Only the free, ionized form of calcium exerts physiologic effects, hence measurement of serum ionized calcium levels provides the most clinically relevant determination.^{39,40} Ionized calcium performs a wide range of vital physiologic functions, including hemostasis (platelet aggregation, blood coagulation), hormone release, muscle contraction (skeletal, smooth and cardiac muscle), bone formation, cell division, and many other aspects of cell function. Even small changes in calcium levels can cause extreme and immediate physiologic effects.^{39,44}

Total blood calcium levels may not always reflect the ionized calcium status. Alterations in serum protein levels cause parallel changes in total blood calcium levels without modifying ionized calcium values. A decrease in serum albumin causes an associated decrease in total serum calcium levels. Because of this, calcium levels may be reported *as albumin-adjusted* total calcium.⁴³

Alterations in the pH of blood affect ionized calcium levels. Plasma proteins are more ionized in an alkaline pH, providing an increase in the number of anion-binding sites for the positively charged calcium. Alkalosis decreases ionized serum calcium by increasing protein-calcium binding. Acidosis, on the other hand, increases ionized serum calcium by decreasing calcium-protein binding.^{40,41}

Two principal hormones, vitamin D and parathyroid hormone (PTH) operate in concert to regulate the plasma concentration of calcium. Both vitamin D and PTH raise serum calcium levels, but of the two, PTH has by far the strongest effect.

Vitamin D

Vitamin D compounds ingested from food or formed by the action of ultraviolet light on the skin are inactive prohormones.^{40,42} Inactive vitamin D, called *cholecalciferol*, is converted by a series of reactions in the liver and kidneys to an active metabolite. The final step in the conversion of vitamin D to an active form is controlled in the kidneys by PTH.⁴² The in vivo conversion of inactive vitamin D to the final active product, 1,25-dihydroxycholecalciferol, is shown in Fig. 37.8.

FIGURE 37.8 Conversion of cholecalciferol or vitamin D to an active form (1,25-dihydroxycholecalciferol) involves hydroxylation in the liver and kidneys. Active vitamin D is important in transporting calcium across the gastrointestinal tract. *UV*, Ultraviolet.

Active vitamin D increases plasma calcium, magnesium, and phosphate ion concentrations by promoting their absorption across the intestinal epithelium to the extracellular fluid.

Inadequate vitamin D intake or absorption, or insufficient exposure to sunlight, can lead to poor intestinal absorption of calcium and phosphate. In children, the resulting calcium and phosphate deficiency leads to defective mineralization of bone, a condition known as *rickets*.^{40,41,45} In adults, vitamin D deficiency results in impaired bone mineralization, a condition known as

osteomalacia.^{39,41}

Parathyroid Hormone

PTH is an 84-amino acid polypeptide hormone secreted from *chief* cells of the parathyroid gland in response to low serum ionized calcium concentrations. Hyperphosphatemia (indirect effect) also stimulates PTH secretion.⁴¹

PTH is the body's major hormonal regulator of calcium and phosphate metabolism. In PTH, the body possesses an extremely potent negative feedback agent for controlling serum calcium levels. In general, PTH increases the extracellular calcium concentration and decreases the extracellular phosphate concentration⁴² (Fig. 37.9). A small decline in the level of circulating ionized calcium produces a rapid increase in PTH secretion from the parathyroid glands. A sustained deficit in serum calcium levels (e.g., lactation, pregnancy) may produce hypertrophy of the parathyroid glands, sometimes fivefold or greater, to maintain adequate PTH output.^{39,41}

FIGURE 37.9 Parathyroid hormone (PTH)-calcium feedback loop that controls calcium homeostasis. Four organs—the parathyroid glands, intestine, kidney, and bone—together determine the parameters of calcium homeostasis. –, Negative effect; +, positive effect; 1,25 D,

1,25-hydroxyvitamin D; *ECF*, extracellular fluid. (From Melmed S, et al., eds. *Williams Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016:1256.)

An elevation in serum calcium ion concentration produces an abrupt decline in PTH synthesis and output. Conditions associated with chronic elevations of serum calcium (e.g., immobility, malignancy, Paget disease) blunt PTH output and provoke a diminution in gland size. Parathyroid gland function and PTH secretion may be inhibited by chronic hypomagnesemia, but acute hypermagnesemia may also depress gland function.^{41,42,46}

The increase in serum calcium levels and decrease in serum phosphate levels in response to PTH secretion is the result of the hormone's direct effect on bone and the kidney and its indirect effect on the intestinal tract (Fig. 37.10).

FIGURE 37.10 Ca²⁺ homeostasis in an adult eating 1000 mg/day of elemental Ca²⁺. Hormonal effects on Ca²⁺ absorption from the gastrointestinal tract, bone remodeling, and Ca²⁺ reabsorption in the kidney are shown. *PTH*, Parathyroid hormone. (From Costanzo LS. *Physiology*. 5th ed. Philadelphia: Elsevier; 2014:436.)

Effect on Bone.

Bone is a living tissue that is constantly being remodeled.⁴⁰ In the healthy adult, bone-forming cells called *osteoblasts* are balanced by bone-destroying cells called *osteoclasts*.³⁹ Exchangeable calcium salts in bone serve as a large, rapid buffer that plays a vital role to keep calcium in the extracellular fluid stable. In addition to calcium, bone also provides an important reservoir for other ions such as magnesium and phosphorus.^{39,41}

The most pronounced immediate control of blood calcium is due to PTH effects on bone.⁴² When ionized serum calcium levels decline, PTH is released and acts directly on bone to mobilize skeletal calcium stores.⁴⁰ PTH promotes the activation and proliferation of osteoclasts, stimulating rapid resorption of calcium (and phosphate) from bone tissue to the extracellular fluid. Over time, abnormally high levels of circulating PTH can produce extensive absorption of calcium from the bone matrix.^{39,42}

The reservoir of calcium in bone is approximately 1000 times greater than the amount of calcium in the extracellular fluid. Only after sustained PTH activation, therefore, does bone erosion and destruction become apparent. With protracted PTH stimulation, however, the bones eventually become severely depleted of calcium.³⁹

An increase in extracellular fluid calcium causes PTH levels to decline via a negative feedback loop. Decreased PTH levels stimulate rapid deposition of calcium and phosphate bone salts, an effect that lowers serum calcium levels back to normal.

Effect on the Intestinal Tract.

Parathyroid hormone indirectly enhances both calcium and phosphate absorption from the intestines by promoting formation of 1,25-dihydroxycholecalciferol, the active form of vitamin D. When the plasma calcium level is low, PTH stimulates 1α -hydroxylase, an enzyme in the kidney necessary for the formation of 1,25-dihydroxycholecalciferol. Active vitamin D in turn increases intestinal absorption of calcium and phosphate.⁴⁰

In the absence of PTH, or in the presence of severe kidney disease, 1,25-dihydroxycholecalciferol is not formed, and the effect

of vitamin D on calcium and phosphate regulation is lost. Patients with chronic renal failure often suffer from hypocalcemia, in part because the diseased kidneys lose their ability to form active vitamin D. Consequently, these patients are unable to absorb a sufficient amount of calcium from the gastrointestinal tract.⁴²

Effect on the Kidney.

PTH has two major effects on the kidney: it increases calcium reabsorption, and it increases phosphate excretion. PTH elevates serum calcium by augmenting the reabsorption of calcium from nephron tubules to the extracellular fluid. The major site of PTH-mediated calcium reabsorption is the distal convoluted tubule.^{39,42}

Accompanying calcium reabsorption is enhanced phosphate excretion. PTH promotes phosphaturia by reducing phosphate ion reabsorption from the proximal convoluted tubule. The PTH-mediated phosphate loss from the kidney is generally strong enough to overcome the PTH-induced phosphate absorption from bone and intestines.³⁹

Calcitonin

Calcitonin is a hormone secreted from the thyroid parafollicular cells, or C cells, in response to elevated serum ionized calcium.⁴⁰ It has an effect opposite to that of the PTH system, lowering the serum ionized calcium concentration. Calcium levels are reduced by a calcitonin-mediated inhibition of bone osteoclasts, which shifts the balance toward osteoblasts and bone deposition.^{40,42}

The serum calcium-lowering effect of calcitonin is weak, especially in adults. Its effect in lowering serum calcium is rapidly outweighed by the more powerful activity of PTH.³⁹ The rather weak effect of calcitonin is demonstrated by the observation that removal of the thyroid gland causes no significant alterations in bone density or long-term serum calcium levels.^{39,40,42}

Parathyroid Gland Dysfunction

Hypoparathyroidism

Hypoparathyroidism is characterized by low PTH levels or a

peripheral resistance to PTH effects.^{42,43,47} It may be an inherited or acquired disorder. Patients with hypoparathyroidism typically have low plasma calcium levels (ionized calcium < 4.5 mg/dL and total calcium < 8.5 mg/dL).¹¹ The serum phosphate concentration may be elevated because of decreased renal excretion of phosphate.

Inadvertent surgical removal of the parathyroid glands or damage to gland blood supply during parathyroid surgery, radical neck dissection, or thyroid surgery are the most common causes of hypoparathyroidism.^{43,47} Hereditary hypoparathyroidism, parathyroid gland injury from irradiation or trauma, amyloidosis, chronic severe magnesium deficiency (e.g., alcohol abuse, poor nutrition, malabsorption) and acute hypermagnesemia are other possible causes of hypoparathyroidism.^{43,46,47} Clinical signs of hypoparathyroidism reflect the degree of hypocalcemia and the rapidity of calcium decline. A sudden drop in ionized calcium usually produces more severe symptoms than a slow decline.⁴¹⁻⁴³ Recommended treatment of chronic hypoparathyroidism includes activated vitamin D and calcium supplementation, as well as magnesium if indicated.^{43,46,47} Use of recombinant human PTH (Natpara) can decrease calcium and vitamin D dosage requirements in patients with hypocalcemia caused by hypoparathyroidism, but current treatment recommendations restrict PTH to patients whose serum calcium is not controlled with calcium and active vitamin D alone.^{47,48}

The decreased serum calcium ion concentration accompanying hypoparathyroidism produces hyperexcitability of nerve and muscle cells by lowering the threshold potential of excitable membranes. Cardinal features of neuromuscular excitability are muscle spasms and spontaneous nerve discharge. Symptoms vary in severity and may take the form of muscle cramps, perioral paresthesias, acral numbness, hyperactive deep tendon reflexes, and tetany. The patient may feel restless or hyperirritable. Life-threatening laryngeal muscle spasm may occur, producing stridor, labored respirations, and asphyxia.^{39,42,43}

Two classic manifestations of latent hypocalcemic tetany are Chvostek sign and Trousseau sign. Chvostek sign is a contracture or twitching of ipsilateral facial muscles produced when the facial nerve is tapped at the angle of the jaw. Trousseau sign is elicited by

the inflation of a blood pressure cuff slightly above the systolic level for three minutes. The resultant ischemia enhances muscle irritability in hypocalcemic states and causes flexion of the wrist and thumb with extension of the fingers (carpopedal spasm).³⁹ Fig. 37.11 illustrates some of the clinical manifestations of hypoparathyroidism and hypocalcemia.

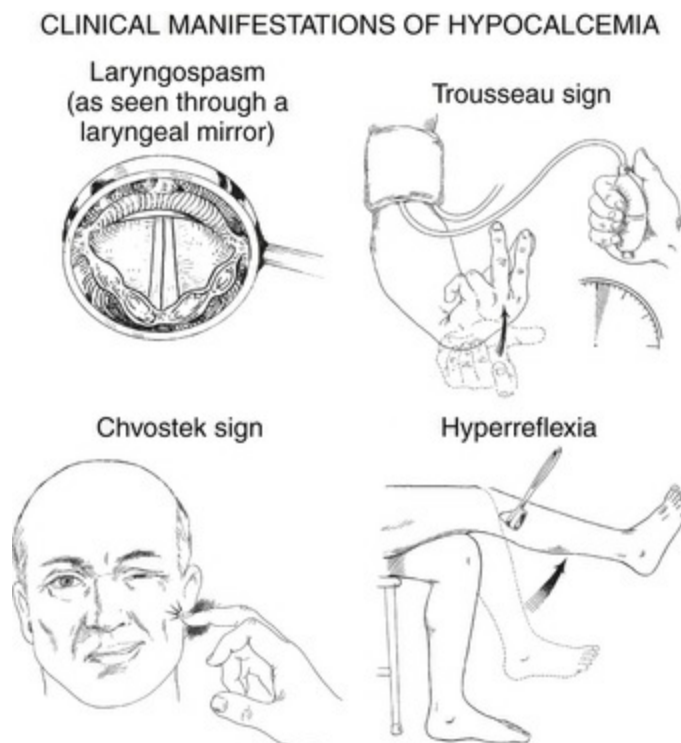

FIGURE 37.11 Hypocalcemia produces hyperexcitability of nerve and muscle cells. Chvostek sign and Trousseau sign are two classic manifestations of hypocalcemic tetany. Deep tendon reflexes may be hyperactive. Laryngeal muscles are sensitive to tetanic spasm.

Hyperparathyroidism

Primary hyperparathyroidism is a common endocrine disorder characterized and diagnosed by the presence of elevated serum PTH levels despite high serum calcium levels. It may result from a parathyroid adenoma, gland hyperplasia, or parathyroid cancer.^{41,42,44} In approximately 80% of cases, primary hyperparathyroidism is caused by hypersecretion of a single parathyroid adenoma.^{41,44,49,50} Multi-gland disease accounts for 10%

to 15% of cases. Hyperparathyroidism may also exist as part of a multiple endocrine neoplastic syndrome (MEN-1, MEN-2A).^{41,42} Carcinoma of the parathyroid gland is found in less than 1% of patients and is associated with particularly high serum calcium levels.^{44,50}

The prevalence of primary hyperparathyroidism is approximately 0.1% to 0.5% of the general population, with a higher occurrence in females and a mean age at diagnosis between 52 and 56 years.⁴² Pregnancy and lactation predispose an individual to pituitary adenoma formation and hyperparathyroidism.⁴²

There are many causes of hypercalcemia, but hyperparathyroidism and cancer account for 90% of all cases.⁴² Primary hyperparathyroidism is the most common cause of hypercalcemia in the general population. Sustained overactivity of the parathyroid glands leads to hypercalcemia. Most patients remain asymptomatic until the total serum calcium level rises above 12 mg/dL.⁴² Severe hypercalcemia, generally defined as greater than 14 mg/dL, may be life-threatening and demands immediate attention.⁴²

With the development of sensitive laboratory assays for calcium and PTH, today most patients with hyperparathyroidism are either asymptomatic or mildly symptomatic at diagnosis.⁴⁴ With advanced disease, sustained high levels of PTH lead to exaggerated osteoclast activity in bone, resulting in diffuse osteopenia, subperiosteal erosions, and elevated extracellular calcium levels. As osteoblasts attempt to reconstruct the ravaged bone, they secrete large amounts of the enzyme alkaline phosphatase.^{39,40} An elevated serum alkaline phosphatase level, therefore, is a diagnostic feature of bone disease and hyperparathyroidism.⁵⁰ Despite an increased mobilization of phosphorus from bone, serum phosphate concentration usually remains normal or low as a result of increased urinary excretion.

The effect of hyperparathyroidism on bone becomes clinically apparent when osteoclastic absorption of bone overwhelms osteoblastic deposition. With severe and protracted disease, the entire skeleton may be involved, making bones painful and susceptible to fracture. Owing to early diagnosis, the destructive bone disease associated with hyperparathyroidism, osteitis fibrosa cystica, is not common today.

Many of the nonskeletal manifestations of primary hyperparathyroidism are related to the accompanying hypercalcemia.^{49,50} Sustained and marked hypercalcemia may produce calcifications and other deleterious effects in the pancreas (pancreatitis), kidney (nephrolithiasis, nephrocalcinosis, polyuria), blood vessels (hypertension), heart (shortened ventricular refractory period, increased ventricular excitability, bradyarrhythmias), and acid-producing areas of the stomach (peptic ulcer).⁴⁹⁻⁵¹ The mnemonic “stones, bones, and groans” summarizes renal, skeletal, and gastrointestinal features of advanced hyperparathyroidism. Hypercalcemia raises the threshold of excitable cells and causes progressive depression of the nervous system.³⁹ Central and peripheral nervous system depressive effects begin to appear in many patients when blood calcium levels rise above approximately 12 mg/dL and become marked as the calcium rises to 15 mg/dL.³⁹ Profound muscle weakness, confusion, nausea, vomiting, and lethargy are additional features of the disorder. [Fig. 37.12](#) illustrates some of the clinical manifestations of hyperparathyroidism.

FIGURE 37.12 The patient with hyperparathyroidism

exhibits manifestations of hypercalcemia. With severe, protracted disease, skeletal destruction becomes evident.

Secondary hyperparathyroidism develops in patients with chronically low levels of serum calcium, such as those with chronic renal failure. Vitamin D deficiency and gastrointestinal malabsorption may also lead to secondary increases in PTH activity in response to the hypocalcemia. The clinical course is marked by the same PTH-mediated skeletal assault seen in the primary form of the disorder, but because it is an adaptive response, secondary hyperparathyroidism is seldom associated with hypercalcemia. The bone disease seen in patients with secondary hyperparathyroidism associated with chronic kidney disease is termed *renal osteodystrophy*.⁴²

Hypercalcemia due to malignancy occurs in as many as 20% of cancer patients. Malignancy is the second most common cause of hypercalcemia in adults.⁴² The hypercalcemia may be due to local invasion of bone by cancer cells, but many cases are due to elaboration of a PTH-like peptide (parathyroid hormone–related peptide, PTHrP) from tumor cells. The overproduction of PTHrP by cancer cells mimics the effects of PTH, including bone destruction, hypophosphatemia, and hypercalcemia.⁴²

Table 37.4 compares common clinical features of hyperparathyroidism and hypoparathyroidism.

TABLE 37.4

Clinical Features of Hyperparathyroidism and Hypoparathyroidism

System	Hyperparathyroidism	Hypoparathyroidism
Cardiovascular	Hypertension, cardiac conduction disturbances, shortened QT interval	Prolonged QT interval, hypotension, decreased cardiac contractility
Musculoskeletal	Bone pain, pathologic fractures, muscle weakness, muscle atrophy	Neuromuscular excitability; spasms; cramps
Neurologic	Somnolence, cognitive impairment, depression, hypotonia	Tetany, paresthesias, numbness in fingers and toes, seizures
Gastrointestinal	Anorexia, nausea, vomiting, constipation, abdominal pain, pancreatitis, peptic ulcer	Abdominal cramps
Renal	Tubular absorption defects, diminished renal function, kidney stones, polyuria	None significant

Anesthesia Implications for Hyperparathyroidism.

The preferred and definitive treatment for symptomatic primary hyperparathyroidism is surgical removal of the culprit gland or glands. Optimal management for asymptomatic hyperparathyroidism is more controversial.⁴⁴ Historically, parathyroidectomy was performed with bilateral neck exploration. The new standard for most surgeries involves preoperative imaging studies to localize the abnormal tissue, which permits directed and limited resection of only the hypersecreting gland or glands. This minimally invasive surgical approach is usually performed under general anesthesia, but cervical plexus block anesthesia and monitored anesthesia care may be used, especially for excision of a single adenoma.⁵⁰⁻⁵⁴

Mild hypercalcemia (less than 12 mg/dL) preoperatively can be managed by saline infusion (150 mL/hr).^{11,42} Isotonic saline hydration and loop diuretics (furosemide, 40 to 80 mg IV every 2–4 hours) can rapidly decrease serum calcium levels by hemodilution, increased glomerular filtration, and enhanced excretion.^{8,11,44} Less frequently, intravenous bisphosphonates (pamidronate, zoledronate, alendronate, etidronate) or calcitonin are used to lower serum calcium by inhibiting osteoclastic bone resorption.^{8,11,42}

The hypercalcemic patient may be dehydrated because of anorexia, vomiting, and the impaired ability of the kidneys to concentrate urine.⁴² Special attention must be directed preoperatively to restoring fluid balance with noncalcium-containing solutions. Perioperative hydration aims to dilute serum calcium, maintain adequate glomerular filtration and calcium clearance, and ensure adequate intravascular volume. Vigorous hydration dictates the use of bladder catheterization, central venous pressure monitoring, and frequent determinations of serum electrolytes.

Elevated calcium levels may depress the central and peripheral nervous systems. The use of preoperative sedatives in the hypercalcemic patient who appears lethargic or confused should be avoided. General anesthetic requirements may also be decreased in the patient with preoperative somnolence.¹¹

Careful review of the patient's renal status is especially crucial in patients with secondary hyperparathyroidism. Associated complications of renal impairment (volume overload, anemia,

electrolyte derangements) may affect anesthetic medication dosages and selection.

Cardiac conduction disturbances, a shortened QT interval and a prolonged PR interval on the electrocardiogram (ECG) are observed with hypercalcemia.¹¹

Awareness of the effects of pH on the ionized portion of plasma calcium is important. Alkalosis shifts ionized calcium to the protein-bound form and decreases serum levels.

The erosive effects of elevated PTH on bone and the systemic effects of chronic hypercalcemia should be considered in the anesthetic plan for patients with severe untreated disease. Patients with clinically significant bone disease are susceptible to fractures, and care must be exercised in positioning and padding.⁵⁵

The response to neuromuscular blockade may be unpredictable. Muscle weakness, hypotonia, and muscle atrophy may increase the patient's sensitivity to nondepolarizing skeletal muscle relaxants. Careful titration of muscle relaxants in concert with neuromuscular blockade monitoring is prudent.¹¹

Parathyroid tissue resembles brown fat, and this can occasionally make it difficult for the surgeon to locate. Furthermore, parathyroid tissue is sometimes footloose and can be found in such ectopic places as the deep recesses of the mediastinum, pericardium, or the thymus gland.⁴⁰⁻⁴² The 5-minute half-life of PTH allows it to serve as a useful intraoperative marker.⁵⁴ The surgeon may use periodic intraoperative assays of serum PTH and ionized calcium levels to help guide surgical resection. PTH levels decline quickly after successful resection of the source. In most cases, the parathyroid gland is further confirmed histologically by frozen section.^{51,52}

Blood loss from parathyroid surgery is usually minimal, and advanced monitoring is not required based on the surgical procedure. Serum calcium, magnesium, and phosphorus levels should be monitored in the postoperative period until stable.

Temporary hypocalcemia is commonly observed even after successful parathyroid surgery for hyperparathyroidism.^{42,55} In most cases, serum calcium levels start to decline within 24 hours of surgery.^{11,42,47} Transient postoperative hypocalcemia may be the result of parathyroid gland suppression (by preoperative hypercalcemia) or rapid bone uptake of calcium ("hungry bone

syndrome").^{41,55} Inadvertent removal of all parathyroid gland tissue induces a marked decline in total serum calcium concentration from normal levels to 6 to 7 mg/dL. Even a small amount of remaining parathyroid tissue is usually capable of sufficient hypertrophy to preserve normal calcium-phosphate balance.^{39,44}

After parathyroid surgery, meticulous observation for signs of musculoskeletal irritability should be performed. The threshold for the development of hypocalcemic neuromuscular excitability is variable, but tetany is generally observed when calcium falls from its normal level to total serum calcium levels of approximately 6 mg/dL.³⁹

Laryngeal muscles are especially sensitive to tetanic spasm, and laryngospasm may cause life-threatening airway compromise in the hypocalcemic patient.³⁹ Respiratory distress or stridor following parathyroid surgery may be secondary to laryngeal muscle spasm, edema, bleeding in the neck, or bilateral recurrent laryngeal nerve injury. Unilateral recurrent laryngeal nerve injury produces hoarseness and usually requires only close observation. Bilateral recurrent laryngeal nerve injury causes aphonia and requires immediate airway support and intubation.^{39,44} An expanding postoperative hematoma in the pretracheal space is potentially life-threatening and demands immediate treatment.

Hypocalcemia may be apparent on electrocardiographic tracings as a prolonged QTc interval, reflecting delayed ventricular repolarization.^{11,43} Cardiac dysrhythmias, decreased cardiac contractility, and hypotension may occur, and heart failure (although rare) is a danger.^{42,43}

In addition to parathyroid surgery, circulating levels of ionized calcium can decline from other causes in the perioperative period. Precipitous increases in circulating levels of anions such as bicarbonate, phosphate, and citrate lower ionized calcium levels.⁴¹ The rapid transfusion of citrated blood, or the rapid administration of bicarbonate may induce overt tetany in a previously asymptomatic hypocalcemic patient. Hyperventilation and alkalosis decrease ionized calcium levels by increasing calcium binding to proteins.⁴² Vigorous diuresis can also augment calcium loss.

Patients with severe symptomatic hypocalcemia require prompt therapy.⁴³ Acute hypocalcemia may be treated with an initial

intravenous bolus of 10 mL of 10% calcium chloride or calcium gluconate administered over 10 minutes, followed by an infusion of 0.5 to 2 mg Ca⁺²/kg per hr.^{41,42} Calcium, magnesium, phosphate, potassium, and creatinine levels should be monitored diligently during calcium replacement. Chronic magnesium deficiency can impair the secretion of PTH and should be corrected if low.^{40,46,47}

Approximately 5% of patients will exhibit persistent hyperparathyroidism and hypercalcemia after parathyroid surgery because of insufficient removal of the disease-causing tissue.

Pancreas

The pancreas is a flattened, elongated, retroperitoneal organ that has both exocrine and endocrine functions. Acinar cells, which make up the exocrine portion of the pancreas, account for approximately 98% of the gland's weight. Gastrointestinal enzymes and bicarbonate are synthesized in acinar cells and secreted into the pancreatic ducts to aid the digestive process.

Islets of Langerhans

The islets of Langerhans, which make up 1% to 2% of the pancreas' weight, constitute the endocrine pancreas. The islets are microscopic collections of cells scattered throughout the gland. They produce hormones that do not enter ducts but rather are secreted directly into capillary blood vessels. Each islet cell has an abundant blood supply. Venous blood from the islets drains into the hepatic portal vein and then into the general circulation.⁵⁶

At least four distinct cell types are found in the islets of Langerhans, identified as α (alpha), β (beta), δ (delta), and PP (pancreatic polypeptide) cells. Each cell type secretes a different peptide hormone. The β cells constitute approximately 60% of the islet mass and secrete the hormone insulin. Amylin is a hormone that is also secreted from the β cells parallel with insulin secretion.⁵⁷ The α cells constitute approximately 25% of the islet cells and secrete the hormone glucagon. The δ cells represent approximately 10% of total cells and secrete the hormone somatostatin.⁵⁷

Insulin and glucagon are crucial in regulating carbohydrate, fat, and protein metabolism. Their secretion is part of a hormonal regulatory system that accommodates repeated periods of feast and fasting throughout the day. Somatostatin may play a role in regulating gastrointestinal function by restraining the rate at which nutrients are digested and absorbed. It also depresses the secretion of both insulin and glucagon.⁵⁷ As noted earlier in this chapter, somatostatin is a GH inhibitory hormone, a hypothalamic hormone that suppresses GH release from the anterior pituitary gland. Pancreatic peptide inhibits exocrine pancreatic secretion.

Energy Balance

Glucose is the body's most abundant circulating fuel. The breakdown of glucose into simpler compounds releases energy the body uses for cellular metabolism. The energy-yielding breakdown of glucose to pyruvate is called *glycolysis* or the *Embden-Meyerhof pathway*.

Despite daily fluctuations between feeding and fasting, plasma glucose concentration is maintained within an amazingly narrow range. This is accomplished by the counterbalancing effect of multiple hormones that control the storage of glucose and other nutrient fuels after meals and regulate fuel mobilization between meals. In most healthy individuals, the liver stores enough glycogen to maintain a normal plasma glucose during 8 to 12 hours of fasting.⁵⁸ An overnight fast usually lowers the blood glucose to 80 to 90 mg/dL. The blood glucose concentration increases briefly to 120 to 140 mg/dL after a meal before returning to control levels.⁵⁷ In a person with impaired glucose tolerance (prediabetic), the fasting plasma glucose (FPG) level is 100 to 125 mg/dL, and in the diabetic patient, the FPG is equal to or greater than 126 mg/dL.^{57,59}

Certain metabolic processes ensure the efficient storage of nutrients so they can be available for later use. Glycogenesis, or the storage of glucose as glycogen, occurs primarily in the liver and muscle. Lipogenesis, which represents the formation and storage of fat as triglycerides, occurs primarily in adipose tissue.

Other metabolic processes work in the opposite direction, providing adequate energy sources during times of fasting. Gluconeogenesis is the formation of glucose from lactate, pyruvate, amino acids, and glycerol; it is an important hepatic glucose production mechanism during fasting and starvation. Glycogenolysis, the breakdown of glycogen into glucose, occurs primarily in the liver. Lipolysis, the breakdown of stored triglycerides to free fatty acids and glycerol, is stimulated by the enzyme hormone-sensitive lipase.

The rates of glycogenesis, lipogenesis, gluconeogenesis, glycogenolysis, and lipolysis are determined largely by the actions of insulin and the opposing actions of the so-called counterregulatory hormones (GH, cortisol, epinephrine, and glucagon). Insulin plays an important role as an anabolic hormone.

It promotes growth and the constructive phase of metabolism. The potent anabolic effects of insulin are balanced by the opposing catabolic actions of the counterregulatory hormones, which mobilize fuel substrates from protein, carbohydrate, and fat stores to meet the energy demands of various tissues in response to fasting or stress.⁵⁶

The “push and pull” effect of these two hormone systems helps maintain normal glucose concentrations in the healthy individual. In diabetes, when insulin concentrations are low or absent, the unopposed counterregulatory hormones begin to exert more prominent metabolic effects.

Glucose Usage by the Brain

Different tissues have different glucose requirements. In addition, most tissues are able to adapt to alternative sources of fuel when glucose is scarce. Muscle and most tissues in the body use glucose for energy when it is available, but they can also shift to alternative sources of fuel (amino acids or fat) in the absence of glucose.

The brain is unique in that it is one of the few organs that uses only glucose for energy. It is said to be an obligate glucose organ. Erythrocytes, the retina, and the epithelium of the gonads also depend on glucose as their sole source of energy.⁵⁷ Unlike most other tissues, obligate glucose organs cannot immediately switch to alternative fuels when glucose levels fall. The brain's absolute, uninterrupted requirement for glucose dictates that the blood glucose concentration always be maintained above a critical level. The central nervous system accounts for approximately 50% of total body glucose utilization, and normal cerebral function requires the delivery of approximately 125 to 150 g of glucose per day.⁶⁰ During prolonged starvation, ketone bodies can substitute for glucose as cerebral fuel.

Insulin

Of the hormones secreted from the islet cells, insulin is of greatest physiologic importance. In 1922, the Canadian Frederick Banting and the American Charles Best first isolated this critical hormone from the pancreas in its pure form. The clinical importance of this

event is demonstrated by insulin's history of lifesaving effects in those with DM, a previously uniformly fatal disease.

Insulin was the first mammalian peptide hormone produced with the use of recombinant DNA techniques.

Storage and Release

Insulin is synthesized within the β cells of the pancreas, and it is packaged and stored in membrane-lined vesicles within the β -cell cytoplasm. Approximately 200 units of insulin are stored in the pancreas in this form. With stimulation, insulin is released via exocytosis from the β cell to the surrounding capillaries, where it enters the portal circulation. In the first pass through the hepatic circulation, the liver removes approximately 50% of the insulin delivered to it. Total daily insulin secretion is estimated to be approximately 60 units, but the total daily peripheral delivery is approximately 30 units.⁵⁶

Insulin circulates unbound to any carrier protein. The circulating half-life of insulin is approximately 7 minutes, and it is mainly cleared from the circulation in 10 to 15 minutes.⁵⁷ Almost all tissues in the body can metabolize insulin, but the major site of hormone degradation is the liver, and, to a lesser degree, the kidney. As a result, patients with liver dysfunction or kidney disease may have prolonged effects of insulin with increased risk of hypoglycemia. Very little insulin

Effects of Insulin

Insulin is a hormone of energy or fuel storage. It is important to many cellular mechanisms related to growth, and it is intimately involved in the regulation of carbohydrate, fat, and protein metabolism.

Following ingestion of a meal, insulin levels increase sharply in response to stimulation by abundant circulating nutrient substrates. Insulin promotes the storage of carbohydrate, fat, and protein for future use when substrate supply is low.^{57,60} Fig. 37.13 outlines the effects of insulin on nutrient substrates.

FIGURE 37.13 The effect of insulin on the overall flow of metabolic substrates. Insulin promotes the uptake of glucose into insulin-responsive tissue to meet energy needs. In the liver and skeletal muscle, insulin promotes the storage of excess glucose as glycogen. In adipose tissue, excess glucose is stored as triglyceride (TG). Insulin inhibits the breakdown of triglyceride into glycerol and free fatty acids (FFA). Amino acid uptake into muscle is increased for protein synthesis, and protein breakdown is inhibited.

The cellular effects of insulin on target cells are initiated by a reversible binding to specific cell-membrane insulin receptors linked to the enzyme tyrosine kinase. Most cells in the body have insulin receptors, but the major targets of insulin action are the liver, muscle, and adipose tissue.^{56,57,60}

Effects on Carbohydrate Metabolism.

Insulin is the body's key hormone controlling glucose removal from the plasma. It facilitates rapid uptake, storage and use of glucose in all cells, but especially liver, muscle, and adipose cells. The brain is one of the few tissues in the body that does not require insulin for glucose transport into its cells.^{57,60}

In the liver, and to a lesser extent in muscle cells, insulin promotes the efficient storage of excess glucose in the form of glycogen (glycogenesis).⁵⁶ Under normal circumstances, approximately 60% of the glucose ingested with a meal is stored in the liver as glycogen (up to approximately 100 g). In addition to

promoting hepatic glucose storage, insulin limits hepatic glucose output by inhibiting enzymes responsible for gluconeogenesis.^{56,57}

Between meals, when blood glucose levels fall, insulin secretion decreases and glucose can be released back into the blood (glycogenolysis) and be made available for local energy use or delivery to the central nervous system. Glycogen content in the liver is limited and is largely depleted after an overnight fast. Therefore, gluconeogenesis becomes the predominant source of glucose after prolonged fasting.⁶⁰

Effects on Protein Metabolism.

The actions of insulin on protein metabolism are also directed toward nutrient storage and growth (anabolism). Insulin stimulates the uptake of amino acids from the extracellular fluid to the cell. Once inside the cell, it promotes the synthesis of specific proteins. Insulin also conserves amino acids in existing proteins by inhibiting the breakdown of protein stores. Because insulin is required for protein synthesis, it is firmly established as an essential hormone for normal development and maintenance of healthy tissues.⁵⁷

Effects on Fat Metabolism.

The acute effects of insulin on fat metabolism are not as readily apparent as the effects on carbohydrate metabolism, but in the long run they are no less important.

Insulin favors fat storage. After a meal, carbohydrates not used for energy or stored as glycogen are converted, under the direction of insulin, to fatty acids. Fatty acids and glycerol combine to form triglyceride, the storage form of fat. Insulin not only stimulates triglyceride storage in adipose tissue but also strongly inhibits the breakdown of stored triglyceride to free fatty acids and glycerol. Insulin blocks triglyceride hydrolysis and the liberation of free fatty acids into the circulating blood by suppressing the enzyme hormone-sensitive lipase.⁶¹ Under ordinary conditions, insulin continually exerts a “braking effect” on free fatty acid release. A major consequence of lower concentrations of circulating free fatty acids is the decreased use of fatty acids for fuel.⁵⁶ Insulin suppresses fatty acid mobilization in the fed state when glucose is readily available to meet energy needs.

In the fasted state, when insulin levels are low, free fatty acids are released into the circulation and provide metabolic fuel to most cells.^{56,57} Organic acids called *ketoacids* or *ketone bodies* are generated in the liver from free fatty acid oxidation. Ketoacid production is increased in the fasted state when insulin levels are low. Conversely, ketoacid production is markedly reduced when insulin levels are high. Insulin is the body's major antiketogenic hormone.⁵⁷⁻⁶⁰

Effects on Ion Transport.

Insulin stimulates the translocation of vital electrolytes from the extracellular compartment into cells. Potassium, phosphate, and magnesium uptake into cells is mediated by an insulin mechanism.⁵⁶ Exogenous insulin administration may appreciably lower serum potassium, phosphate, and magnesium levels. Hypokalemia secondary to vigorous insulin treatment can be of great clinical significance.

Insulin's metabolic actions are complex and wide ranging. Overall, insulin promotes glucose transfer into cells and fosters glucose use for energy. When energy needs are met, insulin promotes glucose storage. Conversely, lack of insulin causes lipolysis and fat utilization for energy instead of glucose, except in neuronal cells.

Control of Insulin Secretion

Insulin synthesis and secretion are stimulated by “feast” or energy abundance. Ingestion of a meal increases the rate of insulin secretion four- to fivefold.⁵⁹ Plasma insulin levels rise, reaching peak values 30 to 60 minutes after eating is initiated.⁵⁶ High insulin levels in turn direct nutrients to appropriate storage sites. Between meals, insulin levels drift downward, the storage process is reversed, and metabolic substrates are mobilized in the form of glucose, free fatty acids, and amino acids.

Plasma glucose is by far the most important regulator of insulin release. Elevated plasma glucose levels directly activate β cells of the pancreas, stimulating insulin synthesis and secretion. Low plasma glucose concentrations inhibit this response. Very little

insulin is secreted at the normal FPG levels of 80 to 90 mg/dL and below.^{56,57,61} As the blood glucose rises above 100 mg/dL, secretion of insulin rises rapidly. A maximal insulin response occurs at blood glucose levels of 400 to 600 mg/dL.⁵⁶ The dramatic rise in insulin secretion with increasing blood glucose is matched by the rapid turn-off of insulin when blood glucose is reduced.

Amino acids also are potent stimulators of insulin release, although the β -cell response to amino acids is not as pronounced as the response to glucose. Fat has little if any stimulating effect on insulin release.⁵⁶

Both adrenergic and cholinergic fibers of the autonomic nervous system innervate the islets. Parasympathetic vagal activity and sympathetic β -receptor stimulation increase insulin release. A general sympathetic discharge has a suppressive effect on insulin release (via α -adrenergic receptor activation).⁵⁷ Pancreatic insulin secretion, however, does not require intact autonomic innervation; appropriate secretion responses occur in the transplanted pancreas as well.

Gastrointestinal hormones that accompany the digestive process potentiate insulin secretion. Food ingestion seems to send an “anticipatory” signal to the pancreas to discharge insulin in preparation for the absorption of glucose and amino acids.⁵⁷ The gut hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1), termed *incretin hormones*, help lower blood glucose levels by potentiating insulin production and decreasing glucagon secretion from the pancreas. GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase-4 (DPP-4).⁵⁷ As discussed later in this chapter, drugs that mimic GLP-1 and inhibit DPP-4 have been developed to treat type 2 DM. [Box 37.3](#) lists some [Box 37.3](#) factors that influence insulin secretion.

Factors That Influence Insulin Release

Stimulators

- Glucose, mannose, fructose
- Amino acids

- Gastrointestinal hormones
- Acetylcholine (parasympathetic stimulation)
- β -Adrenergic stimulation

Inhibitors

- Hypoglycemia
- Somatostatin
- Glucagon, cortisol, growth hormone
- α -Adrenergic stimulation

Glucagon

Glucagon is a polypeptide hormone produced by α cells of the pancreatic islets as a biologic antagonist to insulin.^{56,57} The most important role of glucagon is to enhance hepatic glucose output (glycogenolysis, gluconeogenesis) and increase plasma glucose. A decrease in blood glucose concentration below 90 mg/dL increases the plasma glucagon level by severalfold.⁵⁷ Hyperglycemia, on the other hand, decreases glucagon release from the α cells.

Insulin and glucagon have several biologic actions that are diametrically opposed. Whereas insulin is considered a hormone of energy storage, glucagon is considered a hormone of energy release.⁵⁷ Between meals, when blood glucose levels are low, the concentration of glucagon increases to maintain fuel production at a level that meets the energy needs of the individual, particularly the need for glucose delivery to the brain.⁶⁰

Glucagon works in concert with other counterregulatory hormones to increase blood glucose concentration. These hormones are also secreted in response to various stresses such as toxemia, injury, and surgery.⁵⁶ Nondiabetic surgical patients may experience an increased plasma blood glucose, as much as 60 mg/dL above their preoperative levels, in response to surgical stress.^{62,63}

Glucagon in high concentrations also (1) causes relaxation of bile

ducts and promotes bile flow and, (2) enhances cardiac contraction.⁵⁷

Diabetes Mellitus

DM is a complex metabolic derangement caused by relative or absolute insulin deficiency. Carbohydrate, protein, and fat metabolism is markedly impaired. Diabetes has been called “starvation in a sea of food.” Glucose may be present in abundance, but because of insulin lack or insulin resistance, it is unable to reach cells for energy provision. Criteria for diagnosing diabetes are outlined in [Box 37.4](#). The FPG diagnostic level was reduced from a previous value of 140 mg/dL based on findings that patients with a FPG of 126 mg/dL or higher are at risk for diabetes-related

[Box 37.4](#) complications.^{64,65}

Criteria for Diagnosing Diabetes: 4 Options

1. A1C \geq 6.5%

or

2. Fasting Plasma Glucose (FPG) \geq 126 mg/dL

Fasting defined as no caloric intake for at least 8 hours

or

3. 2-hr Plasma Glucose \geq 200 mg/dL during an oral glucose tolerance test

75-g anhydrous glucose dissolved in water

or

4. Random Plasma Glucose \geq 200 mg/dL

In patients with symptoms of hyperglycemia or hyperglycemic crisis

From American Diabetes Association. Standards of Medical Care in Diabetes-2015. *Diabetes Care*. 2015;38(suppl 1):S1–S93.

The incidence of diabetes has increased dramatically over the last 40 years. The rise can be attributed to a combination of three main factors: (1) an overweight population, (2) more sedentary lifestyles, and (3) a rise in the elderly population.⁶⁶ As our population ages, the effect of the disease will become even more alarming. As outlined in Fig. 37.14, many pathophysiologic features of DM are directly attributable to a lack of insulin on carbohydrate, fat, and protein metabolism.

FIGURE 37.14 The pattern of substrate flow in the diabetic state. Lack of insulin enhances hepatic glucose production because of increased gluconeogenesis and glycogenolysis. The diabetic state promotes protein breakdown, and the released amino acids are converted to glucose in the liver (gluconeogenesis). Lipolysis is augmented, and this increases free fatty acid supply to the liver, resulting in enhanced ketogenesis. Free fatty acids provide an energy source to muscle and other facultative tissue. Glucose uptake by the brain is sustained. *FFA*, Free fatty acids; *TG*, triglyceride.

Today, diabetes affects over 29 million Americans or 9.3% of our population. It is the leading cause of renal failure, a major cause of hypertension and other cardiovascular diseases, and a leading cause of blindness in adults^{65,66}

Type 1 Diabetes Mellitus

Approximately 5% of diabetic patients have type 1 DM.^{65,66} This type of diabetes was formerly known as *insulin-dependent diabetes* or *juvenile-onset diabetes*. Individuals with type 1 DM have an absolute deficiency or lack of insulin and are therefore entirely dependent on exogenous insulin therapy. In the absence of sufficient exogenous insulin, the disease course may be complicated by periods of ketosis and acidosis.⁶⁷

In most cases, type 1 DM is caused by an unusually vigorous autoimmune destruction of the β cells of the pancreatic islets. Environmental factors such as infection or exposure to specific antigenic proteins are cited as possible initiators of the immune assault.⁶⁷⁻⁶⁹ Type 1 DM patients are also more likely to have other autoimmune diseases such as Graves' disease, Hashimoto thyroiditis, myasthenia gravis and Addison disease.⁶⁷⁻⁷⁰ A genetic predisposition for development of the disease is also involved.⁵⁹

Type 1 DM usually develops before the age of 30 years, but it can develop at any age.⁵⁹ The classic symptoms of type 1 DM appear abruptly when at least 80% of the β cells are destroyed.⁵⁹ The remaining β cells are usually eliminated inexorably over 2 or 3 years. The lack of insulin has three major sequelae: (1) increased blood glucose levels, (2) increased utilization of fat for energy, and (3) depletion of the body's protein stores. In patients with type 1 DM, daily exogenous insulin therapy is essential for life.

Type 2 Diabetes Mellitus

Approximately 95% of the patients with diabetes have *type 2 DM*.⁶⁵ Type 2 DM is characterized by impaired insulin secretion, peripheral insulin resistance (a decreased number of insulin receptors or an insulin receptor or postreceptor defect), and excessive hepatic glucose production.^{59,71} Obesity is the major risk

factor for type 2 DM with over 80% of type 2 DM patients considered obese, primarily of the visceral or central type.⁵⁹ Type 2 DM was formerly known as *noninsulin-dependent diabetes* or *maturity-onset diabetes*.

Type 2 DM occurs in patients who have some degree of endogenous insulin production but produce quantities insufficient for sustaining normal carbohydrate homeostasis. Early in the disease process, insulin resistance contributes to an increase insulin secretion and subsequent hyperinsulinemia. The exact mechanism causing insulin resistance remains unclear, although it is present in a number of metabolic abnormalities (hypertension, abdominal fat) classified as metabolic syndrome. Eventually a decline in insulin secretion occurs, which leads to an increase in hepatic glucose production and ultimately a hyperglycemic state. Insulin levels may be low, normal, or even elevated, but a relative (rather than absolute) insulin deficiency exists.⁷⁰ Typically, type 2 DM occurs in patients who are between the ages of 50 and 60 years and with a family history of the disease.^{59,71}

There is a strong genetic predisposition to type 2 DM, but the genetics are not fully defined.^{70,71} Type 2 diabetes is more common in African Americans, Latinos, Native Americans, and Asian Americans/Pacific Islanders.⁶⁵ There is a strong association between nonalcoholic fatty liver disease (NAFLD) and hepatic insulin resistance. More than 90% of obese patients with type 2 DM have NAFLD.⁷²

With the rise in childhood obesity, there is an alarming rise in the number of young people with type 2 DM. Type 2 DM has an insidious onset; indeed, it is estimated that half of those who have type 2 DM are not even aware of it. The disease course is rarely associated with ketosis or acidosis, but in poorly controlled patients it may be complicated by a nonketotic, hyperosmolar, hyperglycemic state.

Treatment for this class of diabetes consists primarily of oral glucose lowering agents, exercise, and diet therapy. Weight reduction in the obese diabetic patient improves tissue responsiveness to endogenous insulin and, in many patients, restores normoglycemia.⁷³

The distinction between insulin-treated diabetics and insulin-

dependent diabetics is important. Some patients with type 2 DM benefit from exogenously administered insulin, especially during times of illness or stress. Patients with type 1 DM, on the other hand, are insulin-dependent and require exogenous insulin daily to live.

Diabetes Associated With Other Conditions

Diabetes may result from other conditions such as pancreatitis, cystic fibrosis, polycystic ovary syndrome, Cushing syndrome, pheochromocytoma, and acromegaly.⁷⁰ Gestational diabetes mellitus (GDM) is defined as impaired glucose tolerance with onset or first recognition during pregnancy. The prevalence of gestational diabetes in the United States is as high as 9.2%.⁷⁴ Women who are affected by GDM have more than a sevenfold increased risk of developing type 2 diabetes 5 to 10 years after delivery.

Insulin Deficiency

Effect of Insulin Deficiency on Carbohydrates

Insulin deficiency results in a decreased uptake and use of glucose by insulin-sensitive cells. Glycogen storage is decreased, and gluconeogenesis is uninhibited with insulin lack, causing the liver to increase its glucose output. This produces an intracellular deficit and an extracellular surplus of glucose.⁵⁶ As the diabetic state evolves, glucose-deprived cells meet their energy requirements by drawing on fat and protein reserves.

The hyperglycemia produced by insulin lack has immediate adverse consequences. When the blood glucose concentration increases to a threshold level (approximately 180 to 200 mg/dL), the amount of glucose filtered at the kidney glomerulus cannot be totally reabsorbed. The excess filtered glucose spills into the urine (glucosuria) and acts as an osmotic diuretic, pulling water with it. The increased urine output (polyuria) contributes to extracellular dehydration and electrolyte depletion. Intracellular dehydration also occurs because of the osmotic transfer of water out of cells and into the hypertonic extracellular fluid. In an attempt to compensate for the hypovolemia, the diabetic patient may drink large quantities

of water (polydipsia).

Effect of Insulin Deficiency on Fat

With insulin lack, all the insulin-mediated fat storage effects noted earlier are reversed.⁵⁷ The most important effect of insulin lack on fat metabolism is the activation of hormone-sensitive lipase, which causes uninhibited lipolysis of stored triglycerides, releasing free fatty acids and glycerol into the blood. This fat mobilization increases circulating lipids and may contribute to the atherosclerotic and angiopathic changes that complicate the disease.⁵⁷

Insulin deficiency produces a shift from carbohydrate to fat metabolism. Free fatty acids become the main energy substrate for essentially all tissues (the brain excluded). With uncontrolled diabetes, the excess free fatty acids are converted in the liver to ketone bodies (acetoacetic acid, β -hydroxybutyric acid, and acetone). This ultimately leads to greater circulating levels of ketoacids and an elevated hydrogen ion concentration in body fluids. The ketone body acetone is a volatile acid and is excreted via the lungs. Consequently, one can frequently identify ketonemia in the patient with uncontrolled type 1 DM by detecting a fruity "acetone breath."

Effect of Insulin Deficiency on Protein

The insulin deficiency of diabetes causes protein storage to halt and catabolism to ensue. Plasma amino acid concentration increases, and the excess circulating amino acids are converted in the liver to glucose (gluconeogenesis). The protein-wasting effects are among the most serious consequences of DM. Weight loss, weakness, and widespread organ dysfunction result. The diabetic may attempt to compensate for the protein loss and caloric drain by increasing food intake (polyphagia).

Many proteins, including hemoglobin and structural tissue proteins, become glycosylated in the presence of high circulating blood glucose levels. Glucose adducts can alter protein function and may contribute to the organ damage and functional derangements observed in individuals with diabetes.⁵⁶

Long-Term Diabetic Complications

Diabetic patients are subject to long-term complications that confer substantial morbidity and premature mortality.⁶⁵⁻⁶⁷ Whereas the rates of diabetes-related complications have declined substantially in the past two decades, a large burden remains because the number of diabetic patients continues to increase.⁷⁵ These complications include retinopathy with potential loss of vision; nephropathy leading to renal failure; peripheral neuropathy with risk of foot ulcers and amputations; and autonomic neuropathy causing sexual dysfunction and gastrointestinal, genitourinary, and cardiovascular symptoms. Hypertension and atherosclerosis in diabetics promote peripheral arterial, cardiovascular, and cerebral vascular disease in these patients.^{70,76}

Cardiovascular disease is markedly increased in patients with DM and is the leading cause of diabetes-related deaths.^{65,66,77} Arterial thrombotic lesions in the diabetic population are widely distributed in the extremities, kidneys, eyes, skeletal muscle, myocardium, and nervous system. Owing to these diffuse lesions, diabetes, especially poorly controlled DM, carries a serious risk for the development of microvascular (e.g., nephropathy, retinopathy, neuropathy) and macrovascular (e.g., atherosclerosis, stroke, coronary artery disease, myocardial infarction [MI]) complications.⁷⁶⁻⁷⁸

The incidence of circulatory insufficiency to the legs and feet is greater in diabetic men and women compared with their nondiabetic counterparts. As a result, approximately 60% of nontraumatic lower-limb amputations in adults occur in people with diabetes.⁶⁵ Not surprisingly, lower-extremity bypass grafting and amputations are more common surgical procedures in the diabetic population.

Cardiomyopathy in diabetic patients is independent of coronary artery disease and often progresses to impaired myocardial relaxation and ultimately diastolic dysfunction.⁷⁹ Systolic dysfunction, decreased ejection fraction, and heart failure may occur with severe and longstanding disease. Guidelines for cardiovascular evaluation of patients for noncardiac surgery, published by The American College of Cardiology/American Heart Association, recognize diabetes as an intermediate clinical predictor

of perioperative cardiovascular risk.⁸⁰

Furthermore, more than 70% of diabetic individuals have a medical history of hypertension, a rate of occurrence two to three times that for nondiabetic individuals. The risk of stroke is 1.5 times higher in people with diabetes, and their recovery rate after a stroke is poor.⁶⁵ Glucose-induced vasodilation further complicates an organ's ability to defend against an increase in systemic blood pressure.

The eyes are vulnerable to vascular disease because of the dense network of capillary vessels in the retina. Individuals with DM are 25 times more likely to be legally blind than individuals without DM.⁵⁹ Diabetic retinopathy is characterized by microaneurysm formation, swelling and narrowing of retinal blood vessels, and neovascularization. These vascular lesions may result in vitreous hemorrhage and retinal scarring or detachment. Loss of vision from diabetic retinopathy is the leading cause of new cases of blindness in people aged 20 to 74 years in the United States.^{65,81}

Diabetic renal disease is the leading cause of kidney failure in the United States.^{59,65,81} The nephropathy may be caused by hemodynamic alterations, inflammation, and thickening of the glomerular capillary basement membrane and other structural changes in the glomerulus.⁵⁹ Renal insufficiency or chronic renal failure is often the end result.

The diabetic process also interferes with normal nerve function. Diabetic neuropathy occurs in over 50% of individuals with longstanding disease.^{59,66} Both the peripheral and autonomic nervous systems may be involved. Resting tachycardia is a common manifestation of cardiac autonomic neuropathy and it occurs at a relatively early stage of the disease. A heart rate of 90 to 130 beats/min may be observed and is associated with vagal denervation. Postural hypotension and blunted autonomic reflexes is common in the diabetic with autonomic neuropathy. Orthostatic hypotension occurs as a result of the impairment of the sympathetic response to postural change and abnormalities in baroreceptor sensitivity. Manifestations of orthostatic hypotension may include postural syncope, dizziness, and lightheadedness.^{82,83}

Diabetic patients with autonomic neuropathy are at increased risk for developing painless myocardial ischemia. The possibility of

an MI should be considered in the patient with a history of unexplained hypotension or dyspnea.^{82,83}

Other signs of autonomic neuropathy in the diabetic patient include early satiety, impaired bladder control, lack of sweating, impotence, and nocturnal diarrhea.^{66,67,73} The patient with diabetic autonomic neuropathy has impaired gastric emptying and is at risk for aspiration of stomach contents in the perioperative period.^{84,85}

Box 37.5 summarizes major chronic complications of DM.

Chronic Complications of Diabetes Mellitus

Microvascular

- Retinopathy
- Neuropathy (sensory, autonomic, motor)
- Nephropathy

Macrovascular

- Coronary artery disease
- Peripheral vascular disease
- Cerebrovascular disease

Other

- Infection
- Cataracts
- Stiff joint syndrome
- Glaucoma
- Poor wound healing

There is a strong relationship between long-standing hyperglycemia of diabetes and end-organ diseases, especially with type 1 DM. The hemoglobin A1C (HbA1C), or glycosylated hemoglobin level, provides an estimate of the patient's overall plasma glucose control during the past 2 to 3 months. A HbA1C value of less than 7.0% has been shown to prevent microvascular complications of retinopathy and nephropathy in adults, but whether it prevents macrovascular outcomes remains unclear.^{59,64,86}

Anesthetic Management of the Diabetic Patient

The American Diabetes Association conservatively estimates that 12% to 25% of hospitalized adults have DM, and that an estimated 25% to 50% of diabetic patients will require surgery.⁶⁴ Diabetes is the most common endocrine disorder encountered in surgical patients. As discussed, long-standing diabetes predisposes the patient to many disorders that may require surgical intervention. Cataract extraction, kidney transplantation, ulcer debridement, coronary artery bypass grafting, and vascular repair are some of the operations frequently performed on diabetic patients.

Diabetic patients have higher morbidity and mortality in the perioperative period compared with nondiabetics of similar age.⁶⁴ Increased complications may be the result of comorbidities associated with long-term disease or poor patient glycemic control.

Preoperative Considerations

The diabetic patient may come to the operating room with a spectrum of metabolic aberrations and end-organ complications that warrant careful preanesthetic assessment.

The presence of hypertension, coronary artery disease, or autonomic nervous system dysfunctions can result in a labile cardiovascular course during anesthesia. It is essential that the cardiovascular and volume status of the patient be thoroughly evaluated before surgery. A recent EKG is advised for all adult diabetic patients because of the high incidence of cardiac disease.⁸²⁻⁸⁴

Autonomic nervous system dysfunction may result in delayed gastric emptying, making these patients prone to aspiration, nausea

and vomiting, and abdominal distention. Preoperative aspiration prophylaxis with gastroprokinetic agents is recommended for patients with a prolonged history of poor glycemic control.^{8,78,85} The incretin mimetics agents prolong gastric emptying and this effect may warrant additional considerations when determining preoperative gastric aspiration prophylaxis for patients on these drugs. Control of the airway with intubation is a safe choice for the patient with gastroparesis undergoing general anesthesia.

Patients with significant autonomic neuropathy may have an impaired respiratory response to hypoxia. These patients are especially sensitive to the respiratory-depressant effects of sedatives and anesthetics and require particular vigilance in the perioperative period.^{8,11} Autonomic neuropathy contributes to a diminished thermoregulatory response to hypothermia requiring careful monitoring of core temperature.⁷⁸ Peripheral neuropathies (e.g., paresthesias, numbness in the hands and feet) should be adequately documented in the preanesthetic evaluation. Their presence may affect the decision to use regional anesthesia. Neuraxial blockade may exacerbate neural deficits in patients with diabetic polyneuropathy.⁸⁷

Glycosylation of tissue proteins and the development of periarticular thickening of the skin may produce a “stiff-joint syndrome” in diabetics, especially those with type 1 DM of long duration.⁸⁸ An estimated 68% of patients with type 1 DM demonstrate restricted joint mobility.^{11,88} Limited motion of the atlantooccipital and temporomandibular joints can make endotracheal intubation in diabetic patients more difficult compared with nondiabetic patients.^{89,90} Demonstration of the “prayer sign,” an inability to approximate the palms of the hands and fingers, may help identify patients with tissue protein glycosylation and potentially difficult airways.

Evidence of kidney disease should be sought, and basic tests of renal function (urinalysis, serum creatinine, blood urea nitrogen) evaluated preoperatively. The presence of renal impairment may influence the choice and dosage of anesthetic agents, and potentially nephrotoxic drugs should be avoided.^{84,91}

The anesthetist should examine the patient's history of glycemic control, including the FPG level on the morning of surgery, to

ensure preoperative optimization of the patient's metabolic state.⁹² Sustained hyperglycemia with attendant osmotic diuresis should alert the anesthetist to possible fluid deficits and electrolyte depletion. Preoperative electrolyte levels should be evaluated.

An important part of the preoperative evaluation is a review of oral hypoglycemic and insulin regimens.

Oral Glucose-Lowering Agents.

Oral glucose-lowering agents and insulin are used as adjuncts to diet therapy and exercise for treating type 2 DM. Currently available oral hypoglycemic agents fall into the following major classifications: (1) biguanides, (2) sulfonylureas, (3) meglitinides, (4) thiazolidinediones, (5) glucagon-like peptide 1 (GLP-1) agonists, (6) DPP-4 inhibitors, (7) α -glucosidase inhibitors, (8) sodium-glucose co-transporter-2 (SGLT2) inhibitors, and others.⁹³ Most patients with type 2 DM require multiple drugs to achieve glycemic control. [Table 37.5](#) outlines medications commonly used to treat type 2 DM. The goal of drug therapy for type 2 diabetes is to achieve and maintain a near-normal glycated hemoglobin (A1C) concentration without inducing hypoglycemia; the target is generally an A1C of <7% or <8% in older patients.

TABLE 37.5
Oral Drugs for Type 2 Diabetes

Drug Class (A1C Reduction)	Mechanism	Adverse Effects
Biguanide (1%–1.5%) Metformin (Glucophage) Metformin extended release	Decreases hepatic glucose production and increases peripheral insulin sensitivity	B12 deficiency; gastrointestinal effects; rare lactic acidosis
Sulfonylurea (1%–1.5%) Glimepiride (Amaryl) Glipizide (Glucotrol), Glyburide (DiaBeta, Micronase)	Increases insulin production and secretion by pancreatic β cells and increases peripheral insulin sensitivity	Hypoglycemia; weight gain; possible aggravation of myocardial ischemia
Meglitinide (0.5%–1%) Nateglinide	Increases insulin production and secretion by pancreatic β cells	Hypoglycemia; weight gain; must be taken before each meal

(Starlix) Repaglinide (Prandin)		
Thiazolidinedione (1%–1.5%) Pioglitazone (Actos) Rosiglitazone (Avandia)	Decreases hepatic glucose production and increases insulin sensitivity of adipose, muscle and liver cells	Increased risk of heart failure (contraindicated in NYHA class III or IV heart failure), weight gain, decrease bone mineral density and fractures, hepatotoxicity, bladder cancer
GLP-1 Receptor Agonist (1%–1.5%) (“Incretin Mimetics”) Exenatide (Byetta, Bydureon) Liraglutide (Victoza) Albiglutide (Tanzeum) Dulaglutide (Trulicity) Lixisenatide (Lyxumia)	Potentiates insulin release, lowers serum glucagon levels, slows gastric emptying and promotes satiety	Only available via subcutaneous injection; nausea; vomiting; acute renal failure; acute pancreatitis; should not be used in patients with gastroparesis; medullary thyroid C-cell cancer in animals
DPP-4 Inhibitor (0.5%–1%) Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin (Tradjenta) Alogliptin (Nesina)	Inhibits metabolism of endogenously released incretin hormones. Potentiates insulin release, lowers serum glucagon levels, slows gastric emptying and promotes satiety	Hypersensitivity reactions (urticarial, angioedema, anaphylaxis, Stevens-Johnson syndrome, vasculitis); acute pancreatitis; fatal hepatic failure; long-term safety unknown
Alpha-Glucosidase Inhibitor (0.5%–1%) Acarbose Miglitol	Blocks the intestinal enzymes that digest starches into absorbable monosaccharides, resulting in slower and lower rise in postprandial plasma glucose	Abdominal pain; diarrhea; flatulence; contraindicated in patients with intestinal disease
SGLT2 Inhibitor (0.5%–1%) Canagliflozin (Invokana) Dapagliflozin (Farxiga) Empagliflozin (Jardiance)	Blocks the transport of glucose from the proximal renal tubule, decreasing renal glucose reabsorption and increasing glucose excretion	Genital mycotic infections; recurrent urinary tract infections; volume depletion; hypotension; hyperkalemia; hypomagnesemia; hyperphosphatemia; fractures; cardiovascular and long-term safety unknown

DPP-4 inhibitor, Dipeptidyl-peptidase-4 inhibitor; *GLP-1*, glucagon-like peptide.

Modified from Drugs for Type 2 Diabetes. *Med Lett Drugs Ther.*

2017;59(1512):9–18.

Metformin, a biguanide, decreases hepatic glucose production and increases peripheral insulin uptake. Metformin is generally preferred as the first-line oral hypoglycemic agent and is available in fixed-dose combinations with many other glucose lowering

drugs.⁹⁴ Lactic acidosis has been reported in surgical patients taking metformin, and some recommend that metformin be discontinued 24 hours or more prior to surgery.^{95,96} Impaired renal function, liver failure, major surgery, heart failure and alcoholism may increase the risk of lactic acidosis. Alternatively, perioperative administration of metformin has been reported without increased risk of adverse outcomes.⁹⁷ Furthermore, a Cochrane Database systematic review concluded that there was no evidence from prospective comparative trials or from observational cohort studies that metformin was associated with an increased risk of lactic acidosis, compared to other antihyperglycemic treatments.⁹⁸

Sulfonylurea agents increase the secretion of insulin from the pancreas and thus require the presence of functioning β cells. Persistent and severe hypoglycemia is a possible adverse effect of sulfonylureas.

Meglitinides, or nonsulfonylurea secretagogues, increase insulin production by pancreatic β cells in a manner similar to the sulfonylureas.^{59,93} Multiple daily doses are required. Hypoglycemia is a possible adverse effect of meglitinides.

Thiazolidinedione derivatives lower blood glucose levels in patients with type 2 DM by decreasing hepatic glucose production and by increasing the insulin sensitivity of adipose tissue, skeletal muscle and the liver.⁹³ Thiazolidinediones have been associated with cardiac problems and liver failure. A meta-analysis found increased risk of MI with rosiglitazone, but a randomized controlled trial (Rosiglitazone evaluated for cardiovascular outcomes in oral agent combination therapy for type 2 diabetes [RECORD]) subsequently showed no significant increased risk of MI, stroke, or cardiovascular death compared to metformin or sulfonylurea. Restrictions that were placed on rosiglitazone in 2010 because of concern about its cardiovascular safety have been lifted (November 2013, US Food and Drug Administration [FDA]).

GLP-1 receptor agonists are approved for treatment of patients with type 2 DM and are only available via subcutaneous injection. This class of drugs, called *incretin mimetics*, potentiates insulin release, lowers serum glucagon levels, slows gastric emptying and promotes satiety. The first GLP-1 receptor agonist, exenatide, was derived from the saliva of the gila monster, a lizard which eats only

five to ten times a year in the wild. The GLP-1 receptor agonists dulaglutide, exenatide, and albiglutide are approved as once-weekly treatment for type 2 DM. The FDA has issued a boxed warning about the risk of thyroid C-cell tumors for patients taking GLP-1 agonists.⁹⁹

DPP-4 inhibitors are oral agents that inhibit the destruction of incretin mimetics by blocking the dipeptidyl peptidase-4 enzyme responsible for GLP-1 degradation. The long-term safety of inhibiting DPP-4, which degrades not only incretin hormones but also cytokines and other peptides, is unknown. Both GLP-1 receptor agonists and DPP-4 inhibitors have been linked to acute pancreatitis.⁹⁹

α -Glucosidase inhibitors block the intestinal enzymes that digest starches into absorbable monosaccharides, resulting in a slower and lower rise in postprandial plasma glucose.

SGLT2 inhibitors block the transport of glucose from the proximal renal tubule, decreasing renal glucose reabsorption and increasing glucose excretion. Because of their diuretic effect, these agents may lead to dehydration, hypovolemia, and hypotension, particularly in the elderly patient with renal dysfunction. Cardiovascular side effects and an increased risk of fractures have also been reported.¹⁰⁰ The FDA has warned that the use of SGLT2 inhibitors may lead to ketoacidosis in some patients.¹⁰¹

Pramlintide (Symlin) is an injected antihyperglycemic medication for use in patients with type 2 or type 1 DM who use insulin. It is a synthetic analog of human amylin, a naturally occurring hormone synthesized from pancreatic β cells and normally cosecreted with insulin. Amylin, similar to insulin, is absent or deficient in patients with DM and its administration contributes to glucose control during the postprandial period.⁹³

Insulin Preparations.

Insulin preparations are generated today by DNA recombinant technology, mimicking the amino acid sequence of human insulin. Most insulin formulations in the United States are prepared as U-100 (100 international units [IU]/mL). A current exception to this concentration is the concentrated form of insulin glargine (Toujeo), which contains 300 IU/mL, instead of insulin glargine (Lantus) at

100 IU/mL.¹⁰² An inhaled rapid-acting insulin (Afrezza) was approved by the FDA in 2015 for treatment of patients with type 1 and type 2 DM. Afrezza produces peak insulin activity in approximately 60 minutes. Cough and throat irritation is a common side effect and the long-term pulmonary safety of inhaling insulin is unknown.^{67,103}

Insulin preparations differ in onset and duration based on delivery methods. In addition to subcutaneous bolus injections, insulin delivery devices (e.g., implantable pumps, mechanical syringes) are used to facilitate exogenous administration. Regular insulin is most often used for intravenous administration. The greatest risk with all forms of insulin is hypoglycemia.

Protamine is added to some insulins to prolong their effect. Protamine containing insulins (e.g., neutral protamine Hagedorn, protaminated insulin aspart) may cause sensitization by stimulating antibodies against protamine sulfate. In patients taking protamine containing insulins, particular care must be exercised (slow and titrated doses) to monitor for hypersensitivity reactions when administering protamine sulfate to reverse the coagulation effects of heparin. The available insulins can be divided on a pharmacokinetic basis into three broad categories: rapid acting, intermediate acting, and long acting (Table 37.6).

TABLE 37.6
Pharmacokinetic Properties of Insulin Preparations

Insulin Type	Onset	Peak	Duration
Rapid-Acting			
Aspart (Novolog)	15 min	1 hr	3–4 hr
Lispro (Humalog)	15 min	1 hr	3–4 hr
Glulisine (Apidra)	15 min	1 hr	3–4 hr
Regular (Humulin R, Novolin R)	30–60 min	2–4 hr	6–8 hr
Intermediate-Acting			
NPH	1–3 hr	6–8 hr	12–16 hr
Long-Acting			
Detemir (Levemir)	1 hr	3–9 hr	6–24 hr
Glargine (Lantus) U-100	1 hr	No peak	29 hr
Glargine (Toujeo) U-300	1 hr	12–16	32–34 hr

Time course is based on subcutaneous administration.

Adapted from Atkinson M. Type 1 Diabetes Mellitus. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, eds. *William's Textbook of Endocrinology*. Philadelphia: Elsevier; 2016:1452–1483.

It is imperative to know the surgical patient's normal insulin dosage regimen and their treatment compliance. Many diabetic patients are on a regimen of long-acting insulin at bedtime and rapid-acting insulin analogues given with meals (“basal-bolus regimen”). Rapid acting insulins, such as lispro, aspart, and glulisine have an onset of action of 1 hour or less and are used to reduce glycemia that occurs after meal ingestion.⁶⁷ Long-acting insulins, including glargine, detemir, and degludec, have delayed absorption from subcutaneous tissue and prolonged effects. They are titrated to produce a steady, basal insulin level through the night.^{67,104}

Continuous subcutaneous insulin infusion (CSII) is increasingly used by motivated patients desiring an optimal physiologic regimen.¹⁰⁵ These infusion pumps administer rapid-acting insulin through a catheter that is usually inserted into the subcutaneous tissues of the anterior abdominal wall. The pump delivers a basal insulin infusion (usually approximately 0.5 to 1 unit/hr) and can be programmed to increase and decrease at predetermined times of the day.⁶⁷

Intraoperative Management

Diabetic patients represent a heterogeneous group requiring individualized perioperative care. The diabetic surgical patient's operation should be scheduled early in the day if possible to minimize disruptions in treatment and nutrition regimens. The specific approach to management depends on the type of diabetes (type 1 or type 2), the history of glycemic control, the presence of comorbidities, and the type and length of surgery. No specific anesthetic technique is superior overall for diabetic patients. Both general anesthesia and regional anesthesia have been used safely.

Focus on the cardiovascular system should be a major component of anesthesia care. Silent myocardial ischemia and infarction is more common in the diabetic patient and the incidence of MI is higher in the postsurgical diabetic patient. Cardiovascular autonomic neuropathy contributes to hemodynamic instability and may complicate the anesthetic course. Indeed, the neurovascular compensatory mechanisms to anesthesia-induced vasodilation may

be impaired, requiring the use of vasoactive drugs.^{82,83}

Special care must be taken in positioning and padding the diabetic patient on the operating table. Decreased tissue perfusion and peripheral sympathetic neuropathy may contribute to the development of skin breakdown and ulceration.

Surgery, particularly major surgery, produces a catabolic stress response and elevates stress-induced counterregulatory hormones.^{11,62,63,106} In the diabetic patient, the hyperglycemic, ketogenic, and lipolytic effects of the counterregulatory hormones compound the state of insulin deficiency. For this reason, perioperative hyperglycemia and other metabolic aberrations are common in the surgical diabetic patient and may be more difficult to manage.^{84,92,106}

Frequent blood glucose determinations are an integral part of any diabetic management technique. An accurate and rapid means of monitoring blood glucose levels should be available. The practitioner should be aware that point-of-care testing devices using capillary blood measures can vary by 20%, especially during periods of hypotension and poor tissue perfusion.¹⁰⁶⁻¹⁰⁸ Point-of-care monitoring is sufficient for stable patients, but a higher threshold for hypoglycemia and more frequent monitoring may be indicated to ensure patient safety.⁹² Arterial blood gas analysis and central laboratory measurement of blood glucose remain the gold standard, and aberrant glucose values should be verified by the central lab.¹⁰⁷ During a long surgical procedure or for major surgery, frequent (at least hourly) intraoperative blood glucose measurement is the prudent course, especially for a brittle diabetic patient.

Preoperative hyperglycemia is associated with perioperative morbidity.^{92,109-111} Not surprisingly, high intraoperative blood glucose levels are associated with higher postoperative blood glucose levels.¹⁰⁹ Persistent hyperglycemia (preoperative HbA1C > 6.7, postoperative blood glucose > 200 mg/dL) has been shown to impair wound healing and wound strength.¹¹² In addition, reports suggest that postoperative infection is more prevalent in diabetic patients with uncontrolled blood sugar levels.^{113,114} Studies also provide evidence that hyperglycemia worsens the neurologic outcome after ischemic brain injury.^{92,115-118}

Avoiding hyperglycemia in the perioperative period is advisable; however the risks of intensive insulin therapy (IIT) were highlighted in the landmark international trial, Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR), which questioned the safety of IIT.¹¹⁹ Since then, several studies have demonstrated that aggressive glucose control, with near normal blood glucose targets, produced no survival benefit and a higher incidence of hypoglycemia and even death in surgical and critically ill patients.¹²⁰⁻¹²⁴ Symptoms of hypoglycemia are difficult to recognize in the anesthetized or sedated surgical patient, and its presence can produce irreversible neurological sequelae.

Various regimens have been tendered on how to best manage the metabolic changes that occur in the surgical diabetic patient.^{8,106,120,125-130} The universal goal with all techniques is to avoid hypoglycemia and minimize metabolic derangements associated with marked hyperglycemia. Experts differ on optimal protocols for case management.^{91,125-128} It is also not clear what level of glycemic control is associated with the best risk/benefit ratio. With these caveats considered, current recommendations target a blood glucose range of 140 to 180 mg/dL in the perioperative period.^{84,129} Mild transient hyperglycemia prevents the poor outcomes associated with severe hyperglycemia and avoids the potentially catastrophic effects of hypoglycemia.^{8,91,106,123,129,130} Frequent blood glucose determinations during surgery and in the immediate postoperative period are central to safe practice.^{106,127,128}

Current recommendations regarding insulin use in the perioperative period include adjustments to the patient's usual insulin regimen based on the length of surgery, the type of surgery and the degree of glycemic control.^{84,92,106,129,131} Common protocols include administration of 80% to 100% of the patient's usual long-acting subcutaneous insulin dose on the evening before surgery. If the patient normally receives a morning dose of long-acting insulin, some protocols recommend that on the day of surgery 50% of the patient's usual long-acting insulin dose be given subcutaneously to provide basal insulin needs. The patient's usual doses of rapid-acting and short-acting insulins are held on the day of surgery. Patients should arrive to the admitting area early enough to have

their FPG level monitored and to determine the need for IV dextrose (5% dextrose in water, 75 to 200 mL/hr).⁸⁴

Alternatively, and especially for critically ill patients and long surgical procedures, a separate and continuous IV insulin infusion can be used to meet basal metabolic requirements, combined with IV bolus injections as needed.^{84,106,129,132} Effective insulin infusion protocols (usually 0.5 to 2 units/hr), are assiduously titrated to frequent blood glucose determinations.

Sliding scale administration of bolus short-acting insulin as the sole glucose management technique is associated with roller coaster-like swings in blood glucose levels, termed *glucose variability*, and correlates with poor outcomes in various populations.^{92,129,133,134}

For surgical patients who are well-controlled on CSII, the pump can be continued into the perioperative period and programmed to deliver a basal insulin dose, with adjustments based on frequent serial blood glucose measurements.^{129,130,135–137} For longer surgical procedures (lasting longer than 2 hours), some experts recommend that the pump be discontinued and a continuous insulin infusion implemented for the perioperative period.^{129,136}

Patients treated with oral hypoglycemic agents demand the same individualized perioperative management as those with type 1 diabetes, although their metabolic course is typically more stable. The duration of action of the patient's oral agent must be noted. Sulfonylurea and meglitinide agents stimulate insulin secretion and hypoglycemia is a particular concern with these agents during periods of fasting.¹⁰⁶ For the well-controlled surgical patient with type 2 DM, most authors recommend holding the patient's oral hypoglycemic or noninsulin injectable medication the day of surgery.^{84,92,106} Special consideration may focus on those patients receiving metformin and holding the drug 24 to 48 hours before surgery, particularly if the patient has renal dysfunction or will be receiving radiocontrast dye.^{92,106}

Regardless of the technique chosen, central to any management plan is assessing plasma glucose frequently and regularly.¹³⁸

Acute Derangements in Glucose Homeostasis

Hypoglycemia

Hypoglycemia is encountered more often in the diabetic patient than in the nondiabetic patient, and it can develop insidiously during the perioperative period. Insulin and oral glucose lowering agents (especially sulfonylureas and meglitinides) are drugs that are potential causes of hypoglycemia in the surgical diabetic patient. Approximately 90% of all patients with DM who receive insulin have had a hypoglycemic episode.¹³⁹ Liver disease (impaired hepatic glucose output and impaired insulin metabolism), the altered physiology associated with gastric bypass surgery, or an insulin-secreting tumor of the islets of Langerhans (insulinoma) are conditions that are complicated by hypoglycemia. Renal failure is associated with hypoglycemia due to prolonged insulin clearance.¹³¹

Hypoglycemia is defined by the American Diabetes Association as blood glucose values less than 70 mg/dL.^{64,65} The blood glucose concentration at which signs and symptoms of hypoglycemia appear varies widely from one person to the next, but blood glucose levels in the range of 45 to 50 mg/dL commonly produce symptoms in the otherwise healthy patient.^{57,138} Because the brain relies on glucose for energy requirements, it is most sensitive to glucose deprivation.^{57,58,138} Manifestations of impaired cerebral function (e.g., confusion, dizziness, headache) are associated with glucose lack. As the blood sugar level declines below 50 mg/dL, aberrant behavior, seizures, and loss of consciousness may occur. Other signs of hypoglycemia (e.g., tachycardia, diaphoresis, anxiety, tremors, piloerection, pupillary dilation, and vasoconstriction) reflect sympathetic-adrenal hyperactivity.⁵⁷

Acute treatment for the hypoglycemic surgical patient is administration of 10 to 25 g IV of 50% dextrose (20–50 mL). Blood glucose measurement should be repeated after 15 minutes with an additional glucose bolus if needed and initiation of a glucose infusion of 5% dextrose.^{11,59,92} The goal is to achieve a blood glucose level greater than 100 mg/dL.⁸⁴ Unless prompt glucose therapy is provided, irreversible brain damage may result.

Hypoglycemia is potentially catastrophic during surgery because most of the neurologic symptoms of glucose lack are masked by sedation and general anesthesia. Signs of sympathetic adrenal

discharge also may be blunted by general anesthesia or severe diabetic autonomic neuropathy, making the diagnosis of hypoglycemia extremely difficult. β -Adrenergic receptor blocking agents can reduce the hyperglycemic effects of epinephrine, in addition to diminishing the symptomatic warning signs of hypoglycemia.^{58,59,138} Frequent blood glucose determinations, maintenance of mild hyperglycemia, and diligent monitoring help to avoid this feared complication during anesthesia.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is a condition in which insulin deficiency leads to the biochemical triad of hyperglycemia, ketonemia, and acidemia.^{67,81} DKA is triggered by a hyperglycemic event, usually in a patient with type 1 DM. Noncompliance with insulin therapy, critical illnesses (e.g., MI, trauma, cerebral vascular accident, burns), and infections are common precipitants of DKA.¹⁴⁰ The FDA has warned that SGLT2 inhibitors may cause ketoacidosis in patients with type 2 DM.¹⁴¹

As described earlier, stressful events stimulate the release of hyperglycemic counterregulatory hormones. The patient with type 1 DM is unable to secrete insulin to counterbalance the serum elevations of glucose, free fatty acids, and ketone bodies produced by these stress-induced hormones. Unless exogenous insulin is provided, the glycemic event may progress over hours to a few days to severe ketoacidosis, dehydration, and acute metabolic decompensation.⁶⁷

Patients with DKA classically present with hyperglycemia (> 250 mg/dL), tachycardia, metabolic acidosis (arterial pH commonly < 7.3), a calculated anion gap greater than 10 to 20 mEq/L, electrolyte depletion, hyperosmolarity (> 300 mOsm/L), nausea, abdominal pain, and lethargy.^{59,67} Large fluid deficits, on the order of 5 to 10 L, are common in DKA.⁶⁷ Blood levels of ketone bodies (beta-hydroxybutyrate, acetoacetate, and acetone) are elevated, and the patient's breath may have a fruity odor from excess acetone production. Lactic acidosis secondary to poor perfusion may compound the ketoacidosis. The respiratory center is typically stimulated by the low plasma pH, resulting in rapid, deep breathing (Kussmaul respiration). Acidosis, hyperosmolarity, and

dehydration may depress consciousness to the point of coma.^{59,67,140} Hypotension, and tissue catabolism may also be present. Patients have decreased total body potassium levels, but because of the acidosis and insulin-lack, serum potassium is low. As the acidosis is corrected and with insulin administration, potassium moves into cells and the serum levels can decline abruptly.⁶⁷ Fig. 37.15 outlines the pathophysiologic events leading to DKA.

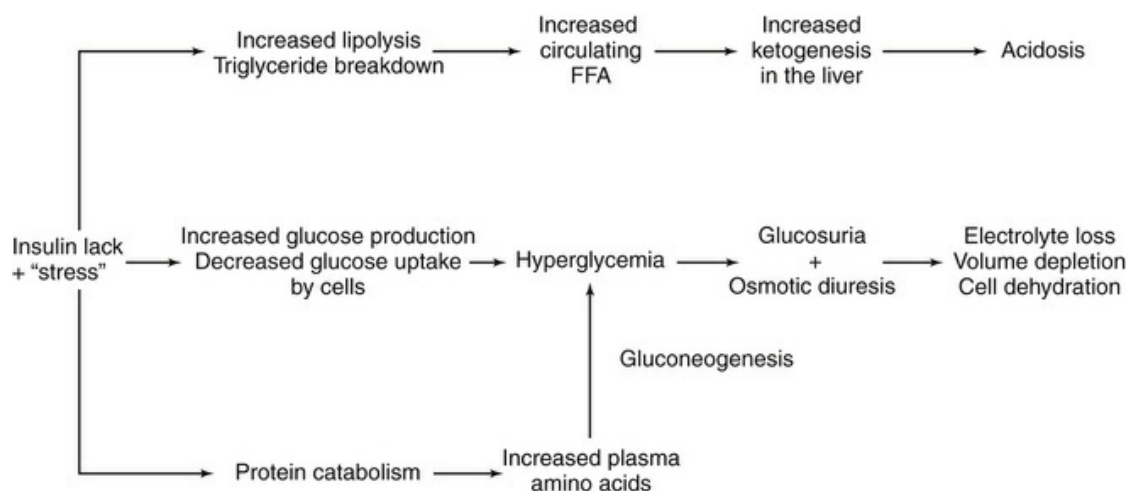

FIGURE 37.15 Substrate flow with diabetic ketoacidosis. FFA, Free fatty acid.

Gangrene and infection of an ischemic lower extremity are common surgical conditions associated with DKA. Preoperative management of the emergency surgical patient with DKA requires an aggressive approach to restore intravascular volume, correct electrolyte abnormalities, improve acid-base balance, and treat insulin deficiency.^{59,140} Early invasive hemodynamic monitoring should be considered.⁶⁷ The airway must be protected in the obtunded patient. Elective surgery for a patient in an unstable metabolic state such as DKA is not recommended; however, in a stabilized patient with DKA, once the surgical problem that initiated DKA has resolved, medical management is often more effective.^{8,84}

Hyperglycemic Hyperosmolar State

Hyperglycemic hyperosmolar state (HHS), or hyperosmolar nonketotic coma, is a life-threatening hyperosmolar condition

triggered by a hyperglycemic event. This syndrome commonly occurs in elderly patients with type 2 DM, but it also develops in patients with no history of diabetes. Patients generally have some endogenous insulin secretion, but the hyperglycemic episode overwhelms the pancreas and produces severe hyperglycemia and glucosuria.^{59,140} The amount of insulin secreted is usually sufficient to prevent lipolysis and ketone production. Therefore, unlike DKA, this syndrome is not usually associated with significant ketoacidosis, but poor perfusion can result in lactic acidosis. [Table 37.7](#) compares common features of DKA and HHS.

TABLE 37.7

Features of Diabetic Ketoacidosis (DKA) and Hyperglycemic Hyperosmolar Syndrome (HHS)

	DKA	HHS
Plasma glucose	Greater than 250 mg/dL	Greater than 600 mg/dL
pH	Less than 7.3	Greater than 7.3
Serum bicarbonate	Less than 18 mmol/L	Greater than 15 mmol/L
Serum osmolarity	+	++
Ketonemia	+	Normal or slightly elevated
Mental obtundation	Variable	Present
Hypovolemia	Present	Present
Serum potassium	Normal or slight +	Normal

⁺, Increase; ⁺⁺, large increase.

Common precipitating factors of HHS include infection, sepsis, pneumonia, stroke, and MI.^{59,140}

A spectrum of symptoms is associated with HHS, culminating in mental confusion, lethargy, and coma.^{59,140} Profound dehydration is present (average total body water deficit 9 L), resulting in increased plasma viscosity, hypotension, and tachycardia. Laboratory evaluation may reveal a biochemical profile of marked hyperglycemia, absent or minimal ketonemia, and hyperosmolarity (> 330 mOsm/L).^{59,140} Arterial and venous thromboembolic events are common. As with DKA, despite depleted total body potassium stores, the serum potassium levels at presentation may be normal or elevated due to acidosis and insulin-deficiency. Even with appropriate treatment, the mortality figures for HHS are substantially higher (15%) than those for DKA (less than 5%), in part because HHS commonly affects an older patient population,

often with accompanying comorbidities.^{11,59,140}

Treatment goals for DKA and HHS are similar and include identification and management of the precipitating problem, vigorous isotonic rehydration, correction of hyperglycemia with insulin, and electrolyte replacement.^{59,140} Hazards inherent in aggressive fluid administration include cerebral edema and heart failure. Especially in the elderly patient, this dictates central hemodynamic monitoring during treatment.

Adrenal Glands

The adrenal glands are located at the superior poles of each kidney and consist of two distinct anatomic and physiologic entities, the adrenal cortex and the adrenal medulla. The adrenal medulla comprises the central 20% of the adrenal gland and primarily secretes the hormones epinephrine and norepinephrine. The adrenal cortex constitutes the outer part of the adrenal gland and secretes three main types of hormones: mineralocorticoids (e.g., aldosterone), glucocorticoids (e.g., cortisol), and androgenic hormones (e.g., dehydroepiandrosterone).¹⁴²

Adrenal Cortex

The adrenal cortex is composed of three layers, each having distinct properties. The zona glomerulosa is the outermost tissue of the cortex; it secretes mineralocorticoid hormones, primarily aldosterone. The zona fasciculata is the middle layer; it secretes primarily the glucocorticoid hormones cortisol and corticosterone. The zona reticularis is the innermost layer of the adrenal cortex; it secretes primarily adrenal androgenic hormones.^{142,143} (Fig. 37.16). The adrenal androgens, of which dehydroepiandrosterone is the most important, have effects similar to the male sex hormone testosterone and account for secondary sexual characteristics in females.¹⁴² The glucocorticoids and mineralocorticoids are discussed in more detail in the following sections.

FIGURE 37.16 Histology of the adrenal gland. Higher magnification clearly illustrating the zonation of the cortex. The corresponding endocrine function and the different zones of the cortex and the medulla are noted. *DHEAS*, Dehydroepiandrosterone sulfate. (In Koeppen BM, Stanton BA. *Berne and Levy Physiology (Updated)*. 7th ed. Philadelphia: Elsevier; 2017:768. Modified from Young B, Woodford P, O'Dowd G. *Wheater's Functional Histology*. 6th ed. Philadelphia: Elsevier; 2014:328.)

Hormones Secreted From the Adrenal Cortex

The adrenal cortex synthesizes more than 30 types of steroid hormones. All hormones secreted from the adrenal cortex have a steroidal structure and share a common cholesterol backbone. As a group, adrenocortical hormones are termed *corticosteroids*. Corticosteroids have similar chemical structures but widely diverse functions. ^{144,145}

Glucocorticoid hormone production and release is controlled by ACTH from the anterior pituitary gland. Mineralocorticoids, on the other hand, are separately controlled by the renin-angiotensin system. These separate lines of control have important clinical consequences. Primary adrenal failure invariably produces cortisol and aldosterone deficiency, whereas ACTH deficiency from

pituitary disease produces glucocorticoid deficiency but normal aldosterone concentrations because the renin-angiotensin system is intact.¹⁴⁵

Glucocorticoids.

Cortisol (hydrocortisone) is the prototypical glucocorticoid, and it accounts for 95% of glucocorticoid activity from the adrenal cortex.¹⁴³ As previously stated, cortisol biosynthesis and secretion is largely controlled by ACTH (corticotropin). ACTH, in turn, is controlled by corticotropin releasing hormone (CRH) from the hypothalamus. Classic endocrine negative feedback loops are in place to control the secretion of both ACTH and CRH. When cortisol levels are high, the feedback system inhibits the release of ACTH from the anterior pituitary and CRH from the hypothalamus.¹⁴⁵ This powerful negative feedback circuit is known as the *hypothalamic-pituitary-adrenal (HPA) axis*. [Fig. 37.17](#) summarizes the mechanisms regulating cortisol release.

Regulation of cortisol secretion

FIGURE 37.17 Normal negative feedback regulation of cortisol. Hypothalamic-pituitary-adrenal axis. Adrenocorticotrophic hormone (ACTH) is secreted from the anterior pituitary under the influence of two principal secretagogues, corticotropin-releasing hormone (CRH) and arginine vasopressin; other factors, including cytokines, also play a role. CRH secretion is regulated by an inbuilt circadian rhythm and by additional stressors operating through the hypothalamus. Secretion of CRH and ACTH is inhibited by cortisol, highlighting the importance of negative feedback control. *ACTH*, Adrenocorticotrophic hormone; *ADH*, antidiuretic hormone; *ANP*, atrial natriuretic peptide; *CRH*, corticotropin-releasing hormone; *ECF*, extracellular fluid. (From Melmed S, et al., eds.

Williams Textbook of Endocrinology. 13th ed. Philadelphia: Elsevier; 2016:497.)

ACTH stimulates glucocorticoid hormone synthesis by activating the P450 side chain cleavage enzyme (P450_{ssc} or desmolase). Desmolase catalyzes the conversion of cholesterol to pregnenolone, the first step in corticosteroid hormone synthesis (Fig. 37.18).¹⁴⁵ In

In addition to glucocorticoid hormone synthesis, ACTH controls adrenal gland growth. ACTH deficiency results in adrenal gland atrophy.

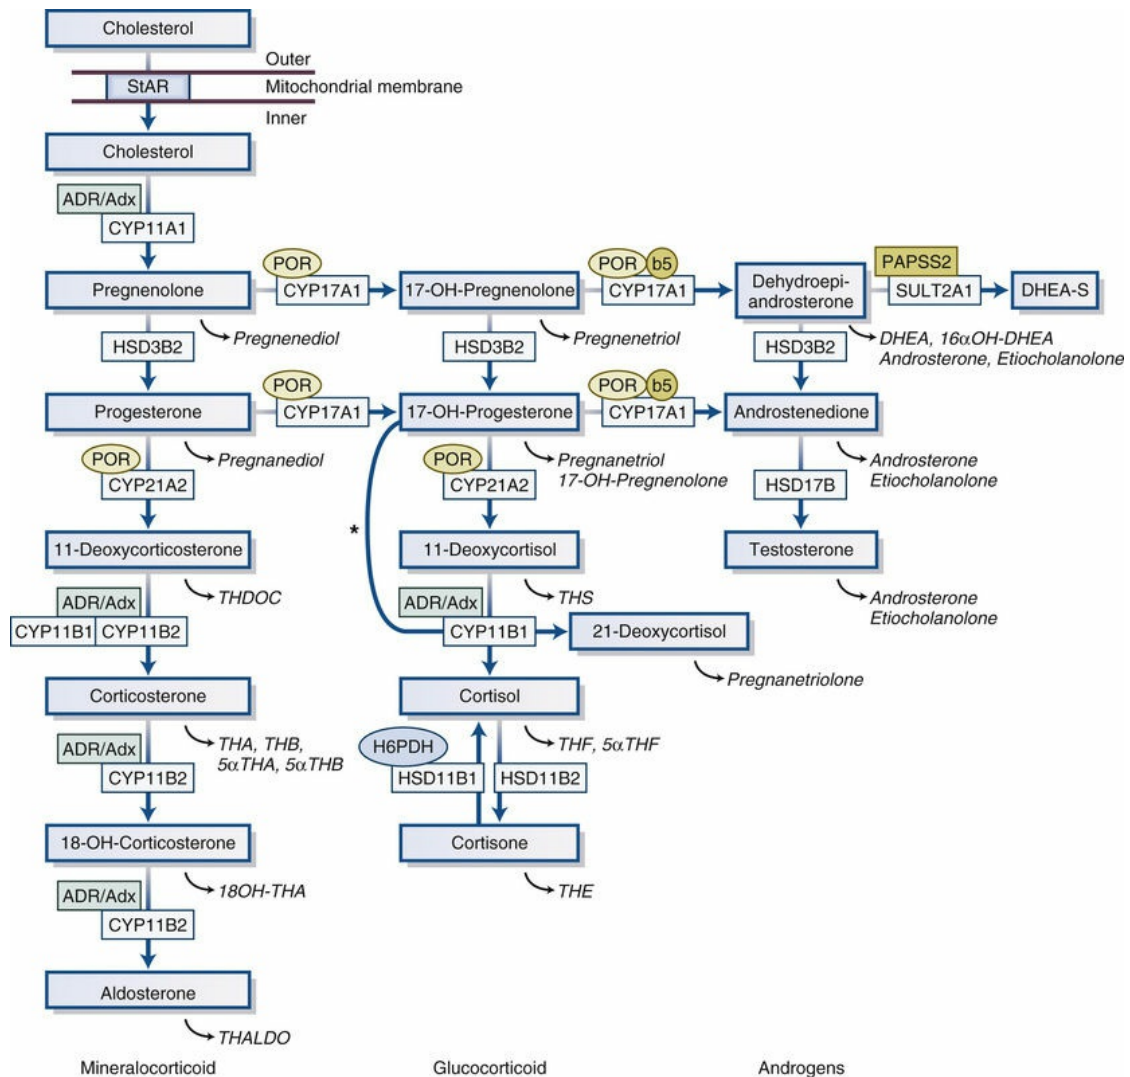

FIGURE 37.18 Adrenal steroidogenesis. After the steroidogenic acute regulatory (StAR) protein-mediated uptake of cholesterol into mitochondria within adrenocortical cells, aldosterone, cortisol, and adrenal androgens are synthesized through the coordinated action of a series of steroidogenic enzymes in a zone-specific fashion. The mitochondrial cytochrome P450 (CYP) type I enzymes (CYP11A1, CYP11B1, CYP11B2) requiring electron transfer via adrenodoxin reductase (ADR) and adrenodoxin (Adx) are marked with a *box labeled ADR/Adx*. The microsomal CYP type II enzymes (CYP17A1, CYP21A2) receive electrons from P450 oxidoreductase (*circle labeled POR*). The 17,20-lyase

reaction catalyzed by CYP17A1 requires, in addition to POR, cytochrome *b5*, indicated by a *circle labeled b5*. Urinary steroid hormone metabolites are given in italics below the plasma hormones. The asterisk (*) indicates 11-hydroxylation of 17-OH-progesterone to 21-deoxycortisol in cases of 21-hydroxylase deficiency. The adrenal conversion of androstenedione to testosterone is catalyzed by the aldo-keto reductase AKR1C3 (HSD17B5). CYP11A1, P450 side-chain cleavage enzyme; CYP11B1, 11 β -hydroxylase; CYP11B2, aldosterone synthase; CYP17A1, 17 α -hydroxylase; CYP21A2, 21-hydroxylase; DHEA, dehydroepiandrosterone; DHEA-S, dehydroepiandrosterone sulfate; H6PDH, hexose-6-phosphate dehydrogenase; HSD11B1, 11 β -hydroxysteroid dehydrogenase 1; HSD11B2, 11 β -hydroxysteroid dehydrogenase 2; HSD17B, 17 β -hydroxysteroid dehydrogenase; HSD3B2, 3 β -hydroxysteroid dehydrogenase type 2; 17-OH-progesterone, 17 α -hydroxyprogesterone; PAPSS2, 3'-phosphoadenosine, 5'-phosphosulfate synthase 2; SULT2A1, sulfotransferase 2A1; THA, tetrahydro-11-dehydrocorticosterone; THB, tetrahydro-corticosterone; THALDO, tetrahydro-aldosterone; THDOC, tetrahydro-11-deoxycorticosterone; THF, tetrahydro-cortisol; THS, tetrahydro-11-deoxycortisol. (From Melmed S, et al., eds. *Williams Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016:494.)

Secretion rates of CRH, ACTH, and cortisol follow a circadian rhythm: levels are highest in the early morning, decline throughout the day, and reach a nadir in the evening.^{142,143}

The daily cortisol production is 15 to 25 mg, and most of this is produced and released in the morning.¹⁴²⁻¹⁴⁴ Physical and mental stress increase the secretion of CRH and ACTH and typically raise cortisol production levels to more than 100 mg/day.^{142,143} Surgical stress is a potent stimulator of the HPA axis. The type of surgery and the duration of the procedure affects the amount of cortisol released. The normal cortisol blood concentration averages 12 mcg/dL, and this may increase to 30 to 50 mcg/dL during and after major surgery.¹⁴³ As noted earlier, deep general anesthesia or regional anesthesia may blunt this stress response, but does not **Box 37.6** it (Box 37.6).

Control of ACTH Hormone Secretion

Stimulation

- Corticotropin-releasing hormone
- Sleep-to-waking period
- Stress
- Hypoglycemia
- Hypotension
- Sepsis
- Trauma; Burn
- Decreased plasma cortisol
- α -Adrenergic receptor stimulation

Inhibition

- Elevated plasma cortisol
- Opioids

ACTH, Adrenocorticotropic hormone.

After release from the adrenal cortex, cortisol circulates in the blood either as free cortisol (the physiologically active form) or bound to cortisol-binding globulin (transcortin) or albumin. Approximately 90% to 95% of cortisol is transported in the bound form, and 6% is free. The circulating half-life of cortisol varies between 70 and 120 minutes, but it has a more prolonged end-organ effect.¹⁴⁵ Like other steroid hormones, cortisol exerts its effects by binding to intracellular receptors in the target cell and altering gene transcription and translation. Most of the metabolic actions of cortisol therefore are not immediate, but may take several hours to fully develop. Cortisol is inactivated mainly in the liver and kidney, and excreted in the urine as 17-hydroxycorticosteroids.¹⁴³

Cortisol Actions.

Glucocorticoids have effects in virtually all cells in the body.¹⁴² They are needed for the proper use of proteins, carbohydrates, and fats by the body. Furthermore, glucocorticoids have a permissive effect on catecholamine hormones from the adrenal medulla and help mediate their effects on the heart and vasculature.¹⁴⁵ Cortisol is central to the body's response to physical and mental stress.^{142,143} Almost any stress, psychologic or physical, causes an immediate and marked increase in ACTH and cortisol secretion. Important perioperative stressors may include pain, anxiety, trauma, infection, intense heat or cold, and surgery. An inadequate cortisol response during critical illness and surgery can lead to hypotension, shock, and death.^{142,144}

Glucocorticoids have some mineralocorticoid and androgenic effects that may become significantly apparent with hormone excess or supraphysiologic replacement dosages.

Effect on Carbohydrate Metabolism.

Overall, glucocorticoids enhance the production of high-energy fuel for metabolic needs.¹⁴² A key function is their ability to stimulate gluconeogenesis in the liver. The rate of gluconeogenesis increases six- to tenfold in the presence of cortisol.¹⁴³ Furthermore, cortisol mobilizes amino acids from extrahepatic tissues (mainly muscle), making them available for gluconeogenesis and glycogenesis in the liver.¹⁴³ In extrahepatic tissues, cortisol moderately decreases the rate of glucose uptake and use. Cortisol is called diabetogenic because it increases blood glucose concentrations.

Effect on Protein and Bone Metabolism.

Cortisol decreases protein synthesis and increases protein breakdown in essentially all body tissue except the liver.¹⁴³ In the presence of sustained cortisol excess, the catabolic effects are marked. This is especially apparent in skeletal muscles, which become weak and atrophic, but also skin and connective tissue. Glucocorticoids inhibit osteoblast activity, and inhibit intestinal calcium absorption. Both may account for the osteopenia and osteoporosis that characterizes glucocorticoid excess.^{145,146}

Effect on Fat Metabolism.

Plasma free fatty acids are mobilized from adipose tissue under cortisol's effect. An increase in total circulating triglycerides and cholesterol is observed.¹⁴⁵ In times of starvation or other stress, these two effects help shift metabolic systems to the use of fatty acids instead of glucose for energy. Excess cortisol results in a distinctive obesity, with chest, abdominal, interscapular, and facial fat expansion, leading to a “buffalo-like” torso and “moon facies.”¹⁴²⁻¹⁴⁴

Effect on Inflammation and Immunity.

Cortisol can diminish the body's inflammatory responses by suppressing all aspects of the inflammatory process. Migration of white blood cells into the inflamed area is also decreased. At pharmacologic doses, cortisol stabilizes lysosomal membranes and decreases antibody production.¹⁴² These effects are the basis for therapeutic use of corticosteroids to reduce inflammatory responses associated with asthma, allergic reactions, arthritis and other inflammatory disorders.

Corticosteroids are used to treat a diverse variety of human diseases, primarily relying on their antiinflammatory and immunologic actions, and are given orally, parenterally, and by numerous topical routes (e.g. skin, inhalation, eyes).¹⁴⁵ **Box 37.7**

Box 37.7 summarizes some of the therapeutic uses of corticosteroids.

Therapeutic Uses of Corticosteroids

Endocrine: Replacement therapy (Addison disease, pituitary disease), Graves ophthalmopathy

Skin: Dermatitis pemphigus

Hematology: Leukemia, lymphoma, idiopathic thrombocytopenic purpura, hemolytic anemia

Gastrointestinal: Inflammatory bowel disease (ulcerative colitis, Crohn disease)

Liver: Chronic active hepatitis, transplantation, organ rejection

Renal: Nephrotic syndrome, vasculitides, transplantation, organ rejection

Central nervous system: Cerebral edema, raised intracranial pressure

Respiratory: Angioedema, anaphylaxis, asthma, sarcoidosis, tuberculosis, obstructive airway disease

Rheumatology: Systemic lupus erythematosus, polyarteritis, temporal arthritis, rheumatoid arthritis

Muscle: Polymyalgia rheumatic, myasthenia gravis

From Melmed S, et al., eds. *William's Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016:505.

Cortisol decreases the number of eosinophils and lymphocytes in the blood. T lymphocyte and antibody output are decreased from the atrophy of lymphoid tissue. As a result, with pharmacologic doses of cortisol, the level of immunity to foreign invaders of the body is reduced, and infection may ensue from infection that would otherwise not be pathologic. The ability of cortisol to suppress immunity makes pharmacologic administration of glucocorticoids useful in preventing the immunologic rejection of transplanted organs and in treating a variety of autoimmune disorders.

Mineralocorticoids.

In contrast to the diverse actions of glucocorticoids at numerous target sites, mineralocorticoids have a relatively restricted action primarily at the renal distal tubule (also salivary and sweat glands). Mineralocorticoids are required for life as they play a major role in the regulation of extracellular sodium and potassium ion concentrations and total body fluid balance. Aldosterone is the body's principal mineralocorticoid, accounting for 90% of all mineralocorticoid activity.¹⁴³ Daily secretion from the zona glomerulosa, the thin zone of cells on the surface of the adrenal cortex, is approximately 0.1 mg. As noted previously, in large part, the zona glomerulosa functions autonomously of the other two adrenal cortex zones. Most distinctly, control of aldosterone

secretion from the zona glomerulosa is largely independent of ACTH control (Fig. 37.19). After secretion from the adrenal cortex, aldosterone circulates 60% bound to serum proteins. It has a relatively short half-life of approximately 20 minutes.¹⁴³

FIGURE 37.19 Regulation of aldosterone secretion. Hyperkalemia and activation of the renin-angiotensin system in response to hypovolemia are the predominant stimuli to aldosterone production. Adrenocorticotropin hormone (ACTH) has only a minor tonic stimulatory effect.

(From Berne RM, et al, eds. *Physiology*. 5th ed. St Louis: Elsevier; 2004:905.)

The four main physiologic controllers of aldosterone secretion are as follows, in order of importance¹⁴³:

1. Serum potassium–potent controller
2. Angiotensin II (activation of the renin-angiotensin system)–

potent controller

3. Serum sodium–minor effect

4. ACTH–minor or no effect in most physiological conditions

With a total loss of mineralocorticoid secretion, death would ensue within days without treatment.^{143,144}

Aldosterone Functions.

One of our body's most significant protectors of volume status is the renin-angiotensin-aldosterone system. Renin is a proteolytic enzyme released from the juxtaglomerular cells of the kidney afferent arteriole in response to hypovolemia, sympathetic nervous system stimulation, hypotension, or hyponatremia.¹⁴⁵ Renin acts on the plasma protein angiotensinogen to form angiotensin I (a 10–amino acid peptide), which is acted on by angiotensin-converting enzyme (primarily in the lung) to form angiotensin II (an 8–amino acid peptide). Angiotensin II is an extremely powerful vasoconstrictor and a potent stimulus of aldosterone synthesis and release.¹⁴²

Aldosterone's primary target cells are called *principal cells*, and are located in the kidney distal convoluted tubules and cortical collecting ducts. Here, aldosterone causes the reabsorption of Na⁺ from the tubular fluid in exchange for secretion of K⁺ (or H⁺) into the tubular fluid for excretion. Aldosterone's effect on the extracellular sodium ion concentration is limited because simultaneous with the Na⁺ absorption is absorption of nearly equivalent amounts of water. Sodium and water reabsorption expands the extracellular fluid volume and elevates arterial blood pressure.¹⁴³

Aldosterone's action on sweat glands and salivary glands is similar to that on renal tubules. The effect on sweat glands is important in hot environments, where body salt conservation is needed.¹⁴³

Disorders Associated With the Adrenal Cortex

An excess or deficiency of corticosteroids is associated with

distinctive clinical syndromes.

Primary Aldosteronism.

J.W. Conn described the first case of primary mineralocorticoid excess in 1954, a year after the biochemical composition of aldosterone was identified.¹⁴⁷ Conn syndrome results from hypersecretion of aldosterone from an adrenal adenoma independent of stimulus. Primary aldosteronism may also be caused by adrenocortical hyperplasia or, rarely, carcinoma.¹⁴² Systemic hypertension with coexisting spontaneous hypokalemia are pathognomonic of hyperaldosteronism.¹⁴²

Manifestations of the syndrome reflect the exaggerated effects of aldosterone. Aldosterone's action of promoting renal excretion of K^+ (or H^+) in exchange for Na^+ reabsorption results in hypokalemic metabolic alkalosis. Hypertension associated with mineralocorticoid excess results from aldosterone-induced sodium retention and subsequent increase in extracellular fluid volume. Sodium levels tend to be normal due to concurrent fluid retention.^{142,145,148}

Primary aldosteronism is associated with low renin levels, a result of the elevated blood pressure's negative feedback to the juxtaglomerular cells. With secondary hyperaldosteronism, the stimulus of excess aldosterone resides outside of the adrenal gland and is often associated with an increase in circulating renin levels.¹⁴²

Treatment.

Treatment of primary aldosteronism involves surgical removal of the adenoma or medical management. Surgical intervention is more successful for primary aldosteronism caused by adrenocortical adenoma than for gland hyperplasia because adenomas are almost always unilateral. When the affected adrenal gland is removed, the patient is cured in most cases. Medical management includes potassium supplementation and antihypertensive drugs. For patients with adrenal hyperplasia, pharmacologic antagonism of the mineralocorticoid receptor with spironolactone or eplerenone has been used successfully.¹⁴²

Management of Anesthesia.

Preoperative management of the patient with Conn syndrome includes correcting electrolyte concentrations, restoring intravascular fluid volume to normal, and managing hypertension.^{11,84} Hypokalemia may produce muscle weakness and enhance nondepolarizing muscle relaxant responses, making neuromuscular blockade monitoring especially valuable. Electrocardiographic signs of potassium depletion include prominent U waves and arrhythmias. Plasma electrolyte concentrations and acid-base status should be checked often during the perioperative period. Inadvertent hyperventilation may further decrease plasma potassium concentration.

Hypertension may be controlled preoperatively with sodium restriction and aldosterone antagonists such as spironolactone.¹⁴⁸ Spironolactone, 25 to 100 mg every 8 hours, slowly increases potassium levels by inhibiting the action of aldosterone on the distal convoluted tubule. Patients with primary aldosteronism have a higher incidence of left ventricular hypertrophy, albuminuria, and stroke than patients with essential hypertension.¹⁴² Measurement of cardiac filling pressures may be needed to assess fluid volume status in the perioperative period.¹¹

Laparoscopic adrenalectomy is advocated as the operation of choice for surgically remediable mineralocorticoid excess. Compared with open laparotomy, patients who undergo laparoscopic adrenalectomy have similar improvement in blood pressure control and correction of hypokalemia.¹⁴⁹

Glucocorticoid Excess (Cushing Syndrome).

Cushing syndrome is a diverse complex of symptoms, signs, and biochemical abnormalities caused by excess glucocorticoid hormones. Clinical features reflect cortisol excess, either from overproduction of the adrenal cortex or exogenously administered glucocorticoid. Understanding the normal physiologic effects of glucocorticoids is important for comprehending the clinical features of Cushing syndrome and glucocorticoid excess.¹⁴⁵ (Box 37.8).

Clinical Features of Glucocorticoid Excess (Cushing Syndrome)

- Hyperglycemia
- Systemic hypertension
- Weight gain; central obesity; fat pad on back of neck (“buffalo hump”); moon face
- Increased susceptibility to infection
- Poor wound healing
- Hypokalemia
- Alkalosis
- Hirsutism; acne
- Loss of libido; menstrual disturbances
- Osteopenia; osteoporosis
- Skeletal muscle weakness
- Cataracts
- Skin stria; ecchymoses; facial plethora
- Mood disorders

The catabolic effects of excess cortisol result in muscle atrophy and skin that is thin, atrophic, and unable to withstand the stresses of normal activity. The clinical picture of Cushing syndrome includes central obesity with thin extremities, florid complexion, moon facies, purplish striae, muscle weakness, and easy bruising.^{142,143,150,151} Glucocorticoid-induced osteoporosis affects 50% of patients who are treated with corticosteroids for longer than twelve months.¹⁴⁵ Glucose intolerance occurs, and overt DM is present in up to one-third of patients with Cushing syndrome.¹⁴⁵ Mineralocorticoid effects may be present and include fluid retention and hypokalemic alkalosis. Hypertension is a prominent

feature of Cushing syndrome, occurring in up to 75% of cases.^{145,151} Women manifest a degree of masculinization (e.g., hirsutism, hair thinning, acne, amenorrhea), and men manifest a degree of feminization (e.g., gynecomastia, impotence) due to androgenic effects of glucocorticoid excess.^{142,143}

Causes of Cushing syndrome can be ACTH-dependent (e.g., pituitary adenoma, ectopic secretion of ACTH by nonpituitary tumor), ACTH-independent (e.g., adrenal tumor, adrenal carcinoma), or iatrogenic (e.g., administration of supraphysiologic doses of glucocorticoids for conditions such as arthritis, allergies, and asthma).

Cushing disease, first described by Harvey Cushing in 1932, specifically denotes an anterior pituitary tumor cause of the syndrome. The pituitary tumor, most often an adenoma, produces excessive amounts of ACTH and is associated with bilateral adrenal hyperplasia.¹⁴² Patients often develop skin pigmentation as a result of the melanocyte-stimulating properties of ACTH. The term *Cushing syndrome* is used to describe all causes of glucocorticoid excess, whereas Cushing disease is reserved for pituitary-dependent Cushing syndrome.¹⁴⁵

Overall, the most common cause of Cushing syndrome today is the pharmacologic administration of glucocorticoids for various autoimmune and inflammatory conditions.¹⁴² When iatrogenic causes are excluded, the most common cause of Cushing syndrome is Cushing disease, accounting for approximately 70% of cases.¹⁴⁵

Ectopic ACTH syndrome results from autonomous ACTH production by nonpituitary tumors. Tumors that are associated with ectopic ACTH production include small cell lung carcinoma, pancreatic tumors, medullary carcinoma of the thyroid gland, thymic or pancreatic carcinoids, and pheochromocytoma tumors.¹⁴² Small cell lung carcinomas account for most of the cases of ectopic production of ACTH.^{145,152}

Excluding iatrogenic cases, approximately 10% to 15% of Cushing syndrome cases are caused by autonomous cortisol production by an adrenal tumor, usually an adenoma, and most often unilateral.¹⁴² This form of hyperadrenalism is associated with suppressed plasma ACTH levels.¹⁴²⁻¹⁴⁴ Adrenal tumors that are malignant are not common and are usually large by the time Cushing syndrome

becomes manifest.

Diagnosis.

There are several tests used in the diagnosis of Cushing syndrome. A widely used initial test is the low-dose overnight dexamethasone suppression test, which measures the plasma cortisol concentration in the morning after a 1 mg dose of dexamethasone.¹⁴⁵

Dexamethasone suppresses CRH, ACTH, and plasma cortisol secretion in normal subjects but not in those with Cushing disease. Diagnosis of Cushing syndrome may also be based on salivary cortisol levels, plasma ACTH, urinary 17-hydroxycorticosteroids, and urinary free cortisol excretion.^{142,153}

Treatment.

Treatment for Cushing syndrome depends on the cause.¹⁵⁴⁻¹⁵⁶ For Cushing disease, selective removal of the pituitary corticotrope tumor (microadenectomy), usually by a transsphenoidal approach, is the primary treatment option. Complications depend on the tumor size and therefore the extent of tissue removal and include hypopituitarism, diabetes insipidus (transient or permanent) and cerebrospinal fluid rhinorrhea.¹⁴⁵

Management of Cushing syndrome caused by an adrenal tumor consists of surgical removal. A laparoscopic approach is the surgical treatment of choice for unilateral adrenal adenomas.^{145,154,157,158} Adrenalectomy for unilateral adrenocortical adenoma has a cure rate of 100%.¹⁵⁸ For larger tumors or those suspected of malignancy, an open laparotomy may be preferred.¹⁴²

Plasma cortisol levels may decline promptly with pituitary or adrenal tumor resection. A continuous infusion of cortisol (100 mg/day IV) may be initiated intraoperatively.¹¹ Because the contralateral adrenal gland is preoperatively suppressed, glucocorticoid replacement may be necessary for several months after unilateral adrenalectomy until adrenal function returns.^{142,145}

The treatment of choice for ectopic ACTH-secreting tumors is surgical removal, but this may not always be feasible because of the nature of the underlying process (e.g., metastatic carcinoma). Ketoconazole, an antifungal drug that blocks the early stages of steroid synthesis, or metyrapone, an 11- β -hydroxylase inhibitor

may be used to help lower cortisol levels. Mitotane, an agent that blocks steroidogenesis at several levels, is used to treat cancer of the adrenal gland that cannot be treated with surgery.^{142,145,154,155}

Management of Anesthesia.

Important perioperative considerations for the patient with Cushing syndrome include normalizing blood pressure, plasma glucose levels, intravascular fluid volume, and electrolyte concentrations.^{8,11,84} The aldosterone antagonist spironolactone may be used to minimize extracellular fluid volume and correct hypokalemia under these conditions.

Osteopenia is an important consideration in positioning the patient for the operative procedure.⁸ Pathologic fractures, even after minor trauma, are not uncommon.¹⁴⁵ Special attention must be given to the patient's skin, which can easily be abraded and bruised by tape or minor trauma. Glucocorticoids are lympholytic and immunosuppressive, placing the patient at increased risk for infection and mandating particular enforcement of aseptic techniques when indicated.^{8,142}

Obstructive sleep apnea is common in patients with Cushing syndrome and the characteristic "buffalo hump" may also complicate airway management by making supine positioning more difficult. The choice of drugs for induction and maintenance of anesthesia is not specifically influenced by the presence of hyperadrenocorticism.^{8,11} As a suppressor of cortisol synthesis, etomidate may transiently decrease plasma cortisol levels.^{8,11} Muscle relaxants may have a more exaggerated effect in patients with hypokalemia and preexisting myopathy, and a conservative approach to dosing is warranted when significant skeletal muscle weakness is present.

If unilateral or bilateral adrenal resection is planned, glucocorticoids will be indicated postresection. Glucocorticoids should be administered at doses equivalent to adrenal output for maximum stress (hydrocortisone, 100 mg IV over 24 hours) and titrated until a daily maintenance dose of steroids is achieved.^{11,84}

Thromboembolic phenomena occur more often in patients with Cushing syndrome, with an 11% incidence of deep venous thrombosis and a 2% to 3% incidence of pulmonary embolus

postoperatively. The thromboembolic events are believed to be secondary to the prevalence of obesity, hypertension, elevated hematocrit, and increased factor VIII levels in these patients.¹⁵⁹

Primary Adrenocortical Insufficiency (Addison Disease).

In 1855, an English physician, Dr. Thomas Addison, first described a relatively rare clinical syndrome characterized by wasting and skin hyperpigmentation and identified its cause as destruction of the adrenal glands. Primary adrenocortical insufficiency (Addison disease) becomes apparent when 90% of the gland is destroyed.¹¹ Infectious diseases, including tuberculosis, acquired immunodeficiency syndrome (AIDS), and fungal infections, are the most common causes of primary adrenocortical insufficiency worldwide.¹⁶⁰ In the Western world, most cases are the result of autoimmune destruction of the gland. Fifty percent of these patients have an associated autoimmune disease, thyroid disease being the most common.¹⁴⁵ Less commonly, primary adrenal insufficiency is congenital or caused by adrenal hemorrhage, malignancy, or trauma.^{142,160}

Clinical features of primary adrenocortical insufficiency reflect destruction of all cortical zones, resulting in adrenal androgen, glucocorticoid, and mineralocorticoid hormone deficiency^{145,160-162} (Table 37.8). Weakness and fatigue are cardinal features. Reduced appetite with weight loss, vomiting, abdominal pain, and diarrhea are frequently reported. Hypoglycemia is often present.¹⁶¹ Volume depletion is a common feature of the disease and is manifested by hypotension. Hyponatremia, azotemia, and anemia are commonly revealed by laboratory screening. Hyperkalemia may be evident, and is associated with serious cardiac toxicity and dysrhythmias.^{143,161}

TABLE 37.8
Clinical Features of Primary Adrenal Insufficiency

Feature	Frequency (%)
Symptoms	
Weakness, tiredness, fatigue	100
Anorexia	100
Gastrointestinal symptoms	92
Nausea	86

Vomiting	75
Constipation	33
Abdominal pain	31
Diarrhea	16
Salt craving	16
Postural dizziness	12
Muscle or joint pains	13
Signs	
Weight loss	100
Hyperpigmentation	94
Hypotension (< 110 mm Hg systolic)	88–94
Vitiligo	10–20
Auricular calcification	5
Laboratory Findings	
Electrolyte disturbances	92
Hyponatremia	88
Hyperkalemia	64
Hypercalcemia	6
Azotemia	55
Anemia	40
Eosinophilia	17

From Melmed S, et al., eds. *Williams Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016:528.

The adrenal-pituitary axis is intact in primary adrenal insufficiency, and ACTH concentrations are elevated as a result of the reduced production of cortisol. Increased melanin formation in the skin and hyperpigmentation of the knuckles of the fingers and toes, knees, elbows, lips, and buccal mucosa are distinguishing features reflecting increased ACTH levels.

Treatment.

Treatment for adrenal insufficiency aims to replace both glucocorticoid (antiinflammatory) and mineralocorticoid (salt retention) deficiency ([Table 37.9](#)).^{11,142,145,161,163} Replacement therapy typically includes hydrocortisone 15 to 20 mg on awakening and 5 to 10 mg in early afternoon. In primary adrenal failure, mineralocorticoid replacement is usually also required in the form of fludrocortisone, 0.1 mg/day.¹⁴⁵ Patients with Addison disease are highly susceptible to the deteriorating effects of stress and require supplementation of standard replacement dosages under stressful conditions.^{143,145,161,163} (see section on [Perioperative Steroid Replacement](#)).

TABLE 37.9

Steroid Preparation

Steroid	Glucocorticoid Potency*	Mineralocorticoid Potency (Salt Retention)	Approximate Equivalent Dose
Cortisol (Hydrocortisone)	1.0	1.0	20 mg
Prednisone	4.0	0.25	5 mg
Prednisolone	4.0	0.25	5 mg
Methylprednisolone	5.0	0	4 mg
Dexamethasone	30	0	0.75
Fludrocortisone	12	125	

* Glucocorticoid and mineralocorticoid potencies are relative to cortisol, with cortisol being 1.0. Prednisone, prednisolone, methylprednisolone and dexamethasone have less mineralocorticoid effect than hydrocortisone.

Secondary Adrenocortical Insufficiency.

Secondary adrenocortical insufficiency is caused by ACTH deficiency from two primary etiologies: (1) iatrogenic HPA axis suppression after exogenous glucocorticoid therapy, or (2) ACTH deficiency secondary to hypothalamic or pituitary gland dysfunction (e.g., tumor, infection, surgical or radiologic ablation).

Up to 1% of the Western population is taking long-term glucocorticoid therapy.¹⁴⁵ Iatrogenic suppression of the HPA axis may follow long-term treatment with glucocorticoids, resulting in negative feedback to the hypothalamus and pituitary, decreased ACTH output, and eventual adrenal cortex atrophy.^{11,145,161,164} HPA axis suppression by exogenous glucocorticoid has been described with topical, ocular, rectal, inhaled, as well as systemic, therapy.^{161,165-167} The longer the duration of treatment and the more potent the pharmacologic glucocorticoid, the greater the likelihood of HPA axis suppression. The HPA axis suppression may persist for many months after cessation of therapy.¹⁴⁵ Patients with HPA axis suppression may develop acute adrenal insufficiency during periods of stress (critical illness, surgery). Interindividual variability to glucocorticoids is considerable and there is no absolute dose, duration of treatment, or time since steroid withdrawal that will predict adrenal suppression. In general, sustained and clinically important adrenal suppression does not occur with prednisolone treatment of 5 mg/day or less for periods less than 14 days.¹⁴⁵ Treatment periods long enough to provoke signs of Cushing syndrome are usually associated with adrenal suppression of

clinical importance.¹⁴⁵

Clinical manifestations of secondary adrenal insufficiency resemble the primary disease, except secondary insufficiency is less likely to be associated with severe hypovolemia, hyperkalemia, or hyponatremia because the renin-angiotensin-aldosterone system is intact and mineralocorticoid secretion is usually preserved.^{11,145} Hyperpigmentation is absent because ACTH levels are low.

Acute Adrenal Crisis.

Acute adrenal crisis or Addisonian crisis is a sudden exacerbation or onset of severe adrenal insufficiency. It is a rare event associated with high morbidity and mortality if allowed to progress unrecognized.¹⁶⁸ A patient with chronic adrenal insufficiency may deteriorate rapidly into an acute insufficiency state as a result of some superimposed stress, such as infection, acute illness, or sepsis. The stress of surgery or trauma in the patient with inadequate adrenal reserves can precipitate acute adrenal crisis in the perioperative period.^{8,168}

Symptoms of adrenal crisis reflect acute deficiency of corticosteroids and include severe weakness, nausea, hypotension, fever, and decreasing mental status. In the surgical setting, adrenal crisis is manifest as hemodynamic instability or cardiovascular collapse. The index of suspicion for adrenal crisis should be particularly high in a patient with a history of Addison disease or recent prior use of exogenous steroids, progressive hyperkalemia, and hyponatremia.^{155,161} **Box 37.9** outlines clinical and laboratory features of adrenal crisis.

Clinical and Laboratory Features of Adrenal Crisis

- Dehydration, hypotension, or shock out of proportion to severity of current illness
- Nausea and vomiting with a history of weight loss and anorexia
- Abdominal pain (“acute abdomen”)
- Unexplained hypoglycemia

- Unexplained fever
- Hyponatremia, hyperkalemia, hypercalcemia
- Azotemia
- Hyperpigmentation or vitiligo
- Other autoimmune endocrine deficiencies, such as hypothyroidism or gonadal failure

From Melmed S, et al., eds. *William's Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016: 529.

The anesthetist should be mindful of the adrenal suppressive effects of the nonbarbiturate hypnotic etomidate. Etomidate inhibits cortisol synthesis by inhibiting the enzyme 11- β -hydroxylase and blocking the conversion of 11-deoxycortisol to cortisol.^{169,170} Even a single dose of etomidate for induction of anesthesia can cause transiently decreased cortisol synthesis and its administration should be avoided in patients susceptible to adrenal insufficiency.^{11,169,171–173}

Acute adrenal crisis is a medical emergency requiring aggressive treatment of the steroid insufficiency and associated hypoglycemia, electrolyte imbalance, and volume depletion. Early recognition and immediate intervention are crucial steps in altering the course of acute adrenal insufficiency.¹⁶¹ Initial therapy begins with rapid intravenous administration of a physiologic saline solution with continuous cardiac monitoring.^{145,168} Steroid replacement therapy begins with hydrocortisone, 100 mg IV, followed by hydrocortisone, 100 mg IV every 6 to 8 hours for 24 hours. After the first day, steroid doses are reduced by 50% per day if the patient is stable.^{145,168} Because of possible hypoglycemia, it is normal to give 5% dextrose in saline. If the patient is hemodynamically unstable, inotropic support may be necessary.

Perioperative Steroid Replacement.

Case reports of perioperative cardiovascular collapse in surgical patients on pharmacologic doses of glucocorticoids were first

reported in 1952.¹⁷⁴ These reports and subsequent knowledge regarding the stress response associated with surgery and the suppression of the HPA axis with supraphysiologic doses of corticosteroids has led to the practice of administering perioperative glucocorticoids to patients who have taken steroids in the preoperative period.

Synthesis and secretion of cortisol can increase five to tenfold under conditions of severe stress, such as surgery, trauma, or infection.^{8,163} In general, major surgery of long duration produces a greater adrenal output response than minor surgery of short duration. For the adult patient who has received supraphysiologic doses of glucocorticoids (oral, topical, or inhaled), it may take 12 months from the time of discontinuation of steroids for the adrenal gland to recover full function.^{11,84,163}

Debate exists regarding who should receive perioperative steroid coverage and what the appropriate steroid dose should be.^{84,145,163,164,175}

Some authors recommend that patients on chronic glucocorticoids undergoing surgery receive only their usual daily dose of glucocorticoid perioperatively. These recommendations are based upon studies that have shown that surgical patients treated with their usual steroid dose do not develop hypotension or any other perioperative signs of adrenal insufficiency.¹⁷⁵

However, many clinicians believe that because acute adrenal crisis is life-threatening, even a small risk of adrenal insufficiency warrants supplemental steroid treatment. Many experts suggest that patients are at risk for adrenal insufficiency and therefore require steroid supplementation under the following circumstances^{8,11}:

1. The patient has taken oral pharmacologic doses of prednisone greater than 20 mg/day or its equivalent (16 mg/day methylprednisolone, 80 mg/day of hydrocortisone, 3 mg/day of dexamethasone):
2. The period of treatment was for 3 weeks or longer: and
3. The treatment occurred during the immediate 12 months before surgery.

Under these conditions, supplemental intravenous administration of hydrocortisone is advocated to compensate for the amount the body may be unable to produce in response to maximal stress.¹¹ The precise amount of glucocorticoids required for adequate supplementation has not been established.^{145,163} Therapeutic aims are to tailor the steroid dose considering the length and severity of surgical stress, while administering the minimal dose that will fully protect the patient.^{145,163} A common perioperative protocol for steroid supplementation is included in [Table 37.10](#).¹¹ If the surgical patient is undergoing treatment with glucocorticoids at the time of surgery, supplemental doses are usually administered in addition to the patient's daily maintenance dose.^{8,11,145,163}

TABLE 37.10
Guidelines for Perioperative Adrenal Supplementation Therapy

Type of Surgery Stress	Additional Hydrocortisone Dose
Superficial Surgery	
Dental Biopsies	None
Minor Surgery	
Inguinal hernia Colonoscopy	25 mg IV before induction of anesthesia
Moderate Surgery	
Colon resection Total abdominal hysterectomy Total joint replacement	50–75 mg IV before induction of anesthesia; taper by 50% per day, over 1 to 2 days
Major Surgery	
Cardiovascular Thoracic Liver	100–150 mg IV before induction of anesthesia; taper by 50% per day, over 1 to 2 days

Modified from Wall RT. Endocrine disease. In Hines RL, Marschall KE, eds. *Anesthesia and Co-Existing Disease*. Philadelphia: Elsevier; 2012:399.

The benefits of perioperative steroid supplementation are tempered by the potentially negative effects of decreased glucose tolerance, immunosuppression, and impaired wound healing. Again, many clinicians believe that any potential risks associated with short-term glucocorticoid administration are outweighed by the benefits.^{8,11,145}

Adrenal Medulla

The adrenal medulla is a catecholamine-producing endocrine gland that is derived embryologically from neuroectodermal cells. Cells of the adrenal medulla are called *chromaffin cells*. Some chromaffin cells called *paraganglia* cluster outside of the adrenal medulla on either side of the aorta. The largest paraganglia is the organ of Zuckerkandl, which is a major source of catecholamines during the first year of life.^{176,177}

The adrenal medulla is enervated by preganglionic cholinergic fibers of the sympathetic nervous system. Preganglionic fibers bypass the paravertebral ganglia and run directly from the spinal cord to the adrenal medulla. Catecholamine secretion from the adrenal medulla is stimulated by stress (e.g. anesthesia, surgery, MI, hypoglycemia). Epinephrine accounts for approximately 80% of the hormone secreted by the adrenal medulla, and norepinephrine accounts for 20%.¹⁷⁶ Norepinephrine is converted to epinephrine in the adrenal medulla by the enzyme phenylethanolamine-N-methyltransferase (PNMT). The ability of the adrenal medulla to synthesize epinephrine is probably influenced by the flow of glucocorticoid-rich blood from the adrenal cortex through the medulla. High concentrations of glucocorticoids stimulate the enzyme PNMT. Fig. 37.20 outlines the biosynthetic pathway for catecholamines.

FIGURE 37.20 Biosynthetic pathway for catecholamines.

The term *catecholamines* comes from the catechol (ortho-dihydroxybenzene) structure and a side chain with an amino group—the “catechol nucleus” (*left*). Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) (rate-limiting step) by tyrosine hydroxylase (TH); TH inhibitor, α-methyl-para-tyrosine (metyrosine). Aromatic L-amino acid decarboxylase (AADC) converts dopa to dopamine. Dopamine is hydroxylated to norepinephrine by dopamine β-hydroxylase (DBH). Norepinephrine is converted to

epinephrine by phenylethanolamine *N*-methyltransferase (PNMT); cortisol serves as a cofactor for PNMT, which is why epinephrine-secreting pheochromocytomas are almost exclusively localized to the adrenal medulla. (From Melmed S, et al., eds. *Williams Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016:557.)

Catecholamines in the adrenal medulla are stored in chromaffin granules.¹⁷⁶ Stimulation of the sympathetic nerves to the adrenal medulla causes large quantities of epinephrine and norepinephrine to be released into circulation, affecting many cardiovascular and metabolic processes. Catecholamines are short-lived signaling molecules and are removed from circulation by metabolism through two enzyme pathways. The enzyme catechol-*O*-methyltransferase (COMT) converts epinephrine to metanephrine and norepinephrine to normetanephrine. Metanephrine and normetanephrine are then oxidized to vanillylmandelic acid (VMA) by the enzyme monoamine oxidase (MAO). The byproducts of metabolism, VMA, normetanephrine, metanephrine, and free unchanged catecholamines are excreted in the urine.¹⁷⁶ Fig. 37.21 outlines major pathways of epinephrine, norepinephrine, and dopamine metabolism.

Vanillylmandelic acid (VMA)

FIGURE 37.21 Catecholamine metabolism. Metabolism of catecholamines occurs through two enzymatic pathways. Catechol-O-methyltransferase (COMT) converts epinephrine to metanephrine and converts norepinephrine to normetanephrine by meta-O-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid, which is then converted by COMT to VMA. Dopamine is also metabolized by MAO and COMT to the final metabolite homovanillic acid (HVA). (Modified and redrawn from Young WF. *Endocrine Hypertension*. In Melmed S, et al., eds. *Williams Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016:559.)

Norepinephrine stimulates α - and β -adrenergic receptors. It causes constriction of most blood vessels of the body and increases blood pressure through α_1 receptor stimulation. High circulating norepinephrine levels increase cardiac activity, inhibit gastrointestinal function, and dilate the pupils. Epinephrine has greater affinity for β -adrenergic receptors. Its actions are seen primarily in the heart, producing positive chronotropic and inotropic effects. Epinephrine causes less constriction of blood

vessels than norepinephrine, and in fact causes some vasodilation, mediated through its action on β_2 -adrenergic receptors primarily in skeletal muscle vasculature. Norepinephrine and epinephrine release from the adrenal medulla can increase the metabolic rate of the body by as much as 100% above normal.

Pheochromocytoma

In 1905, the term *pheochromocytoma* was first used to describe the appearance of a tumor (cytoma) noted during autopsy resection to be a dusky (pneo) color (chromo). Cesar Roux of Lausanne, Switzerland, and Charles Mayo of the United States were the first surgeons to successfully remove a pheochromocytoma.

Pheochromocytomas are catecholamine-secreting tumors derived most commonly from chromaffin cells in the adrenal medulla, and less commonly from extraadrenal catecholamine secreting paragangliomas. Paragangliomas are found where there is chromaffin tissue along the paraaortic sympathetic chain, in the wall of the bladder, within the organ of Zuckerkandl and, less commonly, in the mediastinum.^{177,178}

Most pheochromocytomas secrete both norepinephrine and epinephrine (and, less frequently, dopamine). Norepinephrine typically represents a higher fraction of the secreted catecholamines, compared to a normal gland.^{84,179} In the majority of cases it is impossible to predict the precise catecholamine secretion from clinical features alone. The tumors are not innervated, and neural stimulation does not stimulate hormone release.¹⁷⁸

Pheochromocytomas generally adhere to what is known as the “rule of ten.” They involve both adrenal glands in approximately 10% of adult patients with the tumor; 10% to 15% of the tumors arise from extraadrenal chromaffin cells; and at least 10% of the tumors are malignant. Malignant pheochromocytomas are primarily extraadrenal.^{177,180} Metastasis usually proceeds through venous and lymphatic channels to the liver.¹⁷⁸

Biochemical testing and subsequent diagnosis of a catecholamine-secreting tumor is based on findings of elevated concentrations of fractionated catecholamines (epinephrine, norepinephrine, dopamine), fractionated metanephrine and normetanephrine, and

VMA in urine or plasma.^{177,178,181,182} CT of the abdomen and pelvis is the primary imaging modality used for diagnosis.

Incidence and Associated Diseases.

Pheochromocytomas are rare, occurring with an annual incidence of 2 to 8 cases per 1 million people.¹⁷⁷ The tumors have a strong genetic component and experts now believe that somewhere between 20% to 35% of pheochromocytomas are familial. Inherited syndromes that have been linked to pheochromocytoma include von Hippel-Lindau syndrome, MEN type 2A and MEN type 2B, neurofibromatosis type 1 (formerly known as von Recklinghausen disease), and familial pheochromocytoma/paraganglioma syndrome.^{180,183} Approximately 50% of patients with MEN type 2A or 2B develop pheochromocytomas and these tumors secrete predominantly epinephrine¹⁷⁷ (Table 37.11). It is recommended that patients with a family history of MEN syndrome be regularly screened for pheochromocytoma.

TABLE 37.11

Manifestations of Multiple Endocrine Neoplasia*

Syndrome	Manifestations
MEN type 1 (Wermer syndrome)	Hyperparathyroidism, pituitary adenomas, pancreatic islet-cell tumors
MEN type 2A (Sipple syndrome)	Medullary thyroid cancer, primary hyperparathyroidism, pheochromocytoma, pigmented skin lesions (lichen amyloidosis)
MEN type 2B (Gorlin syndrome or mucosal neuroma syndrome)	Medullary thyroid cancer, pheochromocytoma, mucocutaneous neuromas (typically involving the tongue, lips, and eyelids), skeletal deformities (e.g. kyphoscoliosis, lordosis), intestinal ganglioneuromas

*Multiple endocrine neoplasia (MEN) is a group of rare diseases caused by genetic defects that lead to hyperplasia and hyperfunction of two or more components of the endocrine system.

Pheochromocytomas can occur at any age, but usually occur within the third to the fifth decade of life, with equal frequency in both sexes in adults.¹⁷⁷

Clinical Manifestations.

Signs and symptoms of a pheochromocytoma reflect exaggerated catecholamine release that may occur continuously or as paroxysms. Manifestations vary in their intensity and

approximately 50% of intraadrenal pheochromocytomas are discovered as part of incidental radiographic findings or surgery performed for other reasons.^{178,184,185}

The combination of paroxysmal diaphoresis, tachycardia, and headache in the hypertensive patient is a recognized triad of symptoms for pheochromocytoma.^{8,11,84,183} A catecholamine-mediated paroxysm typically consists of a sudden and alarming increase in blood pressure, a severe throbbing headache, profuse sweating, a forceful heartbeat, tachycardia, a sense of doom, anxiety, pallor, and nausea.^{178,186} These hyperadrenergic spells are often followed by physical exhaustion. Clinical manifestations associated with pheochromocytoma are outlined in [Table 37.12](#).

TABLE 37.12

Clinical Manifestations of Pheochromocytoma and Approximate Frequency

Symptom	%	Symptom	%
Hypertension	90	Chest pain	19
Headache	80	Dyspnea	19
Excessive perspiration	71	Flushing or warmth	18
Palpitation (with or without tachycardia)	64	Numbness or paresthesia	11
Pallor	42	Blurring of vision	11
Nausea (with or without vomiting)	42	Tightness of throat	8
Tremor or trembling	31	Dizziness or faintness	8
Weakness or exhaustion	28	Convulsions	5
Nervousness or anxiety	22	Neck-shoulder pain	5
Epigastric pain	22	Extremity pain	4
		Flank pain	4

The typical duration of a pheochromocytoma spell is 15 to 20 minutes, but it may be much shorter or last several hours. The paroxysm may be spontaneous or triggered by abdominal palpation, exercise, change in posture, lifting, defecation, or any event that provokes increased pressure in the abdomen.¹⁷⁸ Micturition may trigger symptoms if the pheochromocytoma is present in the urinary bladder wall. Mental or psychologic stress does not usually initiate a crisis.¹⁷⁸

Owing to the usual predominance of norepinephrine secretion, the symptoms associated with many pheochromocytomas reflect primarily α -adrenergic activity. Vasoconstriction in the extremities may produce pain, paresthesias, intermittent claudication, or

ischemia.¹⁷⁸ Hyperglycemia may be present as a result of inhibition of insulin and enhanced hepatic glucose output. An overall increase in metabolism accelerates oxygen consumption and can cause hyperthermia. The cardiac output and heart rate may be significantly increased.

Hypertension is the most common symptom, occurring in more than 90% of patients.^{84,178,187} Severe paroxysmal hypertension is present in approximately 40% of patients and is a distinctive manifestation of the disease.^{84,178} Sustained hypertension is often resistant to conventional treatment. When pheochromocytomas are predominantly epinephrine or dopamine secreting, hypertension can alternate with periods of hypotension associated with syncope, particularly in the presence of a contracted vascular space.^{177,188}

Catecholamine-induced increase in myocardial oxygen consumption, hypertension, and coronary artery spasm can precipitate acute coronary syndrome or congestive heart failure even in the absence of coronary artery disease.^{11,178,189} ECG changes are common. Nonspecific ST-segment and T-wave changes may be seen. Sinus tachycardia, supraventricular tachycardia, and premature ventricular contractions are commonly noted. Ventricular tachycardia and sinus node arrest have been reported.^{84,178,189}

Some pheochromocytomas may first present as a hypermetabolic state during anesthesia for unrelated surgery.^{185,190} The hypertension, tachycardia, hyperthermia, and respiratory acidosis of a pheochromocytoma may mimic light anesthesia, thyroid crisis, malignant hyperthermia, or sepsis.^{186,191}

Surgery and Preoperative Management.

The treatment of choice for pheochromocytoma is complete surgical resection. Most tumors can be completely excised and hypertension cured. Postsurgical survival rates are greater than 94%.^{177,192}

The pharmacologic effects of circulating catecholamines present major anesthetic challenges. Uncontrolled catecholamine release can have serious and potentially lethal cardiovascular complications. Careful pharmacologic management is indicated for all surgical patients, even in those who are asymptomatic and normotensive.^{177,190,193} Preoperative treatment aims to reverse the

effects of excessive adrenergic stimulation. Antihypertensive therapy in concert with reexpansion of the intravascular fluid compartment before surgery greatly improves cardiovascular stability intraoperatively and has helped to decrease the surgical mortality rate for elective procedures from approximately 50% to the current rate close to 0% to 6%.^{177,192,194} Combined α - and β -adrenergic blockade is a commonly used preoperative management approach to control blood pressure and heart rate and prevent intraoperative hypertensive crisis.^{193,194} Table 37.13 outlines some of the drugs used in the preoperative management of pheochromocytoma.

TABLE 37.13

Drugs Used in the Preoperative Management of Pheochromocytoma

Drug	Action	Preoperative Blood Pressure Control	Comments
Phenoxybenzamine	Nonselective α -blocker	Initial dose 10–30 mg/day, increasing daily dosage by 30 mg as needed	Long half-life; may accumulate; S/E postural hypotension, nasal congestion, diarrhea, retrograde ejaculation, miosis
Doxazosin	Selective α_1 antagonist	1 mg/day PO up to 8 mg/day PO	First-dose phenomenon; may cause syncope; dizziness; drowsiness
Prazosin	Selective α_1 antagonist	1 mg/day PO up to 20 mg/day PO	First-dose phenomenon; may cause syncope; dizziness; drowsiness
Propranolol	Nonselective β -blocker	60 mg/day PO, in divided doses, for three days before surgery	Should not be administered without first creating α blockade
Atenolol	Selective β_1 -blocker	Oral 50 mg/day initially; may increase to 100 mg/day	Long-acting, selective β_1 antagonist eliminated unchanged by kidney; Should not be administered without first creating α blockade
Labetalol	α - and β -Blocker	Oral 200 mg tid	A much weaker α -blocker than β -blocker; may cause pressor response in pheochromocytoma
Nicardipine sustained release	Calcium channel blocker	30 mg twice a day; up to 120 mg/day	Arterial vasodilator; edema; flushing; headache
α -Methyltyrosine	Inhibitor of biosynthesis of catecholamines	Initial PO 1 g/day; up to 4 g/day in divided doses	For patients not amenable to surgery; may be nephrotoxic

α -Adrenergic Receptor Blockade.

Phenoxybenzamine remains a preferred drug for preoperative α -adrenergic blockade and blood pressure stabilization.¹⁷⁹ It is a

nonspecific presynaptic (α_2) and postsynaptic (α_1) adrenergic receptor antagonist of long duration (24 to 48 hours).⁸⁴ The initial dose is 10 to 20 mg once or twice daily, and the dose is increased every 2 to 3 days as needed to control blood pressure and hypertensive spells preoperatively.¹⁷⁷ Most patients with pheochromocytoma require an eventual oral dose between 60 and 100 mg/day.^{8,177,178} Because of the long duration of phenoxybenzamine and a concern regarding hypotension post tumor resection, some practitioners discontinue the drug 24 to 48 hours before surgery. Others recommend that one-half to two-thirds of the normal oral dose be given the morning of surgery.^{8,111}

Typically, patients require 10 to 14 days of α -adrenergic antagonist therapy to stabilize blood pressure, restore fluid volume, and decrease symptoms. Establishing normotension facilitates reexpansion of the intravascular fluid compartment. Satisfactory α -adrenergic blockade is implied if the hematocrit decreases by 5% during treatment.¹¹

Selective α_1 -adrenergic receptor antagonists (prazosin, doxazosin, terazosin) have also been used for preoperative control of hypertension.^{180,194} The appeal of selective α_1 -receptor antagonists is that, in theory, they leave the α_2 -receptor intact, thereby inhibiting the release of norepinephrine, allowing more effective management of blood pressure and heart rate, and resulting in less post resection hypotension.^{180,193-197}

Labetalol, a mixed α - and β -receptor antagonist, is a much weaker α -blocker than β -blocker. It has not been as effective as a first-line drug in controlling the blood pressure response but it may be used as an adjunctive agent.^{11,84,198}

β -Adrenergic Receptor Blockade.

A β -adrenergic receptor antagonist is often introduced before surgery to control tachycardia, hypertension, and cardiac dysrhythmias. Caution must be exercised for the patient with a history of asthma, congestive heart failure, and catecholamine-induced cardiomyopathy. An additional important caveat is that β -adrenergic receptor antagonists should not be administered until after α -adrenergic blockade is established. Blocking β_2 -receptor-mediated vasodilation without prior α -adrenergic blockade can

increase the blood pressure even further in the patient with pheochromocytoma.^{186,198} A helpful mnemonic for the reader is “a before b.”

Other Treatment Regimens.

Calcium channel blockers (e.g., nifedipine) have been used with variable success as monotherapy for the preoperative management of pheochromocytoma. In addition to their peripheral vasodilating effects, calcium antagonists also inhibit calcium dependent norepinephrine release from the tumor.¹⁸⁰ Some regimens successfully use these agents in conjunction with other vasodilating drugs.^{199,200}

End-points of treatment prior to surgery for pheochromocytoma resection include: normotension, resolution of symptoms, elimination of arrhythmias, and no ST-segment or T-wave abnormality on the ECG that cannot be attributed to a permanent defect.^{8,11,201}

Anesthetic Management.

Pheochromocytomas are excised by open laparotomy or minimally invasive adrenalectomy (laparoscopic or retroperitoneoscopic).^{202–205} The minimally invasive surgical technique is considered the procedure of choice for resection of solitary intraadrenal tumors smaller than 6 to 8 cm.^{180,194} The minimally invasive approach is associated with better perioperative outcomes, less analgesia use, earlier mobilization, and faster recovery compared to open laparotomy.^{203,205–208} During pneumoperitoneum for laparoscopy, significant catecholamine release has been reported and should be anticipated by the anesthetist.²⁰⁹

Effective anesthetic management is based on (1) selecting drugs that do not stimulate catecholamine release, (2) implementing monitoring techniques that facilitate early and appropriate interventions, and (3) responding expeditiously to catecholamine-induced changes in cardiovascular function.

A number of drugs and conditions can precipitate hypertension in the surgical patient with pheochromocytoma. Dopamine antagonists (metoclopramide, droperidol), radiographic contrast media, indirect-acting amines (ephedrine, methyl dopa), drugs that

block neuronal catecholamine reuptake (tricyclic antidepressants, cocaine), and histamine may enhance the physiologic effects of tumor product.^{11,178}

Pheochromocytomas are vascular tumors. Large-bore intravenous lines and a peripheral arterial catheter should be established preoperatively. Central venous pressure monitoring will help guide fluid management and intervention with inotropes or vasoactive drugs.^{11,84} Arterial blood gases, electrolyte concentrations, and blood glucose levels should be assessed regularly during the anesthetic.

Critical intraoperative junctures are (1) during induction and intubation of the trachea (hypertension), (2) during surgical manipulation of the tumor (hypertension), and (3) after ligation of the tumor's venous drainage (hypotension). An adequate depth of anesthesia with induction may be accomplished with barbiturates, etomidate, or propofol. Anesthetic depth can be enhanced by mask ventilation of the lungs with a volatile anesthetic prior to laryngoscopy and intubation. Lidocaine (1 to 2 mg/kg IV) administered 1 minute prior to intubation may help attenuate the hemodynamic response to laryngoscopy. Short-acting opioids administered prior to intubation also may help blunt the blood pressure responses to intubation. Morphine sulfate should be avoided because of its propensity for histamine release.

Sevoflurane or isoflurane and short-acting opioids provide cardiovascular stability and possess the ability to rapidly change anesthetic depth, which are attractive features in the anesthetic management of the patient with pheochromocytoma.^{8,11,84} The tachycardia and increased sympathetic stimulation associated with desflurane make it a less desirable choice for these cases.

The use of selective α_2 -receptor agonist dexmedetomidine may be useful in managing blood pressure and heart rate. Activating α_2 -receptors results in sympathetic inhibition and has been shown to reduce the release of catecholamines resulting in decreased blood pressure and heart rate.²¹⁰⁻²¹²

The use of succinylcholine has been questioned because compression of an abdominal tumor by drug-induced skeletal muscle fasciculations may provoke catecholamine release. However, a predictable adverse effect of succinylcholine has not

been supported clinically when administered to patients with pheochromocytoma. Skeletal muscle paralysis with a nondepolarizing muscle relaxant devoid of vagolytic or histamine-releasing effects is desirable. Pancuronium should be avoided for its known chronotropic effect.^{8,11,84}

The anesthetist should anticipate a labile cardiovascular course during surgery, necessitating antihypertensive control (Table 37.14). Acute hypertension may be treated with intravenous sodium nitroprusside, phentolamine, nicardipine, clevidipine, magnesium sulfate, or other antihypertensives, as well as high concentrations of inhaled anesthetic.^{8,11,84,179,191,213} Sodium nitroprusside is especially advantageous because of its rapid onset and short duration of action. Lidocaine, labetalol, or esmolol may be administered to decrease tachydysrhythmias. β -Adrenergic receptor antagonists must be used cautiously in patients with catecholamine-induced cardiomyopathy because even minimal β -adrenergic blockade can accentuate left ventricular dysfunction.^{11,84} The short half-life of esmolol makes it the preferred choice for β -adrenergic blockade intraoperatively. Dysrhythmias associated with hypertension may be resolved by simply lowering an abnormally high blood pressure. Indirect-acting sympathomimetics have an unpredictable pressor effect in these patients and should be avoided.

TABLE 37.14

Drugs Used in Intraoperative Management of Pheochromocytoma

Drug	Action	Intravenous Dosage	Comment
Phentolamine	Nonselective α -blocker	1 mg test dose, then 1 to 5 mg bolus every 5 min or infuse initially 1 mg/min as needed	Rapid onset, the response to bolus is maximal 2 to 3 minutes and lasts 10 to 15 minutes; tachycardia; tachyphylaxis develops
Esmolol	Selective β_1 -blocker	Loading dose 0.5 mg/kg infused over 1 min, followed by maintenance infusion 0.05 mg/kg per min. Incremental increase in dose as needed to a maximum 0.2 mg/kg per min	Ultrashort-acting; elimination half-life approximately 9 minutes; may be used during anesthesia
Labetalol	α - and β -blocker	IV 10-mg bolus	A much weaker α -blocker than β -blocker; ratios of α - to β -blockade have been estimated to be approximately 1 : 3 (oral dose) and

			1 : 7 (IV dose); may cause pressor response in pheochromocytoma if α -blockade inadequate
Nitroprusside	Direct vasodilator	IV infusion initially 0.5–1.5 mcg/kg per min. Rates > 4 mcg/kg per min may lead to cyanide toxicity within 3 hrs. Maximal dose should not exceed 800 mcg/min	Powerful vasodilator; short-acting; Cyanide toxicity; methemoglobinemia
Magnesium sulfate	Direct vasodilator	Initial loading dose of 50 mg/kg over 10 minutes followed by 15 mg/kg per hr	May potentiate neuromuscular blockade
Clevidipine	Dihydropyridine calcium channel blocker	Initial dose 1–2 mg/hr; doubled every 90 seconds if needed; typical infusion 4–6 mg/hr; onset 2–4 min; duration 5–15 min	Arterial vasodilation; metabolism by plasma esterases; ultrashort acting; tachycardia common
Nicardipine	Dihydropyridine calcium channel blocker	1–2 mcg/kg per min initially and increased to 7.5 mcg/kg per min as needed	Arterial vasodilation; tachycardia common
Dexmedetomidine	Selective α_2 adrenergic receptor agonist	IV infusion: initially 1 mcg/kg over 10 minutes, then 0.5 mcg/kg per hr	

IV, Intravenous.

Modified from Schwartz JJ, et al. Endocrine function. In Barash PG, et al., eds. *Clinical Anesthesia*. 7th ed. Philadelphia: Wolters Kluwer; 2013:1342.

After surgical ligation of the veins that drain a pheochromocytoma, the decrease in circulating catecholamines and the associated down-regulation of adrenergic receptors can precipitate an abrupt and marked decrease in blood pressure.^{213,214} Hypotension often responds to fluids, but intravenous administration of phenylephrine, vasopressin, or dopamine may be needed until the peripheral vasculature adapts to the decreased level of endogenous α -stimulation.^{213,214} Adrenocortical insufficiency should be considered as a potential cause of post resection hypotension if both adrenal glands were manipulated during surgery.¹⁷⁷

Hyperglycemia is common before excision of the pheochromocytoma. With tumor removal, the sudden withdrawal of catecholamine stimulation can result in hypoglycemia. Blood glucose levels should be monitored at frequent intervals intraoperatively and postoperatively.

Postoperative Management.

The most common postoperative adverse event is sustained

hypertension.¹⁷⁸ Fluid shifts, pain, hypoxia, hypercapnia, adrenergic instability, urinary retention, or residual tumor are all causes of postoperative hypertension. A past medical history of coronary artery disease and incidences of intraoperative hemodynamic instability are independent predictors for postoperative cardiovascular morbidity.²¹⁵ Continued invasive monitoring is indicated during the initial postoperative period to assess blood pressure changes and cardiac status. Fifty percent of patients remain hypertensive during the immediate postanesthesia recovery period, despite successful removal of the pheochromocytoma.^{11,201} Postoperative catecholamine levels decrease to normal over several days and most patients are normotensive by the time of hospital discharge.¹⁷⁸

Thyroid Gland

The thyroid gland is an endocrine gland located anterior to the trachea between the cricoid cartilage and suprasternal notch. It produces and secretes two important thyroid hormones: triiodothyronine (T_3) and thyroxine (T_4). The vascular supply to the gland is derived from the superior and inferior thyroid arteries. Blood flow is equivalent to approximately five times the weight of the gland, which is a blood supply as rich as almost any tissue in the body. The gland consists of two lobes and an isthmus. The recurrent laryngeal nerves run along the lateral borders of each thyroid lobe.²¹⁶

Microscopically, the thyroid is divided into lobules, each of which is composed of 20 to 40 follicles. The follicles are the functional units of the thyroid gland. They are lined by epithelial cells that surround central deposits of a proteinaceous substance called *colloid*. The major constituent of the colloid is a large glycoprotein called *thyroglobulin*, which serves as the backbone for the synthesis and storage of thyroid hormones.²¹⁶

Synthesis of Thyroid Hormones

Iodide Trapping

Approximately 1 mg of ingested iodine is required each week to form normal quantities of thyroid hormones. Dietary iodine is reduced in the gastrointestinal tract to iodide. Common table salt is iodized with sodium iodide for the prevention of iodine deficiency.

The first stage of thyroid hormone formation is the transport of iodides from the extracellular fluid into the thyroid cells and follicles. Approximately one-fifth of the circulating iodide is removed from the blood by active transport into the thyroid cells and used for the synthesis of thyroid hormones, a process called *iodide trapping*. The iodide transport pump normally concentrates the intracellular iodide to approximately 30 times its concentration in the blood. Iodide trapping is the rate-limiting step in thyroid hormone synthesis and is under the control of TSH from the anterior pituitary. Once inside the thyroid gland, iodide ions are

oxidized back to iodine.²¹⁶

Thyroid Hormone Formation

Thyroid hormones are formed in the follicles of the thyroid gland under the control of TSH. Thyroglobulin contains the amino acid tyrosine, which combines with iodine to form various iodotyrosines, including the two major thyroid hormones.

Thyroxine and triiodothyronine remain part of the thyroglobulin molecule, stored as colloid within the thyroid follicle until release. Enough hormone is synthesized and stored under basal conditions to supply the body with its normal hormone requirements for 2 to 3 months. As a result, if complete thyroid hormone synthesis ceases, the physiologic effects are not seen for several months.^{216,217}

Although iodine is required for hormone synthesis, paradoxically, excess iodine (100 times the normal plasma level) can cause the gland to recede and inhibit production of thyroid hormone.

Release of Thyroxine and Triiodothyronine

TSH controls the release of hormones from the thyroid gland. On release, T_4 and T_3 are cleaved from the thyroglobulin molecule and secreted into the circulating blood. Thyroglobulin remains within the colloid.²¹⁶

Under normal conditions, approximately 93% of the hormone released from the thyroid gland is T_4 and 7% is T_3 .²¹⁶ The secretion of T_4 from the thyroid gland is 80 to 100 mcg/day. When thyroid hormones reach their target tissues, most of the T_4 is deiodinated to T_3 , with T_4 serving mostly as a hormone precursor.

Triiodothyronine, therefore, is the primary thyroid hormone that stimulates target tissues and it is more potent and less protein bound than T_4 .²¹⁷

Transport of Thyroxine and Triiodothyronine to Tissues

Thyroid hormone exists in circulation in both free and bound

forms. The amount of free hormone, which is the metabolically active fraction, is extremely small; less than 0.03% of total circulating T_4 and 0.3% of total circulating T_3 . The majority of circulating hormone (99%) is bound to plasma proteins. Most of the thyroid hormones bind to the circulating protein thyroxine-binding globulin.^{216,218}

Because of the very high amount of protein binding, free thyroid hormones are released to the tissue cells very slowly. The half-life of T_4 in circulation is 6 to 7 days, and the half-life of T_3 is approximately 24 hours.^{216,217}

Functions of Thyroid Hormones

Increased Cellular Metabolic Activity

Thyroid hormones bind to nuclear receptors in target cells (virtually all cells of the body) where they activate gene transcription and initiate protein formation (Fig. 37.22). Consequently, the level of enzymes, structural proteins, transport proteins, and other substances increases considerably under the direction of T_4 and especially T_3 . The net result is a generalized increase in metabolic activity, heat production, and oxygen consumption of all or almost all tissues in the body.^{216,218} The basal metabolic rate can increase by as much as 60% to 100% above normal when large quantities of thyroid hormones are secreted.¹⁶² The rate and depth of respiration increase due to the enhanced metabolic rate and increased oxygen use and carbon dioxide formation by cells. The use of energy substrates is greatly accelerated. Protein synthesis is increased; however, protein catabolism is also increased. When the quantity of thyroid hormone is slightly increased, the muscles react with vigor; however, when the quantity is excessive, muscles become weakened from excess protein catabolism.

FIGURE 37.22 Homeostasis in the hypothalamus-pituitary-thyroid axis and mechanism of action of thyroid hormones. Secretion of thyroid hormones (T₃ and T₄) is controlled by trophic factors secreted by both the hypothalamus and the anterior pituitary. Decreased levels of T₃ and T₄ stimulate the release of thyrotropin-releasing hormone (TRH) from the hypothalamus and thyroid-stimulating hormone (TSH) from the anterior pituitary, causing T₃ and T₄ levels to rise. Elevated T₃ and T₄ levels, in turn, feedback to suppress the secretion of both TRH and TSH. TSH binds to the TSH receptor on the thyroid follicular epithelium, which causes activation of G proteins, and cAMP-mediated synthesis and release of thyroid hormones (T₃ and T₄). In the periphery, T₃ and T₄ interact with the thyroid hormone receptor (TR) to form a hormone-receptor complex that translocates to the nucleus and binds to so-called thyroid response elements (TREs) on target genes to initiate transcription. (From Kumar V, et al. *Robbins and Cotran Pathologic Basis of Disease*. 9th ed. Philadelphia: Elsevier; 2015:1083.)

Effect of Thyroid Hormone on Growth

Thyroid hormones are necessary for normal growth in infants and children. In a hypothyroid state, the rate of tissue growth is greatly reduced. Thyroid hormone is required for normal growth and development of the brain during fetal life and for the first few years of postnatal life.²¹⁶

Effect of Thyroid Hormone on Specific Systems

Thyroid hormones have direct and indirect effects on the excitability of the heart. The heart rate and the force of contraction are augmented with increasing thyroid hormone production. As such, the heart rate is a sensitive sign of excessive or diminished thyroid hormone production.²¹⁶ Vasodilation occurs from increased cellular oxygen consumption and results in increased blood flow to most tissues.²¹⁶

Thyroid hormones increase the rate of hormone secretion from most endocrine glands, especially the pancreas. The heightened cellular requirement for glucose mandates higher insulin secretion. Thyroid hormones also enhance the secretion of digestive juices and the motility of the gastrointestinal tract, in addition to increasing an individual's appetite and food intake. In adults, thyroid hormones enhance the rapidity of cerebration.²¹⁶

Regulation of Thyroid Hormone Secretion

Specific feedback mechanisms operate through the hypothalamus and anterior pituitary gland to precisely control the rate of thyroid hormone secretion. Thyrotropin-releasing hormone (TRH) from the hypothalamus causes cells of the anterior pituitary lobe to produce and secrete TSH. Potent stimuli to TRH and TSH release include low levels of T_3 and T_4 , stress, and exposure to cold.²¹⁶ TSH increases all known activities of thyroid gland cells, resulting in increased gland size and vascularity and increased hormone synthesis and release. These varied effects are mediated by activation of the second messenger cAMP in thyroid cells. High circulating levels of primarily T_3 , and to a lesser extent T_4 , inhibit

the secretion of TRH and TSH through a negative feedback effect on the hypothalamus and anterior pituitary. Fig. 37.23 summarizes the regulation of thyroid secretion.

FIGURE 37.23 Neuroendocrine and peripheral control of thyroid-stimulating hormone (TSH) secretion. Positive and negative stimuli are indicated at various levels within the hypothalamic-pituitary-thyroid axis. *AGRP*, Agouti-related protein; *α MSH*, melanocyte-stimulating hormone; *ARC*, arcuate nucleus; *CART*, cocaine and amphetamine regulated transcript; *D2*, deiodinase type II; *DA*, dopamine; *NPY*, neuropeptide Y; *PVN*, paraventricular nucleus; *SS*, somatostatin; *T₃*, triiodothyronine; *T₄*, thyroxine; *TRH*, thyrotropin-releasing hormone. (In Jameson JL, DeGroot LJ.

Thyroid Gland Disorders

Thyrotoxicosis and Graves' Disease

Hyperthyroidism is defined as thyroid gland hyperactivity.

Thyrotoxicosis is more specifically defined as a state of thyroid hormone excess.²¹⁸ Today, these terms are often used interchangeably.²¹⁹ The most common cause of thyrotoxicosis in the United States is Graves' disease, affecting approximately 0.5% of the population and accounting for 60% to 80% of thyrotoxicosis cases.^{218,220} Graves' disease is an autoimmune disease in which TSH-receptor antibodies bind to and stimulate the thyroid gland, resulting in gland enlargement and excessive production and secretion of T₄ and T₃.^{218,220} These unique immunoglobulin G (IgG) autoantibodies mimic the actions of TSH, but their effects are continuous and uncontrolled. Graves' disease is four to five times more common in women than men and the peak incidence occurs between 40 and 60 years of age.^{219,220} Potential risk factors for Graves' disease include genetic susceptibility, stress, and cigarette smoking. There is a threefold increase in Graves' disease in the postpartum period.²¹⁸

Other important causes of thyrotoxicosis include toxic nodular hyperthyroidism, due to the presence of autonomously functioning thyroid nodules, and thyroiditis, which results in the release of stored hormones.²²¹ A TSH-secreting pituitary tumor is a less common cause of thyrotoxicosis. Thyroid cancer is most often associated with a euthyroid state, but may cause hyper- or hypothyroidism. Cancer of the thyroid gland is increasing at an alarming rate and is projected to replace colorectal cancer as the fourth leading cancer diagnosis by 2030.²²²

Iodine containing radiocontrast agents or angiography dyes may precipitate thyrotoxicosis in susceptible individuals. The antiarrhythmic agent amiodarone is iodine rich and may cause either hypo- or hyperthyroidism.²²³ Due to structural similarity with

thyroid hormones, 14% to 18% of patients treated with amiodarone develop overt thyroid dysfunction.²²³

Signs and Symptoms.

Clinical manifestations associated with thyrotoxicosis reflect the widespread hypermetabolic effects of excess thyroid hormones. The thyroid gland is usually enlarged two to three times its normal size with Graves' disease. Physical manifestations include tachycardia, hand tremor, and muscle weakness.²²⁴⁻²²⁶ Despite extreme fatigue, sleep is often difficult. Weight loss (despite increased food consumption), anxiety, fatigue, and increased thermogenesis and oxygen consumption are clinical findings of thyrotoxicosis.^{218,220}

The aberrant immunologic response associated with Graves' disease targets primarily the thyroid gland but also other tissues, most notably extraocular muscles (Graves' ophthalmopathy) and skin (thyroid dermopathy). Ophthalmopathy is observed in 30% to 50% of patients with Graves' disease.^{218,220,227-229} Thyroid-associated ophthalmopathy may cause exophthalmos (protrusion of the eyeballs), eye redness, and periorbital edema. Papilledema, diplopia, and loss of visual acuity may occur. Graves' ophthalmopathy results from autoimmune-mediated inflammation and swelling of the periorbital connective tissue and extraocular muscles.^{218,219,220} Management of Graves' ophthalmopathy includes high-dose glucocorticoids, cyclosporine, and orbital radiotherapy, but effect treatment remains a therapeutic challenge.²²⁸

The systolic blood pressure is typically elevated 10 to 15 mmHg, and the diastolic pressure is reduced under the influence of excess thyroid hormone. The blood volume increases slightly due to vasodilation. Mean arterial pressure usually remains unchanged, but the pulse pressure increases.^{224,225} Blood flow to the skin increases in response to the increased need for heat elimination.²²⁴

The effects of thyrotoxicosis on the heart are pronounced.²²⁶ Thyroid hormones have a direct effect on the excitability of the heart, and also by increasing the number of β -adrenergic receptors. Sinus tachycardia and cardiac dysrhythmias affect almost all patients.²²⁴ The prevalence of atrial fibrillation ranges between 2% and 20%.²²⁴ The cardiac output increases with thyrotoxicosis, sometimes 50% to 300% above normal.²²⁴ With protracted high

thyroid hormone levels, heart muscle strength may eventually become depressed because of protein catabolism.

Diagnosis of thyrotoxicosis is more difficult in the elderly because many of the hyperkinetic manifestations of hyperthyroidism are absent.²³⁰ Elderly patients may initially present with myocardial failure or atrial fibrillation.^{218,220,230} The hyperthyroid individual, but particularly the elderly, may feel constant fatigue from the exhausting effect of thyroid hormone on the musculature and the central nervous system.

Diagnosis.

The diagnosis of primary hyperthyroidism is established in most cases by the combined findings of abnormally high “free” serum T₄ and T₃ levels and depressed TSH levels.^{219,228} With Graves' disease, the diagnosis may be supported by the presence of thyroid-stimulating immunoglobulins.^{218,220,231} Serum alkaline phosphatase and calcium concentrations are elevated in approximately 20% of patients with Graves' disease and reflect bone turnover.²¹⁸

Other autoimmune diseases such as myasthenia gravis, rheumatoid arthritis, systemic lupus erythematosus, and type 1 DM are more common in patients with Graves' disease.

Treatment.

A variety of treatment options are available for patients with thyrotoxicosis. The three primary treatment options are radioactive gland ablation, surgery, and antithyroid drug therapy.²³²⁻²³⁵ None of these options are ideal; drug treated patients have a high relapse rate and ablative therapies (total thyroidectomy, radioactive iodine) induce life-long hypothyroidism.²²⁸

Radioactive Iodine.

A common therapy for Graves' disease in the United States is ablation of the thyroid gland with radioactive iodine (¹³¹I). An injected dose of radioactive iodide is absorbed by the hyperplastic gland and it slowly destroys most of the thyroid secretory cells. Two to four months is needed to reverse the hyperthyroidism with this approach. Hypothyroidism is common after treatment. Use of ¹³¹I is contraindicated during pregnancy and breast feeding.

Thyroidectomy.

Total thyroidectomy for treatment of Graves' disease is an option, especially when antithyroid drugs are ineffective, if radioiodine treatment is refused, when malignancy is suspected, in children or pregnant women, or if the thyroid goiter is exceptionally large.²²⁸ Patients should be treated preoperatively with antithyroid medication and rendered euthyroid prior to surgery.

Complications associated with thyroid surgery occur in less than 1% of cases and include damage to the recurrent laryngeal nerve (RLN), hypoparathyroidism (hypocalcemia), and neck hematoma. Postoperative bleeding into the operative site can rapidly produce death by asphyxia and requires immediate evacuation. Thyroid carcinoma, reoperation for recurrent goiter, nonidentification of the RLN, and total thyroidectomy are associated with a significantly increased risk of operative RLN injury.²³⁶ Unilateral damage to the RLN causes postoperative dysphonia that usually improves in a few weeks. Bilateral RLN injury is much more serious, because both vocal cords may assume a median or paramedian position and cause aphonia and airway obstruction.²¹⁹ Immediate intubation and ventilatory support may be required. Vocal cord function can be assessed postoperatively by asking the patient to phonate "E". Additionally, various nerve integrity monitors may be used during thyroid surgery to help the surgeon identify the RLN.²³⁷⁻²⁴¹

Thyroidectomy is usually performed under general endotracheal anesthesia.²⁴¹ The laryngeal mask airway has been used to facilitate laryngeal nerve monitoring using fiberoptic endoscopic examination of vocal cord movement.^{242,243} Bilateral cervical plexus block can be used for those patients who pose a general anesthesia risk or in concert with general anesthesia for postoperative pain control.²⁴⁴⁻²⁴⁶

Antithyroid Drugs and β -Adrenergic Receptor Blockade.

The main class of antithyroid medications is the thionamides, which include methimazole, carbimazole, and propylthiouracil (PTU). All thionamides inhibit thyroid hormone synthesis by interfering with the incorporation of iodine into tyrosine residues of thyroglobulin. A euthyroid state is usually obtained in 6 to 7 weeks. PTU also inhibits conversion of T_4 to T_3 , but it is not usually a first-

line treatment because of rare but severe hepatic toxicity. Agranulocytosis is the most serious side effect of these drugs.^{228,235}

β -Adrenergic blocking agents (propranolol, metoprolol, atenolol) are often added to the antithyroid regimen to reduce cardiovascular symptoms. Propranolol has the additional advantage of inhibiting the peripheral conversion of T_4 to T_3 .^{232,235} Adrenergic blocking agents aggravate bronchospasm and therefore may be contraindicated in the patient with asthma or severe chronic obstructive pulmonary disease.

For the patient preparing for surgical thyroidectomy, the aim of preoperative pharmacologic management is to restore the metabolic state to normal with antithyroid agents and then to induce involution of the gland with iodine.²¹⁹ Seven to ten days before surgery, oral potassium iodide (saturated solution of potassium iodide [SSKI] or Lugol solution) may be added to the course of therapy. Iodides in high concentration decrease all phases of thyroid activity and decrease the gland size and vascularity.²²⁸

Preoperative Assessment—Hyperthyroidism.

The key to successful preoperative preparation of the hyperthyroid surgical patient is a careful assessment of the extent of thyrotoxicosis and the severity of end-organ manifestations. Thyrotoxicosis is associated with increased operative risk, so elective surgery should not proceed until the patient has been rendered euthyroid by medical management.^{8,11,218} Antithyroid medications and β -adrenergic blocking agents should be continued through the morning of surgery.⁸

Hyperthyroid patients have increased blood volume, decreased peripheral resistance, and a wide pulse pressure. The cardiac output, heart rate, and systolic blood pressure may be increased. Appropriate corrections of the patient's fluid volume and electrolyte status should be accomplished before surgery.

Only life-threatening emergency surgery should be performed in an untreated symptomatic hyperthyroid patient.^{8,11} In an emergency situation, the otherwise healthy patient can be expeditiously prepared for surgery with the oral administration of potassium iodide (3 to 5 drops every 6 hours) and carefully titrated intravenous propranolol (1 to 10 mg) or esmolol infusion (50 to 300

mcg/kg per min).⁸ Elderly patients who require emergency surgery and have rapid ventricular rates require central pressure monitoring to guide therapy.

Preoperative Assessment—Goiter.

A careful preoperative evaluation of the airway is mandatory in all hyperthyroid and hypothyroid patients undergoing surgery. Thyroid gland enlargement can be asymptomatic, but it can also cause tracheal deviation and tracheoesophageal compression.^{220,241} Chronic pressure on the trachea can result in tracheomalacia, a weakening of the thyroid cartilage that can cause tracheal collapse. Its presence may necessitate a more prolonged intubation and vigilant observation after surgery. Hoarseness, difficulty swallowing, sore throat, a feeling of pressure in the neck, coughing, orthopnea, or dyspnea suggests tracheal compression that can be caused by thyromegaly.²⁴¹ Imaging tests may be employed to evaluate thyromegaly. Ultrasonography is the most sensitive method for assessing gland architecture; CT is also used.²⁴¹

Although an enlarged thyroid gland is not in itself a predictor of airway management problems, difficult intubation is reported in 5% to 8% of cases for goiter surgery.^{247,248} A patient with a large goiter and an obstructed airway poses the same challenge as any other patient in whom airway management is problematic. An awake fiberoptic intubation with topical anesthesia is of proven value under these conditions.²²⁰ Other suggested available equipment for management of an anticipated difficult airway include rigid bronchoscope, video laryngoscopes, and laryngeal mask airways. There are situations where it may be beneficial to have a surgeon present in the room at induction.²⁴¹

Intraoperative Management.

A goal of the perioperative management of the hyperthyroid patient is prevention of sympathetic nervous system stimulation. This is accomplished by providing sufficient anesthetic depth and avoiding medications that directly or indirectly stimulate the sympathetic nervous system.^{8,11}

A preoperative anxiolytic medication is generally warranted. The antisialagogues, atropine and glycopyrrolate, should not be

routinely administered because of their vagolytic effects and ability to impair sweating.

Induction of anesthesia may be achieved with a number of intravenous medications. Ketamine should be avoided because it can stimulate the sympathetic nervous system. Pancuronium should be avoided because it has the potential to increase the heart rate.

Because of the increased incidence of myasthenia gravis and skeletal muscle weakness in the hyperthyroid patient, precaution dictates careful titration of muscle relaxant doses with neuromuscular blockade monitoring.⁸⁴ Respiratory failure has been described in surgical patients with uncontrolled hyperthyroidism.²⁴⁹

Isoflurane or sevoflurane are attractive choices for inhalation anesthetics because of their ability to offset sympathetic nervous system responses to surgical stimulation and because they do not sensitize the myocardium to catecholamines. Hyperthyroid patients do not generally require a higher minimum alveolar concentration (MAC) for inhalational anesthesia.^{8,11} The increased cardiac output accompanying hyperthyroidism may accelerate the uptake of an inhaled anesthetic, resulting in the need to increase the delivered concentration, and this may be perceived clinically as an increased anesthetic requirement.^{8,11}

Monitoring of the hyperthyroid patient should focus on early recognition of increased thyroid gland activity suggesting the onset of thyroid storm. Core body temperature should be monitored closely. The ECG should be assessed for tachycardia or dysrhythmias. Hypotension occurring during surgery is better treated with direct-acting vasopressors than with indirect-acting vasoactive drugs that stimulate the release of catecholamines. Hypercarbia and hypoxia should be stringently avoided because they stimulate the sympathoadrenal axis.

Meticulous care of the eyes is required. The patient with proptosis is at risk for corneal exposure and damage, so special care should be taken to lubricate and protect the eyes perioperatively.

[Box 37.10](#) summarizes key anesthesia implications for patients with hyperthyroidism.

Anesthesia Implications for the

Hyperthyroid Patient

- Determine the extent of thyrotoxicosis and end-organ complications.
- Ensure a euthyroid state prior to surgery.
- Evaluate the airway closely.
- Avoid sympathetic nervous system activation and sympathomimetic drugs.
- Titrate muscle relaxants carefully, considering possible myopathy.
- Position carefully (decreased bone density and predisposition to osteoporosis).
- Monitor closely for early signs of thyroid storm.
- Pad and protect the eyes.

Thyroid Storm.

A feared complication in the hyperthyroid patient is thyroid storm or accelerated hyperthyroidism. Thyroid storm is an extreme acceleration of thyrotoxicosis caused by acute stress in the previously undiagnosed or incompletely treated hyperthyroid patient.²¹⁹ Treatment with antithyroid medications helps protect the patient against thyroid storm. β -Adrenergic blocking agents do not prevent thyroid storm. Precipitating events may include trauma, surgery (especially thyroid surgery), the peripartum period, acute illness, and infection.^{250–252} Thyroid storm associated with surgery may occur anytime in the perioperative period but has been reported most often 6 to 18 hours after surgery.^{250–253}

Thyroid storm is an uncommon, life-threatening medical emergency that represents a severe exacerbation of hyperthyroid signs and symptoms. The clinical manifestations may include marked tachycardia, hyperthermia, hypertension, and arrhythmias (Box 37.11). Metabolic acidosis may be present secondary to

Box 37.11 Increased lactate production from overactive metabolism.

Clinical Manifestation of Thyroid Storm

- Fever greater than 38.5°C
- Tachycardia
- Confusion and agitation
- Tremor
- Weakness
- Dysrhythmias
- Nausea and vomiting
- Hypertension
- Heart failure

Similarities exist between the clinical features of thyroid storm and those of pheochromocytoma, neuroleptic malignant syndrome, light anesthesia, and malignant hyperthermia, making clinical diagnosis challenging in some cases.²⁵⁰⁻²⁵³ The clinical picture of severe hypermetabolism in a patient with a history of hyperthyroidism, exophthalmos, or goiter strongly supports the diagnosis.²¹⁹ To prevent substantial morbidity and mortality, emergency treatment should not await laboratory confirmation. Mortality rates are as high as 20% to 30%, even with early diagnosis and management.²¹⁸ The high mortality associated with thyroid storm underscores the importance of achieving a euthyroid state before surgery.

Management of perioperative thyroid storm includes identifying and treating the precipitating cause, administering antithyroid medications, and providing hemodynamic support. Carefully titrated β -adrenergic receptor blockers blunt adrenergic manifestations, and a short-acting agent like esmolol may be safer in this setting. Caution is essential in the patient with asthma or

heart failure. Antithyroid drugs (PTU 200–400 mg PO or via nasogastric tube [NGT] or rectally every 6 hr) block thyroid hormone synthesis.²³⁵ PTU is preferable in this setting because it has the additional action of inhibiting the generation of T₃ from T₄.²¹⁹ Iodides in the form of Lugol solution or SSKI acutely retard the release of preformed hormone from the thyroid gland.²¹⁹ Supplemental glucocorticoids (50–100 mg hydrocortisone IV every 6 hr) support the response to stress and inhibit the peripheral conversion of T₄ to T₃.²¹⁹

Supportive measures include intravenous hydration with glucose-containing crystalloid solutions, correction of electrolyte and acid-base imbalances, and management of hyperthermia. Salicylates may displace T₃ and T₄ from carrier proteins; therefore, acetaminophen is the recommended antipyretic for lowering body temperature in concert with a cold blanket or ice packs as required.^{218,219} Adequate oxygenation is of paramount importance during thyroid storm. Vasoactive medications and advanced hemodynamic monitoring may be necessary to help manage the labile cardiovascular course.²¹⁸

Hypothyroidism

Hypothyroidism is a state of thyroid gland hypofunction resulting in decreased circulating concentrations of thyroid hormones. Laboratory findings show decreased plasma T₃ and T₄ concentrations and increased TSH levels in patients with primary disease.²¹⁸ The clinical spectrum of thyroid hormone deficiency can range from the asymptomatic patient with no overt physical findings to the classic myxedema coma patient with profound symptoms. Hypothyroidism is the most common disorder of thyroid function, occurring in 5% to 10% of women and 0.5% to 2% of men.²¹⁸

Primary hypothyroidism accounts for 95% of all cases of hypothyroidism. An autoimmune-mediated inflammation and destruction of the thyroid gland, known as *Hashimoto thyroiditis*, is the most common form of hypothyroidism in the United States.²⁵⁴ The disorder most often occurs in females of middle age and is associated with other autoimmune disorders such as myasthenia

gravis, type 1 DM, and adrenal insufficiency.

In addition to autoimmune-mediated gland destruction, primary hypothyroidism may also be the result of severe iodine deficiency, colloid goiter, or iatrogenic causes (e.g., previous thyroid surgery, neck irradiation, radioiodine therapy).²¹⁸ As noted previously, the antiarrhythmic agent amiodarone is associated with hyper- and hypothyroidism.²²⁴ Hypothyroidism is associated with tyrosine kinase inhibitors, a class of anticancer drugs.^{255,256} Lithium inhibits the release of thyroid hormone and causes hypothyroidism in some patients.

Rarely, secondary hypothyroidism is the result of pituitary or hypothalamic disorders. Secondary hypothyroidism is associated with decreased concentrations of both thyroid hormones and TSH.²¹⁸ Regardless of the etiology, the clinical manifestations of hypothyroidism are similar.

Signs and Symptoms.

Most cases of hypothyroidism are subclinical, with laboratory findings of increased plasma TSH but no overt signs.²⁵⁴ Patients with more significant disease develop signs and symptoms that reflect a slowed metabolism and impaired cellular functions. Due to the effects of elevated TSH, the thyroid gland is usually enlarged (goiter), nontender, and firm. A bruit over the gland reflects increased vascularity. Patients may have cold intolerance, paresthesias, slow mental functioning, ataxia, puffy face, and slow gastrointestinal function. Dry skin and brittle hair and nails reflect failure of trophic functions.²¹⁸ Lack of thyroid hormone causes the muscles to become weak. Patients with severe hypothyroidism may be hypersomnolent with a decreased ventilatory response to hypoxia and hypercarbia.²¹⁸

Accumulation of mucopolysaccharides and proteinaceous fluid in serous body cavities is a recognized feature of hypothyroidism. The most common sites of effusions associated with hypothyroidism are the pleural, pericardial, and peritoneal cavities.^{164,166} Inappropriate ADH secretion and impaired free water clearance can lead to hyponatremia. Accumulation of mucopolysaccharides and fluid imparts the characteristic edematous appearance called *myxedema*.²¹⁸

Cardiovascular complications include sinus bradycardia, dysrhythmias, cardiomegaly, impaired contractility, heart failure, and labile blood pressure.²²⁴ Symptoms of low exercise tolerance and shortness of breath with exertion may be partially the result of decreased cardiac function. Chronic vasoconstriction produces diastolic hypertension, a narrowed pulse pressure, and decreased intravascular fluid volume.^{218,224} The autonomic nervous system response is blunted, and there is a decrease in the sensitivity and number of β -receptors.²²⁴

Overt hypothyroidism is associated with a number of abnormalities in lipid metabolism that may predispose patients to accelerated coronary artery disease. Plasma cholesterol is elevated in 90% of patients.²²⁴

These “classic” clinical features of hypothyroidism are often lacking in the elderly hypothyroid patient, making the diagnosis of hypothyroidism more difficult.

Extreme hypothyroidism during fetal life, infancy, or childhood is termed *cretinism*. The condition is characterized by physical and mental growth retardation. In the newborn, unless cretinism is treated with adequate iodine or thyroxine within the first few weeks after birth, mental retardation remains permanent.^{216–218} For this reason, pregnant patients who are hypothyroid require treatment. Thyroid testing before and throughout pregnancy and neonatal screening (T_4 or TSH levels) has played a major role in preventing severe cretinism.²⁵⁷

Treatment.

Treatment of hypothyroidism requires replacement with thyroid hormone. The agent of choice is synthetic levothyroxine sodium (T_4) because of its long half-life (7 days), once-daily dosing, and its ability to attain physiologic levels of T_3 .²⁵⁸ Usual adult replacement dosages range from 75 to 125 mcg/day, depending on the underlying autonomous thyroid function.^{218,257}

An area of particular concern during thyroid hormone replacement is the effect on the cardiovascular system. Initiation of thyroid hormone replacement in a patient with coexisting angina pectoris or underlying risk factors for coronary artery disease requires careful monitoring of both cardiovascular and thyroid

status. Myocardial oxygen consumption is augmented by thyroid hormone, and a hypothyroid patient with deficient coronary artery circulation may not tolerate full replacement doses.²⁵⁷

Anesthetic Management—Hypothyroidism.

Patients with mild to moderate hypothyroidism generally have low risk for serious complications when undergoing anesthesia and surgery.²⁵⁹ A 2015 retrospective analysis of 800 hypothyroid patients having noncardiac surgery showed that hypothyroidism was not associated with worse postoperative mortality, wound infections, or cardiovascular complications compared to euthyroid patients.²⁵⁹ Thyroid replacement therapy should be continued preoperatively, but postponing surgery to initiate levothyroxine therapy in patients with mild to moderate hypothyroidism is not supported.^{84,259,260}

Patients with more severe or symptomatic hypothyroidism may be subject to a variety of complications with anesthesia and warrant heightened attention.^{11,84} Depression of myocardial function, abnormal baroreceptor function, and reduction in plasma volume may be present.^{8,11} Slowed hepatic metabolism and renal clearance of injected drugs may prolong their effects, but MAC is not decreased significantly for inhaled agents.^{8,11,84} Regional anesthesia is a prudent choice if the surgery permits it and there are no patient contraindications.¹¹ If possible, elective surgical procedures should be postponed in the presence of severe or symptomatic hypothyroidism to initiate thyroid replacement treatment.^{8,11,84}

All patients with hypothyroidism should undergo careful preoperative evaluation of the airway. A large goiter can be asymptomatic or it can cause airway compromise, tracheal deviation, or compression²⁴¹ (see section on [Preoperative Goiter](#)). In addition to goiter, in the patient with severe hypothyroidism, adequate air exchange may be compromised by an enlarged tongue and myxedematous infiltration of the vocal cords.^{8,11}

Depression of the ventilatory responses to hypoxia and hypercarbia must be considered. Preoperative sedation should be avoided in the patient with macroglossia or preexisting hypoventilation. Hypothyroid patients may respond to opioids with increased central nervous and respiratory system depression,

necessitating cautious dosing. Potent inhalational agents may exacerbate hypotension and myocardial depression. Although ketamine has been proposed as the ideal induction agent, even ketamine can produce cardiovascular depression in the absence of a robust sympathetic nervous system.¹¹

Risk of pulmonary aspiration is present in the patient with associated somatic obesity and delayed gastric emptying.⁸ Intubation of the trachea may be facilitated by the administration of succinylcholine or a nondepolarizing muscle relaxant; however, hypothyroid patients may be more sensitive to standard doses of nondepolarizing muscle relaxants because of coexisting muscle weakness and decreased hepatic metabolism and renal elimination of these drugs.⁸ Maintaining muscle paralysis with minimal doses of muscle relaxants is an appropriate goal.

Supplemental perioperative cortisol should be considered in the patient with severe disease because there exists a potential for adrenal insufficiency with stress.⁸

In hypothyroidism, the number of β -receptors is diminished, and responses to inotropic drugs and sympathetic stimulation may be influenced by the altered β -receptor pool.²²⁴

Body temperature should be monitored closely in hypothyroid patients, and mechanisms for warming the patient should be used during surgery. [Box 37.12](#) summarizes anesthesia considerations for the patient with hypothyroidism.

Anesthesia Implications for the Hypothyroid Patient

- Delay elective surgery for the patient with severe symptomatic disease.
- Evaluate the airway closely.
- Monitor for exaggerated central nervous system depression with anesthetic agents.
- Titrate muscle relaxants carefully, considering possible coexisting muscle weakness.

- Consider decreased hepatic metabolism and renal elimination when dosing medications.
- Maintain normothermia.
- Monitor ventilation closely, considering blunted ventilatory response to hypercarbia and hypoxia.
- Monitor for depressed myocardial function.
- Consider possible reduction in plasma volume when calculating fluid replacement.

Myxedema Coma.

Myxedema coma is a rare syndrome that reflects severe manifestations of untreated or insufficiently treated hypothyroidism. It is a medical emergency with a mortality rate greater than 50%.¹¹ A critical insult (e.g., infection, surgery, cerebrovascular accident, pneumonia, gastrointestinal bleeding, cold exposure) can precipitate myxedema coma in a patient with hypothyroidism.²¹⁸

Generally, the patient is elderly, has severe clinical features of hypothyroidism, and is hypothermic, hypoventilating, hypotensive, and hyponatremic. The response to hypoxia and hypercapnia is measurably decreased, and mechanical ventilation may be required. The patient is typically lethargic or stuporous. The presence of coma is a marker of the patient's clinical deterioration rather than a primary effect of hypothyroidism. The skin is often pale as a result of cutaneous vasoconstriction.²¹⁸

Therapeutic attention is paid to body temperature, shock, and respiratory failure. Treatment consists of hemodynamic and ventilatory support and the intravenous administration of levothyroxine (loading dose, 300 to 500 mcg over 10 min), with continuous ECG monitoring for myocardial ischemia.^{8,84} Supplemental cortisol is appropriate because the myxedematous patient may have adrenal atrophy and decreased adrenal reserve.²¹⁸ Because these patients may be vulnerable to water intoxication and hyponatremia, meticulous fluid replacement is important. Only lifesaving surgery should proceed in a patient with myxedema

coma. [8,11,84](#)

Summary

The number and variety of patients with endocrine disorders presenting to surgery remains a consistent challenge for the practicing anesthesia provider. Our ability to diagnose and treat these disorders continues to evolve. Several advances in imaging and genetic profiling have yielded improved preoperative diagnostics. The increase in knowledge of the pathophysiology associated with each patient's individual condition will result in better anesthesia management.

Hematology and Anesthesia

Judith A. Franco, Mark H. Gabot

When disruptions within the endothelial lining of blood vessels occur, the breach in vessel-wall integrity can be caused by spontaneous plaque disruption, trauma, or iatrogenic reasons such as venous access or surgical intervention. Vessel-wall injury initiates an extraordinary chain of events that causes the cessation of bleeding with the formation of a clot, allowing the site of injury to heal. This event is followed by clot dissolution. *Hemostasis* is the process by which the body maintains the delicate balance between bleeding and clotting. Were it not for this balance, hemorrhage or thrombosis would ensue.

The focus of this chapter is to review the normal and abnormal processes of hemostasis emphasizing the: (1) vessel wall, (2) platelets, (3) coagulation cascade, (4) emerging cell-based theory of coagulation, and (5) the fibrinolytic system. An in-depth discussion surrounding the importance of hemostatic assessment and management during the perioperative period follows. A discussion concerning the patient with special hematologic circumstances concludes the chapter.

The Normal Vessel Wall

The normal blood vessel acts as a conduit to maintain a state of fluidity within the vascular system. Blood vessels are cylindrical and consist of three distinct layers, the intima, the media, and the adventitia (Fig. 38.1).

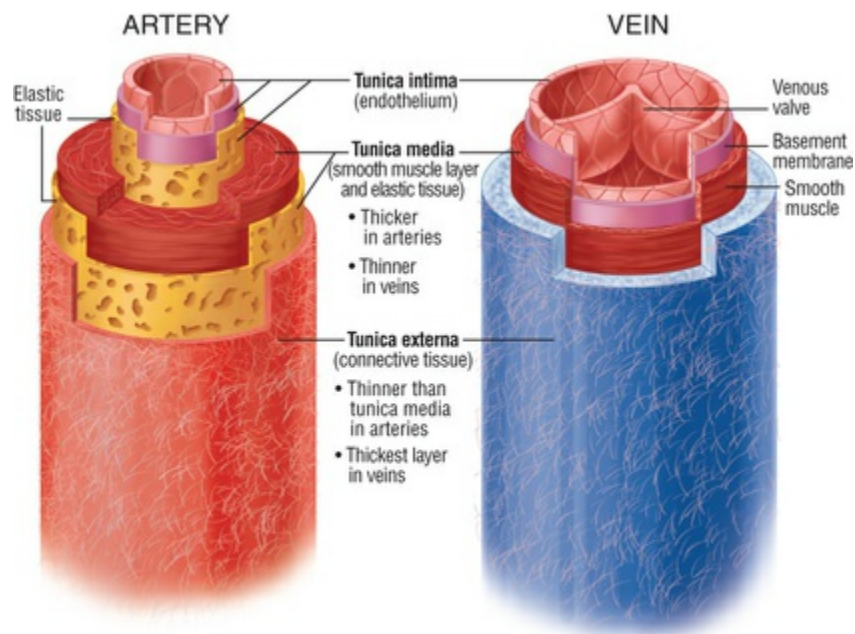

FIGURE 38.1 Artery and vein. Schematic drawings of an artery and a vein show comparative thicknesses of the three layers: the outer layer or tunica externa, the muscle layer or tunica media, and the tunica intima made of endothelium. Note that the muscle and outer layers are much thinner in veins than in arteries and that veins have valves. (From Patton KT, Thibodeau GA. *The Human Body in Health and Disease*. 6th ed. St. Louis: Elsevier; 2014:394.)

The intima (the inner layer) is the lining separating the flowing blood from the vessel; it is made up primarily of endothelial cells. These endothelial cells play an important role in the modulation of hemostasis by synthesizing and secreting many procoagulants (initiators of coagulation), anticoagulants (inhibitors of coagulation), and fibrinolytics (to dissolve the clot) (Table 38.1). One of the important mediators, von Willebrand factor (vWF), is a

necessary cofactor for the adherence of platelets to the subendothelial layer. Tissue factor (TF) (a cofactor from the coagulation cascade) activates the clotting cascade pathway when injury to the vessel occurs. Some mediators (e.g., thromboxane A₂, adenosine diphosphate [ADP]) control blood flow by influencing vasoconstriction. Other mediators (e.g., nitric oxide [NO], and prostacyclin) control blood flow by vasodilation of blood vessels. Endothelial cells can also suppress activation of the coagulation system by their expression of many coagulation inhibitors, such as tissue factor pathway inhibitor.¹

TABLE 38.1

Mediators Responsible for Procoagulant, Anticoagulant, and Fibrinolytic Activities

Property	Mediator	Function
Procoagulant	Coagulation factors	Coagulation
	Collagen	Tensile strength
	vWF	Adhesion
	Protein C	Degrades V and VII
	Protein S	Cofactor for protein C
	Fibronectin	Mediates cell adhesion
Anticoagulant	Thrombomodulin	Regulates anticoagulant pathway
	Antithrombin III	Degrades factors XII, XI, X, IX, & II
	Tissue pathway factor inhibitor	Inhibits tissue factor
Vasodilation	Nitric oxide	Vasodilates
	Prostacyclin	Vasodilates, inhibits aggregation Both promote smooth-muscle relaxation
Vasoconstriction	Thromboxane A ₂	Vasoconstriction
	ADP	Vasoconstriction
	Serotonin	Vasoconstriction
Fibrinolytic	Plasminogen	Converts to plasmin
	tPA	Activates plasmin
	Urokinase	Activates plasmin
Antifibrinolytic	Plasminogen activator inhibitor	Inactivates tPA, urokinase
	α -Antiplasmin	Inhibits plasmin

ADP, Adenosine diphosphate; *tPA*, tissue plasminogen activator; *vWF*, von Willebrand factor.

One of the most important yet simple functions of the endothelial lining is that of forming a barrier separating the fluid contents within the blood vessel (e.g., red blood cells [RBCs], white blood cells [WBCs], albumin, globulins, fibrinogen, and platelets) from the highly thrombogenic material (e.g., collagen and procoagulants) that lies beneath, within the subendothelial space. The smooth endothelial lining physically repels the blood components away

from the vessel wall, preventing activation of the clotting mechanism. When the endothelial wall is damaged, the previously mentioned properties no longer apply.

The second layer of the vessel wall, the subendothelial layer, is extremely thrombogenic and very active. The subendothelial layer contains collagen, a potent and important stimulus for platelet attachment to the injured vessel wall. The subendothelial layer also contains fibronectin, which facilitates the anchoring of fibrin during the formation of a hemostatic plug.

The third layer, the adventitia, participates in the control of blood flow by influencing the vessel's degree of contraction. The endothelial cells produce NO and prostacyclin, which influence the adventitia. NO affects platelet function by inhibiting platelet adhesion, aggregation, and the binding of fibrinogen between glycoprotein IIb/IIIa complex (GpIIb-IIIa) pseudopods. The ability of NO to influence and promote smooth-muscle relaxation results in vascular vasodilation. Once the vessel vasodilates, the increase in blood flow limits the activity of procoagulant mediators by simply washing the procoagulant mediators away. This metabolic reaction occurs within the endothelial lining (Fig. 38.2). Under the influence of nitric oxide synthetase (NOS), L-arginine is converted to NO, which then diffuses into the muscle cells and activates soluble guanylate cyclase, subsequently producing a second messenger, cyclic guanosine monophosphate, causing muscle relaxation.¹ Prostacyclin is a lipid molecule produced in the endothelial cells from prostaglandin. A powerful vasodilator, prostacyclin also interferes with platelet formation and aggregation.

FIGURE 38.2 Functions of nitric oxide (NO) in blood vessels and macrophages. NO is produced by two NO synthase (NOS) enzymes. It causes vasodilation, and NO-derived free radicals are toxic to microbial and mammalian cells. (From Kumar V, et al. *Robbins and Cotran Pathologic Basis of Disease*. 8th ed. Philadelphia: Elsevier; 2010:61.)

Platelets are an essential component of the thrombogenic response to bleeding. Platelets are round and disklike and circulate freely within the blood. They are formed in the bone marrow from megakaryocytes, maintain a concentration count of approximately 150,000 to 300,000/mm³, and survive approximately 8 to 12 days.² Platelets are constantly working to “patch” thousands of minute vascular injuries that occur in perpetuity. Approximately 7.1×10^3 are used each day.³

The platelets flow along the vessel surface. Because they are smaller than some other constituents in fluid blood (e.g., RBCs, WBCs), they tend to be pushed aside, strategically positioned near the vessel-wall surface where they can then “react” in the event of

injury (Fig. 38.3).

FIGURE 38.3 Normal blood flow in intact vessels. RBCs and platelets flow near the center, and WBCs marginate and roll. Endothelial cells and the ECM provide several properties that suppress hemostasis. *EC*, Endothelial cell; *ECM*, extracellular matrix; *FB*, fibroblast; *PLT*, platelet, *RBC*, red blood cell; *SMC*, smooth muscle cell; *WBC*, white blood cell. (From Keohane EM, et al. *Rodak's Hematology*. 5th ed. St. Louis: Elsevier; 2016;178.)

The membrane surface of the platelet serves as a physical barrier between platelet cytoplasm and the surrounding plasma. Platelets contain mitochondria in their cytoplasm enabling them to participate in aerobic metabolism, and have glycogen stores that allow for anaerobic metabolism.⁴ Platelets also contain contractile proteins, store large amounts of calcium and various enzymes, and require the use of their phospholipid surface to promote cellular activity. Platelets contain alpha (α) granules that store proteins (e.g., vWF, fibrinogen, fibronectin, platelet factor 4, and platelet growth factor) and dense granules that store nonproteins (e.g., serotonin, ADP, adenosine triphosphate [ATP], histamine, and epinephrine).² Many of these granules synthesize prostaglandins that enable the platelets to promote vascular and local tissue reactions.^{2,4} Platelets also produce thrombin. In the platelet thrombin's role is to activate some of the coagulation factors and to influence recruitment of platelets to the site of injury. All the contents in the cytoplasm of the

platelet participate in regulating hemostasis. Platelets do not contain a nucleus, RNA (ribonucleic acid), or DNA (deoxyribonucleic acid), so they do not reproduce.²

Platelets are largely inactive unless they become activated as a result of vascular trauma. Adequate hemostasis is not possible in the absence of an adequate quality or quantity of activated platelets. It is important to note that platelets do not work independently to achieve hemostasis. They work in conjunction with plasma proteins of the coagulation cascade (see the following section on [Vessel Injury](#)) to build a stable clot when injury to the vascular integrity occurs.

Vessel Injury

Clot formation in response to injury has traditionally been described to include the adherence of the platelet to the injured vessel wall and the response of the clotting cascade to form a stable clot and stop the progress of bleeding. When the endothelial lining is disrupted, as it might be by plaque dislodgement, surgical instrumentation, or trauma, an intricate process to maintain hemostasis and promote clot formation is initiated.

The vessel wall immediately contracts to cause a tamponade, decreasing blood flow. This contraction is a result of autonomic nervous system reflexes and the expression of thromboxane- A₂ and ADP.^{2,5} The area adjacent to the injury vasodilates and distributes blood to the surrounding organs and tissues. Contraction is followed by three separate stages in the formation of a primary plug: adhesion, activation, and aggregation.

In the adhesion stage, vWF mobilizes from within the endothelial cells and emerges from the endothelial lining. Glycoprotein Ib (GpIb) receptors emerge from the surface of the platelet (Fig. 38.4). The purpose of GpIb is to attach to vWF and attract platelets to the endothelial lining; vWF makes platelets “sticky” and allows them to adhere to the site of injury.

FIGURE 38.4 Anticoagulant properties of normal endothelium (*left*) and procoagulant properties of injured or activated endothelium (*right*). NO, nitric oxide; PGI₂, prostaglandin I₂ (prostacyclin); t-PA, tissue plasminogen activator; vWF, von Willebrand factor. Thrombin receptors are also called *protease-activated receptors* (PARs). (From Kumar V, et al. *Robbins Basic Pathology*. 9th ed. Philadelphia: Elsevier; 2013:81.)

Under the influence of TF (a cofactor of the extrinsic clotting pathway), the platelet then undergoes a conformational transformation as it becomes activated (Fig. 38.5). The once disklike structure swells and becomes oval and irregular. From the platelet surface two other major glycoproteins, IIb and IIIa, project themselves outward. The purpose of the GpIIb-IIIa receptor complex is to link other activated platelets together in an effort to form a primary platelet plug. When this action is complete, the platelets form a mound whose only goal is to seal and heal the site of injury within the blood vessel.

tissue or organ damage and sets in motion a process that terminates in stabilization of hemorrhagic conditions in the absence of pathology. The factors are identified with Roman numerals for ease of interpretation.

TABLE 38.2
Coagulation Factors

Factor	Factor Name	Synthesized	Vitamin K Dependent	Action
I	Fibrinogen	Liver	No	Form a clot
II	Prothrombin	Liver	Yes	When in active form, activates I, V, VII, XIII, platelets, and protein C
III	Tissue factor or thromboplastin	Vascular wall and extravascular cell membranes; released from traumatized cells	—	Cofactor of VII
IV	Calcium	Diet	—	Promotes clotting reactions
V	Proaccelerin	Liver	No	Cofactor of X; forms a prothrombinase complex
VI	(Unassigned)	—	—	—
VII	Proconvertin	Liver	Yes	Activates IX and X
VIII	Antihemophilic	Liver	No	Cofactor to IX
vWF	Von Willebrand	Endothelial cells	—	Mediates adhesion
IX	Christmas	Liver	Yes	Activates X
X	Stuart-Prower	Liver	Yes	Activates II, forms a prothrombinase complex with V
XI	Plasma thromboplastin antecedent	Liver	No	Activates IX
XII	Hageman	Liver	No	Activates XI
XIII	Fibrin stabilizing	Liver	No	Cross-links fibrin
Prekallikrein	Fletcher		—	Activates XII, cleaves HMWK
High-molecular-weight kininogen (HMWK)	Contact activation factor		—	Supports activation of prekallikrein, XII, XI

The clotting pathways are thought to be two separate and distinct pathways (extrinsic and intrinsic) that worked independently of each other but in conjunction with platelet activity and the common coagulation pathway (Fig. 38.6). The extrinsic pathway (TF pathway) becomes activated by the release of TF when injury occurs outside the vessel wall (with organ trauma or crushing injuries). This section of the coagulation cascade consists of factor

III (TF or thromboplastin) and factor VII (proconvertin).

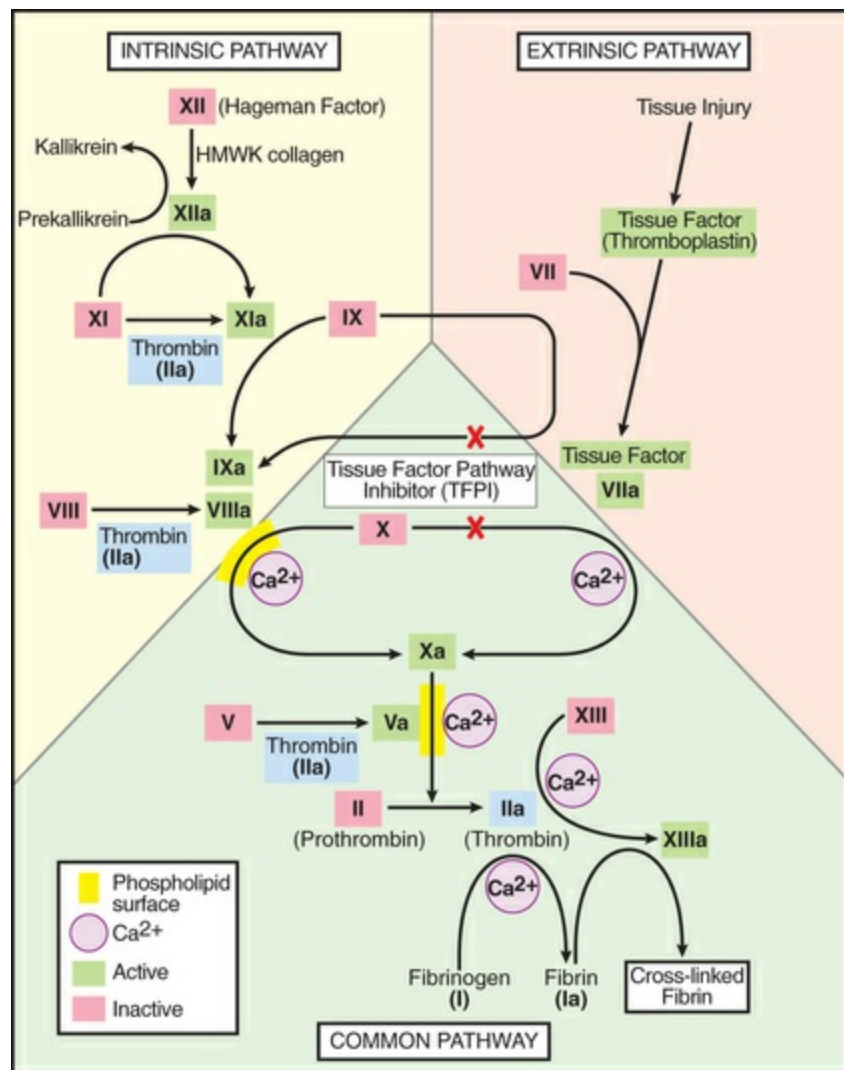

FIGURE 38.6 The coagulation cascade. Factor IX can be activated by either factor Xla or factor VIIa. In laboratory tests activation is predominantly dependent on factor Xla, whereas in vivo, factor VIIa appears to be the predominant activator of factor IX. Factors in *red boxes* represent inactive molecules; activated factors, indicated with a lowercase a, are in *green boxes*. Note that thrombin (factor IIa) (in *light blue boxes*) contributes to coagulation through multiple positive feedback loops. The *red Xs* denote points at which tissue factor pathway inhibitor (TFPI) inhibits activation of factor X and factor IX by factor VIIa. *HMWK*, High-molecular-weight kininogen; *PL*, phospholipid. (From Kumar V, et al. *Robbins Basic Pathology*. 9th ed. Philadelphia: Elsevier; 2013:81.)

When damage occurs outside of blood vessels, TF (factor III) activates proconvertin (factor VII), changing it to activated factor VII (VIIa). (When factor III activates factor VII, it is immediately inhibited by tissue factor pathway inhibitor, so only a predetermined amount of factor VII is activated.) Once factor VII is activated, it in turn activates factor X (Stuart-Prower) of the common pathway. Factor X forms a complex with factor V (proaccelerin, a prothrombinase complex) activating factor II (prothrombin), which, when activated, becomes factor IIa (thrombin). Thrombin in turn activates factor I (fibrinogen) to form activated factor I (Ia, fibrin).

The intrinsic pathway (contact activation pathway) is initiated when damage occurs to the blood vessels themselves. The intrinsic pathway is initiated by prekallikrein, high-molecular-weight kininogen (HMWK), and by the activation of factor XII (Hageman). With the help of calcium (factor IV), the coagulation pathway initiates a domino effect. Each factor, once activated, affects its subsequent factor. Factor XII (Hageman) activates factor XI (plasma thromboplastin antecedent), which activates factor IX (Christmas), which then activates factor VIII (antihemophilic factor), and ultimately (similar to the extrinsic pathway) merges at the common pathway and activates factor X. The result is the generation of fibrin from the activation of prothrombin to thrombin.

Conversion of prothrombin to thrombin is an important reaction for both coagulation pathways. Thrombin assists in activating factors V, VIII, I, and XIII and influences the recruitment of platelets to the injured area. Enough thrombin must be present to activate adequate fibrin to form a stable clot.

Thrombin also behaves as an anticoagulant as follows: It (1) prevents runaway clot formation by releasing tissue plasminogen activator (tPA) from endothelial cells, (2) stimulates protein C and protein S to inhibit clot formation, and (3) forms a relationship with antithrombin III to interfere with coagulation.¹ The common pathway is the terminal pathway of the coagulation cascade. In the common pathway factor X has been activated by the intrinsic and extrinsic pathways. Factor X requires the help of factor V (proaccelerin) and calcium to convert factor II (prothrombin) to its active-state thrombin (IIa). Thrombin then activates factor I

(fibrinogen) to its active form, Ia (fibrin). Factor XIII (fibrin-stabilizing factor) is required to ensure the platelet plug will hold. Factor XIII helps form a cross-linked mesh within the platelet plug, increasing its strength. Fibrin (factor Ia) in conjunction with factor XIII finally secures a stable secondary plug, and bleeding stops. Once a clot is made, it retracts, eliminating its serum. As it retracts it weaves the edges of the vessel together, healing the site of injury.²

Most of the coagulation proteins are synthesized in the liver. Calcium, which is not a true factor, comes from diet; it is needed to “position” the coagulation factors on the surface of the platelet so clotting will ensue. Von Willebrand factor is synthesized in the endothelial cells, and factors II, VII, IX and X are dependent on vitamin K for utilization.

Cell-Based Theory of Coagulation

The cell-based theory is a newer concept for explaining the involvement of the platelet and clotting cascades in hemostasis. It hypothesizes *why* platelets and the extrinsic and intrinsic pathways of coagulation cascade do not work independently of one another, but form a very interdependent relationship.⁶ The theory posits that coagulation takes place on different “cell surfaces” that bear TF. These surfaces play a pivotal role in factor expression leading to hemostasis. The cell-based theory describes hemostasis as taking place in three phases: initiation, amplification, and propagation.

The initiation phase is triggered by injury to the endothelial surface (Fig. 38.7). When injury occurs, TF is exposed at the site of injury. In its presence, the endothelial surface of the blood vessel changes becoming acidic and making its phospholipid surface less repellent to platelets. TF down-regulates anticoagulants that reside in the subendothelial layer (e.g., antithrombin III, thrombomodulin) in an effort to promote coagulation.⁷ This new medium enhances the many enzymatic processes that work to maintain hemostasis by encouraging aggregation and the activation of clotting factors to the site of injury. TF recruits platelets and activates factor VII.

FIGURE 38.7 Cell-based theory of coagulation. (From Jobling L, Eyre L. Haemostasis, blood platelets and coagulation. *Anaesthesia and Intensive Care Medicine* 2013;41(2):51-53.)

In the cell-based theory, TF/VII reaction results in the activation of factors X (common pathway) and IX (intrinsic pathway). Factor X forms a complex with factor V, and together these two activated factors are able to generate a *small* amount of thrombin for clot formation.⁸ Only a small amount of thrombin is created because this reaction terminates almost immediately when tissue factor pathway inhibitor (TFPI) limits the amount of TF expressed. The activation of factor IX from the TF/VII complex does not participate in this initiation stage because IX does not act on TF-bearing cell surfaces.⁷

It is on the platelet cell surface that factor IX (generated from TF/VII) exerts its coagulation contribution to hemostasis. Factor IX attaches to the activated platelet cell surface and binds with a receptor, resulting in the activation of factor VIII, which in turn

activates factor X. Additional thrombin is then produced.

As injury perpetuates and TF is expressed, platelets mobilize to the site of injury.⁷ It is during the amplification phase that thrombin generation gains momentum and acceleration, and activation of clotting factors persists. Thrombin activates factors V, VIII, and IX.⁶ Activated factor XI assists in generating even more factor IX on the platelet surface.⁹ Von Willebrand factor promotes platelet aggregation through its adhesive properties with GpIb, and the expression of the GpIIb-IIIa pseudopods from the surface of platelets facilitates aggregation of additional platelets.

During the propagation phase, all coagulation factors are actively influencing one another, promoting coagulation, and finally activating prothrombin, resulting in a large *burst* of thrombin. Remember, enough thrombin must be present to convert fibrinogen to fibrin to form a stable secondary hemostatic plug. This burst of thrombin does just that.

The cell-based theory is a means of providing a more thorough understanding and an innovative interpretation of coagulation. It explains how cell surfaces do not just express coagulation factors; these surfaces participate in conjunction with platelets and the coagulation cascade pathways to maintain hemostasis. This theory also explains why certain deficiencies fail to cause bleeding, despite changes in laboratory values such as the prothrombin time (PT) or activated partial thromboplastin time (aPTT) indicative of coagulation problems.⁶

Fibrinolytic System

Once a disrupted vessel is sealed there is no longer a need for a hemostatic plug. A counterbalance mechanism, the fibrinolytic system, exists to degrade fibrin. Initially there is an increase in blood flow at the site of injury. This increase in blood flow washes away ADP and thromboxane-A₂ and other procoagulant mediators, which were initially present to encourage hemostasis and limit the size of the clot. Thrombin, which initially behaved as a procoagulant, now acts as an anticoagulant and activates additional anticoagulant mediators. TFPI stops the action of TF. Protein C and protein S inhibit coagulation factors III, V, and VIII. Antithrombin III inhibits thrombin activity by sequestering factors XII, XI, IX, and X. Antithrombin III is a mediator that corrals some of the factors present in the clotting cascade and takes them out of the clotting equation (Fig. 38.8). The clot manufactured is disrupted.

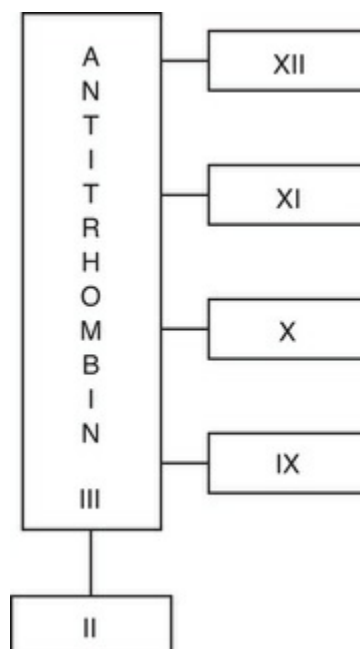

FIGURE 38.8 Antithrombin III corrals clotting factors XII, XI, IX, X. This influences factor II.

The process of fibrinolysis is highly regulated by plasma proteins (Fig. 38.9). A clot is composed primarily of plasminogen, plasmin,

fibrin, and fibrin degradation products. Plasminogen is an enzyme synthesized in the liver. It is stored like the clotting factors in an inactive form. While the clot is forming, plasminogen incorporates itself into the clot. With the assistance of the body's own tPA and urokinase, plasminogen is activated to plasmin. Plasmin then acts on the fibrin causing fibrin to degrade into fibrin degradation products. The circulatory system removes the waste products of the clot. α -Antiplasmin and tissue plasminogen activator inhibitor are important fibrinolytic mediators that stop the process of fibrinolysis when the clot has been digested.

FIGURE 38.9 The fibrinolytic system, illustrating various plasminogen activators and inhibitors. (From Kumar V, et al. *Robbins Basic Pathology*. 9th ed. Philadelphia: Elsevier; 2013:81.)

Platelets, coagulation cofactors, and the fibrinolytic systems are dependent on each other to ensure a person does not bleed to death or clot to death at any given moment. This system of checks and balances maintains hemostasis when a breach in vascular integrity occurs.

Anesthetic Implications

Preoperative Considerations

The preoperative interview is the ideal time for the anesthesia provider to gather detailed information regarding the patient's health status. A thorough history and physical is the best way to identify patients at risk for surgical bleeding or those patients with thrombopoietic tendencies.¹⁰ It is also during the interview that additional laboratory tests can be ordered if necessary to identify potential defects in hemostasis and to guide the decision regarding whether to order and/or administer blood products.

During the preoperative interview, it is important to ask questions directly related to bleeding: (1) Does the patient experience unusual bleeding or bruising (e.g., bleeding gums, epistaxis, mucous membrane bleeding, and bloody stools)? (2) Is there a history of previous bleeding with dental procedures? (3) Are there repeated spontaneous bleeding episodes or a history of excess bleeding that may have occurred after a minor procedure or childhood trauma? (4) Do familial bleeding tendencies exist? (5) Has there been a time when expected bleeding from a surgical procedure was more than anticipated?^{4,11} These questions can reveal an undiagnosed inherited disorder of coagulation. Patients who have undiagnosed inherited coagulopathies may complain of hematomas, runaway bruising, and oozing even after the most minor injuries. An undetected preoperative bleeding tendency can lead to life-threatening blood loss during surgery.⁴ Laboratory evaluation of platelets, coagulation, and fibrinolytic components can be screened with the commonly available coagulation tests.

When approaching the patient scheduled for surgery, a physical examination with a complete systems approach is necessary. The anesthesia provider must be alert to potential disruptions in hemostasis. Any overt physical sign of bleeding such as the appearance of bruising or petechial hemorrhages on the chest, abdomen, or upper extremities warrants further investigation. Small hemorrhages on the skin may also indicate the presence of small hemorrhages on other organs. Remember that the

questionable coagulopathy can be related to any number of disruptions in the hemostasis process: a platelet problem, a factor deficiency, an inherited disorder of coagulation, the presence of circulating anticoagulants, or a disturbance in the fibrinolytic system.

During the physical assessment disorders of malnutrition or liver insufficiency suggesting a vitamin K deficiency may be revealed. These disorders can influence coagulation and explain increased bleeding, even for the simplest surgery. Vitamin K is created from bacteria in the gut and is necessary for the formation of factors II, VII, IX, and X. When illness such as liver insufficiency, cirrhosis, absorption problems, and failure to secrete bile are present, the patient will be unable to form and use these factors for effective coagulation.

Patients with preexisting inherited disorders of coagulation must undergo an adequate preoperative workup prior to surgery. Consultation with a hematologist or transfusion specialist is strongly recommended. Patients with preexisting coagulation disorders require considerable attention in the operating room. If general surgery is anticipated, special attention must be made to ensure no damage to soft tissues occurs. Damage to tissues may transpire during direct laryngoscopy, endotracheal intubation, peripheral or central line placement, and positioning or moving to and from the operating-room table.

The preoperative use of many medications—prescribed, over-the-counter, and herbal remedies—can interfere with normal platelet function and coagulation ([Box 38.1](#)). The anesthesia provider must ascertain whether the patient regularly ingests medications that might interfere with normal coagulation and when were the medications or herbals last taken. For example, many patients take aspirin for a number of reasons. Historically it has been recommended that aspirin be held for 7 to 10 days prior to surgery. Current recommendations are discussed in detail later in this chapter. Aspirin directly affects the life of the platelet by *irreversibly* inhibiting cyclooxygenase resulting in decreased platelet function.¹² Nonsteroidal antiinflammatory drugs (NSAIDs) also inhibit cyclooxygenase, albeit *reversibly*, and the recommendation is to withhold NSAIDs for approximately 24 to 48 hours, depending on

Box 38.1 Herbal life, to avoid any bleeding effects in surgery^{13,14} (Fig. 38.10).

Frequently Encountered Medications That Influence Coagulation

Anticoagulants

- Heparins
- Low-molecular-weight heparins
- Coumarin derivatives
- Direct thrombin inhibitors

Procoagulants

- Vitamin K

Antiplatelets

- Nonsteroidal antiinflammatory drugs
- Persantine
- Thienopyridine

Antifibrinolytics

- Amicar
- Tranexamic acid

Nonherbal Dietary

- Vitamin K
- Vitamin E
- Coenzyme Q10

- Zinc
- Omega-3 fatty acids

Herbal

- Garlic
- Ginger
- Ginkgo
- Feverfew
- Fish oil
- Flaxseed oil
- Black cohosh
- Cranberry

FIGURE 38.10 Schematic illustration depicting the mechanism and site of action of aspirin and nonsteroidal antiinflammatory drugs (NSAIDs).

A preoperative discussion between the patient, surgeon, and anesthesia provider must occur regarding transfusion requirements during surgery. Informing patients about the safety, screening measures, and risks of blood administration cannot be ignored. A

small percentage of patients will have to contend with the negative sequelae of transfusion therapy (e.g., hepatitis, human immunodeficiency virus, and bacterial transmission) despite careful screening and handling. In situations with emergent or trauma patients, many times a preoperative interview is unattainable, and the provider must rely purely on information supplied by family members (if present), physical assessment, and laboratory analysis.

Laboratory Tests

Routine laboratory tests must be evaluated preoperatively. They serve to guide the clinician in determining whether a coagulation disorder exists (Table 38.3). Laboratory tests should be ordered on an individual basis, considering the patient's history and planned surgical procedure.

TABLE 38.3

Possible Causes and Treatment of Hemostatic Disorders

BL	Clinical Coagulation Tests					Possible Cause	Treatment
	aPTT	PT	BT	PC	Fib		
	Abn					Factor VIII, heparin, "lupus anticoagulant," poor sample	No treatment
+	Abn					Factors XI, IX, VIII, heparin therapy	FFP, protamine
+	Abn	Abn				Factors V, X, II, dysfibrinogenemia, heparin, coumarins	FFP, cryoprecipitate, protamine
+		Abn				Factor VII	FFP
+	Abn		Abn			Von Willebrand disease	Desmopressin acetate, cryoprecipitate
+	Abn	Abn	Abn		Low	Hypofibrinogenemia	FFP, cryoprecipitate
+			Abn	Abn		Thrombocytopenia	Platelet concentrate (8–10 units)
+			Abn			Thrombocytopathy, aspirin, NSAIDs	Platelet concentrate
+	Abn	Abn	Abn	Abn	Abn	DIC, severe liver disease, dilutional coagulopathy	FFP, cryoprecipitate, platelet concentrate, whole blood

+, Increased clinical bleeding; *Abn*, abnormal result; *aPTT*, activated partial thromboplastin time; *BL*, bleeding; *BT*, bleeding time; *DIC*, disseminated intravascular coagulation; *FFP*, fresh frozen plasma; *Fib*, fibrinogen; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PC*, platelet count; *PT*, prothrombin time.

The most frequently assessed tests are the bleeding time, platelet count, PT, and aPTT (Table 38.4). Together these tests evaluate vascular contraction, platelet function, coagulation, and the

fibrinolytic system. Results of these routine tests must fall within the normal range. If they are outside normal range, there must be a reasonable explanation, and adequate measures must be taken to correct or control hemostasis before bringing the patient into the operating room. For example, if the patient requires surgery but not emergently, vitamin K can be administered 4 to 6 hours prior to surgery. If the risk of bleeding is moderate, a type and crossmatch may be preferred to a type and screen. If the patient requires surgery emergently, ordering blood components such as packed RBCs (PRBCs), fresh frozen plasma (FFP), platelets, and cryoprecipitate may be advisable.

TABLE 38.4
Coagulation Tests

Laboratory Test	Value*	Description
Bleeding time	3–7 min	Measures platelet function: adhesion, aggregation Not considered a routine test Modest prolongations do not predict surgical bleeding Altered by aspirin and NSAIDs*
Platelet count	150,000–350,000 mm ³	Thrombocytopenic: <100,000 mm ³ Surgical risk: <50,000 mm ³ Spontaneous bleeding: <20,000 mm ³
Prothrombin time (PT)	Normal: Control Average Normal: 12–14 sec	Value is reagent dependent Prolonged with: • Extrinsic pathway disorder • Common pathway disorder Altered by coumarin derivatives*
Activated partial thromboplastin time (aPTT) (intrinsic and common pathway)	Average normal: 25–32 sec	Prolonged with: • Intrinsic pathway disorder • Common pathway disorder Altered by heparin and Lovenox*
Thrombin time (common pathway)	8–12 sec	Measures fibrinogen-to-fibrin reaction
Activated clotting time (ACT)	80–150 sec	Guides anticoagulation dosing
Fibrinogen	>150 mg/dL; 200–350 mg/mL	Measures fibrinogen level
Fibrinogen (degradation products)	<10 mcg/mL	Measures by-products from clot dissolution
D-Dimer	<500 mg/mL	Measures degradation products secondary to fibrinolysis
Thromboelastogram		Measures global hemostasis
Antithrombin III	80%–120%	Measures antithrombin III levels; decreased level may explain subtherapeutic heparin. Severely depressed in DIC

*Values may vary among laboratories.

DIC, Disseminated intravascular coagulation; NSAIDs, nonsteroidal

antiinflammatory drugs.

The bleeding time evaluates the capability of microvascular contraction and the function of platelets. When vascular injury occurs the initial response from the blood vessels is to contract, and the response of the platelets is to adhere to the site of injury. If either of these two processes is compromised, prolonged bleeding will occur, resulting in inadequate hemostasis.

The bleeding time was once thought to be the best indicator of bleeding risk. The use of a bleeding time test, however, is open to much scrutiny, and there are many reasons to question its use and interpretation.¹⁵ In the absence of drug ingestion a prolonged bleeding time suggests primary hemostasis abnormality, and further investigation is recommended. Although the bleeding time is a means of evaluating vascular integrity and platelet function, it is important to appreciate that a prolonged bleeding time is not a good predictor of bleeding or a sign that an abnormality is present.¹⁶ In addition, an isolated prolonged value is not a reason to cancel or delay a surgical procedure.

The platelet count is the actual number of platelets present in blood per cubic millimeter. A normal platelet count does not imply normal platelet function exists, only how many platelets are present in plasma. It is used to evaluate patients who, when examined, have petechiae or unexplained spontaneous bleeding, and to monitor thrombocytopenia (low platelet count). The platelet's primary role is to maintain vascular integrity, aggregate when a plug is necessary to stop bleeding, and help initiate the clotting pathways. A normal platelet count is 150,000 to 300,000/mm³.² Patients are considered thrombocytopenic at counts less than 100,000 mm³. There are varying degrees of thrombocytopenia that must be considered preoperatively. Platelet counts greater than 100,000 are sufficient for hemostasis. When the platelet count declines to 50,000/mm³, spontaneous bleeding rarely occurs, but one should suspect prolonged bleeding under surgical conditions.¹⁷ A platelet count less than 20,000 is considered a critical level, and spontaneous bleeding is likely to occur.^{18,19}

The PT is used to evaluate the efficiency of the extrinsic factors (III and VII) and common coagulation pathway (factors X, V, II, I) in generating enough thrombin to form fibrin to create a stable clot.

The PT is specific to the extrinsic pathway of the clotting cascade. It is the most commonly used test to monitor oral anticoagulant therapy (e.g., the coumarin derivatives). The PT will be prolonged when patients have abnormalities or are deficient in factors specific to the extrinsic and common clotting pathways (III, VII, X, IX, II, I).⁵

Despite the frequent assessment of the PT value preoperatively, this laboratory value has drawbacks. The PT is not a very sensitive test. The PT also fails to identify the specific factor defect in the hemostatic system. It only identifies an existing problem that may or may not cause bleeding.

The international normalized ratio (INR) evaluates the extrinsic and common pathway independently of various reagents used in different laboratory settings and in different areas of the world. The normal INR is 1.5 to 2.5. Many institutions report both PT and INR values.

The aPTT is a test used to evaluate the efficiency of the intrinsic coagulation pathway (factors XII, XI, IX, and VIII) and the common coagulation pathway (factors X, V, II, I, and ultimately XIII) to form fibrin and eventually a stable clot. The aPTT can identify abnormalities in all factors except III and VII. It is also used to monitor anticoagulation status when heparin therapy is used. The aPTT can be prolonged by abnormalities, deficiencies, or inhibitors of any intrinsic or common pathway defect. Factor concentration must be decreased 30% before evidence of a prolonged PT or an aPTT can be appreciated.^{1,17}

Any factor deficiency in either limb of the clotting cascade can alter the PT and/or aPTT, but this does not imply that any prediction of an individual patient risk of bleeding can be anticipated.⁷ For example, a decrease in factor XII will demonstrate an increase in aPTT but will not cause bleeding.⁶ A decrease in factor XI may or may not cause abnormal bleeding. However, a decrease in either factor VIII or IX will definitely cause bleeding with injury. This is seen in hemophilia.

The activated clotting time (ACT) is a simple, quick test that can be used in surgery to monitor the ability of blood to clot. The ACT is also used to regulate heparin therapy. The normal ACT is 90 to 150 seconds. However, the ACT is not a sensitive test.

The thrombin time is a screening tool for assessing the ending

phase of coagulation. Because fibrinogen can be assessed directly, analysis of the thrombin time is less emphasized.

The thromboelastogram (TEG) measures the process of clot formation over time (Fig. 38.11). The benefit of this test is its ability to evaluate: (1) platelet reactions, (2) coagulation, and (3) fibrinolysis. A blood specimen is collected and placed in a machine that measures the speed at which a clot forms. The results of the TEG provide an indication of (1) clot strength, (2) platelet number and function, (3) intrinsic pathway defects, (4) thrombin formation, and (5) the rate of fibrinolysis.² Laboratory tests are only as good as the individual interpreting them and many times will not adequately reflect the potential to bleed or thrombose. The use of coagulation tests is best interpreted when patients are without pathology, are not on any medications that could disrupt the laboratory value measured, and are assessed in conjunction with physical assessment and clinical judgment. It is prudent to consult with a hematologist when there is any suspicion of the potential for abnormal bleeding in surgery or if a coagulation disorder exists. Coagulation tests can be performed in the operating room and may serve as a guide during critical volume loss and coagulopathic alterations.

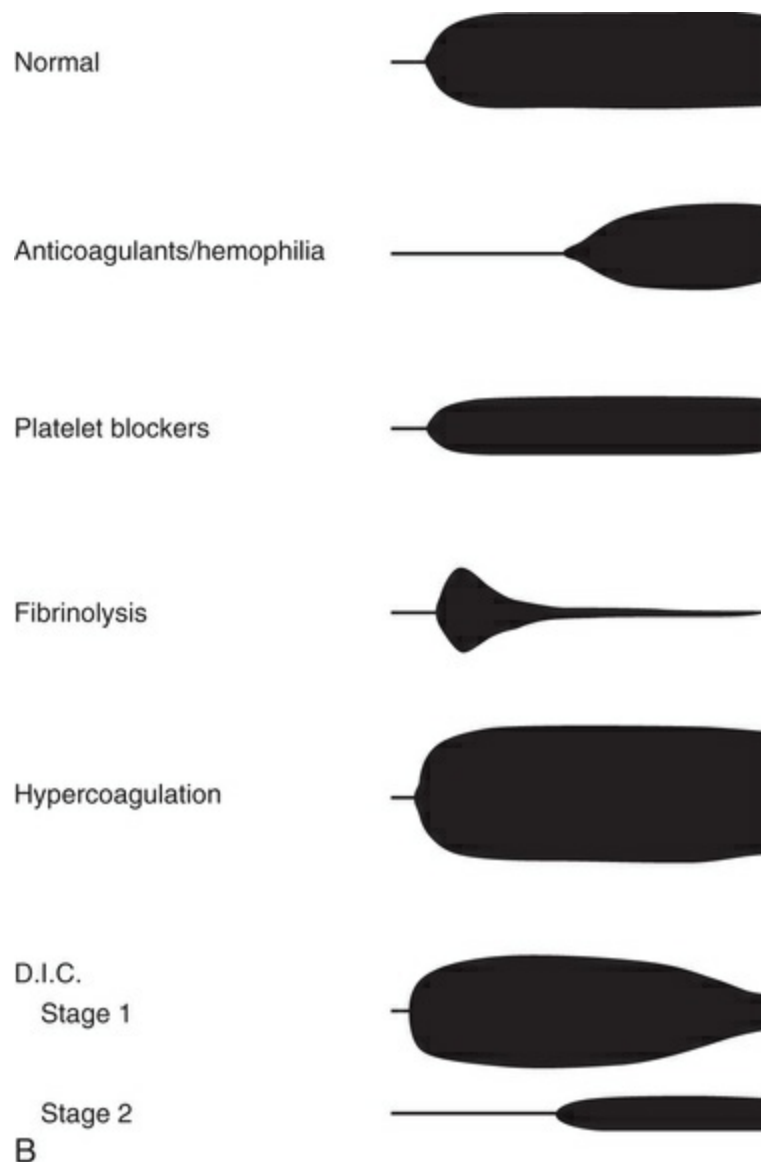

FIGURE 38.11 Measurements taken by the thromboelastogram (TEG) determine the component that is required to treat coagulopathy. (From Cameron JL. *Current Surgical Therapy*. 9th ed. Philadelphia: Elsevier; 2007:940.)

Intraoperative Period

One main focus in the operating room is to recognize and efficiently control blood loss. Frequent evaluation of the patient's clinical status, surgical site, sponges, canisters, and the operating room floor cannot be overemphasized.¹⁷ The surgeon and anesthesia provider are equally responsible in communicating that persistent oozing or frank bleeding is occurring. It is this open communication that helps the surgical team recognize problems and rapidly

intervene by having blood components in the room, rechecking ABO compatibility, and anticipating the need for coagulation-factor replacement if transfusion therapy is necessary.

The most commonly transfused blood components are RBCs, platelets, FFP, and cryoprecipitate (Table 38.5). The major reasons for transfusion therapy in the operating room are to replace volume and coagulation factors and improve oxygen-carrying capacity.²⁰ Each component carries its own concerns.

TABLE 38.5
Blood/Coagulation Factor Replacements for Achieving Hemostasis

Resource	Dose and Effects	Product Content	Use
Packed red blood cells	1 unit (350 mL) increases hemoglobin level by 1 g/dL (10 g/L)	Red blood cells	Symptomatic anemia (guideline hemoglobin level < 6 g/dL if healthy), massive hemorrhage, decreased oxygen-carrying capacity
Platelets	1 unit (250 mL) increases the platelet count by 30,000–60,000/mm ³	Platelets, clotting factors	Thrombocytopenia, massive hemorrhage, platelet function deficit
Fresh frozen plasma	1 unit (250 mL)	All coagulation factors, especially factors II, VII, IX, and X, proteins C and S, and antithrombin III	Bleeding from warfarin therapy, massive transfusion, thrombotic thrombocytopenic purpura, coagulation factor deficiencies, antithrombin III deficiency
Cryoprecipitate	20 mL contains 200 mg fibrinogen, 70–80 units of factor VIII	Fibrinogen, factors V, VIII, and XIII, and von Willebrand factor	Hypofibrinogenemia, massive hemorrhage
Desmopressin	0.3–0.4 mcg/kg	Stimulates release of von Willebrand factor	Uremic platelet dysfunction, some von Willebrand disease cases with bleeding
Vitamin K	10 mg intramuscularly, intravenously, or subcutaneously	Stimulates activation of factors II, V, VII, and IX and proteins C and S	Liver dysfunction, bleeding from warfarin therapy
Protamine sulfate	1 mg neutralizes 100 units of heparin	Heparin antagonist	Reversal of heparin therapy
Factor VII	50 mcg/kg (20–90 mcg/kg)	Recombinant factor VIIa	Hemophilia, massive hemorrhage
Aminocaproic acid	0.1 g/kg loading dose, 1 g/hr	Plasminogen inhibitor	Primary fibrinolysis

From Lawson JH, Bennett KM. Coagulopathy and hemorrhage. In Cronenwett JL, et al., eds. *Rutherford's Vascular Surgery*. 8th ed. Philadelphia: Elsevier;

2014.

PRBCs are transfused to improve tissue oxygenation. Although the oxygen-carrying capacity of red cells decreases with the length of storage, it improves when 2,3-diphosphoglycerate (2,3-DPG) is regenerated once transfused. Platelets are provided to patients when a deficit is appreciated or when massive transfusion is required. Platelets can be given as a single-donor plateletpheresis pack or collected and pooled from multiple donors (random-donor platelets).

Platelet Infusion Guidelines

The recommended dose for platelet replacement is one plateletpheresis pack per each 10 kg of patient weight. This dose should increase the platelet count by approximately 5000 to 10,000 mm^3 .^{5,17} Whereas the normal life span of a platelet is 7 to 10 days, the life span of a donated platelet is only 4 to 5 days.⁹

The American Society of Anesthesiologists Transfusion Task Force recommends¹⁷ that: (1) platelet transfusion may be indicated despite an apparently adequate platelet count or in the absence of a platelet count if there is known or suspected platelet dysfunction (e.g., the presence of potent antiplatelet agents, pulmonary bypass, congenital platelet dysfunction, and bleeding), and (2) in surgical or obstetric patients, platelet transfusion is rarely indicated if the platelet count is known to be greater than 100,000/ μL and is usually indicated when the count is less than 50,000/ μL in the presence of excessive bleeding.¹⁷ Compatible plateletpheresis is recommended, but when matched platelets are unavailable unmatched platelets can be given; however, this incompatibility shortens the life span of the platelet.^{3,20} There are no high-quality data to guide plasma and platelet transfusions around the time of procedures. Current intensivists' consensus expert opinion recommends administration of plasma in moderate- to high-risk procedures when INR is greater than 1.5. They recommend platelet transfusion in low-risk procedures when the platelet count is less than 20,000/ μL for average-risk procedures when the platelet count is less than 50,000/ mm^3 , and for procedures involving the central nervous system when the platelet count is less than 100,000/ mm^3 .²¹ When

pooled platelets are administered to women of childbearing age, Rh sensitization can occur, and administration of RHO (D) immune globulin may be necessary prior to discharge.

Platelets carry the greatest risk of bacterial transmission.^{21,22} Platelets are stored for 4 to 5 days at room temperature providing an excellent medium for the growth and reproduction of bacteria. Standard protocols for blood banks and transfusion services require that a method be in place to detect bacterial contamination of platelets.^{21,23}

Fresh Frozen Plasma Infusion Guidelines

FFP is the fluid portion of whole blood, separated, then frozen to preserve coagulation factors, and subsequently thawed on use. FFP contains all the clotting factors and naturally occurring inhibitors.²⁴ It does not provide platelet replacement. The average volume in a unit of FFP is 200 to 250 mL. FFP must be ABO plasma compatible whenever possible.

FFP is transfused for the following reasons: (1) Correction of excessive microvascular bleeding (i.e., coagulopathy) in the presence of an INR greater than 2.0, and in the absence of heparin; (2) Correction of excessive microvascular bleeding secondary to coagulation factor deficiency in patients transfused with more than one blood volume (approximately 70 mL/kg) and when PT or INR and a PTT cannot be obtained in a timely fashion; (3) Urgent reversal of warfarin therapy when PCCs are not available; (4) Correction of known coagulation factor deficiencies for which specific concentrates are unavailable. FFP is not indicated: (1) If PT or INR and aPTT are normal, or (2) solely for augmentation of plasma volume or albumin concentration. Administer FFP in doses calculated to achieve a minimum of 30% of plasma factor concentration. Four to five platelet concentrates, 1 unit single-donor apheresis platelets, or 1 unit fresh whole blood provide a quantity of coagulation factors similar to that contained in one unit of FFP.^{17,20,24} Dilutional coagulopathies increase when blood is diluted to at least 30% or when a patient loses more than one volume of blood, indicating that only one-third of the coagulation factors are present.²⁷ This deficit is reflected in laboratory values. Laboratory analysis will reveal the need for FFP by a PT and aPTT prolonged

more than 1.5 times normal. The use of FFP for volume replacement is contraindicated. Safety screening for FFP is the same as for RBCs.

Cryoprecipitate Infusion Guidelines

Cryoprecipitate is the precipitate collected off the top of FFP as it is thawed. Cryoprecipitate is then refrozen and thawed on use. It is rich in fibrinogen and contains factors VIII, XIII, and fibronectin. The current guidelines recommend cryoprecipitate for the following: (1) When a test of fibrinogen activity indicates a fibrinolysis; (2) When the fibrinogen concentration is less than 80 to 100 mg/dL in the presence of excessive bleeding; (3) As an adjunct in massively transfused patients when fibrinogen concentrations cannot be measure in a timely fashion; (4) For patients with congenital fibrinogen deficiencies. The guidelines also recommend that when possible, decisions regarding patients with congenital fibrinogen deficiencies should be made in consultation with the patient's hematologist. Transfusion of cryoprecipitate is rarely indicated if fibrinogen concentration is greater than 150 mg/dL in nonpregnant patients. Treat bleeding patients with von Willebrand disease (vWD) types 1 and 2A with desmopressin and subsequently with specific vWF/FVIII concentrate, if available. Cryoprecipitate should be administered if there is no response to or availability of desmopressin or vWF/FVIII concentrate. Treat bleeding patients with vWD types 2B, 2M, 2N, and 3 with specific vWF/FVIII concentrate, if available. If vWF/FVIII concentrate is not available, cryoprecipitate is indicated.¹⁷

It is preferable to transfuse platelets, FFP, and cryoprecipitate with adherence to ABO compatibility to avoid hemolytic reactions, but there are times when this practice is impractical. When massive transfusion occurs, one should be alert to the risk of hemolytic reaction. In addition to viral screening for donor units, the institution of solvent detergents, psoralen derivatives, and methylene blue are being evaluated as a means to decrease emerging viral contaminations, especially when blood products are pooled. The effect of these additives on platelets, FFP, and cryoprecipitate is still under investigation.^{21,23}

Transfusion Guidelines

There is no magic number or an absolute transfusion “trigger” for blood-component administration. There are few if any fixed guidelines or practice standards for transfusion therapy. There are, however, many suggested guidelines and protocols that vary among individual institutions. Past literature recommends a hemoglobin (Hgb) of 10 g/dL as an indicator for RBC transfusion, but transfusion delivery based on one isolated laboratory value without regard to the patient's overall health status is irresponsible.²⁶ A Hgb value of 8 g/dL and even 6 g/dL may be acceptable when ischemia or risk factors for cardiovascular disease are not evident.^{17,20} Strong randomized controlled trial evidence suggests the safety of restrictive transfusion triggers. As a consequence, a Hgb transfusion trigger of less than 7 g/dL is recommended for high risk patients.²⁵

There are also alternatives available to reduce or allay allogenic component replacement: preoperative autologous donation, acute normovolemic hemodilution, blood cell salvage, and recombinant factor VII.²⁷⁻²⁹

Recombinant factor VII was approved by the US Food and Drug Administration (FDA) in 1999 for hemophilia A (factor VIII) and B (factor IX), inhibitor disorders of factors VIII and IX, factor VII deficiency, and as a universal hemostatic agent.^{8,30-32} Its off-label use has successfully treated coagulation insufficiencies associated with platelet dysfunction, intracranial hemorrhage, prostate surgery, and trauma.³³

The exact mode of action of factor VII is undetermined. Both the classic coagulation cascade and the cell-based theory agree that factor VII enhances thrombin generation by augmenting TF/VII at the site of vessel injury and on the surface of the platelet.^{6,30,31} Administration ultimately boosts thrombin to form fibrin for clot stabilization. The recommended dose of factor VII for hemophilia is 90 to 120 mcg/kg. There is no definitive dose for use in the operating room for patients without prior coagulation disorders, but 20 to 45 mcg/kg has been suggested.⁸

Factor VII will reverse prolonged INR, but it fails to replace all the clotting factors.³⁰ The anesthesia provider must remain vigilant intraoperatively, providing interventions that would prevent

acidosis and hypothermia, both of which can interrupt the efficacy of the drug.^{30,31,34} Patients have experienced cerebrovascular accidents, myocardial infarctions (MIs), pulmonary emboli, and arterial and venous thromboemboli. Factor VII should be used cautiously in any patient predisposed to thrombosis. The indications for the use of factor VII remain limited and the treatment is very expensive.^{17,24,32,33,35} An extensive discussion of transfusion management practices can be found in [Chapter 22](#).

Postoperative Management

Patients should be reassessed in the postanesthesia care unit and again within 24 hours of surgery. Unrecognized bleeding can thus be identified and corrected before the patient deteriorates.

Evaluations of (1) the patient's color and mentation, (2) trends in vital signs (with specific attention to tachycardia or hypotension), (3) urine output, (4) hypothermia, (5) hemodynamic values such as central venous pressure, (6) laboratory values, and (7) dressings and/or drain volume must be judiciously monitored.

Specific Disorders

Bleeding diathesis can result from any number of deficiencies in coagulation. A few disorders encountered in practice are described here, as well as points to consider when dealing with a patient requiring anticoagulant therapy. Commonly obtained tests to assess bleeding risk include (PT), (aPTT), and platelet count. PT and aPTT are tests that were developed to test the integrity of the coagulation pathway, and do not predict perioperative bleeding. Abnormal platelet count, whether thrombocytopenia (< 150,000) or thrombocytosis (> 440,000), has been associated with a higher risk of perioperative bleeding. Other available tests include bleeding time, platelet function monitoring, thrombin time (TT), reptilase time, fibrinogen, and D-dimer.³⁶ INR is used to assess the effect of anticoagulants.

Von Willebrand Disease

vWD is a rare bleeding disorder that is inherited or may be acquired secondary to cardiovascular, malignant, or immunological diseases. There are several subtypes. Acquired von Willebrand syndrome (AvWS) has similar laboratory findings: a decreased vWF antigen, vWF ristocetin cofactor activity, or factor VIII. Three mechanisms have been proposed³⁶: (1) Autoimmune clearance or inhibition of vWF for lymphoproliferative diseases, monoclonal gammopathies, systemic lupus erythematosus, other autoimmune disorders, and some cancers; (2) Increased proteolysis of vWF caused by increased shear stress from ventricular septal defect, aortic stenosis, or primary pulmonary hypertension; and (3) Increased binding of vWF to platelets or other cell surfaces. This large plasma glycoprotein (GP) mediates the adhesion of platelets at sites of vascular injury and binds and stabilizes factor VIII.

Inherited vWD patients are characterized by lifelong bleeding episodes, whereas a sudden onset of bleeding symptoms occurs in patients with acquired disease, which can induce acute bleeding episodes during critical surgical procedures.³⁷

vWF is a heterogeneous multimeric glycoprotein that serves

two main functions: to facilitate platelet adhesion, and to behave as a plasma carrier for factor VIII of the coagulation cascade.³⁶ Synthesis of vWF takes place in the endothelial cells and megakaryocytes.^{37,38}

Similar to many coagulopathies, vWD has varying degrees of severity, mild, moderate, and severe. In the milder or moderate forms, regular or spontaneous bleeding is not evident but is likely after surgery or when trauma occurs.¹⁰ In the more severe form of vWD, spontaneous epistaxis and oral, gastrointestinal, and genitourinary bleeding can be relentless.

As noted previously, most patients with vWD exhibit a prolonged bleeding time, a deficiency in vWF and factor VIII, decreased vWF activity measured by a ristocetin (an antibiotic) cofactor (RCoF) assay, and decreased factor VIII coagulant activity (VIII:C).³⁹

Treatment options to control acute hemorrhages or to prevent bleeding complications during surgery include desmopressin, FVIII/vWF concentrates, high-dose intravenous (IV) immunoglobulins, and plasma exchange. Desmopressin is a synthetic analogue of vasopressin that boosts plasma levels of factor VIII and vWF. As the half-life of vWF is reduced in vWD, high doses of FVIII/vWF concentrates administered at frequent intervals may be necessary during bleeding episodes. Perioperative

Box 38.2 Treatment of vWD is outlined in **Box 38.2**.³⁶

Perioperative Treatment of von Willebrand Disease

- The treatment plan should be made according to the severity of disease and the type of surgery.
- *Major surgery:* achieve 100% vWF preoperatively and maintain trough levels of 50% until adequate wound healing.
- *Minor surgery:* achieve 60% vWF level preoperatively and trough daily levels of 30% until adequate wound healing.
- *Dental extractions:* achieve 60% vWF level preoperatively.

- *Delivery and puerperium*: 80% to 100% vWF level predelivery and trough levels of 30% for 3 to 4 days.
- In type 1 vWD with vWF level greater than 10 international units/dL, desmopressin is the treatment of choice, because it produces a complete or partial response in more than 90% of patients. Can be give within 40 to 60 minutes of surgery. Desmopressin increases endothelial cell release of factor VIII, vWF, and plasminogen activator. Goal vWF should be 80 international units/dL to 100 international units/dL and to raise factor VIII. Dosing consideration for tachyphylaxis should be made, as a result of depletion of endothelial stores.
- Type 2 and type 3 require vWF concentrate administration.
- Tranexamic acid is also an important adjunctive therapy as either intravenous or oral therapy.
- Cryoprecipitate can be used; however, ristocetin cofactor activity level should not exceed more than 50% and should be monitored while bleeding is controlled.
- If properly corrected, pharmacologic antithrombotic prophylaxis should be considered postoperatively.

Adapted from Kim J, et al. Perioperative approach to anticoagulants and hematologic disorders. *Anesthesiol Clin*. 2016;34(1):101-125.

Hemophilia

Hemophilia is an X-linked hematologic recessive disorder characterized by unpredictable bleeding patterns. Patients are either deficient in factor VIII (hemophilia A) or factor IX (hemophilia B). Hemophilia affects males almost exclusively, although females carry the gene for the disease. Patients with hemophilia A are grouped as mild (excessive bleeding after trauma or surgery), moderate (rarely have extensive, unprovoked bleeding), and severe (absence of factor VIII in the plasma). Hemophiliacs exhibit spontaneous bleeding, muscle hematomas, and pain at joint sites. Continued joint bleeding often results in

decreased range of motion and progressive joint arthropathy, and often requires orthopedic surgical intervention throughout life.⁴⁰

In the past, the life expectancy for the hemophiliac was short. Because hemophiliacs were deficient in factors VIII and IX, they required blood-component transfusion to replace the deficient or missing factors. The only factor components available were FFP and cryoprecipitate. Screening tests for donated blood units were unavailable, and patient mortality was high. Many hemophiliacs contracted transmissible diseases such as hepatitis and HIV and ultimately died from sequelae of blood transfusion therapy.⁴⁰ Furthermore, hemophiliacs were termed *high risk* for most surgical procedures and often turned down for many elective procedures. Today blood components undergo extensive screening, and newer and safer treatment modalities exist. Most surgeries are available to hemophiliacs, with a lower risk of uncontrolled bleeding.⁴¹

For patients with hemophilia or a family history of hemophilia, a preoperative assessment of hemostasis is imperative. Preoperative laboratory tests should include a platelet count and function, a coagulation panel (PT, aPTT, factor VIII, factor IX, and fibrinogen), in addition to an inhibitor test.⁴¹ If the hemophiliac was given a test dose of factor VII preoperatively, the response to the test dose should be evaluated. The patient should be typed and crossmatched, because even a low-risk procedure can be catastrophic for the hemophiliac.

A clearly defined anesthesia plan is essential for the hemophiliac and close consultation with a hematologist is essential. Factor VIII concentrate can be given prior to surgery. Factor VII is administered intraoperatively to augment thrombin generation and deter bleeding. The dose should be precalculated and vial availability confirmed prior to going into the operating room. Desmopressin (0.3 mcg/kg) also can be administered to increase plasma levels of factor VIII and vWF for mild to moderate hemophiliacs.^{36,42} There is no risk for viral transmission when either of these drugs is initiated. Perioperative management of the hemophiliac patient is outlined in [Box 38.3](#).

Perioperative Management of the Hemophilic Patient

- No procedure is too minor for adequate hemostasis planning including dental procedures, endoscopy with biopsy, arterial blood gas, or arterial lines.
- Preoperative assessment of inhibitor screening and inhibitor assay should be completed within 1 week of surgery.
- Elective procedures should be scheduled early in the day and early in the week to ensure adequate laboratory support and availability of factor concentrates (or plasma).
- Adequate laboratory support is needed to have reliable clotting factor level and inhibitor monitoring.
- Treatment with viral inactivated plasma-derived or recombinant concentrates is preferred over cryoprecipitate or fresh frozen plasma (FFP). Cryoprecipitate, in turn, is preferred over FFP for hemophilia A, because it is generally difficult to achieve high enough factor VIII levels with FFP alone; FFP can be used for treatment of hemophilia B. Other options include desmopressin, tranexamic acid, and epsilon aminocaproic acid.
- Desmopressin can be used for mild or moderate hemophilia A (particularly carriers) and some platelet disorders; however, it is of no value to hemophilia B, because it does not affect factor IX. Individual response to desmopressin is varied and difficult to predict.

Adapted from Kim J, et al. Perioperative approach to anticoagulants and hematologic disorders. *Anesthesiol Clin.* 2016;34(1):101-25.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a result of intravascular coagulation activation with microvascular thrombi formation, which causes thrombocytopenia and clotting factors depletion, leading to bleeding and end-organ complications.³⁶

Clinical presentation of DIC may include thrombosis, hemorrhage, or both. Multiorgan system failure and hemorrhage is the result of widespread thrombotic microangiopathy and

depletion of procoagulant factors (e.g., consumptive coagulopathy), respectively⁴³ (see Fig. 38.11).

The diagnosis of DIC is usually secondary to an underlying pathologic process. Acute DIC manifests as a complication of several disease processes, notably sepsis, the postoperative state, obstetric complications, blood transfusion reactions, and certain malignancies such as acute promyelocytic leukemia. Chronic DIC is seen in solid tumors and in large aortic aneurysms.³⁶

Coagulation activation ranges from mild thrombocytopenia and prolongation of clotting times to acute DIC characterized by extensive bleeding and thrombosis.⁴⁴ Systemic activation of coagulation results in: (1) intravascular deposition of fibrin, (2) thrombotic microangiopathy, (3) compromised blood supply to organs, and (4) multiorgan system failure. Systemic activation of coagulation also promotes the use and subsequent depletion of platelets and coagulation factors, which may induce severe bleeding from multiple sites.

Several factors play an important role in the pathogenesis of DIC. TF release is considered to play a central role in the development of hyperthrombinemia in DIC. Under normal conditions, mediators such as antithrombin and TFPI regulate the process of coagulation. During specific conditions, such as septicemia, liver impairment, capillary leakage, and the release of endotoxins and proinflammatory cytokines, the actions of these regulatory mediators are adversely altered. Experimental models of septicemia have shown increased fibrinolytic activity related to the acute release of tPA from the endothelium. The initial increased fibrinolytic activity is followed by the release of plasminogen activator inhibitor type 1 (PAI-1), which in turn impairs fibrinolysis and leads to accelerated thrombus formation in DIC. Finally, activated protein C mediates the release of inflammatory cytokines such as tumor necrosis factor and interleukins from endothelial cells. Complement activation and kinin generation increase the coagulation response leading to subsequent vascular occlusion.⁴⁵

Diagnosis of DIC is made by evaluation of the patient's clinical presentation in conjunction with laboratory tests such as platelet count, aPTT, PT, fibrin-related markers (e.g., fibrin degradation products, D-dimer), fibrinogen, and antithrombin. Additionally, a

scoring system developed by the International Society of Thrombosis and Haemostasis (ISTH) assists with the diagnosis⁴⁶ (Box 38.4). Acute (overt) DIC is characterized by ecchymosis, petechiae, mucosal bleeding, depletion of platelets and clotting factors, and bleeding at puncture sites. A score of 5 or greater indicates overt DIC. Chronic (nonovert) DIC is characterized by thromboembolism accompanied by evidence of activation of the coagulation system. A score less than 5 suggests nonovert DIC.

International Society of Thrombosis and Hemostasis Scoring System for Disseminated Intravascular Coagulation

1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC?

If yes, proceed; if no, do not use this algorithm.

2. Order global coagulation tests (e.g., platelet count, prothrombin time, fibrinogen, soluble fibrin monomers, or fibrin degradation products).
3. Score global coagulation test results.

_____ Platelet count
(> 100, 0; < 100, 1; < 50, 2)

_____ Elevated fibrin-related marker (e.g., soluble fibrin monomers/fibrin degradation products)
(no increase, 0; moderate increase, 2; strong increase, 3)

_____ Prolonged prothrombin time
(< 3 sec, 0; > 3 sec but < 6 sec, 1; > 6 sec, 2)

Fibrinogen level

(> 1.0 g/L, 0; < 1.0 g/L, 1)

4. Calculate score

5. If 5 or more, compatible with overt DIC; repeat scoring daily.

If less than 5, suggestive (not affirmative) for nonovert DIC; repeat next 1 to 2 days.

DIC, Disseminated intravascular coagulation.

Adapted from Bakhtiari K, et al. Prospective validation of the International Society of Thrombosis and Haemostasis scoring system for disseminated intravascular coagulation. *Crit Care Med.* 2004;32(12):2416-2421.

The management and treatment of DIC depends on identification of the underlying pathologic condition. In obstetric catastrophes, DIC may resolve as a result of prompt delivery. Treatment of sepsis with antibiotic therapy may halt the progression of DIC. Restoration of physiologic anticoagulant pathways with activated protein C in the treatment of sepsis with overt DIC holds promise.⁴⁵ Activated protein C inactivates factors Va and VIIIa resulting in decreased thrombin formation. Its use in treating DIC patients with severe sepsis has been approved by the FDA. For individuals requiring surgery who are bleeding or at risk for active bleeding, correction of coagulopathy with platelets, FFP, and/or cryoprecipitate must be used. Continued replacement of blood products should be based on the clinical presentation and reassessment of laboratory results.⁵

The use of antithrombotics for DIC remains controversial, especially in a patient who is prone to bleeding. Antithrombin administration for patients who have DIC associated with sepsis is useful not only for shortening the duration of DIC symptoms, but also for improving the outcome. However, the optimum dose and dosing period still need to be determined. Bleeding may be exacerbated and improvement of the outcome may be reversed by administration of antithrombin to patients who have DIC

associated with sepsis and are concomitantly receiving heparin.⁴⁵

Box 38.5 Suggestions for treatment of DIC are given in **Box 38.5**.

Treatment of Disseminated Intravascular Coagulation

1. Identify and eliminate the underlying cause
2. No treatment if mild, asymptomatic, and self-limited
3. Hemodynamic support, as indicated, in severe cases
4. Blood component therapy

1. *Indications:* active bleeding or high risk for bleeding

1. Fresh frozen plasma

2. Platelets

3. In some cases, consider cryoprecipitate, antithrombin III

5. Drug therapy

1. *Indications:* heparin for DIC manifested by thrombosis or acrocyanosis and without active bleeding; antifibrinolytic agents are generally contraindicated except with life-threatening bleeding and failure of blood component therapy

Sickle Cell Disease

Sickle cell disease (SCD) is a common hereditary hemoglobinopathy. Under normal circumstances the β -globin gene on chromosome 11 codes for the production of the β -globin chains of the protein hemoglobin A. However, in SCD there is an autosomal recessive genetic abnormality of the β -globin gene codes for the production of the variant hemoglobin, hemoglobin S. Patients may have sickle cell trait (SCT) or symptoms of SCD. There are several types including: hemoglobin SS, hemoglobin SC, hemoglobin SB+ (Beta) thalassemia, and beta-zero thalassemia.

SCT is a heterozygous disorder observed in 10% of African Americans.³⁶ Hemoglobin S levels range from 30% to 50%, and erythrocyte sickling is observed with a partial pressure of oxygen (PO_2) of 20 to 30 mm Hg. In contrast, SCD is a homozygous disorder observed in 0.5% to 1.0% of African Americans. The majority of the hemoglobin molecule is hemoglobin S, and sickling is observed with a PO_2 of 30 to 40 mm Hg. A sickle cell crisis may be triggered by hypoxemia, hypothermia, infection, dehydration, venous stasis, and acidosis. Sickle cell crisis may be characterized by chronic hemolytic anemia, recurrent episodes of intermittent vasoocclusion, severe pain, and end-organ damage. Although previous studies of SCD cite a perioperative morbidity and mortality greater than 50%, perioperative mortality has diminished steadily, which is attributed with overall improvements in anesthetic care.⁴⁷ Persons with SCD often require surgical intervention resulting from secondary conditions, which are directly related to their SCD. A cholecystectomy for gall stones is the most common operation required because of the excess bilirubin resulting from the rapid breakdown of sickle erythrocytes.

There is no universal method for caring for patients with a sickle cell disorder. The optimal percentage of hemoglobin S in patients receiving regular blood transfusions remains to be established, with clinical studies citing a range from 30% to 50%.^{48,49} The benefit of preoperative blood transfusion is still open to debate. Providing preoperative transfusion supplementation always carries a risk of increasing the blood viscosity and causing end-organ damage. A

conservative transfusion regimen has been shown to be as effective as an aggressive regimen in preventing perioperative complications and was associated with fewer transfusion-related adverse events.⁸ Anesthesia management for a patient with SCD includes providing adequate hydration, promoting adequate oxygen saturation, ensuring normothermia, maintaining acid-base balance, and providing proper patient positioning. Supplying adequate analgesia may interrupt intraoperative and postoperative sickle cell crisis.⁵⁰ Suggestions for intraoperative management of patients with SCD are given in [Box 38.6](#).

Intraoperative Management of Patients With Sickle Cell Disease

- Provide adequate hydration (e.g., monitor hemodynamic status, urine output, central venous pressures when available)
- Transfusion of crossmatched red blood cells to replace surgical blood loss (e.g., avoid increasing the Hgb greater than 10–11 g/dL)
- Avoid hypoxemia
- Maintain normothermia
- Maintain normal acid-base status
- Provide adequate perioperative pain management
- Caution using vasoocclusive devices such as tourniquets
- For younger, stable patients undergoing low-risk to intermediate-risk procedures, preoperative transfusion can be considered
- For patients with pulmonary disease or undergoing high-risk procedures, consideration should be made to decrease the hemoglobin S level to less than 30%, although some have suggested levels as high as 50% to 60% could be equally as effective.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is an immune response to heparin that can progress to severe thrombosis, amputation, and in some cases death. HIT is recognized as the most important immunologic complication of heparin therapy and remains one of the few absolute contraindications for heparin use. Heparin continues to be used clinically because of its rapid onset, easy reversibility, and moderate therapeutic window with relatively few side effects. In the United States, approximately 30% of hospitalized patients or approximately 12 million people a year receive heparin. Approximately 5% of patients receiving heparin or low-molecular-weight heparin (LMWH) will develop immune reactions characteristic of HIT; of these patients, approximately 50% or approximately 300,000 people will have clinically significant HIT thrombosis.⁵¹ Overall, clinically symptomatic HIT develops in 1% of hospital patients receiving heparin in any form.⁵²

HIT should be suspected in any patient on heparin or LMWH therapy who develops a decrease of greater than 50% in platelet count from baseline or total platelet count of less than 100,000 per mm³ with normal baseline counts. It occurs in 0.5% to 5% of heparin-treated patients, typically after 5 to 10 days, but in patients with previous heparin exposure HIT can have an earlier onset.³⁶

The classic clinical presentation of HIT includes thrombocytopenia, resistance to heparin anticoagulation, thrombosis, and positive assay tests indicative of HIT. There are two classifications of HIT; [Box 38.7](#) describes the defining characteristics of each type. Of the two classifications, type II is associated with the greatest clinical morbidity and mortality. HIT type II is caused by the formation of immunoglobulin G antibodies directed against heparin-platelet factor 4 (H-PH4) immune complexes. The immunoglobulin G antibody fixes to complements with H-PH4 and subsequently activates platelets via the Fc receptor causing platelet aggregation⁵² ([Fig. 38.12](#)). Despite thrombocytopenia, patients clinically do not present with bleeding tendencies (e.g., spontaneous bleeding, hemorrhage, petechiae). Rather, HIT type II induces a clinically relevant hypercoagulable state with clotting and thrombus formation causing serious sequelae. Amputation and mortality associated with HIT type II is

Box 38.7 estimated to be 20% and 30%, respectively.⁵¹

Heparin-Induced Thrombocytopenia (HIT) Type I and Type II

Type I

- Thrombocytopenia is mediated by direct heparin-induced platelet aggregation (e.g., nonimmune mediated)
- Onset is typically 1 to 4 days after start of heparin therapy
- Mild thrombocytopenia (e.g., less than 100,000 per microliter)
- Thrombocytopenia often resolves spontaneously even with continued administration of heparin
- Typically occurs with high-dose heparin administration
- Not associated with thrombosis and serious clinical sequelae

Type II

- Thrombocytopenia is mediated by the actions of the heparin, platelet factor 4, and immunoglobulin G expression (e.g., immune mediated)
- Onset is typically 5 to 14 days after start of heparin therapy
- Severe thrombocytopenia (e.g., less than 60,000 per microliter)
- Thrombocytopenia does not resolve spontaneously, therefore heparin administration must be discontinued
- Occurs with any heparin dose and route
- Associated with thrombosis and serious clinical sequelae

FIGURE 38.12 Pathophysiology of heparin-induced thrombocytopenia (HIT) type II. *PF4*, Heparin platelet factor 4.

Many tests are available with individual pros and cons; however, the current accepted gold standard test is the ¹⁴C-serotonin release assay. Other useful tests include the heparin-induced platelet aggregation assay, and antibody detection via an enzyme-linked immunosorbent assay.

Diagnosis and treatment of HIT should be based on clinical presentation and laboratory findings. Thrombocytopenia, cutaneous abnormalities (e.g., skin necrosis, ecchymosis, hematoma, purpura, blistering), and tachyphylaxis after heparin administration may indicate developing HIT. If HIT is suspected after heparin administration, a hematologist should be consulted. In patients with high suspicion for HIT, heparin should be stopped immediately with an alternative anticoagulant administration even prior to the confirmatory test.³⁶ Treatment of HIT includes discontinuation of all sources of heparin (e.g., medications, and heparin-coated invasive lines), administration of direct thrombin inhibitors (e.g., argatroban, or lepirudin).^{51,52} Arterial or venous thrombosis that compromises perfusion to distal sites may require prompt surgical intervention (e.g., embolectomy or vascular bypass).

Other Considerations

Perioperative Management of Patients Taking Antithrombotic Drugs

The advent of new antithrombotic medications within the last decade has garnered increasing interest regarding the perioperative management of these potent medications. Antithrombotic medications can be categorized based on their respective method of altering the normal physiologic process of hemostasis: antiplatelet, anticoagulant, and fibrinolytic medications (Figs. 38.13 and 38.14).

See Table 38.6 for common antithrombotic medications.^{53,57}

Selection, dosing, and monitoring of antithrombotic therapy should be adjusted based on the patient's primary diagnosis, comorbidities, type of therapy (e.g., treatment or prophylaxis), and renal impairment. Classification of anti-platelet drugs is noted in Box 38.8.

TABLE 38.6

Pharmacologic Properties of Common Antithrombotic Medications

	Type	Mechanism	Half-life	Reversal Available	General Anesthesia Recommendations	Laboratory Monitoring
ASA	Anti-platelet	COX-1 inhibitor (irreversible)	20 minutes	Platelets	Stop 7 days	None
NSAIDs	Anti-platelet	COX-1 inhibitor (reversible)	2–10 hours	Platelets	Stop 24–48 hours	None
Clopidogrel	Anti-platelet	ADP receptor antagonist	7 hours	Platelets	Stop 5–7 days	None
Ticlopidine	Anti-platelet	ADP receptor antagonist	4 days	Platelets	Stop 7–10 days	None
Prasugrel	Anti-platelet	ADP receptor antagonist	7 hours	Platelets	Stop 7–10 days	None
Abciximab	Anti-platelet	Glycoprotein IIb/IIIa	30 minutes	Platelets	Stop 48–72 hours	None

		receptor antagonist				
Eptifibatide	Anti-platelet	Glycoprotein IIb/IIIa receptor antagonist	2.5 hours	Platelets	Stop 8–24 hours	None
Tirofiban	Anti-platelet	Glycoprotein IIb/IIIa receptor antagonist	2 hours	Platelets	Stop 8–24 hours	None
Fondaparinux	Anti-coagulant	Factor Xa antagonist (indirect*)	14–17 hours	None	Stop 2–4 days	Anti-Factor Xa assay
LMWH	Anti-coagulant	Factor IIa and Xa antagonist (indirect*)	4.5 hours	Protamine (Partial reversal)	Stop 12–24 hours	Anti-Factor Xa assay
Heparin	Anti-coagulant	Factor IIa and Xa antagonist (indirect*)	1.5 hours	Protamine	Stop 6 hours	PTT
Warfarin	Anti-coagulant	Vitamin K epoxide reductase antagonist	2–4 days	Vitamin K, FFP, recombinant Factor VII	Stop 4–5 days	PT
Rivaroxaban	Anti-coagulant	Factor Xa antagonist (direct)	7–11 hours	Andexanet Alfa	Stop 2–4 days	Anti-Factor Xa assay
Apixaban	Anti-coagulant	Factor Xa antagonist (direct)	8–15 hours	Andexanet Alfa	Stop 1–2 days	Anti-Factor Xa assay
Dabigatran	Anti-coagulant	Factor IIa antagonist (direct)	14–17 hours	Idarucizumab	Stop 2–4 days	PTT
t-PA	Fibrinolytic	Plasminogen activator	5 minutes	Anti-fibrinolytic	Stop 1 hour	PT/PTT
Streptokinase	Fibrinolytic	Plasminogen activator	23 minutes	Anti-fibrinolytic	Stop 3 hours	PT/PTT

Classification of Anti-Platelet Drugs

Arachidonic Acid Inhibitors

1. COX Inhibitors: aspirin, indobufen, triflusal, nonsteroidal antiinflammatory agents, sulfinpyrazone
2. NonCOX inhibition of arachidonic acid; phosphodiesterase

inhibitors: dipyridamole, pentoxifylline, cilostazol, trapidil

3. Other: omega-3 fatty acids, eicosanoids (prostacyclin, prostaglandin analogues)

P2Y₁₂ ADP Receptor Inhibitors

1. Thienopyridines (ADP antagonists): ticlopidine, clopidogrel, prasugrel
2. ATP derivatives: cangrelor
3. CPTPs: ticagrelor

Thrombin Protease-Activated Receptor-1 Inhibitors

1. Vorapaxar, E-5555

Platelet Glycoprotein IIb/IIIa Receptor Blockers

1. Intravenous: abciximab, tirofiban, eptifibatide

Drugs With Secondary Antiplatelet Activity

1. Direct thrombin inhibitors, heparin, nitrates, fibrates, calcium channel antagonists, others

ADP, Adenosine diphosphate; *ATP*, adenosine triphosphate; *COX*, cyclooxygenase; *CPTPs*, cyclopentyltriazolopyrimidines.

From Wiviott SD, Guigliano RP. Non-ST segment elevation acute coronary syndromes. In Antman EM, Sabatine MS, eds. *Cardiovascular Therapeutics: A Companion to Braunwald's Heart Disease*. 4th ed. Philadelphia: Elsevier; 2013:155.

The preoperative management of antithrombotic therapy is a pivotal topic in that the risk of perioperative bleeding must be weighed against the risk of disease exacerbation. Excessive bleeding may occur if the anticoagulation medications are continued before surgery. This may lead to potentially serious intraoperative and

postoperative complications or the need for transfusion of blood products. In contrast, abruptly withholding anticoagulant medications places the patient at increased risk for MIs, cerebrovascular accidents, arterial or venous thromboembolism, pulmonary embolism, or death.^{53–56} Situation-specific considerations are leading to new recommendations for perioperative management of patients on antithrombotic therapy (see [Table 38.6](#)). [Table 38.7](#) outlines guidelines for neuraxial anesthesia in patients receiving antithrombotic therapy. Uninterrupted administration of anticoagulant therapy, specifically warfarin, for *low*-risk procedures such as minor ophthalmic, dental, dermatologic, gastrointestinal, orthopedic, and podiatric procedures is generally safe. ([Box 38.9](#)). A thorough assessment of the patient history, diagnosis, and procedure must be made to weigh the risks of potential stroke, MI, and thromboembolism for both cardiac and noncardiac surgeries. Complications of any kind translate into increased cost and prolonged hospitalizations.¹¹

TABLE 38.7

Neuraxial Anesthesia in Patients Receiving Antithrombotic Therapy

Drug	Contraindications and Comments
Antiplatelet medications	<ul style="list-style-type: none"> • NSAIDs: no contraindication • Discontinue ticlopidine 14 days, clopidogrel 7 days, GP IIB/IIIa inhibitors 8–48 hours in advance • Ticagrelor 5–7 days; prasugrel 7–10 days • Epidural catheter removal: 6- to 24-hour delay until restarting ticagrelor, prasugrel, or clopidogrel
Unfractionated heparin, subcutaneous	<ul style="list-style-type: none"> • No contraindication with twice-daily dosing and total daily dose < 10,000 units • Consider delaying heparin until after block if technical difficulty anticipated • The safety of neuraxial blockade in patients receiving doses greater than 10,000 units/day of UFH, or more than twice daily dosing of UFH has not been established
Unfractionated heparin, intravenous	<ul style="list-style-type: none"> • Heparinize 1 hour after neuraxial technique • Remove catheter 2–4 hours after last heparin dose • No mandatory delay if traumatic insertion
LMWH	<ul style="list-style-type: none"> • Twice-daily dosing: LMWH 24 hours after surgery, regardless of technique • Remove epidural catheter 2 hours before first dose of LMWH
Warfarin	<ul style="list-style-type: none"> • Normal INR (before neuraxial technique) • Remove catheter when INR ≤ 1.5 (initiation of therapy)
Fondaparinux	<ul style="list-style-type: none"> • Single injection, atraumatic needle placement or alternate thromboprophylaxis • Avoid indwelling catheters
Direct thrombin inhibitors	<ul style="list-style-type: none"> • ASRAPM: Insufficient information; suggest avoiding neuraxial techniques • Belgian and German Societies: Needle placement 8–10 hours after dose; delay subsequent doses 2–6 hours after needle placement
Thrombolytics	<ul style="list-style-type: none"> • Absolute contraindication

Herbal therapy	<ul style="list-style-type: none"> • No evidence for mandatory discontinuation before placement neuraxial technique • Be aware of potential drug interactions with the “3 Gs”: ginkgo biloba, garlic, and ginseng
Factor Xa inhibitors: rivaroxaban, apixaban	<ul style="list-style-type: none"> • Time between epidural anesthetic technique and next anticoagulant dose: rivaroxaban, 4–6 hours; apixaban, 6 hours • Time before last anticoagulant dose and epidural catheter removal: rivaroxaban, 22–26 hours; apixaban, 26–30 hours • Time between removal of epidural catheter and next anticoagulant dose: rivaroxaban and apixaban, 4–6 hours

For patients undergoing deep plexus or peripheral blocks, use these same recommendations.

ASRAPM, American Society of Regional Anesthesia and Pain Management; GP, glycoprotein; INR, international normalized ratio; LMWH, low-molecular-weight heparin; NSAIDs, nonsteroidal inflammatory drugs; UFH, unfractionated heparin.

Box 38.9

Procedures That May Be Performed Without Warfarin Discontinuation

Ophthalmic

- Cataract extractions
- Trabeculectomies

Dental

- Restorations
- Endodontics
- Prosthetics
- Uncomplicated extractions
- Dental hygiene treatment

Dermatologic

- Mohs micrographic surgery

- Simple excisions

Gastrointestinal

- Upper endoscopy and colonoscopy with or without biopsy
- Endoscopic retrograde cholangiopancreatography (ERCP) without sphincterotomy
- Biliary stent insertion without sphincterotomy
- Endosonography without fine needle aspiration
- Push enteroscopy

Orthopedic or Podiatric

- Joint and soft tissue aspirations and injections
- Nail avulsions
- Phenol matrixectomies

Antiplatelet Drugs and Noncardiac Surgery: Patients With Coronary Stents

Coronary stents are placed to improve coronary artery flow in patients with stable but symptomatic coronary artery disease or acute coronary syndromes, including unstable angina, non-Q wave MI, and ST-elevation acute MIs. Every year more than 2 million patients undergo percutaneous coronary intervention. Of these 2 million patients, greater than 90% will require at least one intracoronary stent. Furthermore, approximately 5% of these patients will undergo noncardiac surgery within the first year after stent placement, whereas many patients will continue to require surgery thereafter.⁵⁴ The clinical efficacy of intracoronary stents is highly dependent on long-term antiplatelet therapy. As a result, anesthesia providers routinely manage patients with coronary artery disease who have had coronary stents placed and are

typically receiving dual antiplatelet therapy with aspirin and thienopyridines (see [Fig. 38.14](#)).

There are two distinct complications associated with stent placement: acute stent thrombosis and stent restenosis. Acute stent thrombosis may lead to abrupt occlusion of the coronary artery and an acute coronary syndrome such as acute MI. Acute stent thrombosis is a serious complication with a mortality rate ranging between 20% and 45%, or an MI rate up to 64%. Stent thrombosis can occur anytime after stent implantation and anytime antiplatelet therapy is abruptly discontinued. Abrupt discontinuation of antiplatelet therapy can lead to a rebound effect, which is characterized by an inflammatory prothrombotic state. During this prothrombotic state there is increased platelet adhesion, platelet aggregation, and thromboxane A₂ activity.⁵⁶ Most events of acute stent thrombosis occur within the first 30 days after stent placement. In contrast, restenosis of a stent is a slowly developing occlusion directly related to excessive endothelial growth over time. In most cases it peaks between 6 and 9 months after stent implantation. Symptoms of restenosis can be insidious and lead to symptoms of coronary insufficiency, or can be silent and lead to acute MI.⁵³⁻⁵⁵

There are two types of stents available: bare-metal stents (BMS) and drug-eluting stents (DES).⁵⁸ For both types of stent patients typically receive dual antiplatelet therapy with aspirin and a thienopyridine (e.g., clopidogrel, ticagrelor) to prevent acute stent thrombosis. The most common cause of acute stent thrombosis is premature discontinuation of dual antiplatelet therapy.⁵⁴ Current recommendations for management of perioperative antiplatelet therapy are given in [Box 38.10](#). The risk of acute stent thrombosis is relatively low but may occur more commonly with DES because of the delayed or incomplete endothelialization process. [Box 38.10](#) outlines additional risk factors for acute stent thrombosis. When considering discontinuing or modifying antiplatelet therapy, it is prudent to involve a multidisciplinary team including a cardiologist, surgeon, and anesthesiologist for guidance regarding preoperative and postoperative management of antiplatelet

Box 38.10

Additional Risk Factors for Acute Stent

Thrombosis

Coronary Anatomy Factors

- Site of stent placement (e.g., bifurcation stenting, side branch occlusion)
- Left main coronary artery stent
- Long stent length (greater than 18 mm)
- Ostial stenting
- Overlapping stents
- Placement of multiple stents
- Small stent diameter (less than 3 mm)
- Suboptimal stent placement

Patient Risk Factors

- Advanced age
- Diabetes mellitus
- Gene polymorphism
- Hypercoagulable states (e.g., diabetes, malignancy, and surgery)
- Major cardiac adverse event within 30 days of percutaneous cardiac intervention
- Reduced left ventricular ejection fraction
- Prior brachytherapy
- Renal insufficiency

Stent Indication Factors

- Acute coronary syndrome
- Type C coronary lesion or total occlusion

Stent-Related Factors

- Type of stent placed
- Hypersensitivity to stent polymer

Pharmacologic Factors

- Abrupt discontinuation of antiplatelet therapy
- Diminished response or resistance to antiplatelet therapy

Adapted from Hall R, Mazer CD. Antiplatelet drugs: a review of their pharmacology and management in the perioperative period. *Anesth Analg*. 2011;112(2):292-318.

This patient population requires special attention preoperatively. Important information should include the date of stent implantation, the type of stent deployed, and antiplatelet therapy if applicable. Additional points to consider are the type of operation planned and the risk of bleeding. The current medication regimen must be assessed because many patients have discontinued their antiplatelet medications preoperatively, whereas others continue them at the request of their cardiologist. Surgery in which the risk of bleeding is low may not require discontinuation of antiplatelet therapy. The PeriOperative ISchemic Evaluation trial (POISE-2) also evaluated the effectiveness of aspirin therapy in a cohort of patients without a recent stent. Administration of aspirin before surgery and throughout the early postoperative period had no effect on the rate of a composite of death or nonfatal MI, but it increased the risk of major bleeding. On the basis of currently available literature, including the POISE-2 trial, aspirin should not be administered to patients undergoing surgery unless there is a definitive guideline-based primary or secondary prevention indication. The guideline

also recommends strong consideration be given to the administration of aspirin for elective noncardiac surgery, without history of percutaneous coronary intervention and stenting, when the risk of myocardial ischemia exceeds the risk of surgical bleeding. Aside from closed-space procedures, intramedullary spine surgery, or possibly prostate surgery, moderate-risk patients taking lifelong aspirin for a guideline-based primary or secondary indication may warrant continuation of their aspirin throughout the perioperative period.⁵⁹

Patients who require emergent surgery should be evaluated on a case-by-case basis, weighing the risks of bleeding against the risks of thrombosis. As a result of the lack of prospective studies and guidelines, a wide variety of potential approaches to the perioperative management of BMS, DES, and antiplatelet therapy have been proposed. In 2016 the American College of Cardiology/American Heart Association (ACC/AHA) released their updated **Box 38.11** for management of patients with DESs.^{60,61} (**Box 38.11**).

Perioperative Considerations for the Patient With a Coronary Stent

Stents

- Type of stent (s) (e.g., BMS, DES)?
- When were stent(s) placed?
- Complications during the revascularization, such as malposition, longer length, overlapping?

Antiplatelet Therapy

- What is antiplatelet regimen?
- What is the recommended duration of antiplatelet therapy?
- Consult patient cardiologist regarding antiplatelet management.

Elective Noncardiac Surgery

1. Elective noncardiac surgery should be delayed 30 days after bare metal stent (BMS) implantation and optimally 6 months after drug eluting stent (DES) implantation
2. In patients treated with dual antiplatelet therapy (DAPT) after coronary stent implantation who must undergo surgical procedures that mandate the discontinuation of P2Y12 inhibitor therapy (clopidogrel or ticagrelor), it is recommended that aspirin be continued if possible and the P2Y12 platelet receptor inhibitor be restarted as soon as possible after surgery.
3. When noncardiac surgery is required in patients currently taking a P2Y12 inhibitor, a consensus decision among treating clinicians as to the relative risks of surgery and discontinuation or continuation of antiplatelet therapy can be useful.
4. Elective noncardiac surgery after DES implantation in patients for whom P2Y12 inhibitor therapy will need to be discontinued may be considered after 3 months if the risk of further delay of surgery is greater than the expected risks of stent thrombosis.
5. Elective noncardiac surgery should not be performed within 30 days after BMS implantation or within 3 months after DES implantation in patients in whom DAPT will need to be discontinued perioperatively

Nonelective Surgery

1. *Determine risk for surgical bleeding:* If not at high risk, continue dual antiplatelet therapy. Discontinuation of dual antiplatelet therapy, in patients with incomplete stent endothelialization, markedly increases the risk of stent thrombosis, myocardial infarction, and death.
2. *High risk for bleeding:* Risk primarily associated with closed space surgeries (i.e., medullary canal spine surgery, intracranial surgery, posterior chamber eye surgery and possibly prostate surgery) where increased tissue pressure would be deleterious. If dual antiplatelet therapy must be interrupted, aspirin should be

continued, when possible. An evolving treatment option involves “bridging therapy” anticoagulation in which drugs of short duration (glycoprotein inhibitor, e.g., tirofiban, eptifibatid; direct thrombin inhibitor, e.g., bivalirudin; unfractionated heparin; low molecular weight heparin; nonsteroidal antiinflammatory drugs, e.g., flurbiprofen; COX-1 inhibitors) are administered for up to 6 hours during the surgery, with the goal of preventing stent thrombosis while dual antiplatelet therapy is interrupted. Restart dual antiplatelet therapy as soon as possible after the surgery.

3. Surgery should be performed in an institution where higher-acuity care and an interventional cardiologist are available when possible. Consult prior to surgery to determine procedural complexities, and determine optimal antiplatelet therapy and requisite patient management.

Outpatients Requiring Noncardiac Surgery

When determining the perioperative management of anticoagulation therapy, consideration must be given to the risk of bleeding as related to the type of surgery in addition to the patient's risk for thromboembolism (Tables 38.8 and 38.9). To date there is a lack of sufficient prospective, double-blind, randomized controlled studies to evaluate perioperative bridge therapies. Recent trials suggest that the bleeding risk using perioperative unfractionated heparin or LMWH may be higher than previously thought. For these reasons, bridging anticoagulation should be approached cautiously, using patient input once risks and benefits have been discussed.⁶²

TABLE 38.8

Risk Factors for Venous Thromboembolism

Major Risk Factors	Moderate Risk Factors	Low Risk Factors
Fracture (hip or leg)	Central venous lines	Prolonged bed rest
Hip or knee replacement	Congestive heart or respiratory failure	Immobility
Major general surgery	Paralytic stroke	Arthroscopic knee surgery
Major trauma	Malignancy	Laparoscopic surgery
Spinal cord injury	Postpartum period	Obesity
Advanced age	Drug therapy	Pregnancy
Previous VTE	Cancer chemotherapy	
Vascular disease or injury	Estrogen contraceptives or replacement therapy	Varicose veins History of unexplained or recurrent spontaneous abortion
Hypercoagulable state	Heparin induced thrombocytopenia Sepsis or infection Erythropoiesis stimulating agents	Severe lung disease, including pneumonia (< 1 month ago) Inflammatory bowel disease
	Blood transfusion

The epidemiology of venous thromboembolism. *J Thromb Thrombolysis*. 2016;41:3-14; Mann DL, et al. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 10th ed. Philadelphia: Elsevier; 2015: 1809-1833; Rogers MA, et al. Epidemiology and Prevention. *Circulation*. 2012;125:2092-2099.

TABLE 38.9

Surgical Risk Factors for Venous Thromboembolism

Type of Surgery	Comments
Major general surgery	High risk; generally defined as abdominal or thoracic procedures under general anesthesia lasting ≥ 30 minutes; prophylaxis indicated
Orthopedic surgery	High risk; hip and knee replacements and other lower extremity procedures without prophylaxis show a VTE rate of approximately 4.3%; > 90% of proximal thrombotic events occur on the operative side. LMWH reduces risk by two-thirds. Half of postoperative lower-extremity thrombi detected by scanning, develop in the operating room, and the remainder occurs over the next 3 to 5 days; prophylaxis indicated
Knee arthroscopy	Surgery is low to moderate risk. VTE prophylaxis optional
Most outpatient or same-day surgery	Low risk; prophylaxis not required unless patient has significant risk factors
Spinal surgery for nonmalignant disease	Low risk; prophylaxis not required unless patient has significant risk factors
