Gynecologic noncancer surgery, cardiac and most thoracic surgery, spinal surgery for malignant disease	Moderate risk; prophylaxis indicated
Bariatric, gynecologic cancer surgery, pneumonectomy,	High risk; prophylaxis indicated

spinal cord injury or other major trauma, major urology procedures	
Intracranial, traumatic brain injury	High risk; anticoagulation relatively contraindicated because of bleeding risk; low dose LMWH has been used
Laparoscopic procedures	Low risk: prophylaxis not required unless patient has significant risk factors

LMWH, Low molecular weight heparin

Prevention of VTE in orthopedic surgery patients: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. *Chest*, 2012;141(2 Suppl):e278S-325S.

Summary

Each time patients consent to undergo a surgical or diagnostic procedure, the hemostatic system is challenged. An understanding of the normal hemostatic system, methods to prevent bleeding and decrease transfusion requirements, alternatives to blood transfusions, and an understanding of hemostatic pharmacology can only enhance patient care and safety when providing anesthesia care.

Thermal Injury and Anesthesia

Valdor L. Haglund

The American Burn Association's National Burn Repository of 2015 estimates approximately 486,000 individuals a year with burn injuries visited emergency departments in the United States (between 2005 and 2014).¹ Of these, approximately 40,000 individuals were hospitalized for acute burn injuries and 30,000 of those were admitted to one of 128 specialized burn centers around the country. These centers undergo a rigorous review by the American Burn Association (ABA) and the American College of Surgeons (ACS) to become verified. The verification process insures the facility provides high-quality, specialized care of burned patients, maintaining the necessary resources and medical services mandated by ABA guidelines.²

As a result of continuous development in the treatment of burns, the lethal dose (LD)₅₀ (the burn size lethal to 50% of the population) for thermal injuries has risen from 42% total body surface area (TBSA) during the 1940s and 1950s to more than 90% TBSA for young thermally injured patients. This vast improvement in survival is due to simultaneous developments in critical care, advancements in resuscitation, control of infection through early excision, and pharmacologic support of the hypermetabolic response to burns.^{3,4}

There has been a decline in the incidence of burn injury over the past 2 decades. This is in part due to an increased focus on burn prevention including increased use of smoke detectors, fire and burn prevention education, decreased smoking, water temperature regulations, and regulation of consumer products and occupational safety. An improvement in all aspects of medical care of these patients has played a major role in improving survival. These include increased access to emergency medical care, advanced ventilation and treatment of inhalation injuries, improved infection

control practices, enhanced nutritional support, early burn wound excision and grafting, and the treatment of the hypermetabolic response. The development of evidence-based practice guidelines and multidisciplinary care models available at regional burn care centers have also contributed to improvements.⁵

Nonetheless, during the period 2005 to 2014 in the United States, more than 1.25 million people sustained burn injuries annually with 486,000 receiving medical treatment.⁶ Approximately 3240 die from fire/smoke inhalation injury—2855 from residential fires and 300 from motor vehicle or aircraft crashes.⁷ Approximately 75% of deaths occur at the scene of the accident/injury or during initial transport.⁸ Roughly 35% of all burn victims are younger than 17 years of age, with more than 15,000 children requiring hospitalization as a result of their burn injuries. Scald injuries predominate among small children, with a progressive increase in the frequency of thermal-related burns in the elderly. Major causes of death in burn patients are multiple organ failure and infection. Major risk factors for mortality are older age (> 60 yrs), a higher total percentage of burned surface area (> 40% TBSA), and inhalation injury. The main causes of early death (less than 48 hours after injury) are shock and inhalation injury. Multiorgan failure and sepsis were the most frequently reported causes of death. Death after a burn injury is not related to the toxic biologic effects of thermally injured skin but to shock associated with metabolic and infectious consequences of a large open wound, sepsis, inhalation injury, and extensive malnutrition, which cumulatively set the stage for life-threatening bacterial sepsis.⁹⁻¹¹

Classification of Burn Injury

Burn injuries, regardless of their etiology, are classified according to the depth and extent of skin and tissue destruction, as well as the TBSA involved. First-degree (superficial) burns are limited to the epidermis, the outermost layer of skin. The epidermis is thin and avascular, usually healing spontaneously and seldom requiring medical intervention. Second-degree burns, also known as deep and superficial *partial-thickness burns*, extend to the dermis. In contrast to the epidermis, the dermis is very vascular and contains numerous blood vessels and nerves. Thus severity of the type of burn varies, depending on the amount and depth of the dermal tissues involved. If the epithelial basement membrane of the dermis is intact, the skin will regenerate, and grafting may not be required. Third-degree burns, or *full-thickness burns*, extend to the subcutaneous tissue lying below the dermis. The entire skin thickness is destroyed with third-degree burns.⁹ Skin grafting is required for these types of burns because the epithelium and the dermal appendages are destroyed. A fourth-degree burn classification is used by some to describe structures burned below the dermis, such as muscle, fascia, and bone. [Table 39.1](#) classifies burns according to depth of skin layers affected, and [Fig. 39.1](#) illustrates the layers of burn injury.

TABLE 39.1
Degrees of Burn Injury

Classification	Tissue Level Involvement	Outcome and Treatment
First-degree burn (Superficial)	Epidermis	Skin appears red and slightly edematous; heals spontaneously; mild pain and no scarring; barrier preserved; sunburn or flash flame
Second-degree burn (Partial-thickness)		
Superficial dermal burn	Epidermis and upper dermis	Heals spontaneously; red and edematous; appears wet, hyperemic, and blistering; heals in 7–10 days; scar uncommon
Deep dermal burn	Epidermis and deep dermis	Requires excision and grafting for rapid return of function; heals in 2–8 weeks; probable scar without surgery
Third-degree	Destruction	Epidermal and complete dermal loss; wound excision and grafting

burn (Full-thickness)	of epidermis and dermis	required; limitation of function and scar formation; waxy white leathery appearance; no pain due to nerve damage
Fourth-degree burn	Skeletal muscle, fascia, bone	Complete dermal loss with injury down to tendon or bone; complete excision, limited function; muscle necrosis; electrical injuries; limb loss common

FIGURE 39.1 Classification of burns. Partial-thickness burns include first- and second-degree burns. Full-thickness burns include third-degree burns. Fourth-degree burns involve tissues under the skin, such as muscle or bone. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 9th ed. St. Louis: Elsevier; 2016:203.)

The burn team assesses the extent of a burn and plans initial resuscitation efforts. Burn wounds can be readily quantified, but estimation of the burn size remains subjective and assessor related. The most widely used estimation is the “Rule of Nines,” which was first described by Lund and Browder (Fig. 39.2). The body is divided into regions that represent 9% or a multiple of 9% of the TBSA. Specific modifications apply to children because the surface areas of their heads and trunks are proportionally larger than their extremities.¹² The rule of nines is a quick method to visually estimate burn size; however, it may not be all inclusive. The extent of burn injury can be more specifically quantified using the Lund and Browder chart. Fig. 39.3 illustrates this method, which is more accurate in determining a burn victim's injury but is also more time-consuming to use. This method is often used when determining the

extent of burn in the pediatric patient.

FIGURE 39.2 Burn assessment chart with body proportions. Numbers under figures indicate age; other numbers indicate percent body surface. (From Herndon DN. *Total Burn Care*. 4th ed. Edinburgh: Elsevier; 2012:407.)

Area	Age 0	1	5	10	15	Adult
A - ½ of head	9½%	8½%	6½%	5½%	4½%	3½%
B - ½ of one thigh	2¾%	3¼%	4%	4¼%	4½%	4¼%
C - ½ of one leg	2½%	2½%	2¾%	3%	3¼%	3½%

FIGURE 39.3 Lund-Browder chart. (From National Association of EMTs. *PHTLS: Prehospital Trauma Life Support*. 7th ed. St. Louis: Mosby/JEMS; 2011.)

According to the ABA's injury severity grading system, a *major burn* is (1) a second-degree burn involving more than 10% of the TBSA in adults or 20% at extremes of age, (2) a third-degree burn involving more than 10% of the TBSA in adults, (3) any electrical burn, or (4) a burn complicated by smoke inhalation. There is much discussion about the use of mathematical models to predict outcome and mortality and which formulas are the most accurate.¹³⁻¹⁵ Associated mortality estimates follow a burn formula derived from the National Burn Registry: if the age of the patient plus percentage TBSA of burn exceeds 115, the mortality is greater than 80%. Additionally, clinical observations estimate the mortality of a burn victim is doubled if inhalation injury is sustained in conjunction with a thermal burn.¹

Etiologies of Burn Injuries

On admission to a burn unit, the team determines the etiology of the burn injury and the circumstances surrounding the injury. This is particularly important because specific pathophysiologic sequelae can be anticipated after an electrical burn, and still others after a thermal burn. An individual burned in a contained space, such as in a house fire, should be suspected of having an inhalation injury as well. There are four types of burn injuries: chemical, electrical, thermal/heat (also referred to as *flame* or *scald*), and inhalation. The ABA's National Burn Repository estimates the types of burns reported in 2015 included: 43% flame or fire, 34% scalds, 9% contact, 4% electrical, 3% chemical and 9% other.²

Chemical burns commonly occur in a laboratory setting or industrial environment. These chemical burns occur when a noxious chemical substance comes into contact with skin. Tissue damage and destruction result from the reaction of the chemical with tissue proteins and cellular components. Skin disruption will continue until the chemical irritant is removed or neutralized. Initial treatment is the application of copious amounts of water or normal saline irrigation. Chemical burns are uncommon in children.

Electrical burns can be the most damaging to skin and surrounding tissue. The extent of the burn depends on the amount of thermal energy conducted through the skin, based on the voltage and duration of contact with the electrical source. Significant tissue disruption can occur where electric current is most concentrated, that is at points of entry and exit, although two wounds are not always apparent. Initially, the extensiveness of skin and underlying tissue involvement may be difficult to diagnose because surface damage may not reflect all tissue damage, and entrance wounds may appear superficial. Approximately 10% to 46% of those who have experienced an electrical injury experience some form of cardiac arrhythmias and damage to the myocardium can occur. Moreover, electrical burns can cause severe damage to bones, blood vessels, muscle, and nerves. If the amount of muscle damaged from the conducted electric current is significant, myoglobin can be

released into the circulation. Myoglobinemia, which affects nephron and renal tubular function, places the patient with an electrical burn at great risk of developing renal failure..

Thermal burns, or burns sustained from any heat source, commonly occur in and around the home. Approximately 70% of burns sustained by those up to the age of 4 years old are the result of scald injuries, whereas flame burns are the most common pattern among children aged 5 years and older. In general, younger children are at higher risk for sustaining burn injuries, and abuse or neglect may account for as much as 15% to 20% of these cases.⁵

Inhalation burn injuries often accompany a thermal burn and should be suspected until aggressively ruled out.¹⁶⁻¹⁸ Inhalation injury can be classified into three types, based on anatomic location.¹⁹ The first type includes upper-airway injuries caused primarily by thermal injury to the mouth, oropharynx, and larynx. The second type includes lower airway and parenchymal injuries to the trachea, bronchioles, and alveoli caused by chemical and particulate constituents of smoke. Inhalation injury usually means injuries of this type. The third type includes metabolic asphyxiation in which certain smoke constituents such as carbon monoxide or hydrogen cyanide impair oxygen delivery or use by the tissues. All three types may coexist in the burned patient.

Damage to the airway can vary, depending on whether the upper airway or lower airway is affected. Upper airway injuries result from inhalation of superheated air or steam and toxic compounds found in smoke.^{17,20} Brief exposure of the epiglottis or larynx to either dry air at 300°C or steam at 100°C can lead to massive edema and rapid airway obstruction.²¹ The addition of an inhalation injury to a cutaneous burn doubles the mortality rate²² and is a greater determinant of death than size of the burn wound. Inhalation of heated air can result in direct injury to the face, oropharynx, and upper trachea, while sparing the lower airway. It is speculated that heat entrained is readily dissipated in the upper airway, and reflex closure of the vocal cords to protect the lower airway from heat-related injury may occur. However, true thermal injury from exposure to live steam can occur in the lower respiratory tract because heat-exchange mechanisms of the airway are unable to cool the gas sufficiently as it is inhaled. Obstruction of the upper airway

is due to excessive edema, macroglossia, and swelling of the pharyngeal soft tissue. Lower airway injuries more commonly arise from the inhalation of soot particles and/or chemicals produced by a fire. In the lower airway, inhaled toxins react with the airway mucosa forming acidic and alkali substances. Capillary permeability is increased. Extensive alveolar and epithelial damage can occur, with the trachea and bronchi becoming necrotic.

Warning signs of respiratory injury include hoarseness, sore throat, dysphagia, hemoptysis, tachypnea, the use of accessory muscles, wheezing, carbonaceous sputum, and elevated carbon monoxide levels.^{19,23-25}

Treatment of the burn patient involves three distinct phases: the resuscitative phase, debridement and grafting, and the reconstructive phase. Each phase has its own set of challenges the anesthesia provider must consider when developing an anesthetic plan.

Treatment of the Burn Patient

The treatment of the burn patient will evolve as they progress through the early resuscitative phase to the later hypermetabolic state. Data from the US Army Surgical Research Unit and the Army Burn Center characterizes the biphasic organ system response to injury (Table 39.2).²⁶

TABLE 39.2
Biphasic Organ System Response to Injury

Organ System	Early Change	Later Status
Cardiovascular	Shock	Hyperdynamic
Urinary	Oliguria	Diuresis
Gastrointestinal	Ileus	Hypermotility
Musculoskeletal	Hypoperfusion	Hyperperfusion
Pulmonary	Hypoventilation	Hyperventilation
Endocrine	Catabolism	Anabolism
Immunologic	Inflammation (SIRS)	Suppression (CARS)
CNS	Agitation	Obtundation

CARS, Compensatory anti-inflammatory response syndrome; CNS, central nervous system; SIRS, systemic inflammatory response syndrome.

From Anderson TA, Fuzaylov G. Perioperative anesthesia management of the burn patient. *Surg Clin North Am.* 2014;94(4):851–861.

Resuscitative Phase

As with any trauma patient, initial treatment of the burn patient should involve attention to the airway, breathing, circulation, and coexisting trauma. All burn patients must be considered at risk for pulmonary compromise, especially if the percentage of TBSA involved is significant, and signs of inhalation injury are present.

Airway Injury

It is essential to aggressively rule out upper airway injury in patients at risk (e.g., involving a fire that occurred in a closed space or the development of unconsciousness or stupor that prevented the patient from protecting their airway). Diagnosis is made by history, the circumstances surrounding the burn injury, and

physical examination. Above the oropharynx, thermal injury can produce significant inflammation occluding the airway. Heat rarely causes damage below the vocal cords because it is effectively dissipated. The other components of smoke such as particulate materials, systemic toxins, and respiratory irritants trigger a cascade of events, resulting in pulmonary edema and a ventilation/perfusion (V/Q) mismatch.²⁷ Airway examination is best accomplished by direct visualization of the airway with a laryngoscope or fiberoptic bronchoscopy.²⁸ Fiberoptic bronchoscopy is the gold standard for the diagnosis of the severity of inhalation injury. Table 39.3 has a commonly used classification of fiberoptic injury findings and associated mortality.²⁹ The chest radiograph is usually normal in the early phase of inhalation injury (unless aspiration of gastric or pharyngeal contents occurred during the accident), becoming abnormal once pulmonary edema or infiltration develops. Treatment of upper airway injury involves *early* endotracheal intubation, even if the patient is not yet demonstrating signs of airway decompensation. Even in the absence of an inhalation injury, the lungs are at risk for compromise if the burn area is large.

TABLE 39.3
Grading Scheme for Fiberoptic Bronchoscopy Findings in Inhalation Injury

Grade	Findings	Mortality (%)
0	Normal (no inhalation injury)	0
B	Positive based on biopsy only	0
1	Hyperemia	2
2	Severe edema and hyperemia	15
3	Severe injury: ulcerations and necrosis	62

Adapted from Chou SH, et al. Fiber-optic bronchoscopic classification of inhalation injury: prediction of acute lung injury. *Surg Endosc.* 2004;18(9):1377–1379; Cancio LC. Airway management and smoke inhalation injury in the burn patient. *Clin Plast Surg.* 2009, 36(4):555–567.

Thermal damage to soft tissues of the respiratory tract and trachea can make intubation an incredibly difficult task because of the malalignment of structures, swelling, and bleeding of the tissues involved. Intubation of the trachea is much easier to perform earlier rather than later, when there may be glottic or facial edema,

which worsens after fluid resuscitation.^{23–32} In the pediatric population, intubation should be performed with an uncuffed endotracheal tube, usually one size smaller than expected according to age and weight. Video, fiberoptic-assisted or supraglottic airway-guided intubation techniques are useful. The use of a retrograde wire, light wand, or video laryngoscope have all been used successfully.³³ Nasotracheal intubation in children may be preferred because it is better tolerated, and tube displacement with movement is less likely. Cuffed endotracheal tubes are traditionally used for pediatric patients younger than 8 years old. They are commonly used in pediatric burns because of the added flexibility of not requiring replacement that can be necessitated by decreasing edema and air leaks, which is the case with uncuffed tubes.^{5,23}

In the absence of an airway abnormality, early tracheal intubation can usually be achieved using a rapid-sequence technique with an intravenous (IV) induction agent and a rapidly acting muscle relaxant. There is general agreement that succinylcholine administration to patients more than 24 hours after burn injury is unsafe,^{34,35} although some authors extend this safe period to slightly longer.³⁶ Receptor up-regulation occurs after a burn injury, with proliferation of acetylcholine receptors throughout the muscle membrane. Succinylcholine can cause potassium (K^+) release from the entire muscle membrane rather than from discrete end-plate junctions, leading to hyperkalemia and possibly cardiac arrest.³⁷ The magnitude of K^+ elevation appears to be related to the size of the burn. This process of receptor up-regulation takes days to develop, allowing an initial 24-hour window of safety. It is wise to avoid the use of succinylcholine in a burn patient more than 24 hours after injury.³⁸

Intubation with a nondepolarizing relaxant or without a relaxant via the techniques mentioned previously allow for safe airway control. Several factors converge to produce an increased dose requirement of nondepolarizing relaxants in burn patients. These include up-regulation of acetylcholine receptors, massive fluid shifts producing significant changes in volume of distribution, and a qualitative decrease in receptor sensitivity. Plasma protein-binding alterations do not effect relaxants clinically because they are not highly bound. Rocuronium, for example, is only 30%

protein bound. Both the dose administered and the serum concentrations required in the burn patient may be increased three- to fivefold to achieve the desired paralysis with a nondepolarizer.³⁹⁻⁴¹

With an abnormal airway or upper airway obstruction, the safest way to secure the airway is with the patient awake. Key actions include effective topical anesthesia, patient positioning, and supplemental oxygenation. Incremental doses of ketamine or dexmedetomidine infusion along with topical anesthesia and avoiding relaxants allow the patients to continue to breathe spontaneously with airway reflexes relatively intact while the airway is secured. Administration of sedatives may worsen airway obstruction and should be given judiciously. However, IV opioid administration may be appropriate for the alert patient in pain. Methods to secure the airway include flexible fiberoptic endoscopy, direct or video laryngoscopy, supraglottic airway-assisted intubation, blind nasal intubation, retrograde wire, light wand, or other video-assisted techniques. When the upper airway is badly damaged and endotracheal intubation is not possible, a direct surgical approach such as tracheotomy is indicated.

After the airway has been secured, the burn patient is taken to the intensive care unit and placed on ventilatory support.⁴² Inspired gases should be humidified to aid clearing of tracheobronchial debris and prevent drying of secretions. The endotracheal tube must be kept in place until the surrounding laryngeal edema has subsided. A progressive air leak around the endotracheal tube, especially in uncuffed pediatric sizes, may be an indication that edematous tissue is returning to normal.^{19,23,28,43}

Administration of nebulized heparin and *N*-acetylcysteine with massive burn and smoke inhalation injury results in a decreased incidence of re-intubation for progressive pulmonary failure, decreased atelectasis, and reduced mortality. The Shriners Burns Hospital formula includes 5000 units of heparin and 3 mL of a 20% solution of *N*-acetylcysteine aerosolized every 4 hours for the first 7 days after the injury.²⁷

Carbon Monoxide Poisoning

Any burn victim rescued from an enclosed-space fire should be

considered at high risk for carbon monoxide poisoning. It is estimated that 50% to 60% of all fire victims die from carbon monoxide poisoning.⁴⁴ Symptoms depend on the carboxyhemoglobin (CoHgb) level, although it is actually the tissue carbon monoxide level that determines the toxicity of carbon monoxide (Table 39.4).

TABLE 39.4
Carbon Monoxide Poisoning

Carboxyhemoglobin (%)	Symptoms
0–10	Normal
10–20	Headache, confusion
20–40	Disorientation, fatigue, nausea, visual changes
40–60	Hallucination, combativeness, convulsion, coma, shock state
60–70	Coma, convulsions, weak respiration and pulse
70–80	Decreasing respiration and stopping
80–90	Death in less than 1 hour
90–100	Death within a few minutes

From Herndon DN. *Total Burn Care*. 4th ed. Edinburgh: Saunders; 2012:411.

Carbon monoxide binds to the hemoglobin molecule with 200 times greater affinity than oxygen, leading to a fall in oxyhemoglobin saturation as tissues become unable to extract oxygen.¹⁹ The end result is a disruption in mitochondrial oxidative phosphorylation, which produces metabolic acidosis at the cellular level. Analysis of blood gases reveals a normal arterial oxygen tension but a decreased total oxygen content, indicating that the hemoglobin oxygen saturation is markedly reduced. Carbon monoxide increases the stability of the oxyhemoglobin molecule, decreasing the release of oxygen to the tissues and producing a leftward shift in the oxyhemoglobin curve (see Fig. 18.8). Pulse oximeters do not detect CoHgb in blood and give falsely elevated readings for oxygen saturation in its presence. The diagnosis of carbon monoxide poisoning requires measurement of arterial CoHgb levels using a laboratory blood co-oximeter which measures concentrations of all hemoglobin moieties (i.e., oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin). The half-life of CoHgb is variable and in patients treated with 100% oxygen, it ranged from 26 to 148 minutes. Treatment continues with 100% oxygen until the CoHgb level is less than 5% or for 6

hours.⁴⁰⁻⁴⁷

Hyperbaric oxygen therapy is an alternative treatment and may be helpful if the CoHgb level exceeds 25% or if clinical signs of toxicity are evident. Hyperbaric oxygen accelerates the clearance of carbon monoxide beyond that achieved using 100% oxygen at 1 atmosphere. The main rationale for its use is prevention of delayed neurocognitive syndrome. It can be difficult to transport and care for patients in the chamber, and debate continues over its effectiveness.⁴⁸

Cyanide Poisoning

Hydrogen cyanide (HCN) poisoning is another toxicity or poisoning that can be seen when individuals succumb to a burn injury. It is produced by the combustion of materials such as plastics, foam, paints, wool, and silk. Cyanide poisoning produces tissue hypoxia by blocking the intracellular use of oxygen. Cyanide binds to the terminal cytochrome on the electron transport chain, causing hypoxia, lactic acidosis, and elevated mixed venous oxygen saturation. The half-life of HCN is approximately 1 hour. Signs and symptoms of poisoning include loss of consciousness, dilated pupils, seizures, hypotension, tachypnea followed by apnea, and high lactate levels. Cyanide has several antidotes, with differing mechanisms of action and diverse profiles. Hydroxocobalamin (vitamin B_{12a}) actively binds cyanide by forming cyanocobalamin, which is directly excreted via the kidney.

Hydroxocobalamin has a rapid onset of action, neutralizes cyanide without interfering with cellular oxygen use, and has a good safety profile. It is safe for use with smoke-inhalation victims, easy to administer, and is the preferred antidote to this type of cyanide poisoning. A hydroxocobalamin dose of 5 grams over 15 minutes is recommended. In addition, aggressive stabilization of cardiopulmonary function augments the hepatic clearance of cyanide via rhodanese and can resolve cyanide poisoning (blood levels, 5.6–9 mg/L), without the use of antidotes.^{19,27,49}

Hypovolemic Shock Associated With Thermal Injury

After the airway has been secured and other life-threatening injuries have been managed, the burn patient must be resuscitated with large volumes of fluid. Aggressive fluid administration and restoration of blood volume are critical for improving chances of patient survival and preventing renal failure. Burns cause a form of hypovolemic shock. These changes are reflected in loss of circulating plasma volume, hemoconcentration, massive edema formation, decreased urine output, and depressed cardiovascular function.^{32,50} Fluid losses are greatest in the first 12 hours after burn injury and then begin to stabilize after 24 hours. Fluid losses occur secondary to direct transudation of plasma and plasma proteins from the wound and from diffuse capillary leakage that shift fluid from the intravascular space to the interstitium of unburned tissue. Capillary leak results from a loss of endothelial integrity and from reduction of intravascular oncotic pressure as plasma proteins are lost through the burn wound and incompetent capillary beds. The end result of changes in microvasculature caused by thermal injury is disruption of normal capillary barriers separating intravascular and interstitial compartments and rapid equilibration of these compartments. This causes severe depletion of plasma volume and a marked increase in extracellular fluid, clinically manifested as hypovolemia and burn-induced edema.^{12,32,50}

Inflammatory mediators are released from burned tissues after injury, causing localized inflammation and burn-wound edema. Localized mediators include oxygen radicals, arachidonic acid metabolites, histamine, prostaglandins, leukotrienes, products of platelet activation, and the complement cascade.^{30,44,51} Most edema occurs locally at the burn site and is maximal at 24 hours after injury. The edema itself results in tissue hypoxia and increased tissue pressure with circumferential injuries. Aggressive fluid therapy can correct the hypovolemia but will accentuate the edema process. In minor burns, the inflammatory process remains sequestered in the wound itself. However, in major burn insults, local injury signals the release of systemic circulatory mediators resulting in a systemic response.

Fluid Resuscitation

Within seconds after an acute burn injury, massive fluid shifts

begin to occur. Therefore fluid resuscitation and airway management are the hallmarks of initial therapy and should be instituted by the first-response emergency medical providers. There are many formulas for calculating a burn patient's initial fluid resuscitation requirements. Crystalloid resuscitation often provides substantial volumes of fluid, often in excess of that predicted by current formulas, resulting in numerous edema-related complications. This phenomenon is coined "fluid creep," and fluid therapy after the initial 24 hours is constantly being refined. In most centers, two formulas are accepted as guidelines for the resuscitation of severely burned patients, the Parkland and modified Brooke formulas.^{52,53} The need for blood transfusion is usually not a major concern during the immediate resuscitation phase in acutely burned patients unless other coexisting trauma exists. Transfusion management is a prominent issue during subsequent surgical intervention.

The current ABA consensus formula for fluid resuscitation and urine output in burn patients is given in [Box 39.1](#). [Table 39.5](#) lists other suggested fluid protocols. Common to all of these formulas is the patient's weight in kilograms and the percentage of TBSA involved. The ACS Committee on Trauma has advocated that only crystalloid formulas be used for all burn resuscitation. Colloid solutions are not advocated in the first 24 hours because capillary permeability remains enhanced, and colloids administered will not remain in the intravascular space. Isotonic crystalloid (Ringers Lactate) is the most commonly used fluid for resuscitation in US burn centers. The Modified Brooke Formula reduces both the protein content and volume of the infused resuscitation fluid. That formula recognizes the findings of studies showing that in the first 3 hours after injury, burn wound edema is most strongly affected by intravascular pressure and later most strongly by capillary permeability. The initially increased capillary permeability decreases across time and establishes a new transcapillary equilibrium 24 hours after the burn at which time the water and protein content of the burn wound peak.⁵⁴ The Parkland formula, uses isotonic crystalloid solutions and estimates the fluid requirements in the first 24 hours to be 4 mL/kg per percentage TBSA burned. Crystalloid solutions generally provide adequate

volume resuscitation, but the large volumes needed result in substantial tissue edema and hypoproteinemia. Consequently, complications of over-resuscitation, including abdominal compartment syndrome, pleural and pericardial effusions, pulmonary edema, fasciotomies, and conversion of partial-thickness lesions to full-thickness lesions are more frequently observed.⁵³ It is important to remember that formulas for fluid guidelines are only that—guidelines. Individual factors must also be taken into account. It is crucial to resuscitate the patient with fluids according to patient response, hemodynamic variables, sensorium, and urinary output (0.5 to 1 mL/kg per hr in adults and 1 mL/kg per hr in children weighing less than 60 pounds),⁵¹ instead of by a fixed formula.³⁰ Fluid resuscitation in children requires extreme precision, owing not only to their size but also their limited physiologic reserve. Because infants and small children have high volume-to-surface-area ratios, formulas that base fluid requirements on surface area burned and weight may underestimate need. The ABA recommends that to counteract the rapid use of glycogen stores and prevent the development of hypoglycemia, a dextrose-containing IV solution be administered for maintenance purposes in burned children in the immediate postburn period.^{17,55,56} Some clinical criteria to indicate adequate **Box 39.1** resuscitation are noted in **Box 39.2**.

Consensus Formula for Fluid Resuscitation and Urine Output in Burn Patients (American Burn Association)

Adults: Lactated Ringer's $2\text{--}4 \text{ mL} \times \text{kg body weight} \times \text{percent TBSA burned}$

Children: Ringer's lactate $3\text{--}4 \text{ mL} \times \text{kg body weight} \times \text{percent TBSA burned}^{*+}$

Formulas for Minimum Urinary Output in Burn Patients

Adults: $0.5\text{--}1.0 \text{ mL/kg per hr}$

Children weighing less than 30 kg: 1 mL/kg per hr

Patients with high-voltage electrical injuries: 1–1.5 mL/kg per hr

TBSA, Total body surface area.

*One half of the estimated volume of fluid should be administered in the first 8 hours after the burn. The remaining half should be administered over the subsequent 16 hours of the first postburn day.

†Infants and young children should receive fluid with 5% dextrose at a maintenance rate in addition to the resuscitation fluid noted previously.

From Pham TN, et al. American Burn Association practice guidelines burn shock resuscitation. *J Burn Care Res.* 2008;29(1):257–266.

TABLE 39.5

Fluid Resuscitation Formulas for Burn Patients

Formula	First 24 Hours	Second 24 Hours
Modified Brooke		
Crystalloid	2 mL LR/% burn per kg, $\frac{1}{2}$ in first 8 hr, $\frac{1}{2}$ in next 16 hr	D ₅ W maintenance
Colloid	None	0.5 mL/% burn per kg
Parkland		
Crystalloid	4 mL LR/% burn per kg, $\frac{1}{2}$ in first 8 hr, $\frac{1}{2}$ in next 16 hr	D ₅ W maintenance
Colloid	None	0.5 mL/% burn per kg

D₅W, 5% dextrose in water; LR, lactated Ringer's solution.

Box 39.2

Criteria for Adequate Fluid Resuscitation

- Normalization of blood pressure
- Urine output (1–2 mL/kg per hr)
- Blood lactate (< 2 mmol/L)
- Base deficit (< -5)
- Gastric intramucosal pH (> 7.32)
- Central venous pressure

- Cardiac index (CI) (4.5 L/min per m²)
- Oxygen delivery index (DO₂I) (600 mL/min per m²)

From Woodsen LE, et al. Anesthesia for burned patients. In Herndon DN, ed. *Total Burn Care*. 4th ed. Edinburgh: Elsevier; 2012:180.

Intraabdominal hypertension (IAH) and abdominal compartment syndrome (ACS) are increasingly recognized as causes of significant morbidity and mortality in critically ill burn patients. These are the most dangerous and frequently reported adverse outcomes of fluid creep in massive burn resuscitation. IAH is a continuum of progressively worsening organ dysfunction, whereas ACS is an “all or none” phenomenon resulting when IAH remains either unrecognized or untreated. IAH and ACS impact end-organ function within not only the abdominal cavity (e.g., kidneys, liver, intestine) but also throughout the body (e.g., brain, lungs, heart). The most recent Consensus Guidelines define IAH as an intraabdominal pressure (obtained by transduction of bladder pressure) greater than or equal to 12 mm Hg, and ACS as an intraabdominal pressure greater than 20 mm Hg with evidence of new organ dysfunction. New organ dysfunction typically manifests as oliguria, impaired mechanical ventilation with high peak airway pressures, worsening metabolic acidosis, and hemodynamic instability. ACS is fatal without treatment. Treatment includes the use of neuromuscular relaxants and increased sedation in mechanically ventilated patients; extension of escharotomies on any anterior trunk burns, judicious use of diuretics, and decompressive laparotomy.⁵⁷⁻⁶²

Invasive hemodynamic monitoring (central venous pressure, pulmonary artery catheter) is indicated in patients who do not respond to fluid resuscitation, have preexisting cardiopulmonary disease, or are at risk of IAH and ACS. Catheters should be removed as quickly as possible to minimize the risk of local and systemic infection.

Hypermetabolic/Hyperhemodynamic Phase

Severe thermal injury with burns over 40% of a patient's TBSA is

followed by a pronounced hypermetabolic response that can persist for up to 1 to 2 years. During this phase, there are significantly increased metabolic rates, multiorgan dysfunction, muscle protein degradation, blunted growth, insulin resistance, and increased risk for infection. The initial stress response to severe injury lasts for the first 2 to 3 days postburn. The subsequent phase is characterized by an increase in metabolism and hyperdynamic circulation. When left untreated, physiologic exhaustion ensues, and the injury becomes fatal.

Catecholamines and corticosteroids are the primary mediators of the hypermetabolic response after severe burns. There is a ten- to fiftyfold surge of plasma catecholamine and corticosteroid levels that last up to 9 months postburn. Glucagon levels are also increased. Burn patients have increased resting energy expenditures, increased cardiac work, increased myocardial oxygen consumption, marked tachycardia, severe lipolysis, liver dysfunction, severe muscle catabolism, increased protein degradation, insulin resistance, and growth retardation.^{63–65} Numerous efforts to control this response have been studied. Specific nutritional interventions and the use of anabolic agents, β -adrenergic receptor antagonists and antihyperglycemic agents have successfully counteracted post-burn morbidities including catabolism, the catecholamine-mediated response and insulin resistance. Early burn wound excision and complete wound closure, prevention of sepsis, the maintenance of thermal neutrality for the patient by elevation of the ambient temperature, and graded resistance exercises during convalescence are simple, nonpharmacologic effective treatment goals.^{63–66}

Pathophysiologic Changes

As with any disease entity, certain pathophysiologic alterations occur after an acute burn injury (Table 39.6). It is important for the anesthetist to understand the basis for these changes because many of these changes must be managed intraoperatively and reflected in the anesthetic plan.

TABLE 39.6

Pathophysiologic Effects of Major Burns

System	Considerations
Respiratory	
Upper airway	Thermal damage to soft tissue and respiratory tract requires early endotracheal intubation; Decreased chest wall compliance, functional residual capacity, and restricted chest wall expansion
Carbon monoxide poisoning	Considered in all victims of enclosed fires; treatment with 100% oxygen by mask, endotracheal intubation strongly advised until status can be evaluated
Neurologic	
Encephalopathy, seizures, increased intracranial pressure	Ongoing neurologic assessment mandatory because status frequently changes
Hematology	
Anemia, thrombocytopenia, and coagulopathies	Coagulopathies, transfusion reactions, and infection are common
Cardiac	
Burn shock phase (0 to 48 hr)	Hypovolemia is a major concern; fluid resuscitation mandatory; expect impaired cardiac contractility, initial myocardial depression, and decreased cardiac output
Hypermetabolic phase (after 48 hr)	Increased blood flow to organs and tissues; manifested by hyperthermia, tachypnea, tachycardia, increased oxygen consumption, and increased catabolism
Renal	
Early	
Reduced renal blood flow and glomerular filtration rate	Secondary to hypovolemia and decreased cardiac output; adequate fluid resuscitation and diuresis prevents renal failure; myoglobinuria and hemoglobinuria common, which alters urine-concentrating ability
Electrical burns and muscle necrosis damage renal tubules	Careful fluid resuscitation, renal function monitoring, and possible diuretic administration
Late	
Increased renal blood flow	Variable drug clearance
Nutrition	
Increased caloric requirements	Tight nutritional support mandatory
Hepatic	
Early	
Decreased function and drug clearance	Hepatomegaly; hypermetabolism and enzyme induction during hypermetabolic phase; sepsis common
Pharmacokinetics	
Decreased albumin	Altered volume of distribution, protein binding Highly protein-bound drugs have a higher free fraction and thus a larger volume of distribution
Increased α_1 -acid glycoprotein	Usually minimal clinical effects of drugs in spite of the changes in protein levels
Denervation phenomenon with spreading of acetylcholine receptors	Succinylcholine avoided 24 hours after injury
Increased nicotinic acetylcholine receptors and decreased function	Requires a twofold to threefold increased concentration of nondepolarizer for paralysis
Skin Integrity	
Vulnerable to nosocomial infections	Strict adherence to aseptic individual patient rooms; wound care, including topical antimicrobial agents and early excision/grafting of the burn wound

Cardiovascular System.

The cardiovascular system is greatly affected in the burn patient. Almost immediately after acute burn injury, intravascular fluid losses commence as a direct result of the loss of vascular and endothelial integrity and the release of circulating mediators. The loss of plasma proteins from within the intravascular compartment (due to disruption of the endothelium) persists for up to 36 hours after the initial burn injury. Hypovolemia results, with subsequent hypotension and circulatory compromise. The size and extent of the burn determine the magnitude of this development. Hence, burn victims can develop “burn shock” within the first 24 to 36 hours after an acute burn injury. A reduction in cardiac output is a hallmark of burn shock and appears to occur within minutes after the injury. It is initially preserved via catecholamine responses which cause tachycardia and vasoconstriction. However, with the progressive loss of intravascular fluids and proteins, left ventricular filling declines, leading to a reduction in cardiac output.

Additionally, cardiac output is thought to be depressed from the release of myocardial depressant factor or proteins from burned tissues. The cardiovascular response to catecholamines is attenuated after burn injury as the result of reduced adrenergic-receptor affinity and decreased secondary-messenger production. Coronary blood flow can be reduced, further decreasing myocardial function. Systemic vascular resistance increases.

Aggressive fluid resuscitation in the first 24 to 36 hours is directed towards restoring intravascular volume and cardiac function. A systemic inflammatory response syndrome is heralded by an increased cardiac output, tachycardia, and reduction in systemic vascular resistance. Thus the patient becomes hypermetabolic, with an increase in oxygen consumption and carbon dioxide production.⁶⁷

Children with extensive burn injuries can become significantly hypertensive weeks after their injury. Heart rate, cardiac output, and cardiac index remain increased in burned children for up to 2 years when compared with normal ranges indicating vastly increased cardiac stress. Aggressive treatment of the hyperdynamic cardiac response may improve long-term morbidity.⁶⁸

Pulmonary System.

The pulmonary system can also be significantly impacted in burn patients. Pulmonary function may decrease significantly even in the absence of inhalation injury. For example, functional residual capacity is reduced, and lung and chest-wall compliance decrease, especially when the chest wall is circumferentially burned. With progressive fluid shift and interstitial edema formation in those individuals with eschar formation, the inability to adequately expand the lungs impairs ventilation. In some cases, escharotomies are performed to alleviate the constrictive pressure in the tissues to improve oxygenation and ventilation. The oxygen gradient between alveoli and arterial blood increases with minute ventilation increasing to as much as 40 L/min from what is normally 6 L/min.

Even without inhalational injury, the lungs are at risk for compromise. There are several mechanisms involved, including the effect of released mediators on the lung. In addition, plasma oncotic pressure is greatly reduced after burn injury, owing to the loss of plasma proteins in burned and nonburned tissue. Impaired vascular and capillary permeability, combined with the amount of fluid resuscitation, can set the stage for the development of pulmonary edema.

Mechanical ventilation is often required after major burn injury, especially when the patient has concomitant inhalation injury. The term *acute lung injury* (ALI) is used to designate the acute onset of impaired oxygen exchange that results from lung injury, and the condition is characterized by a partial pressure of arterial oxygen/fraction of inspired oxygen ($\text{PaO}_2/\text{FiO}_2$) ratio of less than 300. Severe cases of ALI, categorized as acute respiratory distress syndrome (ARDS), are common as well. The risk for mortality from ALI and ARDS is due to respiratory failure and hypoxia, or may result from associated multisystem organ failure or ventilator-associated pneumonia. New strategies for mechanical ventilation are currently being used to support burn patients who have respiratory insufficiency, ALI, and ARDS. These strategies include changes in traditional mechanical ventilation paradigms (such as the use of low-tidal-volume ventilation) and the use of alternative modes of ventilation. Current practice is to use low-volume lung-protective ventilation to reduce overinflation and barotrauma.^{69,70}

This involves using tidal volumes of less than 7 mL/kg of measured ideal body weight and plateau pressures of less than 31 cm of water. Using ideal body weight is an important consideration in patients who have a major burn injury because they often have vast increases in body weight due to massive fluid resuscitation. Modest permissive hypercapnia is allowed.⁷¹ Several nonconventional modes of ventilation have been proposed for the treatment of severe ARDS in patients who have burn injury, including airway pressure release ventilation and high-frequency oscillatory ventilation.^{72,73}

Immune System.

The burn-injured victim is particularly susceptible to infection because the protective function of the skin has been breached and the stage is set for microbial invasion. Within hours after an acute burn, altered immunologic responses become apparent. Leukocyte activity is depressed, as well as humoral and cellular responses. Burn eschar is a prime medium for bacterial growth. Colonization of Gram-negative bacteria increases mortality. Patients often become septic and are vulnerable to pneumonia, particularly when prolonged endotracheal intubation is required. Strict asepsis is therefore required. Of those patients who die after sustaining a burn, infection is the leading cause of death in up to 100% of children and 75% of adults.^{5,33,67}

Renal System.

Renal function may decrease soon after burn injury as a result of myoglobinuria and hemoglobinuria. Myoglobinuria is most common after electrical injury, whereas hemoglobinuria is common after severe cutaneous burns of approximately 40% or greater. Acute kidney injury (AKI) is a common complication following major burn injuries and the incidence of maybe as high as 40%. The development is dependent on the size and severity of the burn and the presence of inhalation injury and is a poor prognostic indicator. AKI is divided into early and late categories. Early AKI is defined as occurring within 5 days of burn injury and results from hypotension and myoglobinuria. AKI occurring after 5 days of injury is defined as late, and sepsis is the most common cause.⁵³

Patients may exhibit an inability to concentrate the urine. Elevated levels of stress hormones (e.g., aldosterone, angiotensin, catecholamines, and plasma renin) also contribute to renal dysfunction observed in the early postburn period. Several burn centers are using the RIFLE criteria to assess AKI. RIFLE is an acronym for risk (R), injury (I), failure (F), loss (L), and end-stage kidney disease (E). (see [Chapter 32](#)). It is often used in patients with renal disease in identifying the risk factors for occurrence of AKI, as well as analyzing the progression between stages of the RIFLE classification and the impact of progression of AKI on morbidity and mortality.^{74,75}

Decreases in renal blood flow alter glomerular filtration. This is usually due to intravascular depletion, hypovolemia, decreased cardiac output, and increased levels of circulating plasma catecholamines. The renin-angiotensin-aldosterone system and the release of antidiuretic hormone are stimulated to conserve sodium and water.⁷⁶ Subsequently, alterations in electrolyte balance take place. Hourly urine output measurements remain the gold standard for assessing adequate fluid replacement and resuscitation (see [Box 39.1](#)). Delayed renal failure in children is rare.⁷⁷

Gastrointestinal System/Nutrition.

Aggressive nutrition support is mandatory in the patient who has sustained severe burn injury. Metabolic rates may be increased by twice the normal rate secondary to the hypermetabolic state. Whole-body catabolism, muscle wasting, and severe cachexia occur with inadequate nutrition. Failure to meet the increased substrate requirements may result in impaired wound healing, multiorgan dysfunction, increased susceptibility to infection, and death.^{78,79} In patients with extensive burns and a pronounced hypermetabolic response, carbohydrate is more effective than fat in maintaining body protein.⁸⁰ The burn-injured patient is resistant to the action of insulin in the liver and skeletal muscle, thus ongoing assessment of blood glucose, with administration of insulin in a tight control protocol, is necessary.

The necessity for continued adequate caloric intake during the preanesthetic period cannot be ignored. It is unwise to arbitrarily discontinue enteral feedings the evening before a scheduled

surgical procedure. This action may result in an excessive loss of calories, especially if the patient is to undergo extensive burn excision and debridement. Preoperative *nil-per-os* (NPO) guidelines must be considered at a safe minimum to prevent the patient from reverting to a catabolic state. For example, intubated patients do not need enteral feedings discontinued before surgery, whereas unintubated patients may remain on nutritional support up to 4 hours before a scheduled surgical procedure.⁸¹ This practice maintains preoperative nutrition without increasing the risk for aspiration. Upon admission to the operating room, a nonintubated patient's nasogastric tube (if present) should be suctioned and general anesthesia induced to ensure rapid protection of the airway. If the patient is not receiving enteral feedings, but rather parenteral feedings through a central venous catheter, the parenteral nutrition line should not be used for administering fluids or drugs during the course of the anesthetic. Parenteral hyperalimentation and lipid infusions should be continued intraoperatively. Monitoring of glucose levels in these patients is advised. The use of infusions pumps is recommended in children to avoid over or under infusions.³³

Burn patients also demonstrate a decrease in overall gastrointestinal function. When the percentage of TBSA involved is greater than 20%, the development of ileus is common.⁸² Other gastrointestinal sequelae include acute ulcerations of the gastric and/or duodenal mucosa known as *Curling ulcers*. Treatment of these stress ulcers includes the administration of acid suppressive therapy (AST) including H₂ blockers, proton pump inhibitors, and antacids.³⁰ Fortunately, with the use of AST, these ulcers have become less frequent.⁸³

Hepatic effects of burn injury are variable. There may be an increase in liver function during the hypermetabolic phase followed by hypertrophy, hepatomegaly, and impairment in protein synthesis. Hepatic dysfunction also may result from drug toxicity, sepsis, or blood transfusions. Preoperative assessment of liver function is advised.^{84,85}

Burn Management: Debridement and Grafting

The goal of burn therapy is to rapidly restore skin integrity. After thorough cleansing, the burn wound is typically treated with antimicrobial agents as early as possible to limit bacterial proliferation on the wound surface and to avoid bacterial wound invasion. Wounds have been shown to re-epithelialize more rapidly with less pain and inflammation when they are covered and a thin layer of wound fluid is maintained in contact with the surface. Subsequent treatment involves surgical procedures such as amputation, grafting, and multiple debridements.⁸⁶ Early removal and excision of the dead burn tissue with rapid closure of the burn wound has now become the standard in management of a severe burn. The early reestablishment of a physical skin barrier provides protection from bacteria, mechanical trauma, and insensible water loss and improves long-term outcomes.⁸⁷

Because most patients with extensive burns require multiple procedures, limiting a single procedure to 20% excision of body surface has been suggested; however, larger areas may be excised depending on the patient's preoperative and perioperative hemodynamic stability and coagulation status. Other surgical endpoints include a time of 2 to 3 hours if the patient's core temperature decreases to 35°C or if there has been blood loss requiring 10 units or more of packed red blood cells.⁸⁸ Generally, the burn patient may require surgical treatment every 2 to 3 days, with staging of burn wound excisions until full grafting has been completed. Significant blood loss during burn surgery continues to be a challenge. Implementation of blood-conserving protocols can decrease blood component requirements. Several options include tumescent epinephrine, thrombin, fibrin, and other systemic hemostatic agents. The best hemostatic protocol must be individualized.^{89,90}

In patients with extensive burns and limited donor sites, the wound coverage may require a combination of skin grafts, cultured skin, and skin substitutes. Several temporary and permanent skin substitutes are available.⁹¹

Anesthetic Implications

To facilitate a safe and effective anesthetic, a thorough preoperative plan must be developed in consultation with the burn team.

Preoperative Evaluation.

The burn patient requires a thorough and complete preoperative assessment. Medical history, including laboratory studies, and physical examination with lung auscultation, assessment of chest compliance, and inspection of the neck and oral cavity to determine potential difficulties with airway management, should be implemented. In addition, the clinician should be aware of any underlying trauma, mechanism of burn (electrical, inhalation), percentage of TBSA injured, location of the burn sites, and the type and extent of the planned procedure. This information may impact the selection of agents, appropriate monitoring, positioning, vascular access, and blood-product requirements. A review of prior surgical procedures and anesthetics can be helpful in determining one's anesthetic plan as these patients tend to have multiple procedures.

The Set-Up and Preparation.

A successful anesthetic that facilitates surgical excision and grafting of a burn wound requires planning and preparation of all necessary equipment (Box 39.3). There are specific anesthetic interventions that should be considered prior to patient arrival in the operating room. Perioperative challenges in the acute burn patient are noted

[Box 39.4](#).

Preoperative Anesthesia Planning for the Burn Patient

- Warm the operating room ahead of time (should not exceed 95°F).
- Check availability of blood products and order more if needed (based on preoperative hemoglobin value, the size of the burn, and extent of the planned debridement).
- Have blood products immediately available in the operating room as surgical debridement is initiated. This is particularly critical in the pediatric patient.
- Have at least one blood warmer primed, plugged in, and turned on. If the burn is large, have two.

- Make sure that you have adequate IV access before the surgeon begins debriding the burn.
- Have an adequate supply of narcotics and muscle relaxants.
- Know and plan ahead of time if invasive lines are needed.
- Plan for airway management and ventilation both intraoperatively and postoperatively as needed.
- Have a plan but be willing to modify it if necessary.

Box 39.4

Perioperative Challenges in the Acute Burn Patient

- Compromised airway
- Pulmonary insufficiency
- Altered mental status
- Associated injuries
- Limited vascular access
- Rapid blood loss
- Impaired tissue perfusion due to:
 - Hypovolemia
 - Decreased myocardial contractility
 - Anemia
 - Decreased colloid osmotic pressure
 - Edema

- Dysrhythmia
- Impaired temperature regulation
- Altered drug response
- Renal insufficiency
- Immunosuppression
- Infection/sepsis

From Herndon DN. *Total Burn Care*. 4th ed. Edinburgh: Elsevier; 2012:174.

Intraoperative Management

Equipment and Monitoring.

Burn patients require all standard monitors intraoperatively, although this otherwise routine consideration may be challenging. Electrocardiogram (ECG) leads are often difficult to place due to a lack of intact skin. Alternatives include stapling lead electrodes to the skin, use of needle electrodes or an atrial pacing-type esophageal stethoscope used for its ECG monitoring capability. Ideally, blood pressure cuffs should be placed on the unaffected limb or at a nonsurgical site. If the extent of surgical debridement is extensive or if movement of the patient's extremities intraoperatively limits accuracy of noninvasive cuff readings, the placement of an arterial line for blood pressure monitoring may be warranted, even in healthy patients. Large burns (i.e., greater than 20% to 30% TBSA) may necessitate invasive blood pressure monitoring after induction of anesthesia, if not in place preoperatively. Rapid and significant blood loss, potential for hemodynamic swings, and the need to verify intraoperative laboratory values more than validate this requirement.

Standard sites for monitoring pulse oximetry may not be available. Alternative sites include the nose, nasal alae or septum, ear, cheek, tongue, or toes. Any preexisting invasive monitors such as an arterial line, central venous catheter, or pulmonary artery catheter should be continued in the operating room. Noninvasive

monitors for cardiac output, index, and stroke volume are also available.⁹² Accurate temperature monitoring is essential because burn patients can become extremely hypothermic intraoperatively. Skin temperature devices are highly inaccurate in these patients, and there may not be a suitable area to apply them. Temperature measurements are obtained from a properly positioned esophageal stethoscope (i.e., distal third of the esophagus). Because many of these patients are in intensive care units, they may already be benefiting from a urinary drainage catheter that supports bladder temperature monitoring.

Critically ill burn patients are usually transported by the anesthesia provider directly to the operating room (OR) from the burn intensive care unit (and vice versa, postoperatively). These patients are typically intubated or have a tracheostomy, are on continuous infusions of pharmacologic agents, and have invasive lines in place. Astute monitoring of the patient's vital signs during transport is, of course, mandatory. Extreme care and diligence should be taken during transport so that none of these become dislodged. Portable oxygen delivery system is another component of required transport equipment. Careful handling and vigilant guarding of the airway is crucial. Amnestic and analgesic drugs should be administered as needed to facilitate moving the patient.

Airway Management.

Acute airway problems are usually addressed immediately upon the patient's entry into the emergency department or once in the burn unit. In the nonintubated patient without an inhalation injury and whose airway is essentially normal, induction and intubation of the airway can proceed as with any other anesthetic with the exception of avoiding succinylcholine as discussed previously. The use of a video laryngoscope or the other airway methods discussed earlier may be considered if securing the airway is judged to be potentially difficult.

If the patient is already intubated, vigilance must be maintained to insure the trachea does not become accidentally extubated. Edema of airway structures may make re-intubation difficult, if not impossible. Thus securing an endotracheal tube in these patients can be most challenging because tape does not readily stick to

burned skin. Some clinicians have used soft straps, nasal septal ties, or sutures to secure the endotracheal tube. Cloth ties encircling the patient's head are frequently used as well.

Temperature Regulation.

Depending on the percentage of TBSA affected by a burn, temperature regulation can be problematic. There is a high risk for development of hypothermia secondary to evaporative heat loss and the body surface area exposed intraoperatively. The temperature in the OR should be between 28°C and 33°C.^{44,93}

Intravenous solutions and skin preparations should be warmed. All methods of heat conservation should be employed while the patient is in the operating room. The use of in-line circuit heat moisture exchangers or lower gas flows will reduce evaporative respiratory tract heat loss. Forced-air warming blankets are effective, but their use can be limited depending on the area of excision or surgical exposure. Over-body heating lamps have been used but need to be at a safe distance from the patient to prevent further burning. Plastic bags also can be helpful to insulate exposed body parts not requiring surgical access.

It has been suggested that keeping a patient warm is more beneficial than rewarming. When hypothermia ensues, deleterious effects of vasoconstriction occur, which may hinder any subsequent warming efforts. Moreover, slow rewarming in the postoperative period can lead to an increase in mortality.⁹⁴ If a patient becomes hypothermic despite efforts at prevention, the surgeon should be advised to conclude the procedure as quickly as possible. Heat loss in burn patients is characterized in [Table 39.7](#).

TABLE 39.7

Heat Loss in Burn Patients

Source of Heat Loss	Amount	Methods to Decrease Heat Loss
Radiation	60	Warm OR* Heat lamps Reflective blankets
Evaporation	25	Warm OR
Convection	12	Place patient on insulated or warming blanket
Conduction	3	Cover patient with watertight material Humidify ventilator gases Intravenous fluid warmer

*To decrease the difference in temperature between the patient and surrounding objects.

Modified from Anderson TA, Fuzaylov G. Perioperative anesthesia management of the burn patient. *Surg Clin North Am.* 2014;94(4):851–861.

Fluid and Blood Replacement.

Surgical burn debridement procedures may be extraordinarily bloody operations. Surgical blood loss depends on the area to be excised (cm²), time since injury, type of excision planned, and the presence of infection. Surgical wound management involves removal of the eschar layer until brisk bleeding of the dermis is observed. The surgical team may remove eschar so rapidly that it becomes difficult to replace blood and IV fluid in a manner that parallels the loss, giving way to hypovolemia and hypotension. Some institutions have suggested stopping the surgical procedure after 2 hours if more than two blood volumes have been lost or if the body temperature falls to 35°C or by greater than 1.5°C from baseline.

There are several formulae to approximate the extent of potential blood loss for a burn patient undergoing debridement. These vary from 200 mL to 400 mL of blood loss for each 1% of BSA excised and grafted to as high as 4% to 15% of the patient's blood volume for every percentage of skin debrided.^{33,44} After excision and debridement, several hemostatic therapies may be used including tumescent epinephrine, phenylephrine thrombin, fibrin, and other systemic hemostatic agents. Gauze soaked in a vasoconstrictor preparation applied to the wounds may result in systemic absorption causing an undesired change in vital signs.⁸⁹ [Table 39.8](#) lists a method for predicting surgical blood loss. A complete discussion of transfusion management can be found in [Chapter 22](#).

TABLE 39.8

Calculation of Expected Blood Loss

Surgical Procedure	Predicted Blood Loss
< 24 hr since burn injury	0.45 mL/cm ² burn area
1–3 days since burn injury	0.65 mL/cm ² burn area
2–16 days since burn injury	0.75 mL/cm ² burn area

> 16 days since burn injury	0.5–0.75 mL/cm ² burn area
Infected wounds	1–1.25 mL/cm ² burn area

From Woodsen LE, et al. Anesthesia for burned patients. In: Herndon DN, ed. *Total Burn Care*. 4th ed. Edinburgh: Elsevier; 2012:175.

Preoperative anemia is another indicator for transfusion and is commonly seen in thermally burned patients with greater than 10% TBSA involvement.^{95–97} There are several reasons for its development. The inflammatory process gives way to destruction of red blood cells that accumulate in thrombosed microcirculation of burned tissues, leading to an erythrocyte loss of up to 18% in full-thickness burns greater than 15% TBSA.⁹⁸ Thus bone-marrow suppression leads to a reduction in the production of erythropoietin after burn injury. Lastly, patients with extensive burns generally undergo numerous surgical procedures, resulting in blood loss and further anemia.

Adequate vascular access is critical before the initiation of surgical debridement. The size and extent of planned debridement will determine how much access is needed. One large-bore intravenous catheter is adequate for the induction of anesthesia in many burned patients, but at least two large-bore intravenous catheters are necessary before beginning a major excision. Obtaining sufficient IV access can be challenging and time consuming, depending on the extent and location of the burn. Critically ill patients or those with limited peripheral sites for IV access will often have a central venous catheter already in place. A large-bore catheter or a central line with multiple ports should be used whenever administration of large amounts of IV fluid and blood products is anticipated.

Availability of blood products should be confirmed before the patient is taken to anesthesia and operation. Ideally, blood products should have been checked and ready for administration at the outset of the procedure. This is particularly important in pediatric patients. Indeed, some clinicians initiate blood transfusion before the beginning of surgical debridement and apply compression dressings after excision and grafting.

Careful planning is essential when managing hemorrhage and potential complications associated with massive transfusion (e.g., citrate toxicity, loss of clotting factors) during debridement. Visual

estimation of blood loss is subjective at best and prone to miscalculation. Surgical suction is often not used during debridements and surgical sponges are difficult to assess. Blood may leak onto the floor, be covered in the surgical drapes, or ooze beneath the patient. Thus proper monitoring of the patient's urinary output, hemoglobin, hematocrit, coagulation, and hemodynamic status is crucial during and after the surgical procedure.

Anesthesia Management

Induction.

No single agent is preferred for IV induction of general anesthesia in the burn patient. As with all anesthetics, plans should be individualized and based on the patient's preoperative status and medical history. The acutely burned patient seldom comes to the OR immediately after injury; generally, the patient is admitted and stabilized in the burn unit first. If the patient requires immediate surgery, he or she can be expected to be extremely labile within the first 24 hours of injury. The effects of the anesthetic agents can be exaggerated, especially if fluid resuscitation is not adequate or has not been fully completed. The loss of intravascular volume coupled with the potential for depressed myocardium can result in a hemodynamically unstable patient under general anesthesia. Careful, slow titration of anesthetic agents is vital. Appropriate premedication of stable patients with benzodiazepines or an opioid decreases anxiety and makes transfer to the OR tolerable. Anxiety, depression, and pain are interrelated in patients with burns.^{93,99,100} Induction of general anesthesia can be performed with the patient in the bed so that subsequent movement onto the OR table provokes little discomfort.

Regional anesthesia has been used for procedures confined to small areas, an extremity, or for surgery during the reconstructive phase. Advantages include prolonged postoperative analgesia, but variables in this patient population restrict its more general use. Performing a regional technique that requires passing a needle through burned tissue should be avoided due to the potential for spread of infection. The hypotension (hypovolemia) and vasodilation (with or without sepsis) that often accompanies spinal

or epidural anesthesia makes this choice suspect until the burn wound has closed. In addition, coagulopathy and cardiorespiratory instability may be reasons to avoid a regional anesthetic technique. The greatest limitation to the use of regional anesthesia is the topographic extent of the surgical field where the anesthetized region must include both the area to be excised and the area to be harvested for skin graft.

In children, regional anesthesia is sometimes a viable option for postoperative analgesia. Caudal or epidural techniques have been used for debridements of the lower extremities or skin harvesting from the buttocks or thighs. Catheters can be used to extend the regional block for postoperative infusion analgesia.

After a burn injury, the pharmacokinetics and pharmacodynamics of the anesthetic drugs can be very different from those in nonburn patients.⁹³ Some pharmacokinetics and pharmacodynamics changes occurring in burn injured patients are noted in [Box 39.5](#). All commonly used anesthetic induction drugs are acceptable. Propofol can be given if the patient is stable. Ketamine is an excellent alternative in unstable patients. Low doses of ketamine produce adequate amnesia and analgesia for the debridement of superficial burns; higher doses may be administered for more extensive procedures such as eschar excisions.¹⁰¹ Postoperative emergence reactions can be minimized with the administration of benzodiazepines in small doses, and an anticholinergic prevents excessive pharyngeal and tracheobronchial secretions. In the pediatric burn patient, an inhalation induction with sevoflurane is certainly acceptable if the child does not have intravenous access prior to induction of general anesthesia and if the airway is

Box 39.5 otherwise normal.

Pharmacokinetics and Pharmacodynamics Changes in the Burn Patient

- Fluid compartment alterations
- Changes in cardiac output
- Variability in organ perfusion

- Decreased renal and hepatic function
- Changes in serum protein levels
- Hypermetabolism

From Anderson TA, Fuzaylov G. Perioperative anesthesia management of the burn patient. *Surg Clin North Am.* 2014;94(4):851–861.

Anesthesia in the burn patient can be maintained with an opioid and/or inhalation agents because the hemodynamic status of the patient permits this. Volatile agents have been shown to be safe and effective, allowing rapid adjustment of anesthetic depth while permitting high oxygen concentrations. These patients may be sensitive to the cardiovascular depressant effects of inhaled anesthetics, especially if acute fluid resuscitation is incomplete. Inhaled agents do not provide analgesia in the postoperative period. Intubated burn patients who require intraoperative ventilation with specialized critical-care ventilators (e.g., percussive ventilators) where standard anesthesia machine ventilators cannot be used, may require a total intravenous technique.¹⁰²

As discussed previously, succinylcholine should be avoided after the first 24 hours. The patient will exhibit resistance to nondepolarizing muscle relaxants, and higher and more frequent redosing is usually necessary. Several factors including up-regulation of acetylcholine receptors, massive fluid shifts producing significant changes in volume of distribution, and a qualitative decrease in receptor sensitivity are responsible.¹⁰³

Pain Management.

The necessity of proper pain management is well understood because almost every patient encounter may be associated with psychologic distress and physical pain. Establishment of pain treatment protocols for burn patients that address their anxiolytic and analgesic needs is essential. Intravenous (patient-controlled analgesia) is preferred early in the course of burn care, because the absorption from intramuscular sites may be erratic or slow for rapid control of pain.

Opioids are an important adjunct in the care of burn patients.

Pain from skin harvest sites frequently exceeds that from burned, debrided, and grafted areas. Morphine, fentanyl, and sufentanil all provide intra- and postoperative analgesia and are acceptable choices. Remifentanyl, a short-acting opioid, may be used for dressing changes. Oftentimes, infusions of opioid will be used in the burn unit for pain control and/or sedation. One option is to continue these infusions during the operative procedure with bolus supplementation. Narcotic-based anesthetics provide the advantage of minimal cardiac depression. In addition, postoperative analgesia must be a vital constituent incorporated into the anesthetic plan.

Nonsteroidal anti-inflammatory agents can be effective analgesics for smaller superficial burns. In larger burn injuries, the anticoagulant effects can lead to problems with hemostasis.

Painful procedures include dressing changes, debridements, nursing care, hydrotherapy, physiotherapy, and surgical procedures. The intensity of pain associated with treatments, together with the fact that they are inflicted repeatedly (sometimes twice a day or more) over long periods of time, explains the unique patient medication requirements in this population.^{99,100}

Emergence From Anesthesia.

The postoperative period should likewise be planned in advance. Critically ill and intubated burn patients should remain intubated postoperatively and transported directly to the burn unit. The anesthetist should safeguard the airway and be respectful of the patient's need for sedation and analgesia during this terminal phase of the anesthetic.

If extubation of the trachea is anticipated, opioids for postoperative analgesia can be titrated according to the need.

Reconstructive Phase

It is important to address the ongoing impact a burn injury can have on the individual. After numerous skin grafting and surgical procedures and some degree of healing has taken place, scarring may remain. To optimize function and prevent contractures and deformity, physical and occupational therapy are important considerations for these individuals. Months to years after hospital

discharge, victims of major burns may return for reconstructive procedures to remove or reduce scar tissue. These procedures improve cosmetic and functional outcomes. Burn patients often experience anxiety, stress, and depression from prolonged hospital stays. The most important anesthetic concern is management of the airway, particularly if contractures of the face and neck are present. There are several options for airway management as mentioned previously from standard laryngoscopy, use of video laryngoscope, or awake intubation using a fiberoptic technique.

Invisible scars may remain as well in the patient who has suffered a burn injury. Psychologic issues should be explored while the patient is still in-hospital. This is especially important when dealing with children. Recreational therapists can help them work through their feelings and fears. Once the child is home and physically healed, group settings such as burn camps can offer opportunities to be with other children who have suffered similar injuries. In such an environment, the child can experience freedom from judgment and not feel ashamed of their burn scars.

Summary

The anesthetic implications for the burn-injured patient can be numerous, as well as extraordinarily challenging. As burn centers continue to evolve and improve their ability to treat and ultimately extend life after a burn injury, there is greater likelihood that an anesthesia provider will be involved in the care of a such a patient. Clinicians should remember these patients are challenged both physically and emotionally. For many, the road to recovery is long and painful. As providers of anesthesia care and as patient advocates, it is important we take into account the unique aspects of the burn patient's overall care. As anesthesiologists, we can play a significant role in helping these patients in their difficult journey to recovery and healing.

Trauma Anesthesia

William O. Howie

The views expressed in this chapter are those of the author, and do not reflect the official policy or position of the University of Maryland Medical Center, the Department of Defense, or the US government.

Etiology of Traumatic Injury

Traumatic injury is a unique condition. Unlike other diseases that have a biologic basis, trauma is a result of an external force that ultimately disrupts normal structure and function of the body. In most situations the initial cause of injury is not a result of genetics or environmental exposure, but circumstance and misfortune. Traumatic injury is a disease of human behavior. Although improvements to automobile safety and development of public policy have successfully reduced the annual number of traumatic injuries caused by motor vehicle collisions (MVCs), falls, and firearms by nearly one-third, traumatic injury still remains the leading cause of death for Americans under the age of 40.¹ This translates to 193,000 deaths in the United States alone, or more simply put, one death every 3 minutes.² The mortality of injury is striking; however, it represents only a small fraction of those affected by trauma.

There is no absolute number that can precisely quantify the toll and cost of trauma. Although figures vary by author, it has been estimated that the cost for medical care and lost productivity in the United States was more than \$671 billion in 2013—of that amount, \$51 billion resulted from MVC alone.³ These figures, although staggering, account only for expenses and do not account for the burden that injury places on utilization of scarce medical resources. Mortality is only the tip of the iceberg. Trauma accounts for nearly 40.2 million emergency care treatments per year in the United States.⁴

Some progress in improving these statistics has clearly been made in the United States, but prevention and treatment of trauma outside of the United States has lagged. The World Health Organization (WHO) estimates that there are 5 million injury-related deaths per year, accounting for 1.7 times more deaths globally than do HIV/AIDS, tuberculosis, and malaria combined.⁵

Coordinated Management of Care

The acute management of a trauma patient presents unusual challenges. In many instances trauma warrants immediate surgical intervention. Mechanism of action, multisystem injury, and preexisting medical conditions create complexities that are unusual when compared with routine perioperative management.

Time is a luxury and often a scarce resource when managing the critically unstable trauma patient. In many cases surgical care cannot be postponed to acquire a battery of preoperative exams. Patient medical history may be unknown or incomplete at best. Patients are often unable to provide a competent medical history. The patient's inability to provide a history may be a result of the injury or of concurrent acute intoxication. Regardless of the cause, this gap in information leaves many preoperative questions unanswered. Although every attempt should be made to ascertain a thorough history, it should not be done at the expense of delays in care.

Management of trauma in the United States has historically occurred at the municipal level, between the emergency medical system (EMS) and community hospital. Coordination between these stakeholders has varied widely across the United States, resulting in a range of outcomes. The evolution of modern trauma systems has challenged the community level care model—integrating prehospital, tertiary care providers, and public policy in the effort to direct trauma care—a multivariate phenomenon.

The implementation of the modern trauma system has resulted in significant improvement in patient outcomes. Pioneering examples of this paradigm shift can be seen throughout many cities in the United States and around the world; the impact of this shift on patient morbidity and mortality was formally recognized in 1998. The Skamania Symposium (Skamania Lodge, Oregon; Academic Symposium to Evaluate Evidence Regarding the Efficacy of Trauma Systems) was the first academic group to evaluate the efficacy of a trauma system.⁶ This group systematically evaluated published data to determine the impact of trauma systems. Their findings were that care in a trauma center (versus a non-trauma center) was

associated with fewer unnecessary deaths and less disability.^{6,7} These findings have been supported by several other groups in the United States. Risk of death is considerably lower among patients who require early operative intervention if they are treated at a designated Level I trauma center. These outcomes are not a result of more rapid assessment and intervention alone, and emphasize the complex factors that contribute to the survival benefit of trauma center care⁸. Studies in the United States show that mature, statewide trauma systems dramatically reduce unnecessary deaths and that they are more cost effective in managing more severely injured patients and for younger versus older patients.⁹

Organization of trauma systems varies across the United States. Even though systems are not the same and may vary widely, the American College of Surgeons (ACS) Committee on Trauma has developed standards to which all trauma systems must adhere to become accredited.¹⁰ Through these standards, a level (Level I, Level II, etc.) can be assigned to a particular center that designates the resources the center can provide to care for an injured patient. Fig. 40.1 describes the characteristics of the modern trauma system, its resources, and the levels of trauma care. What we can take away from the conclusions of the Skamania Symposium and guidance of the ACS Committee on Trauma is that positive outcomes in patient care are directly related to experience and development of a trauma system. Trauma can no longer be considered an *offshoot* skill where the paradigm involves massive fluid resuscitation, but a specific clinical expertise in which management and therapy directly impacts patient outcome. In short, experience and proficiency matter.

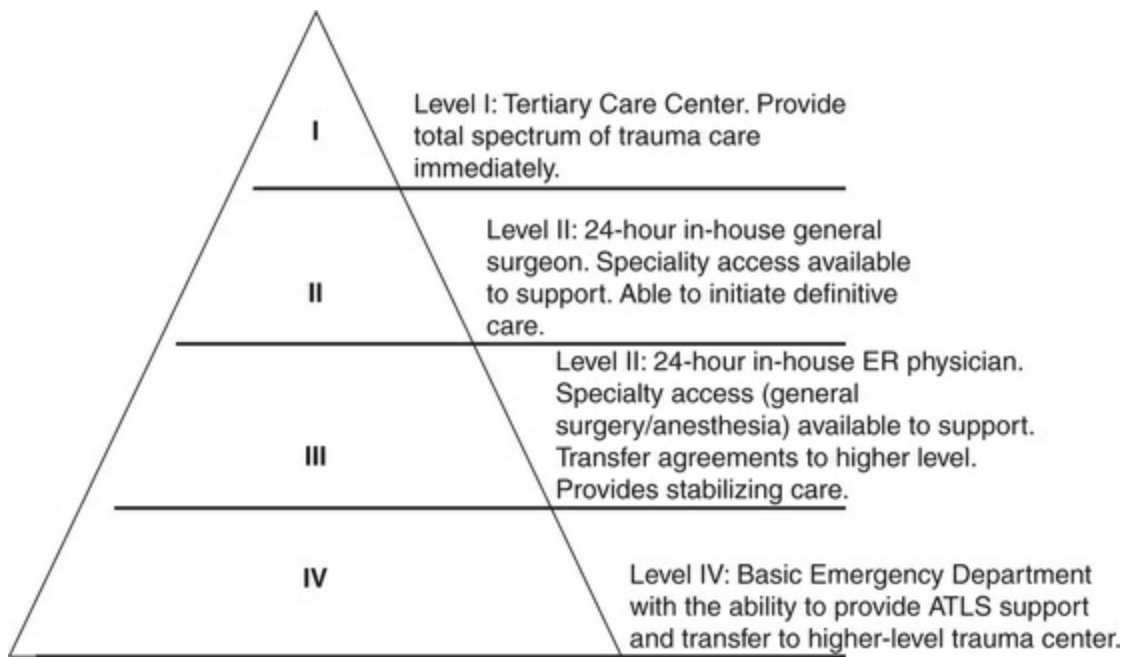

FIGURE 40.1 The levels of trauma care as described in Advanced Trauma Life Support (ATLS). Lower echelons of care provide stabilizing measures, and care sophistication increases with increasing levels.

Early Evaluation of the Trauma Patient and Common Injury Patterns

Immediate Admission of the Trauma Patient

The Advanced Trauma Life Support (ATLS) course developed by the ACS provides a framework for the initial management and evaluation of the trauma patient from the prehospital setting through the hospital phase.¹¹

Prehospital

The prehospital management of trauma patients has a deliberate pathway. The primary goals revolve around ensuring a patent airway and adequate ventilation, in addition to controlling external bleeding. Patients may be intubated in the field or treated with some other method of airway manipulation before arrival at the trauma center. There remains some controversy over the efficacy of rapid sequence induction in the prehospital setting; however, ensuring adequate oxygenation *is* essential. All patients should arrive at the hospital with some degree of supplemental oxygen in place.

Contemporary research indicates that immediate causes of trauma related death are brain injury and hemorrhage; late causes include infection, multisystem organ failure, brain injury, and hemorrhage. Postdischarge causes of trauma related death have been the result of a cardiovascular event, a second major traumatic injury, neurologic injury, and malignancy.¹²

Hemorrhage.

Blood leaving the circulatory system can spill into cavities throughout the body (e.g., thorax, abdomen, retroperitoneum [the pelvis], or fascial planes of long bones), and/or bleed into the environment (i.e., the street). Classically, hemorrhage was met with intravenous (IV) access and volume resuscitation in the prehospital setting. This practice, however, is going through a renaissance of sorts in an effort to determine what is best practice and

management.

As will be discussed later in the chapter, early fluid resuscitation in the absence of surgical hemostasis may not be beneficial because it will likely increase bleeding and may worsen patient outcome. Without hemostasis, mortality increases. The concept of “injury first” has been further defined in the wars in Iraq and Afghanistan. Tactical Combat Casualty Care has replaced the “ABC” acronym (airway-breathing-circulation) with “CABC” (catastrophic bleeding–airway–breathing–circulation), emphasizing the immediate application of direct pressure or tourniquets to control exsanguinating hemorrhage.¹³ The logic behind this change in priority is that if bleeding is not controlled, the patient will face certain death. Although civilian centers may not have to contend with the limited resources seen in austere environments, this change in approach exemplifies the important role hemorrhage control plays in hemorrhagic shock outcomes.

Primary Survey

Upon admission to the hospital or trauma center, ATLS guidelines provide a logical and sequential treatment strategy for rapidly assessing the patient. This process is commonly referred to as the *ABCDE's* of trauma care¹¹:

Airway

Breathing

Circulation

Disability (neurologic status)

Environment/Exposure (undress the patient to fully assess)

The goal of the primary survey is to identify and rapidly manage life-threatening conditions or injuries. This sequence of events will be abbreviated and discussed individually from the anesthesia perspective shortly. Generally, however, the primary assessment involves a rapid assessment using physical examination techniques and American Society of Anesthesiologists (ASA) standard

monitors. In addition, ultrasound and radiography are used to examine body cavities with the initial goal of determining the extent of injury. During this time initial blood samples and IV access are obtained. All aspects of the primary survey are done simultaneously, thereby coordinating the efforts of surgical and anesthesia teams to prepare for potential surgical intervention. In the event the injuries are beyond the scope of the initial receiving facility, the primary survey provides the emergency team with enough information to stabilize and prepare the patient for transfer to a higher-level facility.

Secondary Survey

The secondary survey begins after the completion of the primary survey, and resuscitative and stabilization efforts have been initiated. The secondary survey is a complete head-to-toe assessment that includes a neurologic examination.¹¹ It is important that providers remain vigilant throughout this time period to determine if any patient injuries may have been missed during the primary survey.

Blunt Versus Penetrating Trauma

Blunt Trauma

Direct impact, deceleration, continuous pressure, shearing, and rotary forces may all contribute to the resulting *blunt trauma* that a patient has incurred. These factors are associated with high levels of energy, and result from high-speed collisions and falls from substantial heights. Newton's first law can explain how most traumatic injuries occur: an object tends to remain in motion until it is affected by an outside force. Abrupt deceleration creates negative gravitational forces. When the outside “shell” of the human body decelerates abruptly, the internal organs, which in a sense are separate from the exterior of the body, continue forward at the original velocity and are torn from their attachments by way of rotary and shearing forces. These forces often cause disruption of connective tissue, blood vessels, and nerves.¹¹

Motor Vehicle Collision Trauma

Blunt trauma is most closely associated with motor vehicle collisions and falls. Blunt trauma tends to produce effects body wide. The five types of *motor vehicle collisions* are classified as head-on, rear impact, side impact, rotational impact, and rollover. Injuries can be categorized as those above and those below the waist. The upper portion of the body may collide with the dashboard, steering wheel, or windshield, resulting in injuries of the head, neck, chest, abdomen, and upper extremities. Below the waist, injuries to the knees and femurs occur because of direct contact with the vehicle and lower dashboard. Acetabular fractures are typically a result of tensing the leg when bracing for impact. Blunt trauma rarely occurs in isolated body systems. As such, all blunt trauma victims, including those ultimately without high-risk mechanisms of cervical spine injury, should be suspected of and treated as if they have an unstable cervical spine until proven otherwise.¹¹

Thoracic Trauma

Blunt chest trauma is the third leading result of injury, closely following traumatic brain injury and extremity trauma. Patients with blunt thoracic trauma present a unique series of concerns. These patients represent some of the most severely injured, with blunt thoracic injuries accounting for 20% to 25% of all deaths, and chest trauma has been named as a major contributor in another 50% of trauma related deaths.¹⁴ Thoracic trauma is most often associated with motor vehicle collisions and is responsible for 70% to 80% of all blunt chest trauma.¹⁵

Blunt thoracic trauma often results when drivers who are not wearing safety belts impact the steering wheel during a motor vehicle collision. Penetrating and blunt trauma to the chest may injure several structures and thus compromise optimal resuscitation. Possibly injured structures include the chest wall, the lungs and airways, the heart and pericardium, and the great vessels of the thorax. Injuries to these structures also compromise anesthesia care by affecting gas exchange and cardiac output.

Pneumothoraces are present in as many as 40% of all blunt thoracic injuries. The size and location of the pneumothorax may vary throughout the lung field. Although the etiology and management of pneumothoraces is somewhat commonplace to providers, the presence, or in many cases the assumed absence, of a pneumothorax should not be minimized. It is estimated that as many as 50% of pneumothoraces are not detected on initial radiography.¹⁵ This occurrence presents several clinical intraoperative issues and may alter an anesthetic plan. Nitrous oxide should be avoided in patients with suspected thoracic trauma.

A number of life-threatening injuries, described later, require immediate interventions in patients with thoracic/chest trauma.

Tension Pneumothorax.

Tension pneumothorax develops when the lung is punctured within the thoracic cavity, creating a one-way valve that traps air between the layers of the pleura. With each breath, more and more air becomes trapped in this space, increasing intrapleural pressure to the point that it eventually exceeds all other intrathoracic pressures.

The enlarging pleural cavity then collapses the ipsilateral lung and shifts structures of the mediastinum (e.g., trachea, great vessels, and heart) into the opposite hemithorax, thereby compressing the contralateral lung. The size of a pneumothorax will rapidly increase during positive-pressure ventilation, especially if nitrous oxide is used.

Patients with a pneumothorax often present with symptoms of hypotension, subcutaneous emphysema of the neck or chest, unilateral decrease in breath sounds, diminished chest wall motion, hyper-resonance to percussion of one hemithorax, distended neck veins, or tracheal shift. An upright expirational chest radiograph can provide definitive information if the problem is significant.

Massive pneumothorax can result in reductions in cardiac output and ultimately cardiovascular collapse. Under emergent situations a large-bore intravenous catheter (needle chest decompression) can be inserted into the second intercostal space just above the third rib, along the midclavicular line. Release of pressure should restore cardiac function. Initially the catheter can be temporarily attached to an intravenous line extension tube and placed under water seal by putting it in a bottle of sterile water positioned beneath the level of the patient until proper chest tube thoracostomy can be performed. See [Chapter 29](#) for a complete discussion of the diagnosis and management of a pneumothorax.

Pericardial Tamponade.

Pericardial tamponade that restricts filling of the cardiac chambers during diastole and produces a fixed low cardiac output is also a life-threatening emergency that requires immediate correction with pericardiocentesis. Care should be taken when inducing anesthesia in patients with cardiac tamponade because cardiovascular collapse can occur. Ketamine has been recommended as an induction agent in these patients.

Massive Hemothorax.

Massive hemothorax, which can be caused by bleeding from the heart and great vessels, is treated immediately. Adequate fluid resuscitation is accomplished before placement of chest tubes. Chest tubes allow drainage of blood from the pleural cavity but can lead

to more extensive bleeding and hypotension.

Cardiac Rupture.

Patients with *cardiac rupture* may present with a variety of symptoms related to the extent of cardiac injury. Hypotension coupled with distended neck veins and muffled heart sounds are suggestive of a pericardial tamponade. Most patients with a severe cardiac rupture will die in the prehospital setting before they reach definitive care. Efficient and rapid prehospital transportation coupled with a high index of suspicion and immediate surgical intervention may contribute to survival of patients who have suffered a cardiac rupture.

Traumatic Aortic Rupture.

Traumatic aortic rupture, if complete, is usually fatal, but with an intimal tear with a dissecting aneurysm the patient can be saved if the diagnosis and repair are performed promptly with concurrent well-managed fluid resuscitation and anesthesia care. Management of these cases requires rapid and accurate assessment and appropriate surgical and anesthesia intervention. Anesthetic management should include large bore IV access, an arterial line, and control of blood pressure above 100 mm Hg to reduce the risk of extending the injury, or minimizing the chance of aortic rupture. Surgical management will depend on the patient's presenting symptoms, the degree of injury, and the presence of comorbidities and other injuries. Surgical management may range from nonoperative to open repair, to endovascular stent repair depending on the patient's hemodynamic stability, degree of vessel damage, and surgeon preference.

Tracheal Injuries.

Airway injuries represent a devastating and potentially lethal event after blunt thoracic trauma. Airway injuries upon admission to a trauma center are relatively rare, with a 0.5% to 2% rate among blunt trauma patients and 3% to 8% for those with penetrating cervical trauma. These relatively low incidence rates are likely the result of high victim mortality at the scene of injury.¹⁶ *Partial disruption of the trachea or major bronchi* often is managed through

securing of the airway (by intubation or tracheostomy) and surgical correction. *Total disruption of the trachea* is often fatal unless rapid surgical retrieval of the distal disrupted airway segment is accomplished to allow lifesaving mechanical ventilation. The majority of thoracic airway injuries are found below the carina and are often visible only during bronchoscopy or computed tomography (CT) examination.

Penetrating Trauma

Penetrating injuries can range from a simple pinprick to high-velocity projectile injury. Damage depends on three interactive factors¹⁷:

1. The type of wounding instrument (e.g., knife; missile, such as a bullet; or fragment, such as a piece of shrapnel)
2. The velocity of the missile at time of impact
3. The characteristics of tissue through which it passes (e.g., bone, muscle, fat, blood vessels, nervous tissues, and organs)

Lower-velocity wounds (i.e., stab wound) inflict injury by lacerating and cutting tissue. Moderate- to high-velocity injuries (i.e., bullet) occur as a result of the deceleration of the object as it passes through tissue, causing kinetic energy to transfer to the surrounding tissue. Either situation, low- or high-velocity penetration, ultimately results in disruption of normal anatomy and physiology. Velocity of the projectile is the most significant determinant of wound potential. In other words, penetrating bullet wounds have a greater potential to inflict serious injury when compared with a knife or other handheld projectile.

Damage Control Surgery

Surgical management for the severely traumatized patient is often a multistep process. In many cases patients present to the trauma center with surgical emergencies. Early repair is often simply a life-saving measure and is not intended to be a definitive repair but rather a stabilizing measure intended to reduce operating room

(OR) time and morbidity. After stabilization, patients will be transported for further evaluation (secondary survey) or additional resuscitation measures in the intensive care unit (ICU). Often patients will be returned to the OR several times because the surgical course involves several phases. This staged approach to surgical management is commonly known as *damage control surgery* (DCS).¹⁸

Damage control surgery is a concept that developed in the early 20th century. Its use fell in and out of favor until the 1970s and 1980s. Its utility in modern trauma care was rediscovered as advances in surgical technique, critical care medicine, and technology converged. DCS correlates with current concepts in trauma care that include damage control resuscitation with rapid surgical correction of bleeding and the prevention of the lethal triad of acidosis, hypothermia, and coagulopathy. Current research tends to indicate that patients should receive early intervention in the form of fresh frozen plasma, platelets, and packed red blood cells (RBCs) at a ratio of 1 : 1 : 1.¹⁹ Limitation of crystalloid administration has been recommended.²⁰ DCS is used in various surgical disciplines, from packing the abdomen after abdominal trauma to using external fixators to set complex orthopedic injuries.²¹⁻²³

Damage Control Resuscitation in Trauma

Damage control resuscitation (DCR) combines damage control surgery with body rewarming, restriction of crystalloid fluid administration, permissive hypotension, balanced blood product use (the previously discussed 1 : 1 : 1 ratio), and utilization of a massive transfusion protocol.^{18,20,24,25} Historically, crystalloid solutions, attempts to maintain normal blood pressure, and definitive surgical repair of complex and sometimes unknown traumatic injuries were keystones to trauma surgical care. DCR represents a significant shift in this approach and relies on warming the patient, early correction of coagulopathies, avoidance of large amounts of crystalloid resuscitation, permissive hypotension, reversal of metabolic acidosis, early implementation of massive blood transfusion protocols and utilization of antifibrinolytics (most notably tranexamic acid).^{18,20,26,27}

It is critical that communication between the surgeon, anesthesia team, blood bank, laboratory, and intraoperative support personnel are maintained throughout all phases of the damage control process. It is additionally important to consider admission of the patient postoperatively to an ICU to assist with further stabilization and monitoring of hemodynamic status.

The future of DCR will involve the use of point-of-care testing to tailor blood product ratios to the specific patient presentation, in addition to use of hybrid angiography operating rooms that allow a patient to stay in the same location for interventional radiology and open repair as needed. This concept has been termed RAPTOR, an acronym for resuscitation with angiography, percutaneous techniques, and operative repair.²⁷

Abdominal Trauma

Blunt abdominal trauma is a leading cause of morbidity and mortality among all age groups. Although diagnosis and treatment of penetrating trauma is easily determined, occult bleeding in blunt abdominal injury is often misdiagnosed.^{24,28} Abdominal sonography, Focused Assessment with Sonography for Trauma (F.A.S.T.), computed tomography (CT) scan, magnetic resonance imaging (MRI), or angiography may help in the diagnosis of specific injuries and various treatment modalities. However, extremely unstable patients will require immediate surgery. It is essential that large-bore intravenous access be in place above the diaphragm prior to opening the abdomen in the event of massive hemorrhage as a result of liver or other organ injury.

The ABCDs of Trauma Anesthesia

Although the ATLS curriculum provides an organized framework for the management of traumatic injury, it is not specific to any one discipline. The following sections discuss the implications of the ABCDs of trauma anesthesia and provide an approach to clinical management.¹¹ It cannot be overstated; anesthesia must facilitate rapid surgical management. Trauma anesthesia and surgery is not elective. It should be the goal of the anesthesia team to rapidly move the patient to the OR. Perfusion of tissue (or lack thereof) is directly related to time.

Airway

Endotracheal intubation is a routine procedure of anesthesia practice. Despite its regular use during general anesthetics, intubation poses significant risk and may be extremely challenging when caring for the acutely injured patient. Difficult tracheal intubation is the third most common respiratory-related event leading to death and brain damage as reported in the ASA Closed Claims analysis.²⁹ Although certainly not all trauma patients will have a difficult airway, the anesthetist likely will not have the opportunity or time for a full airway examination because of several variables such as facial injuries and/or hypoventilation and apnea. As such, the provider must anticipate the worst-case scenario.

Emergent intubation in the trauma patient follows the general pathway of the ASA difficult airway algorithm.³⁰ Three assumptions should be made when approaching this type of patient. First, there is no turning back. Intubation is not routinely elective for these patients. Therefore once induction begins the patient must end up with a controlled airway. In addition to requiring a secured airway, trauma patients are assumed to have delayed gastric emptying and a full stomach. As such, they are at increased risk for aspiration. Finally, any patient with blunt trauma or with penetrating injuries to the neck and face must be considered for cervical spine instability.

Rapid sequence intubation (RSI) is the standard method for traumatic airway management. This practice involves several steps often not used during standard induction. One of the greatest differences between routine induction and RSI is the use of a muscle relaxant before knowing whether the patient can be mask ventilated. Although daunting and a deviation from the norm, muscle relaxation is associated with the highest overall rate of successful airway management and provides the greatest possibility for rapidly securing the airway.^{31,32}

Steps to RSI

RSI begins with appropriate planning and team practice. Sufficient personnel must be on hand to (1) provide manual in-line stabilization of the cervical spine after removing the front of the cervical collar; (2) provide cricoid pressure (the Sellick maneuver); (3) oxygenate the patient with bag-valve-mask ventilation, and then perform direct laryngoscopy; and (4) administer medications.

Direct laryngoscopy during manual in-line stabilization of the cervical spine is a safe and effective procedure in patients with potentially unstable necks.³³ Cricoid pressure is applied and intended to prevent both gastric insufflation during bag-valve-mask ventilation and passive reflux of gastric contents. Although caution is appropriate, both cervical spine injury and aspiration during intubation are moderately low-risk events when compared with the possible risks and injury from hypoxia. Therefore it must be remembered that airway management is the priority. In-line stabilization and cricoid pressure should be relaxed if they are interfering with successful intubation.

Whenever RSI is undertaken the need for an emergent surgical airway is always a possibility; appropriate surgical resources should be immediately available in the event of the need for a surgical airway.

Common Indications for Airway Management

Patients with traumatic injury present in varying degrees of injury and may require emergent airway management. The most common indications for endotracheal intubation include: (1) inadequate

oxygenation/ventilation; (2) loss of airway reflexes; (3) decreased level of consciousness (Glasgow Coma Scale [GCS] less than 8); and occasionally, (4) the need for pain management and the ability to safely provide deep sedation during painful procedures. Once it is deemed that the patient requires airway management, it should be done using RSI.³⁴

RSI is a procedure that is conducted to rapidly control a patient's airway, while reducing the likelihood of gastric aspiration. RSI consists of five primary components: (1) preoxygenation, (2) cricoid pressure, (3) induction/muscle relaxation, (4) apneic ventilation, and (5) direct laryngoscopy. Each of these steps will be discussed in detail.³⁴

Preoxygenation.

Adequate preoxygenation is likely the best asset for the anesthetist managing a trauma patient. Preoxygenation provides the greatest amount of time before occurrence of hypoxemia. Preoxygenation is accomplished using 100% high-flow (10–15 L) oxygenation via a nonrebreather facemask or bag-valve facemask. Although there is some debate in the literature, four to eight tidal volume breaths appear to provide superior preoxygenation when compared with 3 minutes of tidal breathing.³⁵

Preoxygenation is challenging in regard to patients who are unable to breathe deeply or follow commands when obtunded. In these circumstances it is appropriate to provide *controlled* positive pressure bag-valve-mask ventilation throughout induction. An increased oxygen reservoir in the lung will benefit the patient more than the (theoretic) increased risk of aspiration caused by ventilating through cricoid pressure

Cricoid Pressure.

Cricoid pressure was first described by Sellick in 1961.³⁶ The goal of this maneuver is to reduce the risk of pulmonary aspiration of gastric contents by compressing the esophagus with the continuous ring of the cricoid cartilage.³⁷ Cricoid pressure is maintained throughout the RSI and is not released until endotracheal tube (ETT) placement has been confirmed. Determining the appropriate pressure to apply to the cricoid ring has been the subject of debate.

Vanner and Pryle³⁸ have determined that 30 Newtons (approximately 10 lbs. of pressure) adequately occludes the esophagus.

Despite the fact that cricoid pressure is considered to be the “gold standard” means of preventing aspiration of gastric contents during the RSI, its effectiveness has only been demonstrated in cadaveric studies and case reports.³⁹ Currently, research is underway to determine the benefits and risks of cricoid pressure as a measure to prevent aspiration during RSI.⁴⁰

Induction Agents.

Anesthetic induction for RSI can be achieved by a variety of agents. At this time no literature is available to support the superiority of one agent over another. All induction agents will cause dose-dependent decreases in blood pressure in the hypovolemic, hemorrhaging patient. Dose-dependent hemodynamic instability can likely be attenuated by reductions in the induction dose. Although no formula can precisely predict the dose for a hemodynamically unstable patient, some authors suggest a dose that is one-tenth to one-half of the normal induction dose of propofol.⁴¹ Ketamine can always be considered as an alternative trauma induction drug.^{42,43} Etomidate use is discouraged because of the suppression of adrenal function.⁴⁴ Recall during induction, an undesirable consequence, is a secondary concern when urgently managing an unstable trauma patient.

Succinylcholine (1.5 mg/kg) provides favorable and rapid muscle relaxation to facilitate intubation. It is generally the preferred agent for RSI for any patient who has no specific contraindication to its use. Succinylcholine administration may cause lethal hyperkalemia in patients with neurologic deficits from spinal cord injury, but not until 24 to 48 hours after injury.⁴⁵

Rocuronium (1.2 mg/kg) and vecuronium (0.2 mg/kg) also can be used for RSI. The onset time for high-dose rocuronium (1.2 mg/kg) is similar to that for succinylcholine with only a slight delay in achieving complete relaxation.⁴⁶ Although these nondepolarizing agents may produce adequate intubating conditions, their use may influence the care that can be provided. Prolonged paralysis will require sedation and will make any subsequent neurologic

assessment more difficult.

Apneic Ventilation.

Apneic ventilation is the concept of pulmonary ventilation using high-flow oxygen. Its purpose is to reduce the potential risk of gastric distension and pulmonary aspiration from positive pressure ventilation. The principle of apneic ventilation is based on Boyle's law in which gas leaves the facemask, fills the lungs, and exchanges in the lungs based upon the concentration gradient of gases in the alveoli. To work appropriately, apneic ventilation assumes that the airway is patent and that a high concentration of oxygen can be reliably administered.

Apneic ventilation remains controversial for practitioners. RSI for the trauma patient is intended to reduce the risk of aspiration in the case of a potentially full stomach, yet many trauma patients who present are unable to take a deep breath prior to induction, resulting in a reduced functional residual capacity and pulmonary reserve. Traditionally with RSI, the practitioner is taught to refrain from positive pressure ventilation during induction. This practice, however, is commonly being modified by clinicians.

To avoid potential hypoxemia or in the event of an already hypoxemic patient, clinical modifications have been made to RSI that include bag-valve-mask ventilation through cricoid pressure, often termed *modified RSI*. This method is actually the technique described by Sellick in 1961.³⁶ As noted by Stewart et al.,

*“multiple specialty societies have recommended that CP is not effective in preventing aspiration; rather it may worsen laryngoscopic view and impair bag-valve mask ventilation. Some experts think that CP should be applied in trauma and patients at risk for aspiration; however, CP, if necessary, should be altered or removed to facilitate intubation”.*⁴⁷

Direct Laryngoscopy.

No evidence indicates that a particular laryngoscope blade or size is optimal for RSI. The choice is likely provider dependent. The provider should use the equipment with which he or she is most

comfortable.

Successful ETT placement is immediately confirmed by capnometry. If unsuccessful, a second direct laryngoscopy should be attempted incorporating some change in technique (e.g., different laryngoscopist, blade, or patient position). There are a variety of adjunct tools available in the event of an unplanned difficult intubation. These include the basic and inexpensive, such as the intubating stylet or bougie, to the more advanced fiberoptic equipment. The use of a video-assisted technique is a prudent step to take at this juncture to minimize the adverse effects inherent with repeated instrumentation of the airway.

If intubation is again unsuccessful (third attempt), the next step should be an airway adjunct to support oxygenation. These adjuncts range from the Combitube to the laryngeal mask airway (LMA). In the situation of “cannot intubate and inadequate facemask ventilation,” LMA insertion should be the immediate next step.³⁰ At this point, if the provider cannot intubate and cannot ventilate, then a surgical airway should be considered as a final option.

It is vital to note that many difficult airway problems can be solved with relatively simple techniques such as a bougie or an intubating LMA. It may be necessary to combine different devices and approaches in some instances. For example, one may opt to use both a video laryngoscope to assist with a fiber optic nasal or oral intubation.

Airway Management of Cervical Spine Injuries

Cervical spine injury remains a significant concern when facing airway management of the trauma patient. The incidence of cervical spine injury after trauma is relatively rare at 2% to 4% of all trauma; 20% of which are spinal cord injuries, 10% are reported as multi-level cervical spine injuries, and 10% are categorized as purely ligamentous injuries.⁴⁸ Cervical spine injury should be assumed until proven otherwise. Immobilization of the neck is essential. To that end, in-line stabilization is essential because it allows for removal of the front of the cervical collar, allowing more area for jaw and mouth movement, while limiting the risk for further injury.

The management and intubation of patients with suspected

cervical spine injuries remains clinically controversial. Despite common belief there is no evidence to suggest that fiber optic intubation provides safer patient outcomes when compared with direct laryngoscopy with in-line stabilization.⁴⁵ Management of a cervical spine injury may be done with the concepts of “emergent,” which involves in line stabilization and RSI, versus “controlled,” which involves an awake fiber optic technique. Fig. 40.2 describes a logical management strategy for these two situations.

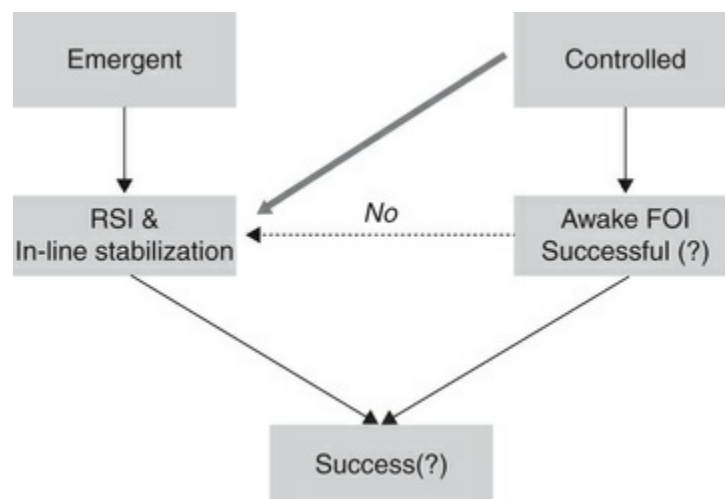

FIGURE 40.2 A logical management algorithm for controlled versus emergent airway management for a patient with a cervical spine injury. *FOI*, Fiberoptic intubation; *RSI*, rapid sequence induction.

Breathing (and Ventilation)

Regardless of the need to manage the airway, the adequacy of breathing and ultimately patient oxygenation is essential to survival. Pulse oximetry is a commonly used noninvasive method to continuously monitor oxygen saturation. Pulse oximetry is often used as a surrogate measure of status. Although pulse oximetry provides a wealth of clinical information, it should be realized that this measurement is not ideal and that the data may provide a false sense of security. For instance, an otherwise healthy patient breathing room air oxygen (21%) will have a partial pressure of arterial oxygen (PaO_2) level of approximately 100 mm Hg and an

arterial oxygen saturation (SaO_2) of 100%. If the patient is placed on a high-flow, nonrebreather mask of 100% oxygen, then the PaO_2 could be expected to be approximately 500 mm Hg and SaO_2 would remain at 100%. Patients who experience declining pulmonary function will have an SaO_2 of 100% over a wide range of PaO_2 readings. It must be recognized that supplemental oxygen, although necessary, can mask pulmonary injury and in some cases respiratory decompensation. It should not be concluded that a saturation of 100% equates to a stable patient or the health of the pulmonary (breathing/ventilation) system.

Pulmonary contusions represent the most common lung injury. It is reported that as many as 70% of patients with blunt thoracic trauma present with some degree of pulmonary contusion.⁴⁹ Pulmonary contusions are injuries to the alveoli without gross disruption of pulmonary architecture. This injury is essentially a *bruise* to the lung tissue resulting in protein-rich fluid leaving ruptured pulmonary capillaries and settling into the alveolar membrane and interstitial space. As a result of the widening of the pulmonary membrane, pulmonary contusions result in varying degrees of reduced gas diffusion that may be clinically relevant. Pulmonary contusions can develop or “blossom” over a range of time and ultimately may develop into acute respiratory distress syndrome (ARDS).

ARDS is an acute diffuse inflammatory lung injury caused by a number of systemic or pulmonary insults.⁵⁰ It is a common problem in trauma care. It may be a result of injury or the resuscitation of the patient. In one study of 621 intubated trauma patients, 64% experienced hypoxemia, with 46% of these hypoxemic patients developing ARDS that was confirmed by chest radiography.⁵¹ Pathologically, ARDS is a result of protein-rich fluid leaving the pulmonary capillaries. As the disease progresses, the pulmonary capillary leakage is compounded by embolic events, which further increase intracapillary pressure and intensify interstitial leakage. ARDS culminates in hypoxia and decreased pulmonary compliance. Ventilating these patients is a challenge. Contemporary research indicates that patients with ARDS should be managed with low tidal volume ventilation, permissive hypercapnia, conservative fluid strategies in those without shock states, and

prone positioning, and that neuromuscular blockers may reduce mortality. Early management of ARDS is vital and extracorporeal membrane oxygenation should be considered for those who do not respond to these aforementioned therapies.⁵⁰

A variety of pulmonary techniques have been described for managing these patients. They range from high-frequency oscillation ventilation to cardiopulmonary bypass. At this time no one technique appears to be superior. It is widely accepted, however, that these patients should be ventilated using low tidal volumes to reduce peak pressures, and the plateau pressures should be maintained at less than 32 cm H₂O.^{50,51} Although attempting to correct an SaO₂ that is less than normal (less than 95%) by increasing the fraction of inspired oxygen (FiO₂) may seem to be a desirable action, it would likely not be the best practice because of the toxic effects of oxygen over time, which can potentially worsen gas exchange.

Circulation

Up to 35% of prehospital trauma fatalities are attributable to hemorrhage, and 40% of trauma-related deaths within the first 24 hours result from hemorrhage and hemorrhagic shock.

Hemorrhagic shock is the leading cause of early and late mortality after trauma.⁵² Hemorrhagic shock is defined as a pathologic event that is triggered by the loss of circulating blood volume and results in a reduction in oxygen delivery to the tissue.

The physiologic response to hemorrhagic shock is a dynamic and complex process. Reductions in blood volume cause an immediate change in vascular tone and global systemic vascular resistance (SVR). Blood is shunted from low metabolic “ischemia-tolerant” vascular beds such as skin and bone, to highly metabolic tissues (e.g., brain, heart, gut) with the intent of maintaining cellular perfusion and aerobic respiration. Early shunting compensates for relative hypovolemia. If short-lived, compensated shock has very few long-term sequelae.

Unfortunately, uncontrolled hemorrhage is a likely event in major trauma. As the degree of blood loss worsens, vascular shunting increases. In this state, patients rapidly progress from a

compensated state to decompensated shock. Vascular shunting continues during decompensated shock. Blood is directed away from lower metabolic organs, such as the kidneys and gut, in an attempt to maintain perfusion in higher metabolic structures. During decompensated shock, changes to SVR are less likely to adequately maintain perfusion. The body attempts to further compensate a dwindling stroke volume and cardiac output by increasing heart rate and contractility.

Unfortunately, compensatory mechanisms are imperfect. Prolonged reductions in perfusion will result in cellular injury. During protracted shock events, venous oxygen reserves are extracted and used as arterial oxygen supply declines. Metabolic imbalances between oxygen demand and delivery produce toxic metabolic by-products. As a result of this imbalance cells are unable to maintain vital metabolic functions. Energy production falls. Intracellular energy-dependent pumps fail, reducing cell wall integrity.

In an attempt to maintain energy production cells transition from aerobic to anaerobic respiration. The conversion to anaerobic respiration is made at a significant cost to the cell. In addition to vast reductions in energy production, lactic acid and free radicals are produced. These toxic cellular by-products induce cellular injury, further reducing cellular function.

Despite vigorous resuscitation, hemorrhagic shock may result in patient death. Research by Newgard et al. examined outcomes of 778 shock patients and 2139 traumatic brain injury patients, 28% of whom died within 28 days. Out of hospital time in excess of 60 minutes was not associated with worse outcomes after excluding confounding variables in the shock cohort. However, shock patients who required early critical hospital resources who were admitted after 60 minutes were approximately twice as likely to die.⁵³ This high mortality rate associated with the delayed treatment of hemorrhagic shock is the basis for the initiation of fluid resuscitation and hemostasis in the field. The “Golden Hour” was initially modeled from data collected from young, healthy males in military service during the Vietnam War. The Golden Hour represents a period of time (60 minutes) in which selected patients will likely survive hemorrhagic shock if perfusion is restored. This

observation, however, cannot be extrapolated to the general population because, as stated, it was based on young, healthy men. It is likely, however, that when generalizing to the population at large, the Golden Hour is actually a nonspecific time that is age and health status dependent. The Golden Hour is likely an inverse relationship. As patients age, their ability to compensate during hemorrhagic shock decreases.

Hemorrhagic shock progresses through stages over time. Stage I of the three stages of shock is often called *nonprogressive shock* or *compensated shock*. A negative-feedback control mechanism of the circulation tries to return the cardiac output and arterial pressure to normal levels. This phenomenon is mediated through the baroreceptor reflexes, central nervous system (CNS) ischemic responses, contraction of blood vessels, release of vasopressin (antidiuretic hormone), formation of angiotensin, and compensation mechanisms that tend to return the blood volume back toward normal by mobilization of fluids from other spaces of the body.

Stage II of shock is also known as *progressive shock*. A positive-feedback mechanism comes into play with this phase of shock. When shock becomes severe enough, components of the cardiovascular system start to deteriorate. This deterioration is associated with cardiac depression caused by ischemia, vasomotor failure, thrombosis of small vessels, increased capillary permeability, release of endotoxins by ischemic tissues, and generalized cellular degeneration.

Stage III of shock is also called *irreversible shock*. This stage occurs when adenosine triphosphate reserves are depleted and toxic substances are released from apoptotic cells. Death follows as the natural consequence of not successfully halting progressive shock.

A successful resuscitation will often leave patients in a temporary hypermetabolic/hyperdynamic state. This is caused by a "metabolic debt" for the period of ischemia. Patients often remain tachycardic despite appropriate resuscitation and sedation. Unfortunately, an apparent successful resuscitation does not mean survival. Morbidity as a result of hemorrhagic shock can be classified as early and late events. Acute irreversible shock presents as the classic massive hemorrhage and death. In this case the resuscitation

attempt does not match the blood loss. Ongoing hemorrhage and hypoperfusion worsens, leading to acidosis, coagulopathy, and death.

Subacute irreversible shock appears clinically opposite to acute irreversible shock. In this instance, fluid volume is restored, hemorrhage is controlled, but the patient has suffered a significant “dose” of shock and cellular ischemia that cannot be overcome. Ultimately the metabolic debt is too great. Over time these patients succumb to multiorgan failure and related sequelae secondary to cellular hypoperfusion. [Table 40.1](#) details ATLS classification of hemorrhagic shock.

TABLE 40.1

Advanced Trauma Life Support Classification of Shock

	Class 1	Class 2	Class 3	Class 4
Blood loss (%)	< 15	15–30	30–40	> 40
Heart rate (beats/min)	< 100	> 100	> 120	> 140
SBP (mm Hg)	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
RR (breaths/min)	14–20	20–30	30–40	> 35
Mental state	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic

RR, Respiratory rate; SBP, systolic blood pressure.

Modified from American College of Surgeons Trauma Committee. *Advanced Trauma Life Support for Doctors*. 9th ed. Chicago: American College of Surgeons; 2013.

Treatment of Hemorrhagic Shock

Patients admitted for care with a traumatic injury often present with obvious signs of blood loss and have the potential to be in compensated shock with an unknown degree of hypovolemia. Quantifying or estimating potential blood loss is a challenging issue. Routine monitors are often inadequate in detecting losses until the late stages of shock when physiologic compensation begins to fail. Patients may have large blood volume losses and yet appear at first to be relatively normovolemic.

Blood loss can be hidden in several locations in the body (e.g., the thorax, abdomen, pelvis, and lower extremities), thereby masking the blood loss, and complicating the treatment plan. In addition,

blood losses at the scene of injury are often not quantified. Blood loss to the environment (street) must be considered. The management of hemorrhagic shock from a traumatic injury follows a logical pathway as described in ATLS.¹¹

Fluid Resuscitation.

The balance between the appropriate amounts of fluid is one of the greatest challenges of successful trauma resuscitation. Resuscitation is commonly seen from one perspective, that of blood pressure. Fluid resuscitation, however, should not only be viewed in terms of blood pressure (i.e., perfusion), but also in terms of the degree and state of repair of the injury. For limited injuries with little or no active bleeding, ATLS resuscitation guidelines advise brisk isotonic crystalloid infusion (up to 2 liters) and component therapy for a larger resuscitation with greater blood loss.¹¹

Unfortunately, therapy is not quite as simplistic in the case of ongoing or massive injury. The administration of fluid, in and of itself, may actually worsen the patient's clinical state if fluid administration is not timed appropriately. This necessary balance of body fluids is easily visualized when one considers a garden hose (vasculature), a water spigot (blood supply), and a sprinkler (perfusion). Imagine that a hose is connected to a water spigot and sprinkler. Water flows to the end of the hose and into the sprinkler in varying rates as the spigot is opened and closed causing variations of pressure. If the hose ruptures, water will move down the hose and exit at the tear. Depending on the rate of pressure, water may not reach the sprinkler at all. To maintain "normal" sprinkler function, water pressure would have to increase. Although this might seem advantageous, an increase in water pressure would also cause more water to exit at the tear in the hose. The additional loss of water or—in the case of a bleeding blood vessel—the additional loss of blood, would cause blood containing nutrients, coagulation factors, catecholamines, and oxygen-carrying capacity to be lost. This would of course be detrimental to the patient.

For these reasons, early resuscitative efforts (before surgical repair) and fluid administration should be done by hypotensive resuscitation. The concept of hypotensive resuscitation was first

described in the early 20th century. Hypotensive resuscitation is a clinical methodology that guides fluid resuscitation in a manner that avoids excessive bleeding by targeting fluid administration toward maintaining a lower than *normal* systolic blood pressure (SBP). Even though targets may vary, most clinician's target SBP at or near 85 to 90 mm Hg.⁵⁴ This reduction in systolic pressure reduces bleeding and ultimately has been shown to reduce mortality.

This finding was most notably described by Bickell, et al.⁵⁵ with a research project commonly referred to as the Houston Trial. The Houston Trial enrolled 598 patients with penetrating thoracoabdominal trauma. The subjects were randomized in the field to a fluid administration or no fluid administration group. The research protocol continued through the primary evaluation and ended as patients were transported to the operating room. The Houston Trial found that there was a significant difference in fluids administered between groups and that the resuscitation group had a higher mortality than the nonresuscitation group ($p = 0.04$). When possible the initial fluid resuscitation should be minimized until hemostasis occurs, and then administered only to avoid cardiovascular collapse. After hemorrhage has been controlled, an SBP greater than 100 mm Hg and heart rate less than 100 bpm can be the goal.

Intravenous Access.

Appropriate intravenous access is a priority when managing a patient in hemorrhagic shock. The speed of intravenous fluid administration is directly related to the radial diameter of the catheter as described by Poiseuille's law. Larger catheters allow for increased flow by reducing turbulence. Patients should have access that has the least impediment to flow. In addition, catheter length should be minimized. As a rule of thumb, IV access should be "short and fat." Although central access is not necessary for resuscitation, patients suffering from significant hemorrhagic shock are often too vasoconstricted to cannulate large veins. Central venous access should be considered early in the management plan. Large-bore single- or double-lumen catheters should be used for central access.

In addition to size, location of the access is essential. IV access should be redundant, and placed in locations that will not deliver fluid directly to an injured area and that may not reach central circulation. For instance, a femoral catheter should not be used when major abdominal, vascular, or pelvic injury has occurred. Intravenous access above the diaphragm would provide the most assurance that the fluid would not “dump” into the abdomen or retroperitoneum. In general, there should always be access above the diaphragm.

Intravenous Fluids.

Isotonic crystalloid infusions expand plasma volume, increase cardiac output, and ultimately cause an increase in blood pressure. In addition, they may reduce vasoconstriction, hemodilute the blood, and induce immune dysfunction. As discussed earlier, vigorous fluid resuscitation must be tempered with the understanding that fluid increases blood pressure and subsequently causes bleeding. Bleeding causes recurrent hypotension and begins a vicious cycle of fluid—bleeding—hypotension.

At the trauma center, RBCs are replaced to provide adequate oxygen-carrying capacity. Shed blood is replaced with a 1 : 1 volume of packed RBCs and a 3 : 1 volume of crystalloids.

Serial electrolyte levels, hemoglobin and hematocrit levels, and arterial blood gas analysis are obtained approximately every hour in severely injured, unstable patients in surgery until the patient is stable. Additionally, coagulation parameters are observed closely in patients with signs of active bleeding. Colloids usually allow rapid restoration of intravascular volume, but can contribute to a later episode of pulmonary edema and increased bleeding if hemostasis has not been achieved. Balanced electrolyte solutions (isotonic solutions) are given to help maintain perfusion.

Dextrose-containing solutions are generally undesirable for use in initial resuscitation fluid administration. Rapid determination of blood glucose levels is critical in patients with diabetes and in children. Although patients are more likely to become hyperglycemic than hypoglycemic after traumatic injury, hypoglycemia can occur. Significant hyperglycemia is associated with further neurologic injury.⁵⁶

Traumatically induced hyperglycemia is so common that it is often called *diabetes of injury*.⁵⁷ Both hypoglycemia and hyperglycemia are implicated in worse patient outcomes in patients with traumatic brain injury. Blood glucose levels ≥ 170 mg/dL upon admission to an intensive care setting have been shown to be an independent predictor of a worse neurological outcome, specifically their GCS score, five days following admission.⁵⁸

Coagulopathy and Trauma

A vast majority of patients that survive their initial injury and reach the hospital are coagulopathic when they die. It is estimated that between 25% to 35% of noncombat related trauma admissions present with a biochemically evident coagulopathy on admission.⁵⁹

Once coagulopathy develops, patient morbidity and mortality drastically increase. Coagulopathy is an independent predictor of mortality. In otherwise healthy patients, an elevated prothrombin time (PT) on admission indicates rapid hemorrhage, massive injury, and a steadily worsening perfusion state.⁵⁹ In addition to the loss of life, coagulopathy indirectly levies a burden on society and the health care system. As such, management strategies to reduce the morbidity and mortality of trauma-induced coagulopathy have become of particular interest.

Clot Formation.

Hemostasis is a complex process involving proteins—cofactors and blood products that converge in a series of reactions intended to produce the fibrin and platelet network (with trapped RBCs) that is a clot. Clot formation begins with an initial vascular insult. Tissue injury immediately causes the release of tissue factor (TF) from the endothelium. At the same time vascular spasm causes platelets to migrate from the vascular lumen towards the site of injury. TF binds with activated, circulating factor VII (FVIIa). The interaction of FVIIa with TF begins the conversion of prothrombin (II) to activated thrombin (IIa) resulting in a “thrombin burst” on the surface of the platelet. Conversion of thrombin completes the coagulation process yielding fibrin (I) connections that stabilize clot formation.⁶⁰ Under normal conditions fibrinolytic pathways

maintain appropriate clot size and location, limiting clot formation to the site of vascular injury.

Pathology and Causes of Coagulopathy.

Massive injury can disrupt the clotting cascade at several points in the process, resulting in life-threatening consequences. Four mechanisms have been identified as primary causes of trauma-induced coagulopathy. These mechanisms are: (1) dilution of factors; (2) hypothermia/acidosis; (3) severe traumatic brain injury (TBI); and (4) hemorrhagic shock. Trauma-induced coagulopathy has both endogenous and exogenous components. Endogenous acute traumatic coagulopathy is associated with shock and hypoperfusion. Exogenous coagulopathy arises from effects of dilution resulting from fluid resuscitation and consumption through bleeding and loss of coagulation factors. Coagulopathy is present in 25% to 35% of injured patients, depending on injury severity, acidosis, hypothermia, and hypoperfusion.⁵⁹

Dilution.

Traumatic injury often requires massive resuscitation to replace blood volume and restore perfusion. ATLS guidelines advocate fluid administration but do not provide clear guidance for the administration of procoagulant products such as plasma, cryoprecipitate, and platelets.¹¹ Although required for initial resuscitation, crystalloid fluid administration dilutes coagulation factors and platelets and increases hydrostatic pressure. This ultimately leads to an inadequate clot and nonsurgical bleeding. Unfortunately, there does not appear to be any “magic concoction” to optimally resuscitate patients while maintaining the ability to form clots.

Resuscitation is a dynamic process. Treating one deficit, for instance anemia, with RBCs will dilute coagulation factors and platelets leading to coagulopathy. The addition of crystalloid or nonblood colloids further exacerbates this tenuous situation.⁵⁹ Various authors advocate a balanced administration of RBCs, plasma, and platelets (1 : 1 : 1) for massive resuscitation. Balanced administration of blood products functionally represents whole blood. Currently the utilization of fresh whole blood has been

limited to military settings. Although it is an improvement, balanced component therapy falls short of the ideal whole blood replacement by virtue of: (1) dilution with anticoagulant and nutritive solutions as blood is collected and processed, (2) losses caused by centrifuging, separation, and readministration, and (3) losses over time in storage.⁶¹

Establishing clinical end-points for correcting coagulopathy is challenging and historically has not been standardized. In an attempt to rectify this, a consensus statement of the College of American Pathologists, the ASA, and the European Task Force for Advanced Bleeding Care in Trauma recommends administering procoagulant products to maintain an international normalized ratio (INR) ≤ 1.5 , and a platelet count $>50,000$. In cases where a coagulopathy is suspected, viscoelastic assays (e.g., thromboelastography [TEG], rotational thromboelastometry [ROTEM]) in addition to a platelet count are recommended. In the event the viscoelastic assays are not available, standard coagulation tests are obtained (e.g., INR, activated partial thromboplastin time [aPTT], fibrinogen concentration, platelet count).⁶² Although these end-points are helpful in creating a standard methodology of care, and for replacement of factors in stable patients, it must be acknowledged that acute care based on laboratory data may be unrealistic. Laboratory analysis is time consuming and may not provide information rapidly enough in an actively bleeding patient. The clinician is frequently required to make decisions about transfusion in anticipation of the patient's course, which is why we recommend empiric 1 : 1 : 1 therapy until the situation is stable enough to guide therapy by laboratory values.

Hypothermia and Acidosis.

Occult hypothermia is an uncommon event. Less than 9% of trauma admissions are hypothermic on presentation.^{63,64} Despite this hypothermia remains an issue. Removal of clothing (Environment in ATLS management), muscle relaxation, cold intravenous fluid administration (resuscitation), and frequent examination (removal of blankets) contributes to heat loss. Hypothermia may result in significant coagulopathy. The vast majority of patient hypothermia can be attributed to radiant heat loss caused by the gradient

differences of patient and environmental temperature.⁶⁴

Hypothermia induces a variety of physiologic changes. Although the precise mechanism is unclear, there is agreement that hypothermia alters platelet function and reduces fibrin enzyme kinetics.⁶⁵ Hypothermia and acidosis compromise thrombin-generation kinetics via different mechanisms. Hypothermia primarily inhibits the initiation phase of thrombin generation. In addition, hypothermia inhibits fibrinogen synthesis, leading to a potential deficit in fibrinogen availability. The clinical effect of hypothermia is a slowly formed and fragile clot that is unable to inhibit bleeding.⁶⁶

Acidosis often accompanies massive injury, hemorrhage, and hypothermia. Acidosis, in and of itself, does not appear to have a significant impact on coagulation.⁶⁶ In the presence of hypothermia, however, acidosis can contribute to a potentially lethal triad of acidosis, hypothermia, and coagulopathy.⁶⁷ It is believed that acidosis impairs coagulation proteases and becomes clinically significant at a pH less than 7.1.^{67,68} Unfortunately, administration of sodium bicarbonate to correct acidosis leads to increased carbon dioxide production and hypocalcemia, which are both direct myocardial depressants.⁶⁹

The management of hypothermic and acidotic patients is fairly intuitive. The most efficacious management is to rewarm the patient and focus on returning perfusion to correct acidosis. Obviously, warming fluids as they are given and controlling the ambient room temperature of the resuscitation unit/operating room is essential. Hypothermia can be minimized when proper care is taken.

Activated Protein C Pathway.

Trauma-induced coagulopathy is often thought of as a result of environmental or therapeutic interventions. Resuscitation necessitates large volumes of intravenous fluid to be administered causing hypothermia and dilution in the face of acidosis, leading to the lethal triad. In many ways, coagulopathy was a “cost of doing business.” Recent research has challenged this belief.

The activated protein C (APC) pathway has been identified for decades. Although the role of the APC in fibrinolytic pathways has

been well established, its pathologic role in trauma-induced coagulopathy is only now emerging.⁷⁰ It is believed that the APC pathway is initiated when thrombin binds with thrombomodulin. The thrombin-thrombomodulin (T-T) complex is a normally occurring anticoagulant that develops as a negative feedback during clotting to limit a clot to the area of injury.⁶⁵ APC is a vitamin K–dependent serine protease that induces anticoagulation by inhibiting factors V and VIII.⁷¹ In a nonpathologic state, APC functions to limit clot propagation, ultimately maintaining blood flow in uninjured vessels. However, in the presence of damaged and hypoperfused tissue, it is believed that the APC pathway may lead to systemic coagulopathy.⁷⁰

Traumatic Brain Injury.

Traumatic brain injury (TBI) in isolation is self-limiting often producing very little blood loss. Despite this, TBI continues to be a significant cause of morbidity and mortality, with TBI accounting for approximately 30% of all injury deaths. On a daily basis, approximately 138 people in the United States die as a result of injuries that include TBI.⁷² Although the mechanism is not fully understood, it is believed that TBI causes a local release of TF from injured neurons, activating the protein C pathway, and triggering the release of anticoagulant mediators.⁷³

Early management of TBI should include rapid administration of plasma. The end-point of plasma administration should be to normalize the PT and INR. Because the plasma requirement needed to reverse TBI-induced coagulopathy is unpredictable, often requiring large quantities of plasma to reduce bleeding and normalize clot formation, administering plasma is recommended early, even before the initial PT or INR laboratory results return. The administration of low-dose recombinant FVIIa (rFVIIa) has been shown to be effective at improving the coagulation status of patients with TBI. In one study the impact of rFVIIa at a dose of 20 mcg/kg improved the INR and coagulation status of patients without adverse effects.⁷⁴

Shock.

Contemporary research suggests that hypoperfusion may be the

sentinel step in trauma-induced coagulopathy. Like TBI it is believed that hemorrhagic shock leads to activation of the protein C pathway, resulting in fibrinolytic coagulopathy.⁷⁵ Although the exact mechanism is unclear, it is believed that occult hemorrhage, and hypoperfusion may increase T-T complexes, resulting in APC and clotting factor inactivation. This finding is consistent with observed clinical presentations. As previously noted, nearly half of all trauma fatalities are caused by coagulopathic patients in hemorrhage and hemorrhagic shock who have no sign of TBI, hypothermia, or significant prehospital resuscitation.⁷⁶

Management strategies for these patients should include a vigorous yet controlled resuscitation. In addition to ATLS guidelines, warm fluids, and early blood product administration, the goal of the resuscitation team should be to maintain perfusion while controlling blood pressure: not too low and not too high. Research has demonstrated that increased SBPs greater than 85 mm Hg increases fluid/blood product administration and blood loss, but has little impact on morbidity and mortality.⁷⁷

Of late, it appears that management strategies aimed at avoiding secondary injury by maintaining cerebral perfusion pressure (CPP) and optimization of cerebral oxygenation may be of tremendous benefit.⁷⁸ Research to date indicates that maintaining a CPP in the range 60 mm Hg to 70 mm Hg is preferred.^{78,79} Additionally, those patients whose CPP was maintained at levels ≥ 70 mm Hg had decreased hospital mortality.⁸⁰

Disability (Neurologic)

Neurologic assessment begins the moment the patient enters the hospital. Patient mentation, behavior, and response to stimuli all provide the clinician with a picture of any neurologic injury. A GCS score is assigned during the primary or secondary survey and reassessed throughout the hospital course. Head injuries are classified grossly as blunt or penetrating, and the severity of the injury is based upon the GCS score.

The GCS evaluates the best eye response, best verbal response, and best motor response with a minimum score of 3 and maximum score of 15. A GCS of 13 or higher correlates with a mild brain injury, 9 to 12 a moderate injury, and 8 or less a severe brain

injury.⁸¹ See [Table 20.6](#) for the Glasgow Coma Scale.

Head Injury

Patients with head injury may sustain primary TBI that cannot be anatomically corrected, only prevented. The goal of care is the prevention of secondary brain damage resulting from intracranial complications that are aggravated by intracranial bleeding, edema, and resultant increased intracranial pressure (ICP). The presence of hypotension on admission and also the need for mechanical ventilation have been identified as potentially modifiable risk factors for morbidity and mortality following severe traumatic brain injury.⁸² Anesthesia management of head-injured patients includes early control of the airway and maintenance of cardiovascular stability.

Management of neurologic injury follows a similar treatment pathway as that for other trauma patients. GCS of less than 8 necessitates endotracheal intubation. Goals for airway management should be to maintain blood oxygen saturation (SpO₂) greater than 90% with normoventilation to help reduce hypercarbia and hypoxemia, both of which contribute to elevated ICP.⁷⁸ Judicious use of induction agents and neuromuscular blocking agents can facilitate a straightforward intubation. Attempts to perform an awake intubation in an obtunded, semicomatose, head-injured patient may promote coughing, bucking, and thrashing about, along with concomitant increases in the ICP that carry the risk of tentorial herniation. Nasal intubation may be contraindicated in the head-injured patient because of possible basilar skull fractures that can facilitate contamination and ultimate sepsis from nasal microorganisms introduced into the cranial vault.⁸³ Late sepsis also can occur from a sinus infection caused by prolonged nasal tracheal intubation. Gastric tubes are placed orally in head-injured patients for the same reasons.⁸⁴

Although hypotension is always a matter of concern, it is even more so for patients with neurologic injury. CPP describes the relationship of mean arterial pressure (blood pressure) and ICP. SBP directly affects cerebral blood flow. Hypoxemia, in addition to hypotension, is associated with increased morbidity and mortality,

and recent research indicates time interval until transport to an emergency department (ED) may be a significant factor.⁸⁵ Cardiopulmonary status must be maintained and ICP must also be controlled.

Patients with a suspected open- or closed-head injury are placed in a head-up position to help promote venous drainage and reduce ICP. Management of ICP is a challenge. There is no exact treatment threshold; however, most experts support treatment for ICP greater than 20 to 25 mm Hg.⁸⁶ No one technique (total intravenous anesthesia [TIVA] vs. general anesthesia [GA]) has demonstrated superiority to another. Although some anesthetic agents may decrease cerebral metabolic demand, they also may reduce cerebral blood flow, which may not be a desired effect when trying to increase cerebral blood flow. Aggressive management of CPP has been correlated with improved patient outcome.^{78,87} Patients with neurologic injury are more likely to die when their blood pressure falls below 90 mm Hg. Clinical targets should be to maintain a mean arterial pressure at a minimum of 70 to 75 mm Hg to maintain a CPP of at least 60 mm Hg.^{80,88} This gross target should be maintained until ICP monitoring can be initiated.

ICP monitoring is indicated for many instances of moderate and severe brain injury. Current ACS Committee on Trauma recommendations are for the placement of a ventriculostomy for ICP monitoring. It is the most accurate, cost-effective, and safe method for monitoring ICP.⁸⁹ Ventriculostomies allow for close monitoring of ICP, as well as treatment of elevated ICP by drainage of cerebrospinal fluid (CSF). Anesthetists should be familiar with this equipment and how to safely calibrate the drainage system, in addition to knowing how to open and close the system, as indicated, for the treatment of these patients.

The goal in treating intracranial hypertension is to promote adequate oxygenation and nutrient supply by maintaining CPP, oxygenation, and glucose supply without hyperglycemia.⁸⁹ The ACS recommends a three tiered approach. Tier 1 interventions include elevation of the head of the bed to 30 degrees (reverse Trendelenburg); short-acting sedation and analgesia (Propofol, Fentanyl, Midazolam); intermittent ventricular drainage; repeat neurologic exams; and repeat CT to exclude surgical mass lesions

and to assist with management. If ICP remains greater than 20 to 25 mm Hg proceed to Tier 2. Tier 2 therapeutic measures include placement of an external ventricular drain to facilitate drainage of intermittent CSF; intermittent hyperosmolar therapy, as needed (mannitol 0.25–1 gm/kg of body weight, with a serum osmolality level checked every 6 hours. Avoid serum osmolality >320 mOsm/L), and hypertonic saline (3% NaCl, 250 mL over 30 minutes); serum sodium (Na) and osmolality must be employed to ensure that Na levels remain less than 160 mEq/L; and avoid mannitol administration if hypovolemia is suspected. Additional neuromonitoring may include brain tissue oxygen partial pressure (PbtO₂), jugular venous oxygen saturation (SjvO₂), and cerebral blood flow (CBF) to determine the ideal CPP. A partial pressure of carbon dioxide in arterial blood (PaCO₂) of 30 to 35 mm Hg can be utilized as long as brain hypoxia is not suspected. Additional neurological evaluation and head CTs should be considered to continue to exclude surgical mass lesions and as a guide to treatment. Neuromuscular blockage may be added if the aforementioned measures do not lower the ICP and restore the CPP to acceptable levels. Tier 3 is implemented in the event ICP remains greater than 20 to 25 mm Hg. Tier 3 interventions include surgical evacuation and control of the underlying pathology. Potential salvage therapies that are recommended include barbiturate or propofol induced coma, hypothermia (< 36°C.) in those cases of “rescue” or salvage therapy when reasonable efforts at ICP control via prior Tier 3 treatments have not been successful.⁸⁹

Patients with significant head injury benefit from the placement of an arterial line in addition to the standard monitoring, which includes capnography and pulse oximetry. The placement of an ICP monitoring device facilitates the observation of changes in ICP dynamics that are influenced by drug administration and other manipulations. Intracranial hypertension exists when the ICP is at a sustained elevation of greater than 15 mm Hg. Therapeutic maneuvers are aimed at maintaining the CPP at approximately 60 mm Hg and oxygen delivery SpO₂ ≥90%. Of note, CPP greater than 60 mm Hg have been linked to improved outcomes. Attempts to elevate the CPP to levels of greater than 70 mm Hg have been associated with increased pulmonary complications, including

ARDS, as a result of volume overload.^{90,91}

The safety of isoflurane, desflurane, and sevoflurane has been demonstrated. Avoidance of nitrous oxide is recommended at least until the full extent of injuries is known, because it may aggravate potential pneumocephalus and pneumothorax in the traumatized patient. In the head-injured patient, ketamine is generally avoided because it tends to increase the ICP. Temporary reduction of ICP is often achieved using small incremental doses of propofol, moderate levels of hyperventilation (short-term), mannitol and/or furosemide for diuresis, and elevation of the patient's head in relation to the heart for a beneficial gravitational influence. Etomidate has been advocated for use in trauma patients because of its minimal hemodynamic effects, but the resulting adrenal suppression is a disadvantage and it is not used for patients with TBI.⁹² Although no significant clinical effects have been reported from single doses of etomidate, long-term use may be associated with increased mortality in multiple-trauma patients.^{60,90-92} Approximately 50% of patients with moderate or severe TBI have at least transient adrenal insufficiency (AI). Younger age, greater injury severity, early ischemic insults, and the use of etomidate and metabolic suppressive agents are associated with AI. Lower cortisol levels are associated with lower blood pressure and higher vasopressor use.⁸⁹

Blood pressure is monitored carefully to avoid hypotension (SBP) less than 90 mm Hg. Hyperosmolar therapy with mannitol 0.25 to 1 g/kg is effective for control of elevated ICP. Steroids have not been shown to improve outcome or reduce ICP.⁸⁹

Special Topics in Trauma Anesthesia

Spinal Cord Injury

Approximately 10,000 *spinal cord injuries* (SCIs) occur each year in the United States, and the median age of injury is 25 years.^{93,94} It is estimated that the annual incidence of spinal cord injury is approximately 40 cases per million population, which translates to 12,500 new cases of SCI per year.⁹³ A coroner's analysis of 512 prehospital deaths from trauma indicated that the leading causes of death in patients with SCI include head and spine injury (36%); hemorrhage (34%); asphyxia (15%), and combined neurotrauma/hemorrhage (15%).⁹⁵ It is estimated that males constitute approximately 80% of all new SCI cases. Of interest, the average age of those affected during the 1970s was 29 years of age, and the mean age at present is 42 years of age.⁹³ The SCI injuries are usually sustained from motor vehicle accidents, falls, assaults, diving injuries, and other sport injuries.⁹⁴ Few severe injuries have as devastating physical and psychologic effects as those caused by spinal cord trauma. Eventual outcome after an acute SCI depends on three factors: (1) the severity of the acute injury; (2) the prevention of exacerbation of the injury during rescue, transport, and hospitalization; and (3) the avoidance of hypoxia and systemic hypotension, which can further compromise neural function.⁹⁶ See [Table 40.2](#) for the common mechanisms of spinal injuries.

TABLE 40.2

Classification of Spinal Injuries

Mechanism of Spinal Injury	Stability
Flexion	
Wedge fracture	Stable
Flexion teardrop fracture	Extremely unstable
Clay shoveler fracture	Stable
Subluxation	Potentially unstable
Bilateral facet dislocation	Always unstable
Atlanto-occipital dislocation	Unstable
Anterior atlantoaxial dislocation with or without fracture	Unstable
Odontoid fracture with lateral displacement fracture	Unstable
Fracture of transverse process	Stable

Flexion-Rotation	
Unilateral facet dislocation	Stable
Rotary atlantoaxial dislocation	Unstable
Extension	
Posterior neural arch fracture (C1)	Unstable
Hangman fracture (C2)	Unstable
Extension teardrop fracture	Usually stable in flexion; unstable in extension
Posterior atlantoaxial dislocation with or without fracture	Unstable
Vertical Compression	
Bursting fracture of vertebral body	Stable
Jefferson fracture (C1)	Extremely unstable
Isolated fractures of articular pillar and vertebral body	Stable

From Kaji Ah, et al. *Rosen's Emergency Medicine*. 8th ed. Philadelphia: Elsevier; 2014:385.

Most SCIs involve the craniocervical junction (33%), which consists of the occiput and the first two cervical vertebrae.⁹⁷ Over 50% of all traumatic SCIs occur in the cervical region. The most common resulting injuries are incomplete tetraplegia (31%), complete paraplegia (25%), complete tetraplegia (20%), incomplete paraplegia (19%).⁹⁸ SCIs can be categorized as complete or incomplete injuries. Complete injuries represent an absence of motor, sensory, bowel, and bladder function below the level of injury. There is some preservation of neurologic function with incomplete injuries.⁹⁶ Spinal cord injury should be ruled out in any traumatized individual. The nature of the accident should help guide the diagnosis. The mechanism of injury usually helps in the diagnosis of possible SCI. Motor vehicle collisions are a major cause of morbidity and mortality. Indeed, 220,000 light motor vehicles involving 350,000 vehicle occupants sustain rollover crashes each year. Such crashes have resulted in 9000 occupant deaths, and 14,100 serious injuries annually. Half of those who are injured in a rollover collision sustain head, neck, and SCIs. It is estimated that these injuries cost approximately \$40 billion annually.⁹⁹ Cervical SCI should be assumed to be present in any patient who has sustained trauma to the head or face, in any unconscious trauma patient, and in any patient who complains of pain before or after careful palpation of the cervical spine. The clinician should be aware of the six conditions that are highly correlated with SCIs: paralysis, pain, position, paresthesias, ptosis, and priapism ([Box 40.1](#)). A comparison of cervical spine injuries and their acuity is noted in [Table 40.2](#).

Six Signs and Symptoms Correlated With Spinal Cord Injuries

Paralysis

Inability to move the arms or legs should always raise suspicion of spinal cord injury.

Pain

Conscious patient may complain of pain localized at the site of the spinal injury.

Position

Patient holding the head upright or the neck with both hands may be indicating a Jefferson-type C1 fracture; the “hold-up” position (arms and hands held over the head as in a robbery) can indicate a C4, C5 fracture; the “prayer position” (arms folded across chest) indicates a possible C5, C6 fracture.

Paresthesias

Complaints of numbness, a “pins-and-needles” sensation, a burning sensation (dysesthesia), or a feeling of electric shock passing down the vertebral column or of water flowing down the back may indicate the presence of a spinal cord injury.

Ptosis

Drooping eyelid and myotic pupil, which are signs of Horner syndrome, may indicate a cervical spinal cord injury.

Priapism

Penile erection occurs in approximately 3% to 5% of spinal cord injuries. Its presence indicates that the sympathetic nervous system is involved.

If SCI is suspected, care should be taken to prevent further extension of the injury. A properly fitted cervical collar should be carefully placed before the patient is moved or extricated.

Precautions should be taken for the prevention of further extension of actual or potential neurologic deficits. Spinal immobilization should be completed before the patient is moved. The head should be stabilized in neutral alignment with no extension, flexion, or rotation. Stabilization can be accomplished by placing a cervical collar on the patient, splinting, and/or sandbagging the head in neutral alignment. The patient should be placed on a long spinal back board before he or she is moved.⁹⁸ All patients with suspected SCI must be assessed for adequacy of a patent airway. Care should be used to avoid extension, flexion, or rotation of the neck in the attempts to open the airway. A gentle “chin lift” maneuver may be adequate for securing a patent airway without disturbing the neutral neck position. Oxygen should be administered by mask immediately in the patient whose airway is secured at the scene. Hypoxia and hypercarbia can further accentuate the damage sustained with SCIs. These injuries at the C1 or C2 level result in complete respiratory paralysis. Death follows within a few minutes if artificial ventilation is not commenced rapidly. In such patients, an LMA, or a laryngeal tube airway may be placed in the patient at the scene by paramedics. Although these devices initially may be adequate for allowing transport to a medical facility, they are replaced with an ETT as quickly as possible after the patient is admitted to a treatment facility.¹¹

If the patient with an SCI is breathing spontaneously on arrival at the treatment facility, the adequacy of ventilation should be assessed immediately. If the patient is not able to protect his or her airway (because he or she is unconscious or semiconscious, has an absent or diminished gag reflex or cough, or has intraoral or facial injuries with significant edema, bleeding, or both), rapid intubation is needed. If ventilation appears to be reasonable, chest and cervical spine radiographic evaluation and neurologic examinations can be started while an arterial blood gas determination is completed. A lateral view of the cervical spine can be obtained quickly, and it reveals most unstable fractures. For a complete evaluation of the cervical spine, multiple films or CT scanning or MRI may be required. An adequate evaluation must include all seven cervical vertebrae; C7 is the most common site of injury.¹⁰⁰

In children, uncooperative adults, or in patients in whom awake

intubation fails, a carefully selected dose of propofol and a neuromuscular blocking agent is used for inducing general anesthesia for the intubation.¹⁰¹ Orotracheal intubation can be safely performed with neck immobilization and in-line stabilization. Although there is debate in the literature, it is preferable to intubate these SCI patients orally. SCI patients have the best chance of recovery if hypoxia, hypercarbia, and hypotension are avoided or rapidly corrected if encountered. Arterial blood gas values indicating that ventilation is suboptimal are corrected by intubation and mechanical ventilation. If there is a delay in establishing the airway, the patient is given ventilation by mask while cricoid pressure is maintained until the airway is secured. Severely traumatized patients who are hypoxic on arrival undergo ventilation by mask with application of cricoid pressure until the intubation is completed. This method prevents further hypoxic insults that can occur during the apneic period between the administration of a muscle relaxant and the completed intubation. Time does not allow the luxury of adequate preoxygenation in an already compromised hypoxic patient with respiratory inadequacy. To prevent further hypoxic insult and the resultant potential life-threatening dysrhythmias, these patients are continuously ventilated while cricoid pressure is applied. This measure helps maintain or improve oxygenation until laryngoscopy and intubation are completed.^{100,101}

Use of Muscle Relaxants in Patients With Spinal Cord Injury

As previously discussed, succinylcholine may precipitate cardiac arrest in patients with massive muscle injury or denervation that is seen in patients with SCIs, crush injuries of muscles, or burns. The basis for this problem involves supersensitivity and up-regulation of the neuromuscular junction to the depolarizing effect of succinylcholine.¹⁰² This phenomenon results in the release of large quantities of potassium during muscle contraction. Normal depolarization results in a small potassium flux across the muscle cell membrane. If a muscle is crushed, burned, or denervated, acetylcholine receptors proliferate around the injured cell, so that

when the muscle is depolarized the flux of potassium is increased significantly.¹⁰³ The problem is thought to develop in response to succinylcholine several days after the injury. Succinylcholine is not recommended for intubation of the patient with acute SCI because muscle fasciculation may exacerbate the SCI. It is also contraindicated for routine use in children.¹⁰⁴ A conservative approach to caring for patients with SCI would be to avoid the use of succinylcholine by using a nondepolarizing muscle relaxant such as rocuronium or nonrelaxant-assisted airway control techniques.¹⁰¹

Spinal Shock

A triad of *hypotension*, *bradycardia*, and *hypothermia* frequently results from a relative sympathectomy in SCI patients. The *spinal shock* is progressively intensified the more cephalad the SCI. Patients with SCIs at the T6 level or higher have severely impaired CNS function. Sympathetically mediated cardioaccelerator responses no longer oppose vagal innervation allowing the heart rate to slow dramatically. Loss of sympathetic tone allows vasodilation, pooling of the peripheral circulation, and decreased venous return to the heart. This situation results in a decreased cardiac output and hypotension. The SCI also interrupts sympathetic pathways from the hypothalamus (temperature control center) to peripheral blood vessels. The patient in spinal shock is unable to constrict vessels or shiver in order to produce heat or to dilate vessels to dissipate heat. The patient's body temperature has a tendency to migrate toward the environmental level.¹⁰¹

Treatment

Patients in spinal shock are hypotensive and bradycardic with warm, pink extremities. In contrast, patients in hemorrhagic shock tend to be hypotensive and tachycardic with cold, clammy skin. Use of invasive monitoring is critical for fluid resuscitation and appropriate intervention with vasoactive drugs, often norepinephrine infusion. An indwelling arterial catheter is mandatory in the acute phase of spinal shock. Moment-to-moment control of arterial blood pressure is essential for the replacement of fluids and for the use of vasoactive drug therapy. In addition,

arterial blood gas assessments are facilitated by an indwelling arterial catheter.¹⁰⁵

The SCI patient is frequently unable to maintain adequate cardiac filling pressures. However, overaggressive fluid therapy can precipitate pulmonary edema. For the maintenance of adequate arterial blood pressure and cord perfusion, pressor therapy may be initiated.¹⁰⁵

Other Considerations

For patients with cervical SCI there will be resultant intercostal muscle weakness, or complete paralysis depending on the degree of spinal injury. The amount of respiratory dysfunction correlates with the level of SCI. Where forced, vital capacity and the ability to protect the airway from secretions or even the ability to take a breath may be significantly decreased or absent. The primary muscles of respiration are located in the diaphragm, which is typically innervated by the C-3 through C-5 nerves and the intercostal muscles that are in turn controlled by T-2 through T-11. SCI above C-3 often leads to apnea, whereby survivors are typically rendered ventilator dependent.¹⁰⁶ There has been some success in weaning certain patients off the ventilator with significant SCI at higher levels with the use of exogenous pacing of the diaphragm via intramuscular diaphragmatic stimulation devices.¹⁰⁷

Recent research by Jones et al. reviewed the records of all patients with an acute SCI from January 1998 through July 2012 at a level one regional trauma center. Records of 163 patients were analyzed and 76 complete SCIs were identified. The investigators determined that 91% of these patients required more than 48 hours of mechanical ventilation (MV). When the level of SCI was considered, MV was needed in 100% of patients with a C-2 through C-4 injury; 90% for a C-5 injury; 79% for a C-6 injury and 80% for a C-7 injury. It was concluded that all patients who suffered a complete CSI above C-5 should undergo an elective tracheostomy. Additionally, the decision to perform a tracheostomy in a patient with an incomplete SCI should be based on the presence of associated intracranial and thoracic injuries.¹⁰⁸

Patients that meet appropriate guidelines for extubation should be extubated as soon as possible to avoid various pulmonary

complications associated with mechanical ventilation and prolonged ICU care.¹⁰⁹ If the patient requires intubation because of associated pulmonary injuries or dysfunction, then a weaning program is started when it can be tolerated by the patient. With frequent assessment of respiratory status this weaning is usually begun within the first few days. Useful guidelines for assessing the adequacy of ventilation include measurement of the tidal volume (greater than 5 mL/kg), negative inspiratory force (-20 to 25 cm H₂O pressure, needed for adequate cough), and vital capacity (greater than 15 mL/kg). Patients with a high SCI often lose innervation of the intercostal and abdominal musculature.

Chest physiotherapy is initiated for all patients as soon as possible in order to reduce the risk of pulmonary congestion and infection. Oral or nasogastric tubes are placed for decompressing the stomach. This measure eases diaphragmatic excursion for improved ventilation and reduces the risk of aspiration. Peptic ulceration with loss of sympathetic innervation in the patient with a high SCI is a well-described complication, especially in patients receiving steroids.¹⁰⁵ Of note, in the past SCI patients were routinely given high doses of steroids in an attempt to minimize secondary injury associated with inflammation and edema. Contemporary evidence-based recommendations caution against the use of routine steroid administration because of increased rates of gastrointestinal bleeding that may lead to death. Indeed, 15 medical societies have advocated against the use of steroids in those with SCI.¹¹⁰

Two additional conditions associated with acute SCI that should warrant provider consideration are SCI without radiographic abnormalities (SCIWORA), and an acute vertebral artery injury (AVI). SCIWORA refers to a patient who displays symptoms of a traumatic myelopathy or SCI despite the presence of a negative conventional x-ray or CT scan. MRI is considered the most accurate modality to diagnose this condition and consequently an MRI is warranted in any patient suspected of having SCIWORA. Patients with SCIWORA may have a broad variety of neurologic deficits ranging from mild and transient paresthesia in the fingers to a complete quadriplegia. The primary treatment for SCIWORA is application of an external immobilization device such as a hard cervical collar for up to 12-weeks post-injury. It is critical that

anesthesia providers consider this an unstable condition that requires the patient's neck to be kept in a neutral position for airway management and intraoperative positioning.^{111,112}

It is estimated that the incidence of VAI in SCI patients is 53% to 88%.¹¹³ Motor vehicle collisions are the most common cause of VAI, where a hyperextension injury of the neck, with or without lateral flexion or rotation, produces a closed injury to the vertebral artery. Additionally, VAI in the elderly is frequently attributable to a fall from a standing position, which produces a C-2 fracture.¹¹² The vertebral artery is considered to be most susceptible to injury at its entry point into the C-6 transverse foramen and the exit point at the atlantoaxial junction. Patients suffering from a VAI may have stroke-like symptoms. It is vital that the presence of a VAI be confirmed because the potentially devastating complications of a cerebrovascular accident leading to death can occur. The current standard diagnostic tool to detect the presence of a VAI is CT angiography. If a VAI is suspected it is important to implement anticoagulant or antiplatelet therapy to reduce the likelihood of serve neurologic deficit or death.¹¹³

Surgical Intervention and Anesthesia Approach

Although external immobilization devices, including a halo vest, are sometimes used, many neurosurgeons believe that prolonged use of external fixation devices is contraindicated in patients with unsatisfactorily reduced spines. Frequently, spinal stabilization and/or decompression procedures are performed after initial resuscitation and diagnostic workup. However, it is important to note that there is research indicating that use of a halo vest for older patients (those aged 60–73) may have higher rates of morbidity and mortality. Consequently, these researchers caution that use of the halo vest should be compared with operative stabilization of cervical spine fractures following blunt trauma in this population.¹¹⁴

Contemporary investigation on the timing of surgical intervention after an initial SCI has not been definitive. There is some research indicating that early stabilization is associated with improved patient outcomes.^{96,115} Conversely, in a study conducted by Liu that involved 595 patients, the investigators determined that early surgical intervention was linked to higher mortality and

neurologic deterioration.¹¹⁶ Research on military personnel experiencing an acute SCI in Afghanistan found that these patients fared better when surgical intervention was delayed until they were transported to a regional medical center. Specifically, those transferred to a regional medical center had half the rate of complications.¹¹⁷ Yet additional research indicates that the optimal timing for surgery in patients with multisystem injuries involves balancing the risks of performing extensive spinal surgery with stabilization performed initially and deferring surgical intervention until such time as the patient is hemodynamically more stable.¹¹⁸

The neurosurgeon and anesthesia team document the current neurologic status and note any deficits before the start of anesthesia and intubation. In an awake intubation, the patient is assessed before and after ETT placement and after the patient is positioned for surgery.

Whether an anterior or a posterior surgical approach is used in cervical SCI depends on the nature of the injury. Internal fixation devices are commonly placed in the acute phase for stabilization of lower SCIs. At times these procedures can be associated with significant surgical blood loss. Careful monitoring and replacement of blood loss are essential. Use of an autotransfusion device often saves considerable banked blood use in these procedures. Antifibrinolytic agents, most notably tranexamic acid (TXA) can be employed. TXA is a lysine analog that inhibits plasminogen activation and has been shown in many studies to be particularly helpful at reducing surgical blood loss.¹¹⁹ Research is currently underway to ascertain the optimal dose of TXA that should be administered for patients undergoing posterior spinal fusion surgery. Two dosage formulations are under comparison: 50 mg/kg loading followed by 20 mg/kg hourly, or 10 mg/kg, then 1 mg/kg hourly.¹²⁰

In cooperative patients who are deferred for elective spinal stabilization procedures, awake fiber optic intubations are often employed. In controlled conditions, this measure allows for the use of local, topical, and transtracheal anesthesia without the risk of pulmonary aspiration that is present in emergency procedures.¹²¹ Glycopyrrolate is commonly given before administering local anesthesia to the airway as an antisialagogue. Once moderate

sedation is accomplished, superior laryngeal nerve block, topical oral pharyngeal, and transtracheal local anesthetic can be employed.¹²² At this point there is little research to suggest that nasal intubation is superior to oral intubation in all potential SCI patients. However, if possible, oral intubation should be considered to avoid potential complications typically associated with nasal intubation such as epistaxis, and the rare instance of inadvertent avulsion of the turbinates.¹²³ Long term use of nasal ETTs has been implicated as a cause of necrosis of the nasal alae. Sinusitis has been reported in both orally and nasally intubated patients.¹²⁴

The choice of airway management technique will depend to a great extent on the patient's injuries, level of cooperation, hemodynamic stability, and ability to protect the airway.¹²⁴ If the patient is cooperative and hemodynamically stable, an awake topicalized fiberoptic assisted approach is considered to produce the least movement of the cervical spine.¹²⁵ This approach also affords an opportunity to perform a "wake-up test" where the patient can respond to requests to test upper and lower extremities prior to induction of general anesthesia to confirm no change for the worse in neurologic status. Intraoperative neural monitoring that utilizes somatosensory evoked potentials and electromyography should be employed throughout the entire operative period of surgical spine surgery in an attempt to minimize secondary injury resulting from surgical manipulation or changes in spinal cord perfusion.¹²⁶

In the case of a patient who is agitated, uncooperative and/or unstable hemodynamically, or who may have ingested drugs or alcohol, any attempt to sedate and topicalize the airway may lead to disastrous results such as airway obstruction, hypoxia, hypotension, or aspiration of gastric contents. This type of patient is best managed by a traditional rapid sequence induction with a direct laryngoscope using properly applied cricoid pressure and manual in-line stabilization of the cervical spine.¹²⁷ It is recommended that the front of the cervical collar be removed to assist with mouth opening. Despite the fact that some research questions the true effectiveness of cricoid pressure to prevent aspiration of gastric contents, it is still typically applied and modified to allow some degree of external laryngeal manipulation

to potentially improve the airway view.¹²⁸ There is some evidence that video-assisted laryngoscopy may cause less distraction of the cervical spine and may offer better visualization of vocal cords than traditional laryngoscopy.¹²⁹

There are some areas of controversy surrounding the issue of manual in-line stabilization (MILS), application of cricoid pressure, and the use of bag-valve-mask ventilation prior to intubation attempts during a traditional RSI in a patient with a potential cervical SCI. A 2015 Cochrane Review examined the effect of applying cricoid pressure during an RSI and concluded that it may not be necessary to safely secure the airway, it may not prevent aspiration of gastric contents, and it may interfere with the clinician's view of the patient's airway.¹³⁰ It is currently recommended that if cricoid pressure is used and it interferes with the intubator's ability to provide adequate ventilation, identification of airway structures, or passing the endotracheal tube, then the cricoid pressure should be lessened or removed.¹³¹

The general consensus for MILS is that despite the fact that it may lead to a less than optimal view, it is still recommended under ATLS Guidelines and the Eastern Association for Surgery in Trauma to minimize the risk of secondary cervical SCI.^{11,37} Although not an extensively studied topic, the use of a modified RSI technique that utilizes effective bag-valve-mask ventilation should be considered in appropriate patients to maximize the degree of oxygenation and also to confirm that mask ventilation is indeed possible.¹³² As noted earlier, the avoidance of hypoxia is particularly important in patients who suffer from an acute TBI or SCI to minimize secondary injury.¹⁰¹

Patients with high thoracic and cervical spine injuries should ideally have their blood pressure monitored with an intraarterial catheter that is placed prior to induction of general anesthesia to permit immediate response to changes in hemodynamic status.¹³³

Intraoperative management of these patients can employ a variety of agents that include opioids (fentanyl, sufentanil, or remifentanil) along with an inhaled anesthetic such as isoflurane. Muscle relaxation is typically provided by a nondepolarizing neuromuscular blocking agent. Succinylcholine can be used to improve intubating conditions in the first 24 hours following an

acute SCI. It may increase serum potassium levels by approximately 0.5 mEq/L in normal patients who have no contraindications to the drug such as a history of malignant hyperthermia, or who have experienced a burn, stroke, or major crush injury more than 72 hours previously.¹⁰² Succinylcholine has been associated with life-threatening hyperkalemia when given to a patient with a SCI 48 hours postinjury.¹³⁴ Research involving 131 patients who were intubated using succinylcholine noted that an additional risk of hyperkalemia was directly correlated with an increasing length of stay in an intensive care unit. The development of hyperkalemia ≥ 6.5 mm/dL was highly significant after the 16th day in the ICU. The investigators concluded that such levels were most likely related to decreased mobility, and prolonged immobilization.¹³⁵

Hemodynamic management of patients with an SCI is typically associated with sympathetic denervation and hypovolemia caused by concomitant injuries, or a combination of the SCI and a secondary injury. The American Association of Neurological Surgeons guidelines for blood pressure controls includes maintenance of a mean arterial pressure range from 85 to 90 mm Hg for up to 7 days postinjury to optimize spinal cord perfusion. To maintain this blood pressure, it may be necessary to administer IV fluids, blood products, vasopressors, and inotropes.¹³³

Nitrous oxide is usually avoided in newly admitted trauma patients, particularly if there is a chance the patient has a head injury, lung insult, or bowel obstruction. Nitrous oxide may increase the volume and pressure in any gas-filled spaces, leading to an increase in the size of a pneumothorax and/or pneumocephalus. Following injury to the chest wall, use of nitrous oxide with positive pressure can cause rapid expansion of a subclinical pneumothorax into a rapidly increasing and life-threatening pneumothorax with mediastinal shift.¹³⁶

Careful selection of anesthetic agents is vital to promote optimal outcomes. The inductions most commonly used in the trauma setting are etomidate, ketamine, and propofol. Etomidate is an imidazole-derived sedative-hypnotic that stimulates gamma-aminobutyric acid (GABA) receptors to block neuroexcitation and induce amnesia. This drug decreases the cerebral rate of oxygen

(CMRO₂), CBF, and ICP, and is often employed for induction of anesthesia in the neurosurgical patient. Unfortunately, there is some literature that supports the notion that a single use of etomidate may increase mortality for those patients with sepsis. In addition, a single dose of etomidate in the trauma patient has been associated with increased rates of hospital-acquired infection. It is believed that these effects may be attenuated with postetomidate hydrocortisone therapy.¹³⁷

Ketamine is a dissociative agent, has a rapid onset when given IV, and may also be used intramuscular (IM) in uncooperative trauma patients who do not have adequate IV access. This drug indirectly increases cardiovascular stimulation through centrally-mediated increased sympathetic tone and increased release of catecholamines. Use of ketamine in those patients with a TBI may lead to increased ICP, but it may help avoid hypotension in hypovolemic trauma patients.

Propofol is a frequently employed sedative-hypnotic that has a rapid onset, profound amnesia, short duration of action, and effective blunting of sympathetic outflow during laryngoscopy.¹³⁷ Propofol decreases CMRO₂, CBF and ICP, which makes this drug a preferred agent for hemodynamically stable TBI patients. Because propofol reduces SVR and has myocardial depressant effects, it must be used with extreme caution in patients with hemodynamic instability. Some providers consider reduction of the standard propofol intubating dose to a range of 0.5 to 1 mg/kg or less in patients with a potential for hemodynamic instability as an acceptable practice.^{137,138} If the blood pressure drops to an unacceptable level, adjunctive use of an intermittently dosed vasopressor, such as phenylephrine, can be used to maintain an acceptable mean arterial pressure in hypovolemic patients.¹³⁷

Autonomic Dysreflexia

Level one trauma centers are frequently chosen to treat acutely injured patients during the initial hospitalization, as well as for future related surgeries, because they have lower rates of morbidity and mortality, and are typically better equipped to manage more complex patients than is a level two trauma center.¹³⁹ In such

settings the anesthesia plan must address the complications associated with acute high thoracic and cervical spinal cord injuries including neurogenic shock, bradyarrhythmias, abnormal temperature regulation below the level of the lesion, and autonomic dysreflexia (AD).¹⁴⁰ More specifically, during the acute phase of a high-level SCI patients often develop neurogenic shock, characterized by profound hypotension that requires inotropic support. From several weeks to six months post SCI, up to 98% of these high paraplegics or quadriplegic patients will experience AD following a painful injury below the level of the spinal cord lesion. AD, a potentially fatal clinical condition, is found in patients who suffer an SCI above T-6, and is characterized by a sudden activation of sympathetic response as a result of a noxious stimuli such as colorectal or bladder distention. It often presents with severe hypertension and other life threatening consequences including seizures, pulmonary edema, myocardial infarction, acute renal injury, and intracranial hemorrhage.¹⁴¹ Management of an acute AD attack includes determining and correcting the noxious stimuli. Because bladder distention and fecal impaction are the most common triggers, bladder catheterization, exclusion of a UTI, and rectal disimpaction should be performed. Rapid reduction of blood pressure should be undertaken. Typical medications to reduce dangerous levels of blood pressure incorporate nitrates: captopril (25 mg sublingual), hydralazine (10 mg IV), and labetalol (10 mg IV).^{142,143}

Orthopedic Injury and Trauma Anesthesia

Trauma to the extremities represents one of the most frequent injuries seen in emergency and ortho-surgical practice. Civilian extremity injuries occur most often as a consequence of falls (43%), and motor vehicle collisions (26%). In 2015, 328,229 lower extremity injuries and 259,244 upper extremity injuries were entered into the National Trauma Data Bank.¹⁴⁴ Despite the fact that many orthopedic injuries are not usually immediately life-threatening and are considered a secondary evaluation of the trauma patient, they can be associated with significant hemorrhage and may be linked to other extensive physiologic determinants such as shock, fat emboli, and thromboembolic hypoxic respiratory failure.¹⁴⁵

Early fracture fixation with intramedullary nails often allows patients to ambulate within 24 hours of surgery, and drastically reduces the incidence of pulmonary complications including ARDS, fat emboli, and pneumonia.^{146,147} In some instances, secondary neurovascular injury may occur with specific patterns because sharp edges of damaged bone may be forced into blood vessels and peripheral nerves at the fracture site. Furthermore, all providers should have a high index of suspicion for compartmental syndrome when high-energy trauma is responsible for the fractures.¹⁴⁸

Because the ideal time to repair open fractures is within the first 12 hours following injury, all patients taken to the OR for emergency surgical repair are considered to have a full stomach. Consequently, steps should be taken to reduce the risk of aspiration and maintain adequate end-organ perfusion if general anesthesia is to be administered.¹⁴⁸

Massive hemorrhage may be associated with pelvic fractures. Mortality rates can be as high as 70% with an open pelvic fracture.¹⁴⁹ Massive hemorrhage may be attributable to displaced pelvic bone fragments, which may sever arteries, veins, and nerves that exit the pelvis to the perineum and the lower extremities. Damage control resuscitative efforts and damage control surgical measures are critical in order to improve the outcome in such cases. Immediate care should include application of a pelvic binder as soon as possible following injury to help tamponade internal hemorrhage. External fixation, angiographic embolization, and application of pelvic packing have been used with some success as elements of damage control surgery.^{149,150} The anesthetist's role at this time should focus on close monitoring of hemodynamic end-organ perfusion in addition to replacing blood loss using previously discussed principles of damage control resuscitation. Currently the primary end-points to help ensure oxygenation and end-organ perfusion are relative normalization of serum lactate, base deficit, pH, early correction of clotting functions, and hemorrhage control.^{151,152} Some controversy exists over the use of TEG to monitor hemotherapy or clotting factors in trauma patients. TEG analyzes coagulation profiles and helps determine blood product resuscitation by means of rapid, data-driven blood component assessment.¹⁵³ Although research remains somewhat

preliminary, TEG may prove useful to provide goal-directed targeted therapy to correct the coagulopathy of trauma.¹⁵⁴

Hypoxic respiratory failure in the orthopedic trauma setting is most commonly seen with pelvic and long bone fractures. Patients with one long bone fracture have approximately a 3% chance of developing fat emboli syndrome (FES). A patient with bilateral long bone fractures of the femur has a 33% chance of experiencing FES.¹⁵⁵ The hypoxia is attributable to seeding of fat cells from the disrupted bone marrow into the venous circulation. It is thought that these fat cells produce potent proinflammatory and prothrombotic reactions that can lead to rapid platelet aggregation and accelerated fibrin generation as they travel through the venous system to eventually lodge in the pulmonary arterial circulation. The resultant pulmonary capillary obstruction leads to diffuse interstitial edema, alveolar collapse, and subsequent reactive hypoxic pulmonary vasoconstriction. Massive fat emboli can produce macrovascular obstruction and profound shock.¹⁵⁶

FES is typically seen 24 to 72 hours after the initial injury. Affected patients develop hypoxemia, neurologic impairment, and a classic petechial rash. Supportive care is the primary treatment for clinically evident FES, which may include endotracheal intubation and mechanical ventilation. There is some evidence that patients at high risk for the development of FES may benefit from low dose methylprednisolone (1.5 mg/kg IV) every 8 hours for 6 doses.¹⁵⁵ It is likely that patients who experience long bone fractures will be taken to the operating room as soon as possible for surgical correction and stabilization of any long bone or pelvic fractures. This is thought to reduce the risk of FES in addition to other pulmonary complications such as pneumonia, pulmonary embolism, and ARDS.^{146,155}

Continuum of Care

A dynamic and comprehensive trauma system is comprised of multiple integrated and coordinated components, with the goal of providing cost-effective services for injury prevention and optimal patient care. At the center of such a care system is what has been termed the continuum of care, which considers injury prevention, pre-hospital care, and post-hospital rehabilitation care.¹⁵⁷ The

American Trauma Society has reported that application of a regionalized, best practice approach, coupled with application of robust and rigorous disease management guidelines across the continuum of care improves patient outcomes.¹⁵⁸

The US military has applied lessons learned from civilian trauma care and developed the Joint Theatre Trauma System, a systematic and integrated way to care for battlefield casualties. The goal of this system is that every soldier, marine, sailor and airman injured in theatre receives the highest quality care possible, and afforded the best chance for survival and functional recovery.¹⁵⁹ Many of the principles included in damage control resuscitation and DCS have been adopted in daily practice in combat related environments with effective results.¹⁶⁰

In an attempt to simplify anesthesia care in an unpredictable and rapidly changing critically injured patient, a basic trauma, and emergency anesthesia checklist has been proposed by Tobin et al. Employing best current evidence, these providers have developed protocols for management of such patients prior to arrival, on arrival, intraoperatively, and postoperatively.¹⁶¹ This checklist is not only helpful to those working in Level I trauma centers, but may prove particularly useful in those hospital settings that do not routinely receive such patients.

Newer approaches to the continuum of care have recognized that pain management is often inadequately addressed. Consequently, contemporary research has placed greater emphasis on the utilization of regional anesthetics to reduce pain, diminish potential postoperative complications that may be associated with general anesthesia and systemic opioid use. Additionally, some experts are more strenuously advocating early use of regional anesthesia to increase a patient's self-care activities, such as coughing and deep breathing, and earlier ambulation. More specifically, data indicate regional modalities are of particular utility in those who have suffered rib, femur and hip fractures and patients undergoing digital reimplantation in addition to free flaps.¹⁶²

Summary

Traumatic injury is a leading cause of morbidity and mortality in the United States and globally. Despite development, innovation, and changes to public policy, traumatic injury continues to pervade modern society. Consequently, a comprehensive understanding of trauma care is important for modern anesthesia practice. Trauma management has moved away from the community-based level and developed into a systems-based approach, coordinating prehospital care with larger centers, public policy, and a rational approach through use of ATLS. The organization of trauma care in the United States has substantially improved survival and quality of outcomes for severely injured patients.

Ideally, the anesthetist's involvement should begin as soon as the patient reaches the trauma facility. Care should follow the general algorithm developed in ATLS. Anesthesia providers and the trauma team should focus on ensuring an adequate airway and breathing while diagnosing and controlling injuries almost simultaneously. The principles of successful management of the trauma patient are based on organization and preparation, assessment of the patient's injuries, proper priority for therapeutic interventions, achievement and maintenance of a patent airway, fluid resuscitation, application of appropriate continuous invasive and noninvasive monitoring, correction of acid-base and electrolyte disturbances, and careful titration of anesthetic and adjunctive agents.

Trauma anesthesia can be a challenging specialty because patients often arrive with an unknown history and they may not be able to communicate comorbidities, allergies, drug/medication use, and myriad other pieces of information. Many such patients require immediate surgical intervention. DCR and DCS must be implemented until such time that the patient is stable enough to offer virtually any level of anesthesia. Frequently these patients require multiple surgical procedures until definitive surgical correction is obtained. Consequently, anesthesia services are provided based on how stable the patient is at any given point in time. As the systolic blood pressure starts to rise above 90 mm Hg

during the early resuscitative phase of DCR, fentanyl, titrated at a range of 50 to 150 mcg doses can be effective at providing analgesia to the trauma patient. If there is a marked drop in the in blood pressure below the targeted range of greater than 90 mm Hg, then the patient requires additional fluid resuscitation. Once the patient is able to tolerate a single bolus dose of fentanyl (up to 250 mcg) without a drop in blood pressure below the target of greater than 90 mm Hg, it is likely that the hypovolemic state has been corrected. Ultimately it is important to monitor for evidence of tissue hypoperfusion throughout the initial intraoperative resuscitation phase tracking arterial pH, base deficit, and lactate. It is also important to consider the effect of citrate toxicity, frequently seen with administration of blood and blood products, and to monitor ionized calcium levels. It is permissible to employ low doses of an inhaled anesthetic agent such as isoflurane, to minimize potential for surgical recall in the early stages of intraoperative resuscitation, unless the systolic blood pressure cannot be maintained at greater than 90 mm Hg. The use of nitrous oxide in the early stages of a trauma resuscitation should be avoided because it can expand any potential gas spaces and worsen pneumothoraces, small bowel obstructions, and pneumocephalus.¹³⁷ Regional anesthetics in the form of peripheral nerve blocks offer advantages to help control pain without producing significant systemic hypotension and their use is gaining popularity in the trauma anesthesia community.¹⁶²

The degree of functional outcome of trauma patients is largely dependent on the early involvement of sound principles of anesthesia care in the resuscitation and overall anesthetic management during the perioperative period. In a well-managed team approach, assessment and treatment are carried out in rapid succession or even simultaneously.

Fortunately, research concerning trauma anesthesia continues to grow exponentially. Therefore it is incumbent that those providing such care to patients regularly review emerging evidence to ensure the highest possible quality of care.

Anesthesia for Organ Transplantation

Michael J. Anderson, Collin J. Willhite

History of Organ Transplantation

Organ transplantation provides hope to patients who are in need. This need is balanced by the supply of organs available and the severity of the patient's condition warranting transplant. Patients awaiting organ transplantation have sustained organ dysfunction and have exhausted other medical treatments and therapies. Organ transplantation can significantly improve and extend the quality of life, but is not without risk.

The concept of organ transplantation has been around since the early 1900s and has evolved into a highly specialized and complex phenomenon. This is due to significant developments in medicine, surgery, anesthesia, pharmacology, and other entities. Alexis Carrel is recognized as a pioneer in the development of the concept of vascular anastomoses. It was this work that earned him the Nobel Prize for Medicine in 1912. His unique method of using fine needle and thread and experimentation on animals along with his publication titled *The Transplantation of Veins and Organs* have granted him the title of the Father of Transplant Vascular Surgery.¹ Many of the techniques developed by Carrel are still used today.

One of the major hurdles involved in organ transplantation was rejection by the recipient's immune system versus the donor tissue. This led to catastrophic results. Ultimately the work of Peter Medawar, an immunologist, who developed the theory of graft rejection as a result of an immunological incompatibility, led to the idea of organ rejection and helped pioneer the use of immunosuppression medications to help prevent this from occurring.² This work led to Medawar receiving the Nobel Prize for Medicine and paved the way for further developments related to immunosuppressive therapies. Early on, either corticosteroids or whole body radiation were employed. In 1974, another major development occurred. Cyclosporine was introduced by Borel et al. and is still used today to prevent graft versus host rejection.³

These developments have paved the way for an evolution of care called *organ transplantation*. Today we have the technology and capability of transplanting kidney, liver, pancreas, heart, lungs, cornea, and stem cells. In this chapter, we will discuss the types of

organ donation, the anesthetic implications of organ transplantation, and anesthetic care for the organ donor.

Types of Organ Donation

Traditionally organ donation has occurred once the donor is declared dead due to an absence of viable brain activity. This can be due to a variety of insults, and specific criteria have been developed to assess and determine if the patient meets the criteria for potential organ donation. This is termed *organ donation after brain death* (DBD). Brain death occurs when the brain is deemed irreversibly nonfunctional due to lack of blood supply and oxygen, which causes brain cells to die. This method remains the most common method of donation employed today. Another method has been introduced and is becoming more prevalent. This method is donation after cardiac death (DCD) and occurs when a patient meets specific criteria defined for DCD. Although this movement towards DCD was implemented due to a shortage of organs for transplantation, ethical considerations remain challenging and are a barrier to widespread acceptance.⁴

Organ Transplantation Considerations

With the improvement of technology and medical advances, organ donation is considered an accepted medical treatment for patients with end-stage organ failure of various types. It is estimated that approximately 79 people receive organ transplants on a daily basis, but 22 people die each day while waiting for a transplant. The number of transplants and donors have steadily increased over the last two decades; however the number of patients on the waiting list has grown at a staggering rate. In 2014, more than 29,532 transplants were performed in the United States, but that is in contrast to the more than 121,000 patients who remain on a national organ transplant waiting list.⁵ The national organ transplant list is maintained by the United Network for Organ Sharing (UNOS) and strict standards are upheld for fair and ethical distribution of organs. Criteria considered includes blood and tissue matching, organ size, medical urgency, wait time, and geographic location of the donor and recipient.⁶ There are currently more than 120 million

people in the United States alone who are identified as organ donors. Many of them will never have the chance to donate based on the original criteria for DBD. This has been the genesis for consideration and development of guidelines for DCD. Fig. 41.1 notes the number of people on the waiting list versus transplants and the number of donors.

FIGURE 41.1 Annual kidney transplant data. (From Organ Procurement and Transplantation Network. Available at <https://optn.transplant.hrsa.gov>. Accessed 2016.)

Renal Transplantation

End-stage renal disease (ESRD) has a tremendous impact on our society in terms of cost and resource allocation. Patients often have many other comorbidities and ultimately may require hemodialysis as a life-saving treatment regimen. The first kidney transplant was performed in 1954 and gained significant momentum with the development of immunosuppression in the 1960s.⁷ The kidney is the most frequent solid organ transplanted today. Renal transplantation provides an improved quality of life and a longer survival rate than dialysis. The 5-year survival rate for patients undergoing renal transplantation is approximately 70%, versus only a 30% survival rate for patients who receive dialysis alone.⁸ After a steady increase in the incidence of ESRD from 1980 to 2001, the incidence rate has plateaued. The incidence is on the rise, however, in patients over the age of 65. Many factors have contributed to this increase, including diabetes and hypertension.⁹

Pathophysiology of End-Stage Renal Disease and Indications for Transplant

Kidney transplantation is a process by which a donated kidney is surgically attached and ultimately replaces the limited to nonfunctioning kidney. Kidney transplantation occurs due to a variety of factors including hypertension and diabetes. It is commonly related to dysfunction and/or destruction of the kidney from glomerulonephritis, chronic interstitial nephritis, or congenital or hereditary disorders such as cystic disease. Kidney dysfunction related to hypertension and diabetes are now the most common indications for kidney transplantation in the United States.⁸ ESRD is defined as a decline in kidney function to less than 10% of normal capacity. This decline in function is measured in glomerular filtration rate (GFR).¹⁰ A GFR of less than 15% of normal capacity requires the patient to undergo chronic renal replacement therapy in the form of dialysis in order to adequately maintain fluid volumes, provide elimination of nitrogenous waste products, and maintain both plasma pH levels and production of erythropoietin.

ESRD has a significant impact on other organ systems, including the cardiac, cerebral, and peripheral vascular systems, as well as the gastrointestinal, hematologic, and central nervous systems. Careful preoperative assessment is crucial in patients with ESRD who are to undergo a surgical procedure requiring anesthesia, especially renal transplantation. [Table 41.1](#) lists the classifications and stages of chronic kidney disease.

TABLE 41.1

Classification and Staging of Chronic Kidney Disease (CKD) by the National Kidney Foundation*

Stage	Description	GFR (mL/min per 1.73 m ²)
1	Kidney damage with normal or ↑ GFR	≥ 90
2	Kidney damage with mild ↓ GFR	60–89
3	Moderate ↓ GFR	30–59
4	Severe ↓ GFR	15–29
5	Kidney failure	< 15 or dialysis

*This widely adopted classification required evidence of kidney damage (such as increased proteinuria) above a glomerular filtration rate (GFR) level of 60 mL/min per 1.73 m² for the diagnosis of CKD but not below this threshold. *Chronic kidney disease* is defined as either kidney damage or GFR < 60 mL/min per 1.73 m² for ≥ 3 months. *Kidney damage* is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine test results, or imaging studies.

From Hsu RK, Hsu CY. Epidemiology of kidney disease. In Skorecki K, et al., eds. *Brenner and Rector's The Kidney*. Philadelphia: Elsevier; 2016:643.

Preoperative Considerations for Renal Transplantation

Thorough preoperative evaluation is crucial in patients awaiting renal transplantation. Prior to transplantation, the patient will undergo a thorough, multidisciplinary evaluation to determine their eligibility for organ transplantation. The average time a patient is on the waiting list for a kidney is greater than 3 years; therefore careful medical management of their comorbidities, including hemodialysis, is crucial to their overall survival and bridge to transplantation.¹¹ Cardiovascular disease is a major factor in patients with ESRD. It can be manifested by ischemic heart

disease (which may be silent, especially in diabetic patients), as well as congestive heart failure and chronic anemia. Congestive heart failure is most often caused by ischemic heart disease and is prevalent in approximately one quarter of cases of chronic kidney disease.¹² Other significant sequelae include hyperlipidemia, peripheral vascular disease, hyperphosphatemia, and hyperkalemia. Preoperative optimization should focus on medical management of heart failure, as well as fluid and electrolyte abnormalities. Assessment of the patient's exercise tolerance and metabolic equivalent is also important. A baseline electrocardiogram (EKG) is an appropriate screening test for a patient who is scheduled to undergo kidney transplantation. Echocardiography may also be helpful to delineate specific cardiovascular abnormalities and assess the patient's ejection fraction and underlying heart rhythm. Ejection fraction is often affected due to heart failure and may improve after transplantation. A detailed cardiac exam should include the potential for coronary angiography and stress echocardiography, especially in those patients with a history of reversible ischemia and those patients who are deemed to be at high risk.¹¹

Chronic anemia is a common occurrence in end-stage renal patients who are awaiting transplant. This is related to decreased erythropoietin production and hemolysis. The heart increases cardiac output to compensate for the anemia, which decreases oxygen carrying capacity and can cause ischemia.¹³ It is not uncommon for end-stage renal patients to have hemoglobin levels in the 5–8 g/dL range. Administration of erythropoietin has the potential to increase the patient's hemoglobin levels over a period. Depending on the surgery and condition of the patient, blood transfusion with packed red blood cells (RBCs) may be warranted. Coagulopathies are also prevalent in this patient population due to a decrease in platelet adhesion. Treatment with desmopressin (DDAVP) or cryoprecipitate may be beneficial.

Electrolyte abnormalities are very common in patients with renal insufficiency and can lead to many untoward effects. These abnormalities can be of significant concern during transplant surgery. Hyperphosphatemia is common and is associated with hypocalcemia. This is caused by decreased calcium absorption due

to the inability to activate vitamin D and can put the patient at risk for pathological fractures. Care should be taken when positioning the patient for intubation and surgery. Hyperkalemia is the most hazardous electrolyte complication. Elevated potassium levels are common in end-stage renal patients, and dialysis is often needed to maintain the potassium levels in a safe range for the patient. Potassium levels of 5.0 to 5.5 mEq/L are generally considered acceptable in this patient population. Assessment of the patient's preoperative labs and review of their medication regimen and dialysis schedule is very important in the preoperative phase. Dialysis in the immediate preoperative phase may be beneficial prior to transplantation to ensure electrolyte levels are within the patient's homeostatic range; however, this may lead to decreased intravascular volume, as well as other volume-related concerns intraoperatively. A summary of the kidney transplant candidates' **Box 41.1** comorbidities and associated conditions are listed in **Box 41.1**.

Kidney Transplant Candidates: Comorbidities and Associated Conditions

- Coronary artery disease
- Diabetes mellitus
- Hypertension
- Vascular disease
- Cardiorenal syndrome
- Anemia
- Fluid and electrolyte disturbances

From Findlay JY. Patient selection and preoperative evaluation for transplant surgery. *Anesthesiol Clin.* 2013;31(4):689–704.

Intraoperative Considerations for Renal Transplantation

Although there is an extensive assessment in the preoperative phase, once the patient is on the transplant list and a match is confirmed via the donor match system, the process speeds up extensively. Cadaveric donation is one method of organ donation in which the organ is procured from the donor via the DBD or DCD method described previously. Once the organ is procured, there is an urgency to implant the kidney as soon as possible. The cadaveric organ can only sustain viability with cold ischemia for a short period.

Another type of organ donation is where a living donor provides an organ to a matched recipient. This occurs more frequently with a family member or friend who is determined to be a match and offers to provide an organ, such as a kidney, to a recipient in need. In this setting, the donor will undergo general anesthesia and the organ will be procured by the transplant team. Once this process is underway, the potential recipient will undergo general anesthesia in an adjacent room. The transplanted organ is generally placed in the right or left extraperitoneal fossa. The right side is generally most preferred.⁷ The transplanted kidney is attached to the recipient's vasculature via vascular anastomoses of the external iliac artery and vein, and the ureter is anastomosed directly to the bladder¹¹ (Fig. 41.2).

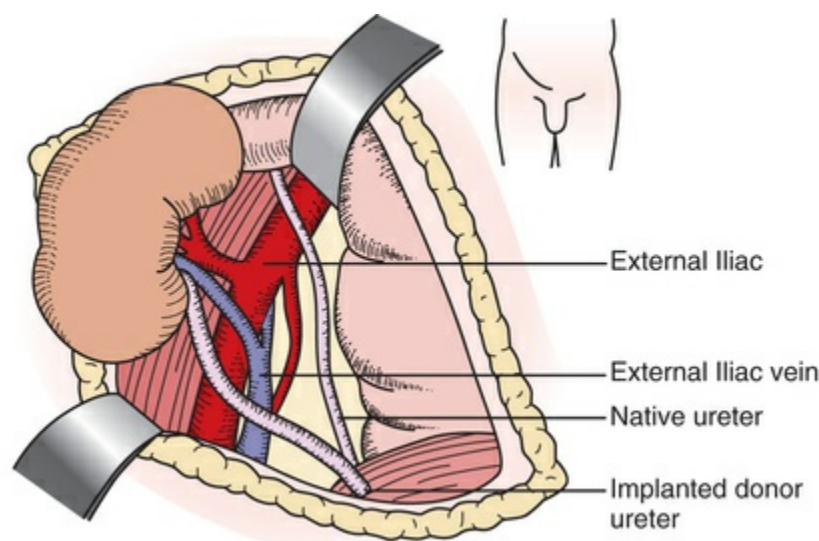

FIGURE 41.2 Anatomy of a typical first kidney transplant.

(From Skorecki K, et al. *Brenner and Rector's The Kidney*. 10th ed.

Philadelphia: Elsevier; 2016: 2252.)

General anesthesia with endotracheal intubation is the most common anesthetic method for kidney transplant surgery. The goals of the anesthetic include providing an appropriate depth of anesthesia and muscle relaxation to optimize the surgical conditions for the surgeon while maintaining hemodynamic stability. Patients with ESRD are at risk for aspiration due to gastroparesis, and care should be taken during induction to intubate the patient safely and effectively. Succinylcholine may be administered in this patient population, but care must be taken to ensure that potassium levels are within normal limits. Rocuronium may also be utilized for a rapid-sequence induction if hyperkalemia is a concern. Rocuronium is primarily excreted by the biliary system, and secondary metabolism is through the renal system. Cisatracurium is an intermediate-acting muscle relaxant that is metabolized through Hofmann elimination. It produces the metabolite laudanosine, which is partially eliminated through the kidneys. The duration of action may be slightly prolonged in renal patients; however, it is generally considered the muscle relaxant of choice in patients with ESRD.¹⁴ Longer-acting neuromuscular blocking drugs such as pancuronium should be avoided. Careful monitoring of neuromuscular blockade is important to ensure both an appropriate level and that the patient can be adequately reversed at the end of the case.

Standard, noninvasive intraoperative monitoring may be adequate for young, healthier transplant recipients. Arterial blood pressure monitoring may be useful in patients with known coronary artery disease (CAD) and uncontrolled hypertension. Central venous pressure (CVP) monitoring is also beneficial in situations where assessment of CVP is indicated. Many transplant recipients require a central line because of the administration of immunosuppressive and vasoactive medications. In some circumstances, pulmonary artery catheter (PAC) and/or transesophageal echocardiography may be useful in situations where heart failure and pulmonary hypertension are present. Large bore peripheral IVs are necessary to ensure the ability to administer adequate volume replacement, including blood transfusion(s) when necessary. This can prove difficult in this patient population due to the presence of one or more arteriovenous fistulas and the potential

for venous thrombosis.

Induction of anesthesia can be carried out safely and effectively in this patient population with propofol. The pharmacokinetics and pharmacodynamics of propofol are unchanged in end-stage renal patients, and it is primarily metabolized in the liver.¹³

Maintenance of anesthesia is generally a combination of volatile inhalational gas and intravenous anesthetics. Volatile anesthetics are titrated to provide an adequate level of anesthesia, and a combination of analgesics and neuromuscular blocking agents can assist with providing an optimal surgical environment. All inhalational anesthetics can be titrated appropriately to provide an optimal surgical environment. They all cause a dose-dependent reduction in renal blood flow and GFR. Desflurane, isoflurane, and sevoflurane are all safe to use in this patient population. It has not been shown to cause renal dysfunction in humans. Conzen et al.¹⁵ showed that low-flow sevoflurane was a safe and effective agent and did not cause any nephrotoxic effects in patients with preexisting renal dysfunction.

Pain management is an important part of transplant surgery. Analgesic medication should be used with caution in the perioperative period in patients with ESRD due to the potential for accumulation of their active metabolites. The effect of morphine is known to be prolonged in end-stage renal patients because of its metabolite, morphine-6-glucuronide. This can have negative untoward effects; therefore careful titration is necessary.¹⁶ Meperidine should also be used with caution due to its metabolite, normeperidine. Repeated doses of meperidine have been associated with seizures, and therefore its use should be carefully considered.¹⁷ Other intraoperative pharmacological considerations include the use of intravenous fluids. Maintenance of intravascular volume is vital to the performance and perfusion of the transplanted kidney. Fluids such as lactated Ringer's are generally avoided due to the presence of potassium in that solution. More often PlasmaLyte and normal saline are used, but care should be taken to avoid the development of a hyperchloremic metabolic acidosis from the administration of too much normal saline. This can ultimately cause worsening hyperkalemia.¹³ Judicious use of colloids such as albumin can be helpful in maintaining intravascular fluid volume

while avoiding a worsening acidosis related to normal saline. Vasoactive agents and other medications may be used to increase renal blood flow and urine output. Dopamine, dobutamine, and fenoldopam may be used intraoperatively to increase renal blood flow. Osmotic and loop diuretics have also been shown to increase kidney function once reperfusion is complete.¹³ Mannitol and Lasix may be administered to assist with osmotic diuresis and should be on hand if requested. Anesthetic considerations for renal transplantation are noted in [Box 41.2](#).

Anesthesia for Renal Transplantation

I. Preoperative Assessment and Preparation

A. Clinical evaluation

1. Evaluate status of coexisting diseases.
 - a. Diabetes mellitus
 - b. Hypertension
 - c. Cardiac disease
 - d. Hyperparathyroidism
 - e. Pericardial tamponade
2. Perform dialysis within 24 hr of transplantation; check weight.
3. Evaluate tolerance to chronic anemia.

B. Laboratory evaluation

1. Complete blood count with platelet count
 2. Prothrombin time, partial thromboplastin time, bleeding time
 3. Blood urea nitrogen, creatinine, calcium, fluid balance
 4. Electrocardiography; chest radiography
- C. Type and cross-match 2 units of washed, packed red blood cells
- D. Determine current drug regimen
- E. Premedication
1. Benzodiazepines, narcotics
 2. Antacids, histamine-2 antagonist, metoclopramide
- II. Monitors
- A. Electrocardiography
 - B. Indirect or direct blood pressure measurement
 - C. Precordial, esophageal stethoscope
 - D. Neuromuscular blockade evaluation

E. Foley catheter

F. Central venous, transesophageal echocardiography, pulmonary capillary wedge pressure measurement, if required

III. Anesthetic Management

A. Regional techniques

1. Continuous spinal or epidural

2. Advantages

a. No need for muscle relaxants

b. Potential respiratory tract infection from intubation is avoided

c. Amount of local anesthetic required is small

d. Patients awake and comfortable postoperatively

3. Disadvantages

a. Patient anxiety

b. Uncomfortable surgical positions, especially for donor

c. Coagulation abnormalities present

- d. Fluid management with sympathetic blockade a challenge
- e. Unprotected airway in patients with delayed gastric emptying

B. General anesthesia

1. Induction with propofol or etomidate
2. Maintenance with volatile anesthetic (isoflurane, sevoflurane, or desflurane) or narcotic-based technique
3. Neuromuscular blockers
 - a. Succinylcholine
 - b. Cisatracurium
 - c. Rocuronium

IV. Miscellaneous Drugs

- A. Mannitol or furosemide
- B. Dopamine
- C. Calcium channel blockers
- D. Prednisone or methylprednisolone

E. Patient specific immunosuppressant therapy

Immunosuppressive Therapy

The vast majority of kidney transplant recipients in the United States are maintained on tacrolimus and mycophenolate mofetil (MMF), with approximately two thirds of patients also treated with maintenance steroids. The greatest source of intraprogram variability in an immunosuppressive regimen is the choice of induction therapy and patient selection for and method of steroid withdrawal. When deciding on a regimen for a given recipient, the following factors are taken into consideration: (1) the patient's immunologic risk; (2) the baseline quality of the allograft; and (3) the anticipated vulnerability profile to specific side effects of immunosuppression. Familiarization with local challenges (e.g., regional distribution of patient risk factors, organ attribution scheme) is essential for successful optimization of immunosuppression protocols for any given patient.¹⁸

The specifics of the therapy are generally practice and institutionally driven. Many institutions have protocols that are used to help guide the anesthetist regarding the specific immunotherapy agents for that particular case. There are two major regimens that are used: the more conventional high-dose regimen or the antibody induction regimen. The conventional regimen consists of either cyclosporine or tacrolimus, both of which are calcineurin inhibitors. These agents are utilized as prophylactic agents to prevent organ rejection. These agents must be administered concurrently with a corticosteroid and an antimetabolite agent such as MMF or azathioprine. The antibody induction regimen uses lower doses of these conventional medications, but includes an antibody that is directed at T-cell antigens and antilymphocytic antibodies. These agents include Thymoglobulin, alemtuzumab, and OKT3. Other antibody induction agents work on interleukin-2 receptor antagonists such as basiliximab (Simulect) or daclizumab (Zenapax). Studies have shown the antibody induction regimen to have better outcomes in terms of reduced graft rejection.¹³ It should be noted that induction of immunosuppression should begin with administration of the

corticosteroid and then an antilymphocyte immediately prior to reperfusion of the donated kidney. The common drugs used for immunosuppression and their mechanisms are listed in [Table 41.2](#).

TABLE 41.2

Mechanisms of Action of Immunosuppressants

Immunosuppressant	Mechanism of Action	Interferes With
Glucocorticoids	Reduce transcription of cytokine genes	Intercellular signaling
Azathioprine	Inhibits purine synthesis	Lymphocyte proliferation
Mycophenolate mofetil	Inhibits purine synthesis	Lymphocyte proliferation
Sirolimus	Inhibits cell cycle progression	Lymphocyte proliferation
Everolimus	Inhibits cell cycle progression	Lymphocyte proliferation
Tacrolimus	Inhibits calcineurin and IL-2 production	Intracellular signaling
Cyclosporine	Inhibits calcineurin and IL-2 production	Intracellular signaling
Rabbit antithymocyte globulin	Depletes T lymphocytes	Antigen recognition
Alemtuzumab (off label)	Depletes T and B lymphocytes	Antigen recognition and antibody production
Rituximab (off label)	Depletes B lymphocytes	Antibody production
Bortezomib (off label)	Proteasome inhibitor	Antibody production
Basiliximab	Blocks IL-2 receptor	Intercellular signaling
Belatacept	Costimulation blockade	Lymphocyte activation
Eculizumab (off label)	Complement inhibitor	Antibody-mediated rejection

IL-2, Interleukin-2.

From Gritsch HA, Blumberg JM. Renal Transplantation. In Wein AJ, et al., eds. *Campbell-Walsh Urology*. 11th ed. Philadelphia: Elsevier; 2016:1069–1088.

Postoperative Considerations for Renal Transplantation

After completion of the surgery and extubation, the patient will be monitored closely in the immediate postoperative period. Careful monitoring of the patient's hemodynamic parameters to include blood pressure and heart rate along with urine output is very important, and any acute changes in urine output should be evaluated to delineate the etiology and appropriate treatment. Aggressive fluid therapy should be initiated if the decreased urine output is deemed to be related to a prerenal etiology. Because of the reimplantation and surgical anastomosis of the ureter during transplantation, a kink in the ureter or other technical problem may

be the cause of a postrenal etiology of diminished urine output and may require surgical exploration and treatment. Intensive care unit (ICU) admissions in renal transplant patients are generally quite low. In a 10-year cohort study, Klouche et al. found the ICU admission rate was 6% in a single center where 1015 kidney transplants were performed.¹⁹ Other postoperative complications include wound infection, wound hematomas, and vascular thrombosis. Cardiac and respiratory complications are also possible, especially in higher risk patients with preexisting cardiac and respiratory comorbidities. [Box 41.3](#) notes some precautions when performing procedures and surgery in patients who have a [Box 41.3](#) kidney transplant.

Precautions for Procedures and Surgery in Kidney Transplant Recipients

- Caution with radiocontrast exposure.
- Maintain hydration.
- Avoid nephrotoxic antibiotics and analgesic.
- “Stress-dose steroids” not always necessary.
- If enteral route of medication is contraindicated, give CNI via IV rout (1/3 total oral dose).
- Monitor allograft function, plasma potassium, and acid-base balance daily.
- Consider wound-healing impairment.

CNI, Calcineurin inhibitor; IV, intravenous.

From Lenihan CR, et al. *Brenner and Rector's The Kidney*. 9th ed. Philadelphia: Elsevier; 2016:2290.

Postoperative Pain Control

Pain management is highly variable and patient specific. The pain associated with kidney transplantation may be severe and very

challenging in the immediate postoperative period. Most often, pain control is achieved by IV opioid analgesics via patient-controlled analgesia (PCA). Multimodal therapy may be beneficial, especially in patients with chronic pain history, and can include an IV ketamine and Ofirmev injection, and the addition of a transversus abdominis plane block prior to incision.⁷ The use of thoracic epidurals for postoperative pain management is controversial due to the risk of coagulopathies and postoperative hypotension. Use of epidural anesthesia should be considered carefully and used sparingly.

Pancreas Transplantation

Transplantation of the pancreas is a definitive treatment for patients with type I diabetes mellitus. Type I diabetics do not have the endogenous insulin required to sustain life. This is due to a variety of factors, including destruction of the pancreatic cells of the islets of Langerhans. Type II diabetics may also need pancreatic transplantation due to the severity of their disease. The pathophysiology of type II diabetes is based on resistance to the effects of insulin within the body. The end results of both type I and type II diabetes are chronic increased blood glucose concentrations and multisystem organ complications. Complications and multisystem effects of diabetes have a profound impact on the vascular system. It is widely known that diabetes plays a significant role in the development of atherosclerosis, CAD, and peripheral vascular disease (both at the microvascular and macrovascular levels). Diabetics are also prone to neuropathies of the peripheral and autonomic system that can cause paresthesias, gastroparesis, and other complications. Diabetic patients receive medical therapy during their wait for a transplant. This therapy includes oral hypoglycemic agents, insulin, or both, along with a prescribed exercise and weight loss program and strict dietary guidelines. The acute risks of diabetes manifest in conditions associated with extreme hyperglycemia. Diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic coma are severe complications of acute hyperglycemia, are associated with electrolyte abnormalities, and may be life-threatening. Unfortunately, many patients who receive maximum medical therapy are still subject to uncontrolled diabetes and the risks associated with the disease. Early identification and management of diabetes is vital to an enhanced quality of life. Identification of uncontrolled diabetes and the need for transplant is an important step. Once a patient is identified, they go through the process of placement on the transplant list. The overall waiting list for pancreas transplant saw a steady decline between 2003 and 2013 but rose slightly again in 2014. The rationale for the overall decline during that time was related to enhancements in surgical techniques and improvements in immunological therapies.²⁰

Pancreas transplantation provides patients with an endogenous source of insulin that will restore normoglycemic conditions. There are several types of pancreas transplants, including pancreas alone (PTA), simultaneous pancreas and kidney (SPK), and pancreas after kidney (PAK). These are performed based on the needs of the patients and the allocation of the organs. There have been several key developments related to pancreas transplantation since 2014. A new organ allocation system specific to the pancreas was instituted in October 2014. This allowed a more streamlined process that combined all type of pancreas transplant types onto one waiting list. Other key developments included revision of the criteria for type II diabetics relating to body mass index (BMI) and the development of a consistent definition relating to pancreas graft failure.²⁰

Most often the whole pancreas is transplanted into the recipient from a deceased donor. Occasionally a living donor may donate the distal pancreas for transplantation, but that is less common.⁷ Alternative therapies are evolving to include transplantation of islet cells and the development of an artificial pancreas.²⁰

Overall the outcomes of pancreas transplantation are very good. The 5-year patient survival rate for PTA is 78%, for SPK it is 93%, and it is 91% for PAK.¹⁹

Preoperative Considerations for Pancreas Transplant

As with any other type of transplant, the preoperative considerations for a patient who is to undergo a pancreas transplant starts with a thorough review of their history and physical exam. Understanding the patient's diabetic history and reviewing their comorbidities should be a top priority. This evaluation often includes a multidisciplinary team that reviews all aspects of the patient's condition to assess the extent of multisystem organ involvement. Due to the known risk of increase micro- and macrovascular disease, a cardiac assessment should include assessment of the patient's exercise tolerance, as well as a 12-lead EKG to assess for previous myocardial infarction that may have gone undetected in the diabetic patient. Cardiac ischemia may be

difficult to assess in this patient population due to the presence of neuropathies and silent ischemia. If CAD is suspected, a more thorough evaluation including stress testing or coronary angiogram should be considered. This may be performed during the assessment for placement on the transplant waiting list.

Pancreas transplant surgery is considered an urgent procedure, so the preoperative evaluation should focus on optimizing the patient's current status and assessing for any acute conditions that may impact the procedure. These can include the presence of ketoacidosis, electrolyte abnormalities, alterations in blood pressure, and volume status. Most often a pancreas transplant involves procurement of the organ from a deceased organ donor and therefore there is a need to transplant the organ as soon as possible and within the 24-hour window for maximum cold ischemia time.

Close assessment of blood glucose measurements is important during the perioperative period, along with evaluation of the patient's insulin regimen and recent administration. Evaluation of fluid and electrolytes is also important to assess for renal function. Volume status is very important, especially if the patient has a history of ESRD and requires hemodialysis.

Immunosuppressive protocols for pancreas transplantation follow patterns similar to other solid organ transplants. Pancreas transplant recipients are believed to require higher levels of immunosuppression, possibly related to the increased immunogenicity of the composite pancreaticoduodenal graft, and/or underlying autoimmune status of the recipient. Currently, most centers use induction therapy with a T-cell-depleting antibody, such as antithymocyte globulin or alemtuzumab, or less often, an interleukin-2 receptor blocking antibody such as basiliximab. For maintenance therapy, more than 80% of pancreas transplant recipients receive tacrolimus and MMF. Glucocorticoids are used in more than 60% of recipients. The standard regimen of antibody induction and maintenance with tacrolimus and MMF, with or without glucocorticoids, has ushered in an era of routine success in pancreas transplantation, with 1-year pancreas allograft survival near or exceeding 90%. Due to growing concern about the negative effects of steroids on β cells and the success of the

Edmonton protocol for islet transplantation reported in 2000, the use of steroid-free regimens has now reached approximately 40% of the transplants. In addition to providing protection against alloimmune rejection and recurrent autoimmunity, modern dosing of tacrolimus-based regimens is not toxic to islet β cells, as evidenced by normal β -cell secretory capacity in pancreas transplant recipients.²¹

Intraoperative Considerations for Pancreas Transplant

Pancreatic transplantation is performed under general anesthesia with endotracheal intubation and muscle relaxation. This holds true for all types of pancreas transplantation, including combined kidney and pancreas transplant. A combination of volatile anesthetic and narcotic agents works well in this patient population. Standard American Society of Anesthesiologists (ASA) monitoring is required and invasive monitoring is often used and may be required, especially in patients where CAD is present and/or when closer hemodynamic monitoring is indicated. Advantages to invasive monitoring with an arterial line includes beat by beat blood pressure monitoring, as well as the ability to monitor arterial blood gases (ABGs), electrolytes, and blood glucose levels in an efficient manner. Placement of an arterial line prior to induction may assist in hemodynamic monitoring during the induction phase. Care should be taken during induction of anesthesia to prevent hypotension. A rapid sequence induction should be considered due to the potential presence of gastroparesis and risk for aspiration during intubation. Administration of an oral nonparticulate antacid may also be considered in the immediate preoperative period. Adequate venous access is always a priority due to volume replacement and the potential for acute blood loss. A central line may also be necessary for administration of immunosuppressive and vasoactive medications.

A midline surgical incision is utilized for pancreas transplants, as well as for combined kidney/pancreas transplants. As with other abdominal surgeries, the use of retraction is necessary to facilitate an optimal working environment for our surgical colleagues, and

therefore muscle relaxation should be utilized to optimize that environment. The transplanted pancreas is placed in the iliac fossa and arterial anastomosis is via the iliac artery and venous anastomosis is via the iliac vein (Fig. 41.3). During the surgery, blood glucose levels should be monitored at least every hour to ensure that blood glucose levels are maintained at less than 200 mg/dL. Medications such as insulin, administered via subcutaneous route or intravenous infusion may be necessary; a dextrose infusion may be needed if hypoglycemia occurs. Dextrose infusion may prevent the development of ketoacidosis and should be available throughout the procedure.⁷ Volume replacement should be a priority, especially prior to unclamping the vascular anastomosis. Close hemodynamic monitoring is necessary during this time in order to prevent hypotension. During the reperfusion phase of the transplanted pancreas, it is imperative that blood glucose levels be monitored more frequently (every 15–30 minutes). This is due to the new pancreas releasing insulin within the circulation and for the prevention of hypoglycemia. Insulin infusions should also be weaned accordingly as the blood glucose normalizes. In some circumstances there may be a delay in the transplanted organ producing sufficient insulin. In these circumstances, the goal should be to maintain blood glucose levels less than 200 mg/dL; some of the literature even recommends keeping it in the 120 to 150 mg/dL range.^{7,22} Tight glycemic control is required to reduce hyperglycemia, but also to decrease stress on the newly transplanted β cells.

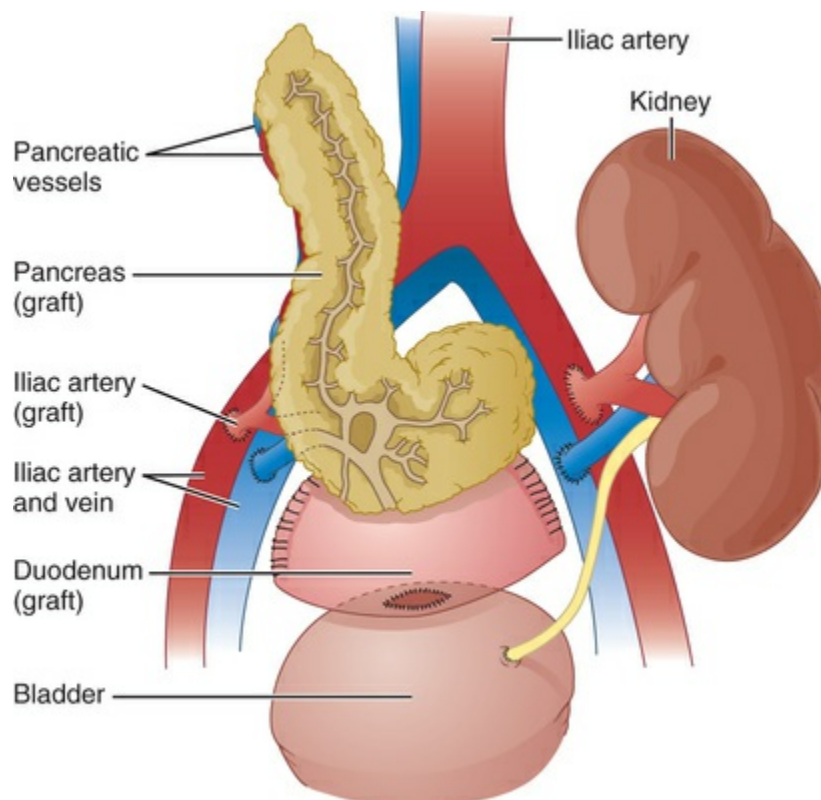

FIGURE 41.3 Simultaneous kidney and pancreas transplant. (From Good VS, Kirkwood PL. *Advanced Critical Care Nursing*. 2nd ed. St. Louis: Elsevier; 2018.)

Postoperative Considerations for Pancreas Transplant

Upon completion of pancreas transplantation, the patient is often extubated and transported to the post anesthesia care unit (PACU) or ICU. Regardless of the patient's postoperative disposition, they require vigilant postoperative monitoring. Frequent blood glucose monitoring, along with electrolytes and ABGs, is an essential component of the early postoperative period. Fluid therapy should be maintained with a goal for euvolemia. Monitoring the patient's hemoglobin and hematocrit may also be required. Pain control is another essential component of care in the immediate postoperative period. Multimodal IV analgesia works well for controlling the patient's pain, and transitioning them to a PCA pump is beneficial in the early postoperative period. Some institutions may use epidural analgesia for their transplant patients. Care should be taken to avoid hypotension associated with epidural infusions.

Monitoring for graft complications is important in the early postoperative period. Early graft failure rates have decreased from 12.8% in 2005–2006 to 8.2% in 2013–2014.⁷ Other complications can include intraabdominal bleeding, graft thrombosis, sepsis, and ultimately, graft rejection. Anesthetic care of patients post pancreas transplant include reviewing the patient's transplant history and posttransplant care and complications if any. Close assessment of the patient's blood glucose should be performed. Other preoperative assessments should be made based on the overall condition of the patient and any other comorbidities that may be present.

Judging efficacy of immunosuppression regimens is more difficult with pancreas transplants than for other solid organ transplants such as liver or kidney, where functional tests are readily available. For SKP transplants, rejection of the pancreas may be followed using kidney function as a surrogate marker. Detection of rejection is more difficult for PAK and PTA procedures, and bladder drainage, which allowed monitoring amylase output, has fallen out of favor. Some centers have found percutaneous biopsies to be more valuable than ultrasound evaluation or measurement of circulating amylase and lipase.²¹

Liver Transplantation

The first successful liver transplant was performed in 1967. Limited amounts of liver transplants were performed in the 1970s; however, survival remained below 20%. The advent of immunosuppressive therapy, particularly the drug cyclosporine in the early 1980s, improved liver transplant survival to over 50% 1-year posttransplant and eventually lead to the adaptation of liver transplant as a viable solution for end-stage liver disease (ESLD) worldwide. Currently 1-year survival data has climbed as high as 85% to 90%, with 5-year survival approximately 70% to 75%.²³ As with other organ transplants, the limiting factor for the overall number of liver transplantations performed is the wide disparity between available donors and patients needing transplant.²⁴ According to UNOS, 140,580 liver transplants were performed between 1988 and the beginning of 2016. As of 2016, there are 14,710 patients awaiting liver transplantation in the United States. This is in sharp contrast to the 7127 transplants performed during 2015.²⁵ Despite the progressive escalation in the severity of liver disease in recipients, graft survival continues to improve.²⁶ In order to increase the number of viable grafts for transplant into recipients, there has been increased discussion and experimentation with alternative organ donation efforts from the general heart-beating brain-dead donor. Some of these methods include using candidates that were previously considered marginal donors, such as non-heart-beating donors who have been infiltrated with a cold preservation solution via the femoral artery following cardiac standstill; extracorporeal membrane oxygenation (ECMO) support to facilitate organ perfusion after cardiac death; ex vivo perfusion of viable organs after cardiac death; and utilizing a split liver graft. Living donor liver transplantation has also been successfully performed utilizing a partial hepatectomy in place of a cadaveric liver. The liver is unique in that it can regenerate itself even after a large section is removed. In a healthy donor, up to 70% of the liver can be removed with the remaining section sufficiently functional to meet the metabolic needs of the donor. Benefits of living donor liver transplant include a shortened waiting period for recipients,

elective nature of the surgery, high quality graft as it is procured from a healthy donor with stable hemodynamics, and a very short cold/ischemic time is possible due to the planned nature of the case. A major factor that must be considered is the impact on the donor from the viewpoint that it is a major abdominal surgery with no personal benefit.²⁴ Due to the concerns for complications with the donor, very few living donor liver transplants are performed, approximately 300 per year.

Liver transplantation is the sole definitive treatment modality for patients with acute liver failure, ESLD, and primary hepatic malignancy. The etiology of ESLD can be categorized into 7 primary categories as noted in Table 41.3. The indications for liver transplantation are listed in Table 41.4.

TABLE 41.3
Chronic End-Stage Liver Disease: Etiologies

Category	Disease	Frequency
Hepatitis	(Hepatitis A)	Never chronic
	Hepatitis B	10% to 15%
	Hepatitis C	40%
Noncholestatic	Laennec cirrhosis	
	Cryptogenic cirrhosis	
	Autoimmune hepatitis	
Cholestatic	Primary sclerosing cholangitis	
	Primary biliary cirrhosis	
Metabolic	Hemochromatosis	
	Wilson disease	
	α_1 -Antitrypsin deficiency	
Malignancies	Hepatocellular carcinoma	Adults
	Hepatoblastoma	Children
	Cholangiocarcinoma	Investigational
	Carcinoid/neuroendocrine	Rare
	Hemangioendothelioma Hemangiosarcoma	Rare
Atresia: children	Biliary atresia	50%
Others	Budd-Chiari	Rare
	Cystic fibrosis	
	Congenital hepatic fibrosis	
	Benign tumors

TABLE 41.4

Indications for Liver Transplantation

Indications	Examples
Acute hepatic necrosis	Viral hepatitis, drug toxicity, toxin, Wilson disease
Chronic hepatitis	Hepatitis B, hepatitis C, hepatitis D, autoimmune hepatitis, chronic drug toxicity or toxin exposure, cryptogenic cirrhosis
Cholestatic diseases	Primary biliary cirrhosis, sclerosing cholangitis, secondary biliary cirrhosis, biliary atresia, cystic fibrosis
Alcoholic cirrhosis	May be considered for transplant if abstinence of alcohol for 6 months and ongoing therapy and evaluation
Metabolic diseases	Wilson disease, cystic fibrosis hemochromatosis, α_1 -antitrypsin deficiency, familial homozygous hypercholesterolemia, glycogen storage disease, tyrosinemia
Malignant diseases of the liver	Hepatocellular carcinoma, carcinoid tumor, islet cell tumor, epithelioid hemangioendothelioma
Chronic Symptoms	Progressive hyperbilirubinemia, portal hypertension as evidenced by bleeding from esophageal or gastric varices, hypersplenism with thrombocytopenia, disabling portosystemic or hepatic encephalopathy, coagulation disorders, generalized wasting and failure to thrive
Acute Symptoms	Acute liver failure, rapid decline in liver function, coagulopathy, jaundice, encephalopathy

Acute liver failure is defined as the development of severe acute liver injury with encephalopathy and impaired synthetic function (international normalized ratio [INR] > 1.5) in the absence of preexisting liver disease or cirrhosis. These patients are given the highest priority for liver transplantation (UNOS status 1). Without transplantation, patients with acute liver failure will have either a complete recovery of function or die within days. These patients should be transferred to a liver transplant center as quickly as possible. Patients suffering from cirrhosis are not immediate candidates for liver transplant. However, the development of decompensation as evidenced by ascites, hepatic encephalopathy, and variceal bleeding are indications of significantly impaired survival and should lead to the patient being worked up for the transplant waiting list. The development of hepatorenal syndrome is an ominous sign and signals the need for immediate transplantation evaluation. The Model for End Stage Liver Disease score, or MELD, is a validated system that UNOS uses for prioritizing patients on the liver transplant waiting list.²⁷ Table 41.5 explains the MELD score. Although the most important aspect of successful organ donation is ABO compatibility, the MELD score is utilized to determine which patients have the greatest need for transplantation. There is some debate to its effectiveness and some

modifications have been proposed; it is utilized widely by transplant centers and UNOS for recipient-donor matching. The MELD is a validated system that uses serum total bilirubin, serum creatinine, and the INR values to mathematically rank adult patients according to their expected survival rate without transplantation. Variations of the MELD score include the MELD sodium and MELD lactate.²⁷ There are many limitations to the MELD score that transplant centers are aware of; for instance, patients suffering from primary hepatocellular carcinoma may not have any, or minimal, increased markers measured by the MELD. Without a transplant these patients face the risk of fulminant liver failure and metastasis that would preclude them from future transplant due to metastatic disease. In order to amend the MELD score for patients with conditions such as this, there are exception points. These are utilized to increase the MELD score for patients with conditions associated with chronic liver disease that may result in impaired survival but not directly accounted for in the MELD scoring system. These include hepatocellular carcinoma, hepatopulmonary syndrome (HPS), portopulmonary hypertension (must maintain mean arterial pressure [MAP] <35 mm Hg with treatment), familial amyloid polyneuropathy, primary hyperoxaluria, cystic fibrosis, hilar cholangiocarcinoma, and hepatic artery thrombosis (if within an appropriate time frame before transplant). Each transplant center has varying protocols for how to deal with these patients that do not conform to the MELD measurements. Other complicating conditions that could be related to a patient's liver disease that are not covered by official MELD exceptions points include recurrent cholangitis in patients with primary sclerosing cholangitis that is refractory to antibiotic therapy or needing repeated biliary interventions; refractory ascites; refractory hepatic encephalopathy; refractory variceal hemorrhages; and portal hypertensive gastropathy with chronic blood loss, among others. Each center has a protocol for dealing with patients of unique medical histories and prioritizing them on a case-by-case basis. Contraindications for a potential recipient to be listed for liver transplantation are often center-specific. A generally accepted list of contraindications at most centers include²⁸:

TABLE 41.5**Three-Month Mortality According to MELD Score***

MELD Score	9 or Less	10–19	20–29	30–39	≥ 40
In hospital	4%	27%	76%	83%	100%
Outpatient	2%	6%	50%		

*The MELD score: $10 \times (0.957 \times \log_e [\text{creatinine}] + \log_e [\text{bilirubin}] + 1.12 \times \log_e [\text{INR}])$.

MELD, Model for End-Stage Liver Disease.

- Cardiopulmonary disease that is uncorrectable
- AIDS
- Untreated tuberculosis
- Malignancy not isolated to the liver that does not meet oncologic criteria for cure
- Hepatocellular carcinoma with metastatic spread
- Intrahepatic cholangiocarcinoma
- Hemangiosarcoma
- Anatomic abnormalities that preclude transplantation
- Uncontrolled sepsis
- Acute liver failure with intracranial pressure (ICP) > 50 or cerebral perfusion pressure (CPP) < 40
- Nonadherence to medical care
- Lack of social support system

Some relative contraindications include advanced age and HIV (not AIDS), however there have been successful transplants in patients over 65 with appropriate evaluation of comorbid complicating factors.²⁹ Another factor that is very prevalent in the United States is class 3 obesity (BMI > 40); many centers consider it a relative contraindication. However, patients will be encouraged to lose weight prior to transplantation and some centers will even perform a gastric sleeve in an effort to optimize the potential recipient.²⁸ It is important to remember that these are generalities and each liver transplant center will vary in what is and is not considered a contraindication. Patients who have a general contraindication are often assessed on a case-by-case basis to

determine their appropriateness for transplant. The etiology of **Box 41.4** liver problems is noted in **Box 41.4**.

Etiology of Liver Problems

- Chronic viral hepatitis: B and C
- Hepatocellular cancer
- Alcohol
- Nonalcoholic fatty liver disease
- Autoimmune: autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis
- Hemochromatosis
- Drugs (methotrexate, amiodarone, acetaminophen)
- Cystic fibrosis, α_1 -antitrypsin deficiency, Wilson disease
- Vascular problems (portal hypertension with or without liver disease)
- Cryptogenic
- Others: sarcoidosis, amyloidosis, schistosomiasis

From Ramsay M. Anesthesia for Liver Transplantation. In Busuttil RW, Klintmalm GB., eds. *Transplantation of the Liver*. 3rd ed. Philadelphia: Elsevier; 2015:611–631.

Preoperative Considerations for Liver Transplantation

Patient demographics and disease severity are highly variable for liver transplantation. Age distribution has shifted toward older patients with liberalization of donor and recipient criteria, as well as advanced medical technologies, allowing patients to survive longer without transplant.³⁰ The detailed anesthetic preevaluation and planning is crucial due to the complex nature of comorbidities

presented by liver failure patients. Careful planning and communication with the surgical team regarding their concerns and plan for approach (e.g., bicaval cross-clamp, piggyback, or venovenous bypass) has a large impact on anesthetic planning.³¹ The primary goal of preanesthetic evaluation is to assess the patient's ability to tolerate surgery and posttransplantation care. A standard preanesthetic evaluation should include airway assessment, previous anesthetics, fasting (NPO) status, and an anesthesia focused review of systems. In addition to the usual preanesthetic evaluation, the transplant anesthetist should concentrate extra efforts on the cardiopulmonary and hepatic systems. Further testing is indicated on a patient specific basis if there is an abnormal result in initial screening or if the patient presents with abnormal signs and symptoms suspicious of undetected comorbidities. Standard laboratory panels should be done preoperatively, including ABO-Rh blood typing, liver biochemical/function tests (including INR), complete blood count, creatinine clearance, serum alpha-fetoprotein, calcium, viral and infective serologies, urinalysis, and urine drug screen. Liver disease can have significant cardiac comorbidities and needs an in-depth cardiopulmonary screening. The cardiac exam should include transthoracic echocardiography, 12-lead electrocardiogram, and noninvasive cardiac stress testing at a minimum. The 2013 practice guidelines from the American Association for the Study of Liver Diseases and the American Society of Transplantation recommend noninvasive stress (exercise or pharmacologic) testing for all pretransplantation patients.²⁸ This is contrary to 2012 recommendations from the American Heart Association and The American College of Cardiology Foundation suggesting noninvasive stress testing in patients with no active cardiac conditions if there are multiple risk factors for CAD present (diabetes, left ventricular hypertrophy [LVH], age > 60, smoking, hypertension, hyperlipidemia).³² One study found that utilizing submaximal cardiopulmonary exercise testing to calculate anaerobic threshold (which corresponds to cardiorespiratory reserve) positively predicted posttransplantation mortality.³³ Invasive cardiac catheterization and coronary angiography is recommended in patients with known CAD, diabetes, or more than

two cardiovascular risk factors in order to assess the extent and severity of the CAD.³⁴ It is prudent to obtain preoperative pulse oximetry and ABG values to screen for HPS. The triad of liver disease, impaired oxygenation, and intrapulmonary vascular dilatations indicates the presence of HPS and worsens the prognosis for cirrhotic patients. Patients with HPS receive MELD exception points. It is important to rule out other pulmonary and cardiac etiologies that could cause low oxygen saturations via chest radiography, pulmonary function tests, and computed tomography (CT) scanning. A transthoracic echo is recommended preoperatively to assess for evidence of valvular heart disease, myocardial wall motion abnormalities, and portopulmonary hypertension. Other pulmonary diseases need to be assessed via pulmonary function testing when indicated with patient comorbidities such as chronic obstructive pulmonary disease (COPD), emphysema, and asthma. Cancer screening for patients with hepatocellular carcinoma should include CT and magnetic resonance imaging scanning to assess for metastases and determination of staging. It is also useful to assess the hepatic vasculature for anastomoses during the transplant procedure. Upper endoscopy should be performed in patients with cirrhosis and portal hypertension to evaluate for esophageal varices. A final and key portion is the psychosocial evaluation. It is utilized to identify major issues that may impair a successful outcome after transplantation. The major psychosocial problems include a lack of insight and knowledge into the nature of the transplant procedure, posttransplant care, and substance use disorders. Due to the fact that some liver transplant patients have a history of alcohol and drug abuse, it is of the utmost importance to provide pretransplant treatment in order to increase the likelihood of success posttransplantation.

There are many unique disease states that patients in liver failure may have that can have a profound effect on patient management. Typically, ESLD patients have high cardiac output, with high resting heart rates and relatively low blood pressures. Due to the hepatic cirrhosis reducing the metabolism of catecholamines, there are thought to be endogenous mediators in hepatic portal blood that “spill over” into the systemic circulation and cause profound

splanchnic vasodilation and thus reduced systemic vascular resistance.²⁷ Due to the increased levels of circulation of catecholamines and generalized increased sympathetic activation, these patients are characterized as having a hyperdynamic circulation, which can fool the anesthetist into assessing cardiac function as adequate. The decreased afterload can actually mask cardiac dysfunction and care needs to be taken not to overlook cardiac disease in otherwise “normal” looking patients. Cirrhotic patients with ESLD often suffer from cirrhotic cardiomyopathy. This is characterized by increased cardiac output and a compromised ventricular response to stress. Cardiac performance declines and the patient begins to suffer both diastolic and systolic dysfunction due to the activation of the cardiac renin angiotensin system and impairment of the β -adrenergic receptor.³⁵ These patients have inotropic and chronotropic incompetence in conjunction with electrical and mechanical dyssynchrony. This is present in as many as 50% of patients undergoing liver transplant.³⁶ CAD is a significant risk factor and positive predictor for poor outcomes in liver transplantations.²⁷ It has been assessed that 25% of ESLD patients have at least one coronary artery that can be classified as moderately or severely stenotic. Exercise stress testing can be difficult in ESLD patients due to their limited overall functional capacity; dobutamine stress and myocardial perfusion imaging can be done to detect ischemia successfully in these patients. In the presence of previously known or previous CAD and/or stable angina, the American College of Cardiology recommends coronary angiography to assess for extent of stenosis. There are no definitive guidelines for revascularization, but in some high-volume centers there are case reports of combined liver transplant/cardiac surgery. Hemodynamically significant left ventricular outflow tract obstruction may be seen due to the combination of LVH and hyperdynamic systolic function found in patients with ESLD.³⁵ This can have a great impact on anesthetic management and precipitate intraoperative hypotension that would respond poorly to increased catecholamine administration.

Portopulmonary hypertension is defined as pulmonary hypertension syndrome with vascular obstruction in the presence of portal hypertension. It is characterized by a mean pulmonary

artery pressure of greater than 25 mm Hg and is caused by an increase in pulmonary arterial flow due to varying degrees of pulmonary endothelial and smooth muscle proliferation with added vasoconstriction.³⁵ The development of intimal proliferation is a major reason that patients with portopulmonary hypertension have an increase in pulmonary vascular resistance. It must be differentiated from the 30% to 50% of patients with ESLD who have elevated pulmonary artery and venous pressures with normal pulmonary vascular resistance. This is a normal finding in an ESLD patient and not a contraindication to transplant.²⁷ A screening transthoracic echo can utilize tricuspid regurgitation to estimate right ventricular systolic pressure (RVSP); if the RVSP is greater than 50 mm Hg the patient should be recommended for a right heart catheterization to exclude other causes of pulmonary hypertension.³⁶ It is generally accepted that severe, untreated portopulmonary hypertension is a contraindication to transplantation.

HPS is characterized by arterial hypoxemia caused by intrapulmonary vascular dilatations. The classical triad of portal hypertension, hypoxemia, and pulmonary vascular dilatations characterizes HPS. An alveolar to arterial oxygen gradient of greater than 15 mm Hg and pulmonary vascular dilatation documented by delayed, contrast-enhanced echo with left heart detection of microbubbles greater than four cardiac cycles is considered diagnostic of HPS.³⁵ The classic hypoxic pulmonary vasoconstriction response to hypoxemia is impaired and leads to poor tolerance of gravitational effects on pulmonary blood flow leading to platypnea-orthodeoxia. This is a paradoxical increase in breathlessness and decrease in arterial partial pressure of oxygen; it occurs when a patient moves from supine to upright because of abnormal pulmonary vessel size. There is no known pharmacological therapy to treat HPS. The outcome of patients with the syndrome who do not receive a transplant is poor. This is why UNOS recognizes it as a MELD exception status. Despite having outcomes after transplant that are less favorable than those who do not have HPS, it is an acceptable number and thus not a contraindication to transplant.²⁷

A common and easily recognizable complication of liver disease

and portal hypertension is the accumulation of ascites in the abdomen. Ascites can cause an increase in intraabdominal pressure, creating difficulty breathing; however a more serious issue called *hepatic hydrothorax* can develop. This is a buildup of ascitic fluid in the thorax often on the right side. It is reasonable and appropriate to arrange preoperative drainage of larger hydrothoraces in patients with respiratory compromise.²⁷

Hepatorenal syndrome is a severe form of acute kidney injury in patients with advanced ESLD. The international ascites club proposed diagnostic criteria for hepatorenal syndrome are listed in [Table 41.6](#). It is a form of prerenal failure that occurs in decompensated cirrhosis. The diagnostic criteria for hepatorenal syndrome is cirrhosis with ascites and a serum creatinine of greater than 1.5 mg/dL in the absence of parenchymal kidney disease, shock, or treatment with nephrotoxic drugs. Additional diagnostic confirmation is aided by no improvement of creatinine after a minimum of 2 days diuretic withdrawal and albumin intravascular volume expansion.³⁵ This is a form of prerenal failure precipitated by blood accumulating in the dilated splanchnic vasculature causing an effective depletion of arterial intravascular volume. This leads the low systemic arterial pressure that follows, renin-angiotensin release, sympathetic system activation, renal vasoconstriction, low renal perfusion, and low GFR.²⁷ Two types have been identified; type I is the more severe manifestation and is characterized by a rapid decline in GFR and a median survival of only 2 weeks, whereas type II is a more progressive and slower course of renal failure. It is important, as with other comorbidities related to ESLD, to differentiate hepatorenal syndrome from other causes of acute kidney failure.

TABLE 41.6

International Ascites Club Proposed Diagnostic Criteria for Hepatorenal Syndrome

1	Cirrhosis with ascites
2	Serum creatinine > 1.5 mg/dL
3	No improvement in serum creatinine after 2 days of volume expansion with albumin
4	Absence of shock
5	No recent treatment with nephrotoxic drugs
6	Absence of parenchymal kidney disease as indicated by proteinuria > 500 mg/day

From Salerno F, et al. Diagnosis, prevention and treatment of hepatorenal syndrome in cirrhosis. *Gut*. 2007;56:1310–1318; Ramsay M. Anesthesia for Liver Transplantation. In Busuttill RW, Klintmalm GB, eds. *Transplantation of the Liver*. 3rd ed. Philadelphia: Elsevier; 2015: 611–631.

Hepatic encephalopathy occurs when circulating neurotoxins, most commonly ammonia, accumulate in the brain and alter neurotransmission via glutamate or altered cerebral energy homeostasis.³⁵ The manifestations of hepatic encephalopathy range from mild apraxia and behavioral changes to decerebrate posturing and coma.²⁷ The actual pathophysiology of these changes is poorly understood but is thought to be related to poor metabolism of gut-produced ammonia and other byproducts. Treatment includes nonabsorbable disaccharides, which are thought to reduce encephalopathy by affecting bacterial function in the colon and thus reducing enteric production of ammonia. Other interventions aimed at reducing encephalopathy center around reducing nitrogen load in the gut, reducing dietary protein, correcting electrolyte and metabolic abnormalities, avoidance of benzodiazepines, and administration of metronidazole and rifaximin.²⁴

In preparing the operating room for surgery, the anesthetist should have standard monitors, in addition to planning for an arterial line, large bore IV access, central venous catheter, PAC, continuous invasive or noninvasive cardiac output/function monitoring, thromboelastogram (TEG), transesophageal echocardiogram, cell saver, rapid infuser devices, blood products in the operating room or immediately available (RBCs, fresh frozen plasma [FFP], platelets, and cryoprecipitate), and transfer to the intensive care unit on mechanical ventilation afterward. PAC is the gold standard in hemodynamic monitoring during liver transplantation to which other monitors are compared.³⁶ It does have its limitations and dangerous side effect profile, which must be carefully considered when placing a PAC. Monitoring of central venous oxygen saturation and mixed venous oxygen saturation is of little value in liver transplant patients and many of the newer noninvasive hemodynamic monitors can provide reliable cardiac function data.

Intraoperative Considerations for Liver

Transplant

Careful monitoring and the availability of measures to maintain hemostasis, normothermia, and normovolemia are essential. Adequate assistance is necessary, as is access to point-of-service laboratory equipment or the presence of a “stat laboratory,” so that current data are obtained. Rapid analyses of basic electrolytes, glucose, ABGs, ionized calcium and magnesium levels, as well as hemostasis profiles (hematocrit, prothrombin time, partial thromboplastin time, fibrinogen, platelet count, thrombin clot time, fibrin split products, and D-dimers), are required. The perioperative use of TEG or rotational thromboelastography allows an accurate assessment of the quality of the clotting system to be made in real time.³⁷ Coagulopathies that may occur during liver transplant procedures are listed in [Table 41.7](#). After placement of a peripheral IV, preferably large bore, awake arterial access may be gained if the patient's condition allows it. It is prudent to limit the amount of sedative premedication, as patients with liver disease are particularly sensitive to it. There are no absolute contraindications to induction agents and the anesthetist may choose midazolam, ketamine, propofol, or etomidate. Although recent data shows that even one induction dose of etomidate can have significant adrenal suppression, it may be prudent to use careful titration of other induction agents. Opioid choice depends on center preference and comfort of the anesthetist. Fentanyl, sufentanil, remifentanyl, and alfentanil have all been used successfully.³¹ Due to the reduced peripheral vascular resistance seen in patients with ESLD, it is common to encounter post induction hypotension. Vasopressors such as phenylephrine are preferred for their α -adrenergic receptor specificity in the presence of an already hyperdynamic heart. Another vasopressor that should be immediately available is vasopressin. Due to its potent vasoconstricting ability, a vasopressin infusion during induction, and possibly in combination with a phenylephrine infusion and boluses can help provide a stable MAP and ensure adequate organ perfusion. Any drugs primarily metabolized by the liver and cytochrome p450 pathways will exhibit an altered pharmacokinetic and pharmacodynamic response in the ESLD patient. Close care should be taken in aseptic technique when placing all invasive lines as the patient will be

profoundly immunosuppressed upon completion of transplantation. Induction of anesthesia should be undertaken using a rapid sequence induction (RSI) technique and succinylcholine with cricoid pressure, as the semi-emergent nature of the surgery is likely to leave the patient unfasted. Preoperative potassium levels should be available to avoid succinylcholine-associated hyperkalemia. Utilization of nondepolarizing muscle relaxants are acceptable. The aminosteroid relaxants vecuronium and rocuronium undergo hepatic metabolism. However, due to the nature of the surgery in both length, and the high likelihood for prolonged recovery and mechanical ventilation in the ICU, careful dosage of rocuronium and vecuronium are appropriate.²⁷ Cisatracurium, which undergoes Hofmann elimination, is also an appropriate relaxant as it is not dependent on hepatic clearance. Quantitative neuromuscular monitoring is recommended regardless of the nondepolarizing muscle relaxant that is chosen. This will allow appropriate dosing and help prevent unnecessary overdosing of muscle relaxants leading to prolonged paralysis. After successful intubation, anesthesia via volatile anesthetics is maintained with age-adjusted minimum alveolar concentration equivalents titrated to the hemodynamic profile. It is useful to monitor entropy during the duration of the transplant to help ensure adequate anesthetic levels. After intubation the central venous catheter should be placed and the PAC (if chosen) will be floated as well. Other large bore peripheral access should be initiated, as well as placement of an oral or nasogastric tube. A transesophageal echo probe may also be placed at this time but discussion must take place with the surgical team prior to placing anything in the esophagus in case there are varices or the patient has altered coagulation factors that may put them at an increased risk for bleeding. Intraoperative neurologic monitoring is crucial as patients with liver disease are at risk for a large range of neurological complications including cerebral edema, encephalopathy, seizures, hypoxia, and central pontine myelinolysis.³⁶ Increased ICP is especially common in patients with acute liver failure. This can be complicated by an increase in cerebral blood flow following hepatic reperfusion and thus higher ICP. In a 2016 study, it was shown that severe posttransplant brain

injury occurred at a rate of 7.8% and was associated with severe pretransplant cerebral edema and a higher posttransplant INR.³⁵ ICP is classically monitored using an invasive catheter placed in the cranial vault and integrated with a pressure transducer. Due to the high likelihood of coagulopathies in liver transplant patients, there is a significant risk of intracranial hemorrhage with this technique. Moreover, this line must be placed as a separate surgical procedure by a neurosurgeon. When an ICP monitor was used in acetaminophen acute liver failure, there was no significant 21-day mortality benefit, and in nonacetaminophen acute liver failure it was associated with worse outcomes. The use of transcranial Doppler, which measures cerebral perfusion pressures noninvasively, has proven advantages, yet its use in the perioperative period has yet to be defined.³⁶ Transcranial Doppler has a diagnostic sensitivity of 67%.³⁵ Antibiotic dosages and timing, as well as immunosuppression administration, should be discussed with the surgery team and implemented as appropriate.

	Gradual recovery

From Kang Y, Audu P. Coagulation and liver transplantation. *Int Anesthesiol Clin.* 2006;44(4):19.

The liver transplantation is divided into three phases: preanhepatic, anhepatic, and neohepatic. Changes in physiologic parameters during each of the three phases are listed in [Table 41.8](#).

The preanhepatic phase includes the dissection and isolation of infra- and suprahepatic vena cava, as well as exposure of the porta hepatis and hilar structures of the liver. The anhepatic phase begins with clamping of the hepatic blood supply and venous drainage until reperfusion of the donor liver. Finally, the neohapatic phase begins at the reperfusion of the allograft. Patients receiving orthotopic liver transplants experience a wide variety of pharmacokinetic characteristics due to the amount of anesthetic drugs that are metabolized hepatically. There is a period of no metabolism during the anhepatic phase and certain medications will experience a complete cessation of metabolism. It is important to also understand that other factors, including massive blood loss and transfusion, can affect plasma concentrations of anesthetic drugs and must be taken into consideration when dosing.³⁸

TABLE 41.8

Relative Changes in Parameters During Liver Transplantation*

Variable	Preanhepatic	Anhepatic	Neohepatic
Glucose	+	-/+	++
Hemoglobin	-/- -	-	-/- -
Platelets	-	-	-
Urine output	++	--	+/+ +
Cardiac index	++	+	+++
Systemic vascular resistance	--	++	---
Peripheral vascular resistance	+	--	+

From Amand MS, et al. Liver transplant. In Sharpe MD, Gelb AW, eds. *Anesthesia and Transplantation*. Boston: Butterworth-Heinemann; 1999:190; Pilla MA, et al. Anesthesia for liver surgery and transplantation. In Longnecker DE, et al., eds. *Anesthesiology*. 2nd ed. New York: McGraw Hill; 2012:1049–1080; Steadman RH, Wray CL. Anesthesia for abdominal organ transplant. In: Miller RD, et al., eds. *Miller's Anesthesia*, 8th ed. Philadelphia: Elsevier; 2015:2262–2291.

During the preanhepatic phase, the ascites is drained and

adequate exposure to the liver and surrounding vasculature is attained. It is very common to experience large fluid shifts during this phase of surgery, and the decreased intraabdominal pressure experienced by relieving the ascites can unmask intravascular volume depletion. Volume expansion should be accomplished with 5% albumin rather than large volumes of crystalloids.³¹ Blood loss during this phase may be significant and is complicated by previous abdominal surgery, sepsis, coagulopathy, and peritonitis.²⁷ Maintaining a low to low-normal CVP will aid with reduction of blood loss but must also be balanced with transfusion of blood and coagulation factors. Preoperative INR has no predictive value on intraoperative blood loss, thus transfusion of FFP is debatable and could cause fluid volume overload.³⁵ Intraoperative clotting panels such as INR, fibrinogen, and platelet count can be useful to guide transfusion therapy; however there are no defined laboratory values for an end goal of treatment. TEG is the gold standard for coagulation management in liver transplant due to the fact that it measures the viscoelastic properties of the blood during all stages of thrombus formation, as well as testing stability, firmness, and fibrinolysis of the clot. Usage of a TEG or derivative technology intraoperatively has been shown to reduce the transfusion requirements.³⁶ Large volumes of intravascular fluid boluses during this phase can cause hemodilution and hypothermia, which will worsen coagulopathies. When utilizing blood product transfusion, it is important to include packed RBCs, FFP, platelets, and cryoprecipitate clotting factors. The transfusion of too many RBCs can lead to a dilutional coagulopathy or thrombocytopenia. Another complication of blood product transfusion is hypocalcemia, as the citrate used to preserve the blood products will bind to calcium in the patient and cause a relative hypocalcemia. Complicating this factor is the reduced hepatic blood flow during surgery that further reduces citrate metabolism.³⁵ Intraoperative cell saver, or blood salvaging techniques, is a cost effective and safe measure to limit transfusion and blood loss during the dissection phase. The primary contraindication for cell saver usage is malignancy, although there are filters available that can effectively remove tumor load from the reperfused blood.

Once adequate exposure of the native liver is achieved, the

second, or anhepatic, phase of the orthotopic liver transplant begins. The surgical approach to liver isolation that is used (bicaval clamp, piggyback, or venovenous bypass) will have a major impact on hemodynamic and fluid management during the anhepatic phase.³¹ The bicaval clamp technique involves clamping the vena cava superiorly and inferiorly to the liver causing venous obstruction distal to the clamp and significantly dropping preload on the right side of the heart that can lead to profound hypotension and tachycardia. A secondary effect of this is the necessity of the anesthetist to treat this hypotension due to clamping by transfusing larger amounts of fluids leading to intravascular volume overload. A newer method is called the *piggyback technique* and involves only side clamping of the inferior vena cava (IVC) to preserve some degree of caval flow and limit the amount of decreased preload on the heart. This technique has many benefits in that it leads to shorter operative and warm ischemia times, as well as reduced blood/coagulation product use, while preserving similar graft function and survival outcomes. Venovenous bypass is seldom used anymore since the development of the piggyback technique and its ability to preserve flow through the IVC. Although there is still debate among transplant surgeons, a reasonable approach is to try IVC side clamping to assess hemodynamic function; if there is profound hypotension associated with a reduced cardiac index unresponsive to inotropes and volume challenges, then venovenous bypass should be initiated. During the anhepatic phase, and especially in the face of hemodynamically significant IVC occlusion, fluid loading should occur with a target CVP of 10 to 20 cm H₂O (will vary from center to center and surgeon to surgeon). As the native liver is now excluded from systemic circulation, the metabolizing capacity of the liver, particularly on lactate with a corresponding rise in plasma lactate, is recognized. This will create a metabolic lactic acidosis that will worsen with reperfusion of the graft; thus it is good practice to treat acidosis during the anhepatic phase to help buffer against worsening acidosis after reperfusion.²⁷

The last phase of the transplant involves reperfusion of the new liver. This occurs after caval and arterial anastomoses. Post reperfusion syndrome is the most significant anesthetic concern during the final phase of transplant. Post reperfusion syndrome is

characterized by decreased cardiac output, systemic hypotension, bradyarrhythmias, asystole, pulmonary arterial hypertension, and raised pulmonary capillary wedge pressure in conjunction with increased CVP.²⁷ Clinically it is defined as a decrease in systemic MAP greater than 30% below baseline for at least 1 minute during the first 5 minutes of hepatic reperfusion. The mechanisms that cause reperfusion syndrome and its associated hemodynamic instabilities are complex and not well understood. Recent analysis of post reperfusion syndrome indicates a 12% to 17% incidence rate and a high correlation with perioperative mortality and renal dysfunction. Preoperative echocardiograms demonstrated that left ventricular diastolic dysfunction was significantly associated with post reperfusion syndrome.³⁹ These findings emphasize the importance of diastolic dysfunction and the importance of an adequate preoperative cardiovascular evaluation. Increasing age of the graft donor is the only other strongly predictive factor for graft post reperfusion syndrome. Key management techniques during reperfusion of the liver include prompt response to the actively moving physiologic parameters and optimizing graft perfusion conditions. The most important of these is maintenance of an adequate perfusion pressure to the new liver and avoidance of high CVPs. Increased CVP can cause graft venous congestion. Clear communication between the surgeon and anesthesiologist is again crucial as the color of the implanted liver can indicate to the surgical team that it may be at risk for venous congestion and require the anesthesiologist to lower CVP. Instituting diuresis may be appropriate at this stage of the procedure with care taken not to over-diurese and promote hemodynamic instability. Postreperfusion syndrome may be so acute and severe that it leads to cardiac arrest. Consideration must be taken for maintenance of the patient's core body temperature as cold preservative is used in the liver and it is not uncommon for the recipient's temperature to drop 0.5° to 1° C during the reperfusion time. A quick return of temperature can be utilized as a sign of good graft function. Stable glucose and acid-base status are also reassuring signs of adequate graft function.²⁷ After adequate hemostasis is assured and the surgical team is happy with their anastomoses and graft function, closure of the fascia and skin will begin and the anesthesiologist can

prepare the patient for emergence and transport to the ICU. Some intraoperative complications that may occur and their management are listed in [Table 41.9](#). Guidelines for anesthesia management of liver transplants are listed in [Box 41.5](#).

TABLE 41.9
Intraoperative Complications and Management

Complication	Management
Hypothermia	Use heat exchanger, fluid warmer, warming blanket, forced-air units, postoperative ventilation, warm blood flush
Hyperkalemia	Elevated by massive transfusion
	Administer binding resins
	Perform diuresis, dialysis, hyperventilation
	Administer sodium bicarbonate, calcium chloride, insulin, or glucose
Hypocalcemia	Administer calcium chloride or gluconate by central line
	Citrate in blood may bind and thus lower calcium
Oliguria	Maintain adequate volume
	Increase renal perfusion pressure
	Administer mannitol, furosemide, and ethacrynic acid
	Renal replacement therapy
Hypotension	Maintain adequate volume
	Check calcium and magnesium
	Rule out cardiac dysfunction
	Administer vasopressors
	Transfuse blood products if anemia or coagulopathy is present
	Monitor for emboli
	Vena caval compression
Hypertension	Maintain adequate anesthetic depth
	Reduce filling pressures
	Avoid long-acting agents that are used to treat hypertension
Postreperfusion syndrome	Anticipate
	Ensure that volume loading is not excessive
	Administer calcium, vasopressors
Coagulation	Monitor coagulation status throughout massive transfusion
	Administer platelets, fresh frozen plasma and other antidotes as indicated

Box 41.5

Anesthesia Guidelines for Liver Transplant

Preanhepatic Phase

- Modified rapid sequence induction
- Invasive monitors (central venous pressure catheter, arterial catheter, pulmonary catheter, transesophageal echocardiography)
- Forced air and rapid infusers with warmers
- IV antibiotics, baseline laboratory values
- Norepinephrine (or vasopressin) to keep mean BP greater than 60 mm Hg
- Dopamine (or epinephrine) to keep CO at greater than 5L/min
- Maintain Hgb at greater than 7g/dL, platelets greater than 40,000, MA (TEG) greater than 45, fibrinogen greater than 100 mg/dL
- Mannitol 0.5g/kg IV over 1 hour, prior to anticipating clamping
- Just before clamping:
- IV heparin if TEG is normal or hypercoagulable
- Increase CVP to 10 cm H₂O with crystalloids
- 25% albumin in severe hypoalbuminemia

Anhepatic Phase

- IV fluids to keep CVP at approximately 5 cm H₂O
- Crystalloids unless hematocrit is less than 21%, at which time blood transfusions should be considered
- Norepinephrine and/or vasopressin to keep mean BP greater than 60 mm Hg and CO greater than 5L/min
- Bicarbonate infusion to correct base deficit

- IV calcium chloride to sustain normocalcemia

Neohepatic Phase

- When SVR is declining, IV vasopressin 1–5-unit bolus to keep mean BP at greater than 60 mm Hg
- Epinephrine 20–100 mcg boluses if heart rate is less than 60/min
- Euvolemia: CVP of 5–10 cm H₂O
- Dopamine, epinephrine, norepinephrine and/or vasopressin to keep CO at greater than 5L/min and mean BP at greater than 60 mm Hg
- TEE if needed for detailed hemodynamic assessment
- Maintain Hgb at greater than 7g/dL, platelets at greater than 40,000, fibrinogen at greater than 100 mg/dL
- TEG:
- Protamine 30 mg IV, if R is more than twofold compared to heparinase-R
- Maintain MA at greater than 45 mm with platelet transfusion
- If Ly30 is greater than 8%, give IV EACA 5 g over 15 min:
- Consider indication for postoperative mechanical ventilation per usual criteria
- Transfer to critical care unit

BP, Blood pressure; *CO*, cardiac output; *CVP*, central venous pressure; *EACA*, epsilon-aminocaproic acid; *Hgb*, hemoglobin; *ICU*,

intensive care unit; *Ly30*, the percentage of clot which has actually lysed after 30 minutes; *MA*, maximum amplitude; *OR*, operating room; *PACU*, postanesthesia care unit; *R*, reagent; *SVR*, systemic vascular resistance; *TEE*, transesophageal echocardiography; *TEG*, thromboelastography.

Postoperative Considerations for Liver Transplant

The vast majority of liver transplant recipients are sent to a specialized ICU after surgery because these patients are critically ill by definition. They have at least one major organ failure and often multisystem organ failure prior to transplant. Couple that with hemodynamic and cardiac instabilities, fluid shifts, coagulopathies, bleeding anastomoses, graft failure, and postoperative ventilation requirements, and the ICU is a necessity. In the near future, it is possible that there will be fast tracking of ideal liver transplant candidates. At this time the focus for this lies primarily on patients with isolated hepatocellular carcinoma who have little to no comorbidities and are highly selectable for expedited recovery. Early extubation is warranted when appropriate and is beneficial in numerous ways. Early reduction of positive pressure ventilation can reduce intraabdominal pressures and help with graft perfusion.²⁷ Early extubation has been shown to reduce ICU stay and diminish resource use with a concomitant reduction in cost by as much as 13%.³⁰ Patient selection is key to successful early extubation and is performed in as many as 70% to 80% of cases in some centers. Pain control is often managed via PCA intravenous narcotic use and orally when the patient is able to take pills. Epidural pain management is often precluded in the presence of coagulopathic or suspected coagulopathic patients.

Lung Transplantation

Lung transplantation is the now accepted therapy for end-stage pulmonary and pulmonary vascular disease. The first human lung transplant was performed in 1963 by Hardy at the University of Mississippi. This patient died of renal failure 18 days after transplantation. Out of 40 transplants that followed in the next 20 years, only one patient survived more than a month.⁴⁰ The first series of successful lung transplants were achieved in 1983 by Joseph Cooper of Toronto University.³⁹ UNOS data as of 2015 reports 30,822 successful lung transplants occurring in the United States since 1988. There are approximately 1500 patients on the lung transplant waiting list in the United States. Over the last few years there have been approximately 1800 donors annually.⁴¹ Despite the similarity of these numbers the stringent exclusion criteria for lung transplantation leaves many patients on the list for extended periods of time. Thousands of patients have died while on the organ waiting list.

The history of lung transplantation has been plagued with difficulties such as high mortality and complication rates. Most early failures revolved around the bronchial anastomosis. Despite many technological improvements along the way, the improvement of immunosuppression protocols has perhaps had the largest impact. Early immunosuppression consisted of high dose corticosteroid therapy, which was a significant contributor to the bronchial dehiscence.⁴² The mortality rate for lung transplant still remains very high (20–30%) with the main complication cited as primary graft dysfunction (PGD).⁴³ PGD presents as acute lung injury and/or acute respiratory distress syndrome that is propagated by a potent activation of inflammation pathways and localized inflammatory cytokine release. This often leads to prolonged mechanical ventilation and high fractions of inspired oxygen.

The most common indications for lung transplantation include COPD, cystic fibrosis, idiopathic pulmonary fibrosis, primary pulmonary hypertension, and α_1 -antitrypsin deficiency. Other less common indications include congenital disease, retransplant (graft

failure), sarcoidosis, obliterative bronchiolitis, pulmonary vascular disease, occupational lung disease, rheumatoid disease, and bronchiectasis.⁴¹ With advances, many of these indications for transplantation can be treated medically. This can often prevent the patient from being listed for transplant as their disease progress can be stymied. One such instance is primary and idiopathic pulmonary hypertension, which have responded well to new pulmonary vasodilators.

The surgical techniques for lung transplantation include single lung transplant, en bloc double, sequential double, or heart-lung combined transplantation. The International Society for Heart and Lung Transplantation registry indicates that there has been an increase in double lung transplants over the past years, whereas the number of single-lung transplants has remained fairly stable. The disease process of the recipient is a major determinant in whether the patient receives a single, bilateral-sequential, or heart-lung transplant. Patients whose transplanted lung will receive most of the ventilation and perfusion often undergo a single lung transplant. These patients include those with COPD and idiopathic pulmonary fibrosis. This technique allows for an increased number of recipients from the limited donor pool. Patients who suffer from a disease which would contaminate a transplanted lung, such as those with cystic fibrosis, are indicated for a bilateral-sequential-single-lung transplant. This technique utilizes bilateral bronchial anastomoses and often cardiopulmonary bypass. The double-lung transplant via a tracheal anastomosis has fallen out of favor as the bronchial anastomoses have fewer complications than the tracheal anastomoses.⁴⁴ Heart-lung transplants are generally reserved for those patients with primary cardiac disease complicated by pulmonary pathology, such as in primary pulmonary hypertension and unreparable congenital defects.

Beginning in 2005, a new system for placing donor lungs with recipients was instituted. The Lung Allocation Score (LAS) allocates lungs primarily based on age, geography, and blood type (ABO) compatibility. The LAS is a score that reflects the waiting-list mortality while avoiding transplanting donor lungs into patients who have a very poor likelihood of survival posttransplant. The new LAS methodology deemphasized the time spent on the waiting

list; this has prevented early listing of candidates simply to improve their probability of receiving a transplant. After implementation of the LAS waiting list, mortality initially decreased; however, it is now returning to pre-LAS baseline.⁴⁵ Patients who are older and sicker are also more likely to receive transplants than those on the previous lung allocation system. Guidelines developed by the International Society of Heart and Lung Transplantation for recipient selection include patients who have clinically and physiologically severe disease for which medical therapy is ineffective or unavailable; risk of death from lung disease without transplantation is greater than 50% within 2 years; the likelihood of surviving 90 days post-transplantation is greater than 80%; absence of nonpulmonary medical comorbidity that would be expected to limit life expectancy substantially in the first 5 years following transplantation; and a satisfactory psychosocial profile and support system.⁴⁶ Guidelines for transplantation by the type of pulmonary disease is noted in [Table 41.10](#).

TABLE 41.10
Guidelines for Lung Transplantation by Pulmonary Disease

Chronic Obstructive Pulmonary Disease	Patients with a BODE* index of 7 to 10 or at least one of the following: History of hospitalization for exacerbation associated with acute hypercapnia ($PCO_2 > 50$ mm Hg) Pulmonary hypertension or cor pulmonale, or both, despite oxygen therapy $FEV_1 < 20\%$ predicted and either $DLCO < 20\%$ predicted or homogeneous distribution of emphysema
Cystic Fibrosis and Other Causes of Bronchiectasis	Oxygen-dependent respiratory failure Hypercapnia Pulmonary hypertension
Idiopathic Pulmonary Fibrosis and NSIP	Histologic or radiographic evidence of usual interstitial pneumonia and any of the following: $DLCO < 39\%$ predicted 10% or greater decrement in FVC during 6 months of follow-up A decrease in pulse oximetry below 88% during a 6-MWT Honeycombing on high-resolution computed tomography (fibrosis score > 2) Histologic evidence of NSIP and any of the following: $DLCO < 35\%$ predicted 10% or greater decrement in FVC or 15% decrease in $DLCO$ during 6 months of follow-up
Pulmonary Arterial Hypertension	Persistent New York Heart Association class III or IV on maximal medical therapy Low (< 350 m) or declining 6-MWT Failing therapy with intravenous epoprostenol or equivalent

Cardiac index < 2 L/min per m ² Right atrial pressure >15 mm Hg

*BODE index, for Body-mass index, airflow Obstruction, Dyspnea, and Exercise, is a multidimensional scoring system and capacity index used to test patients who have been diagnosed with chronic obstructive pulmonary disease (COPD) and to predict long-term outcomes for them.

6-MWT, 6-Minute walk test; *DLCO*, diffusing capacity of the lungs for carbon monoxide; *FEV1*, forced expiratory volume in 1 second; *FVC*, forced vital capacity; *NSIP*, nonspecific interstitial pneumonia; *Pco₂*, partial pressure of carbon dioxide in arterial blood.

From Brown LM, et al. Lung transplantation. In Sellke FW, et al., eds. *Sabiston and Spencer's Surgery of the Chest*. 9th ed. Philadelphia: Elsevier; 2016:240–266.

Contraindications to lung transplantation include active mycobacterium tuberculosis infections, malignancy within the last 2 years, CAD that is not amenable to revascularization, uncorrectable bleeding disorders, BMI of 35 or greater, tobacco use, drug or alcohol dependency, advanced dysfunction of another major organ system (particularly renal, liver, and/or cardiac), progressive neuromuscular disease, noncurable chronic extrapulmonary infections (e.g., HIV, Hepatitis B and C), and unresolved psychosocial problems or medical therapy noncompliance.⁴⁶

Box 41.6 selection criteria are given in **Box 41.6**.

Recipient Selection Criteria

- Clinically and physiologically severe disease
- Medical therapy ineffective or unavailable
- Substantial limitations in activities of daily living
- Limited life expectancy
- Adequate cardiac function without significant coronary disease
- Ambulatory, with rehabilitation potential
- Acceptable nutritional status
- Satisfactory psychosocial profile and emotional support system

Donor selectivity has also changed over the decade. The original criteria were a patient less than 40 years of age, no smoking history, intubation of less than 3 days, no Gram-negative rods or fungus on sputum stain, ratio of arterial oxygen partial pressure to fractional inspired oxygen (P/F ratio) of more than 350 and no infiltrates or pneumothorax on chest radiograph.⁴⁶ This strict donor selection criteria resulted in an 85% graft rejection rate, thus leading to longer waiting times and higher wait list mortality.⁴² Many centers have liberalized their donor acceptance criteria. Some of these liberalizations include no history of COPD, less than 5 days' intubation rather than 3, no fungus on Gram stain, P/F ratio of 250 instead of 350, and minimal chest infiltrates on radiograph.⁴⁴ Age of the donor is very case and center specific, with a recent trend of age in excess of 65 years as a relative contraindication only in the context of the other requirements. Ideal donor criteria are listed in

Box 4177

Ideal Lung Donor Selection Criteria

- Age < 55 years
- No history of pulmonary disease
- Normal serial chest radiograph
- Adequate gas exchange: PaO₂ > 300 mm Hg, FiO₂ = 1.0, positive end-expiratory pressure = 5 cm H₂O
- Normal bronchoscopic examination
- Negative serologic screening for hepatitis B and human immunodeficiency virus
- Recipient matching for ABO blood group
- Size matching

FiO_2 , Fraction of inspired oxygen; PaO_2 , partial pressure of arterial oxygen.

From Brown LM, et al. Lung transplantation. In Sellke FW, et al., eds. *Sabiston and Spencer's Surgery of the Chest*. 9th ed. Philadelphia: Elsevier; 2016:240–266.

Preoperative Considerations for Lung Transplantation

A thorough and recent preanesthetic evaluation is crucial for a patient prior to lung transplantation surgery. The preoperative evaluation should focus on the underlying diagnosis, the ventilation/perfusion scan, pulmonary artery pressures, four chamber cardiac function, and baseline ABGs. These main areas will help the anesthetist direct therapy during transplantation and recovery. This process generally encompasses many specialties while the patient is initially worked up at a regional transplant center for listing. Right heart catheterization and transthoracic echocardiographic exams are crucial components of the preoperative evaluation.⁴² Most patients are notified less than 6 hours before the lung transplant is scheduled.⁴⁴ Short notice in combination with the fact that many patients may have been on the waiting list for a significant amount of time since their last evaluations make preanesthetic evaluation a challenge in efficiency and prioritization. Depending on timing, repeat labs, radiography, and cardiac echocardiography may be performed with emphasis on not delaying the patient to the operating room. Two to four units of packed RBCs should be immediately available in the operative suite. FFP and platelets should be considered on a case-by-case basis. Anesthetic specific evaluation should include routine details such as NPO status, previous anesthetic reactions, airway examination, and cardiovascular assessment. It is also important to discuss thoracic epidural analgesia as its use can provide pain relief and improve pulmonary function after transplantation. Epidural analgesia also benefits the patient by attenuating the stress response thereby decreasing chronic pain, pulmonary complications, and overall patient mortality. Epidural placement can be limited depending on the likelihood of cardiopulmonary bypass (CPB) usage during the case. If CPB is planned, then epidural placement

can occur immediately postoperatively once coagulopathies have been corrected. A prominent preoperative comorbidity associated with posttransplant mortality is mechanical ventilation prior to surgery.⁴⁷ The primary cause of this is patient deconditioning secondary to the requirement for sedation in order for the patient to tolerate invasive ventilation. There have been an increasing number of patients utilizing extra corporeal life support (ECLS) as a bridge to transplant in patients with pulmonary or cardiopulmonary failure.⁴⁶ A major benefit of ECLS (or ECMO) is that these patients can be awake undergoing physical therapy and have the ability to maintain an adequate nutritional status. An anesthetist receiving a patient to the operating room who is on bridge-to-transplant ECMO will still need to manipulate the airway for placement of the double lumen endotracheal tube (ETT); however mask ventilation would not be necessary due to oxygenation supplied through the ECMO circuit. Ventilation of the diseased lungs may prove near impossible and is also not required. Intravenous induction and maintenance is preferred as the permeability of the inhalational anesthetics in the ECMO circuit, in particular the oxygenator, is unknown.⁴³ It is highly likely that patients about to undergo lung transplantation will be highly anxious; it is important, however, to administer anxiolytics sparingly with close monitoring of the patient's respiratory status. These patients often have a limited cardiopulmonary reserve and overadministration of benzodiazepines and narcotics prior to induction could exacerbate preexisting hypercarbia and hypoxia. This can cause increased strain on the heart, which is likely to already have altered function. However, preoperative anxiety can also cause increased amounts of endogenous catecholamine release that can also worsen right heart function in a patient with some degree of pulmonary hypertension already present.⁴⁴ A unique perspective of preanesthetic evaluation in the lung transplant patient is that they are generally brought to the operating room without a guarantee that they will be receiving the donor lungs. It would be prudent to have a discussion outlining the possibility that they may arrive in the operating room, have monitors and lines placed, only to be informed that the donor lungs were not accepted for transplant. The patient will be brought to the operating room; a large bore peripheral IV will be initiated,

standard monitors (EKG, noninvasive blood pressure [NIBP], and pulse oximeter oxygen saturation [SpO₂]) will be placed, oxygen will be delivered via nasal cannula, and an arterial line will be placed utilizing strict sterile technique. The donor team will be performing a visual and bronchoscopic inspection of the donor lungs prior to contacting the recipient team that everything is satisfactory to proceed with anesthetic induction and incision.⁴⁰

Intraoperative Considerations for Lung Transplantation

Induction of anesthesia in the lung transplant recipient is complex and requires extreme vigilance. Mechanical ventilation combined with the administration of anesthetic drugs can lead to severe hypotension and even cardiac arrest. Due to the patients' preoperative lung function, many will already have some degree of pulmonary hypertension which makes them vulnerable to a sudden increase in pulmonary vascular resistance and subsequent right sided heart failure. This, in combination with positive pressure ventilation, myocardial depressant and vasodilation related to anesthetic administration, hypoxia and hypercarbia secondary to apnea/hypoventilation, can all cause significant hemodynamic instability during induction. A variety of vasoactive medications should be both available and prepared, including but not limited to phenylephrine, epinephrine, norepinephrine, dopamine, vasopressin, milrinone, and inhaled nitric oxide (iNO). It is prudent that both the surgeon and perfusion team be present in the operating room during induction in the event of profound hemodynamic instability and cardiac arrest.^{40,42,43,48} Judicious preoxygenation should occur prior to induction of general anesthesia in order to optimize intubation. It is important to note that denitrogenation of a patient with end-stage lung disease will be slower because of increased ventilation/perfusion mismatching. It should also be noted that this same phenomenon will cause a greater time period for an amnestic level of inhaled anesthetic to be achieved, leaving the patient at a higher risk for recall immediately post intubation. Due to the emergent nature of these surgeries, the patients often arrive as "full stomachs," necessitating an RSI.

Anesthetic agents should be chosen that optimize the patients' condition and have minimal cardiac depressant effects.⁴⁴ Induction with etomidate and narcotics, as well as hypnotics such as midazolam, ketamine, and propofol, can all be successfully used to induce general anesthesia. Slow titration of induction agents while closely monitoring the hemodynamic status is crucial. Optimization of hemodynamics through a combination of an inotrope (epinephrine), fluids, and a pulmonary vasodilator (milrinone or iNO) can help offset the detrimental effects of induction. Neuromuscular blockade with succinylcholine or rocuronium is acceptable depending on the need for RSI. There is no evidence that different anesthetic techniques or medications are superior to others. The goal of perioperative anesthetic management is constant maintenance of stable hemodynamics, oxygenation, ventilation, and tissue perfusion.⁴⁰ This can be achieved through diligent administration and slow titration of anesthetic drugs. Generally, the airway will be secured utilizing a left-sided double lumen ETT due to the anatomy of the right upper lobe and the need for a more proximal bronchial anastomosis on the right compared with the left. Although it is technically more difficult, placing a left-sided double lumen tube also eliminates the problem of obliterating the right upper lobe. A single lumen ETT is acceptable with the use of a bronchial blocker. A secondary benefit of utilizing a bronchial blocker is that it precludes the necessity of removing a double lumen tube and replacing it with a single lumen ETT at the end of surgery. After the airway has been secured and appropriate positioning of the double lumen ETT is confirmed fiberoptically, further invasive monitoring should be placed. This generally consists of an introducer with PAC and transesophageal echocardiography (TEE). PAC placement allows for measurement of intracardiac and pulmonary pressures as well as cardiac output. Some also allow for continuous mixed venous oxygen saturations and continuous cardiac output monitoring. TEE monitoring in combination with pulmonary artery pressures allows the anesthetist real time assessment of right ventricular (RV) function. As stated previously, this is an area of major concern due to the high likelihood of pulmonary hypertension. iNO is the agent of choice for decreasing RV afterload due to its selective action on the

pulmonary vasculature while having minimal effect on systemic vascular resistance.⁴⁰ It also allows for quick titration as the patient's condition warrants, whereas milrinone has a longer duration of action. One of the largest drawbacks of iNO is cost. At some institutions inhaled epoprostenol has replaced iNO because of its similar efficacy and cost-effectiveness. Antibiotic and immunosuppression therapies are also being administered during this time and careful communication with the surgical team regarding timing is crucial.

Maintenance of anesthesia can be achieved with either inhaled volatile anesthetics or intravenous anesthesia. Isoflurane has been implicated in improvement in ischemic preconditioning for multiple organs⁴²; however, there is debate on the best maintenance drug. Mechanical ventilation should be tailored to each patient's preoperative pulmonary diagnosis. Preoperative ABG measurements should be utilized to guide ventilator management. Utilizing this technique can lead to permissive hypercapnia; allowing the patients partial pressure of arterial carbon dioxide (PaCO₂) levels to more closely correlate to their preanesthetic levels. The patient will likely tolerate this well and it has been shown to reduce the risk of pulmonary barotrauma and dynamic hyperinflation.⁴⁰ Other methods for reducing barotrauma and hyperinflation include maximizing expiratory time through lower respiratory rates and tidal volumes, as well as intermittent circuit disconnection, to aid in complete exhalation. Dynamic hyperinflation can occur when gas trapping causes over inflation of the lungs, thus leading to an increase in intrathoracic pressure or auto-positive end expiratory pressure (PEEP). Auto-PEEP impedes venous return to the right ventricle and may produce cardiac tamponade physiology by directly compressing the heart if it is not recognized and treated. PEEP must be administered carefully in these patients with constant attention paid to the hemodynamic effects. Extrinsic PEEP from the ventilator can compound intrinsic auto-PEEP while also compounding the effects of dynamic hyperinflation.⁴⁴ Compounding ventilator management will be needed for one-lung ventilation shortly after incision. Once single lung ventilation is initiated the degree of intrapulmonary shunt will increase, as blood flow will continue to a varying degree to the

nonventilated lung. Maintaining adequate ventilation during this time is achieved in the same manner it would in nontransplant thoracic anesthetics. Monitoring of serial ABGs for worsening of the ventilation/perfusion (V/Q) mismatch is important and utilization of inotropic and vasoactive agents can aid in recovery. Shortly after this point the surgeons will clamp the pulmonary artery, which may help improve the intrapulmonary shunt. At this point the patient is on maximal vasoactive and mechanical support and, if still unstable, cardiopulmonary bypass should be discussed and possibly implemented. Some of the concerns with instituting CPB include increased blood loss, increased chance of the patient requiring a blood transfusion, increased V/Q mismatching, and graft dysfunction. Despite these increased risks there is no documented increase in overall mortality when CPB is used.⁴⁸ Patients with more severe pulmonary hypertension are more likely to need CPB. If the patient remains hemodynamically stable following pulmonary artery clamping, then CPB can be avoided. A secondary cause of cardiovascular instability is surgical manipulation and lifting of the heart by the surgeons for adequate exposure. Careful communication between the anesthetist and surgeon is required in the event of sudden hemodynamic changes. Ceasing in manipulation and allowing the patient time to recover before proceeding with the surgical dissection is crucial. During one lung ventilation, several confounding factors affect the heart. One factor is hypotension from decreased RV preload in combination with RV dysfunction secondary to increased pulmonary vascular resistance. Fluid administration can improve preload while administering 100% fraction of inspired oxygen (FiO₂) and pulmonary vasodilators such as iNO can assist in reducing afterload (pulmonary vascular resistance [PVR]).

After the bronchial and vascular anastomoses are complete the remaining pneumoplegia is washed out using retrograde flow through the grafted lung. It is important that extreme care is taken during gentle reinflation of the donor lung. Rapid reexpansion can cause barotrauma with resulting pneumothorax. The anesthetist should be prepared for severe hypotension as the lung is reperfused due to the washout of metabolites from the ischemic lung. This can transiently require high doses of inotropic support. Coronary air

embolus is not uncommon and must also be monitored closely. Due to its anatomic location, the right coronary artery is particularly prone to air embolism. The right coronary artery supplies blood to the right ventricle, thereby compounding previous RV concerns. ST segment depression can occur and these changes usually last less than 15 minutes.⁴⁸ If hypotension and cardiac dysfunction persist, the anesthetist and surgeon should search for a different etiology. The need for CPB or ECMO support is continuously monitored. If the patient is having a bilateral sequential lung transplant, then the process is repeated on the contralateral lung.

Reperfusion injury can also occur and lead to acute injury of the grafted lung. This is characterized by severe hypoxemia, pulmonary edema, impaired gas exchange, and increased pulmonary capillary permeability all generally occurring within the first 24 hours after transplant.⁴⁸ Causes of reperfusion injury have been postulated as poor preservation during transport, loss of lymphatic drainage, inflammatory mediators, and oxygen related free radicals. Gentle ventilation with low level PEEP to encourage alveolar recruitment and prevent atelectasis is important. iNO (if beneficial intraoperatively) should be maintained after reperfusion of the donor lung to aid in providing an optimal environment for reperfusion. Fluid management should be directed to maintain cardiac output while minimizing the risk of pulmonary edema. In general, it can safely be assumed that lung transplant teams will want their patients “dry” and this has led to a general practice of limiting intraoperative crystalloid administration. Ventilation strategies should focus on minimizing peak inspiratory pressures while assuring adequate gas exchange. Ventilation with higher inflation pressures, but not necessarily higher tidal volumes, has been significantly associated with poorer outcomes after lung transplantation.⁴⁹

Postoperative Considerations for Lung Transplantation

The patient will be taken directly from the operating room to the ICU and remain intubated and mechanically ventilated. Early postoperative care focuses on ventilator support and weaning, fluid

and hemodynamic management, immunosuppression, detection of early rejection, and prevention/treatment of infection. Ventilation and weaning techniques are standard after single or bilateral lung transplantation except in certain circumstances. A patient post single lung transplant for emphysema or COPD would not benefit from PEEP as it may cause over inflation of the native lung.⁵⁰ In many patients who do not experience difficulty with ventilation after transplant, weaning can proceed quickly during the first few hours to days post-ICU admission. After the patient is hemodynamically stable and able to be extubated, the primary focus of care shifts to pulmonary rehabilitation, toileting, pain management, physical therapy, immunosuppression, and infection prevention/treatment. Epidural pain management can be left in for days after surgery and is often an important aid in early extubation, inflammation control, and physical rehabilitation. The epidural catheter allows for titration of local anesthetic levels depending on each patient's individual pain response. Generally, it is pulled within a few days of transplant to limit the risk of infection. Acute rejection is a major cause of morbidity, especially in the first 100 days' posttransplantation. During the first month postoperatively, most mortality is generally the result of primary graft failure, non-cytomegalovirus (CMV) infections, cardiovascular complications, and technical problems.⁴⁸ Within 5 years of transplantation 49% of patients develop bronchiolitis obliterans syndrome (BOS).⁴⁰ BOS is progressive and nonreversible. The hallmark clinical feature of BOS is the development of airway obstruction with a reduction of forced expiratory volume 1 (FEV1) that does not respond to bronchodilators. Treatment involves augmenting the immunosuppressant therapy. Unfortunately, most patients either acquire progressive BOS or a lethal opportunistic infection as a result of the augmented immunosuppression.⁵¹ Some risk factors for BOS are listed in [Box 41.8](#). Patients are prone to infection due to immunosuppression, decreased mucociliary action, and decreased cough reflex. Anastomotic airway complications occur in approximately 20% of patients after lung transplantation and tend to be persistent, chronic problems that affect survival.

Risk Factors for Bronchiolitis Obliterans

Syndrome After Lung Transplantation

Probable Role

- Acute rejection
- Cytomegalovirus (CMV) pneumonitis
- Human leukocyte antigen (HLA) mismatching
- Lymphocytic bronchitis/bronchiolitis
- Noncompliance with medications
- Primary graft dysfunction

Potential Role

- Aspergillus spp. colonization of lower airways
- Aspiration
- CMV infection (without pneumonitis)
- Donor antigen-specific activity
- Epstein-Barr virus reactivation
- Etiology of native lung disease
- Gastroesophageal reflux
- Older donor age
- Pneumonia (Gram-negatives, Gram-positives, fungi)
- Prolonged allograft ischemia
- Recurrent infection other than CMV

strategies. *J Cardiothorac Surg.* 2011;6:92.

Intestinal Transplantation

Intestinal transplantation is a complex and challenging surgery and is performed less frequently than other organ transplants. Intestinal transplant is indicated in treating patients who have endured intestinal failure and who have failed maximal medical therapy options, including total parenteral nutrition (TPN). The Intestinal Transplant Registry (ITR) has reported the three most common underlying disease states leading to transplantation in children as gastroschisis (21%), volvulus (17%), and necrotizing enterocolitis (12%). In contrast, the most common indications for intestinal transplantation in adults are ischemia (23%), Crohn's disease (14%), and trauma (10%). Although the most common indications fall under the category of short bowel syndrome (SBS), children and adults may suffer from diseases that result in dysmotility or malabsorption, resulting in poor enteral function. For patients with SBS, the remnant intestinal length and presence or absence of an ileocecal valve have been identified as predictive factors as to whether rehabilitation will be successful.⁵² The main indication for transplantation in children and adults is TPN-dependent SBS complicated by progressive liver disease. Combined intestine-liver transplantation is the only alternative for patients in whom ESLD has developed. Isolated intestinal transplantation may be considered for patients with clinically significant liver disease that has not yet progressed to cirrhosis.⁵² These patients have had previous extensive intestinal resections. Significant advances have been made in both medical treatment as well as surgical procedures, which has led to a decrease in the overall number of intestinal transplants over the past decade. There has also been a decrease in the number of patients on the intestinal transplant waiting list. Only 73 adults and 35 pediatric patients received intestinal transplants in 2013 according to the Scientific Registry of Transplant Recipients.⁵³ The vast majority of patients who remain on the waiting list are pediatric patients.

There are very few academic medical centers that perform intestinal transplantation. The care for these patients in the preoperative, intraoperative, and postoperative periods is similar to

that of other abdominal organ transplant patients. Thorough preoperative assessment is the key to determining the patients' underlying condition and comorbidities and developing an anesthetic plan accordingly. A midline incision is often performed. Invasive monitoring is helpful in terms of monitoring hemodynamics, as well as assessment of electrolytes, blood counts, coagulation, and ABGs. Close monitoring of the patients' volume status is very important in intestinal transplantation. There can be significant fluid shifts during these surgeries along with the potential for significant blood loss. Maintaining euvolemia with a combination of crystalloid and colloid is important as excess edema and fluid administration may cause graft edema and can cause deleterious effects including abdominal compartment syndrome.⁵³ Although recipient survival rates have improved since the early days of intestinal transplantation (most notably 1-year survival), survival rates have plateaued and a significant drop-off in survival is seen after 5 years, often related to chronic organ rejection.^{52,53}

Postoperative pain management can be challenging and may include IV analgesia, PCA, and/or thoracic epidural analgesia. Care should be taken to ensure the patient does not have a coagulopathy prior to placement of the epidural. It should also be noted that psychological support is imperative and can improve overall patient outcomes.⁵³

Anesthetic Considerations for the Organ Donor

Care of the organ donor is a very specialized process that requires knowledge of the patient's underlying condition and also the plan for organ procurement. Each institution frequently has a protocol for management of the organ donor and these protocols are often guided by the transplant surgeon and the transplant coordinators, and are based on what organs are viable for procurement. Other factors include the type of donation, including DCD or DBD. As discussed previously, DBD is the more traditional method, however DCD is becoming more prevalent based on the reasons described earlier in the chapter. Even with the evolution of DCD, there continues to be a significant discrepancy between the number of patients awaiting transplant and the number of organs available (see [Fig. 41.1](#)). At the end of 2015, there were 122,071 patients awaiting an organ transplant, 30,975 transplants were performed, and 15,068 donors were recovered.²⁴

Although there are very few publications that describe anesthetic implications for this patient population, there is a significant body of literature available that describes management of these patients in the ICU prior to organ procurement. It is important for the anesthesiologist to have an understanding of the baseline condition of the patient and to be aware of the physiology and pathophysiology associated with the donor patient as it relates to the individual organs that may be procured. There are a multitude of physiologic changes that occur in the donor and they can vary based on whether brain death has occurred as opposed to DCD.

Pathophysiologic changes associated with brain death include complications at the cellular level and have a profound effect on all organ systems. Some of the significant signs and symptoms and pathophysiologic changes include hyper- or hypotension, bradycardia or other arrhythmias, pulmonary edema, disseminated intravascular coagulation (DIC), hyperglycemia, diabetes insipidus, and hypothermia.

DCD donors are a specialized category and do not meet the

criteria for DBD. DCD donors often experience severe brain damage or spinal cord injury that is not reversible, but is unlikely to progress to brain death. The likelihood of a meaningful quality of life is extremely poor. These cases are termed *uncontrolled DCD* versus controlled DCD and further divided into five categories as described in [Table 41.11](#). Categories 1, 2, and 5 are considered uncontrolled DCD due to the patient experiencing an unanticipated cardiac arrest.

TABLE 41.11

Categories of Controlled and Uncontrolled Donation via Cardiac Death

Category 1	Category 2	Category 3	Category 4	Category 5
Patient is dead on arrival to the hospital	Patient experiences devastating injury and has been unsuccessfully resuscitated	*Controlled DCD A patient where cardiac arrest is imminent	*Controlled DCD A brain death donor in cardiac arrest	Unexpected cardiac arrest in the intensive care unit (ICU)

*Controlled DCD occurs when a planned withdrawal of life support occurs and the transplant team is on standby and ready for rapid organ recovery.

It should be noted that the transplant team must not have any input on the discussion regarding withdrawal of life support. The medical team must discuss the situation with the potential donor's family and after a decision is made to withdraw support, an independent physician who is not involved in transplantation must determine cessation of cardiac function. After confirmation of pulseless activity via physical examination and/or absence of arterial blood pressure waveform over a period of several minutes, death may be declared and organ procurement may commence. Individual institutions may have other criteria that guide their practice for DCD and the anesthetist should have a familiarity with their own institution's guidelines.

Due to many physiological alterations in patients awaiting organ procurement, management of these patients before and during the procurement phase can prove to be challenging. Hemodynamic stabilization is critical in providing an optimum environment for the transplant to occur and for preserving optimal function of the procured organs. Hypertension may be present and should be

treated with a goal of maintaining MAP between 60 and 100.²⁵ Hypotension is more detrimental and may be more difficult to manage. Vasoactive medications may be used in either setting to ensure optimal blood pressure; however they should be limited as much as hemodynamically possible. Care should be taken to ensure adequate fluid balance. Fluid therapy should be aimed at euvolemia as excessive fluid therapy may have detrimental effects, especially in lung transplant patients.²⁷ Invasive monitoring, including arterial line and monitoring CVP, may help guide volume therapy and allow for optimal monitoring of the patient's hemodynamics. Communication between the anesthetist, surgical team, and transplant coordinator is vital to ensuring efficiency and optimal quality of the organs. Once the aorta is cross-clamped and the organs are perfused with hypothermic solution, mechanical ventilation is ceased and anesthetic management of the patient is stopped. The organ procurement coordinator is generally a resource during this time and can ensure appropriate measures are taken.⁵⁴⁻⁵⁶

Anesthetic Considerations for the Living Organ Donor

Another type of organ donation is where a living donor provides an organ to a friend or family member in a directed fashion. This type of donation is on the rise and has some advantages in that a thorough review of each patient's medical, social, and psychological history may be performed. It may be scheduled as an elective procedure and in a controlled and timely fashion to reduce the cold ischemia time related to organ procurement. The anesthetic considerations for each type of transplant are similar to those already discussed. The major difference is that most often the donor for living organ donation is generally in better health. Some of the concerns related to living donation include the potential decreased quality of life and medical risks associated with altered physiology from the donated organ. There is also a financial impact associated with donation that has to be considered. Overall, living donor organ donation can increase the number of donated organs and has shown to have some advantages over deceased donor transplantation, especially in liver transplant.²⁶

Organ donation has evolved significantly over the years and improved technology and pharmacology will continue to enhance transplantation. It should also be noted that increased awareness towards health prevention and maintenance may also continue to play an important role in potentially reducing the number of transplants needed.

Summary

The ability to transplant organs has been a remarkable medical success story. Patients who previously had little hope can now lead active and near-normal lives thanks to these lifesaving procedures. Our understanding of the immune response to transplanted tissues and the development of successful strategies to control and prevent rejection are instrumental in this success. Surgical and anesthetic management of the transplant patient requires constant monitoring and adjustment for a successful outcome. The principles outlined in this chapter will educate the clinician on the current approach to management of these patients.

Outpatient Anesthesia

Rex A. Marley, Terra J. Clapp

The concept of outpatient anesthesia is not unique to the past five decades. It was introduced in dentists' offices with the administration of nitrous oxide. Physicians' offices were next to offer this type of service for superficial procedures that required at most the administration of local anesthesia. In 1909, Nicoll¹ first reported on 8988 outpatient surgical procedures performed at the Glasgow Royal Hospital for Sick Children. In 1916, in Sioux City, Iowa, Waters² opened the first freestanding unit designed for outpatient surgery.

The evolution of and demand for outpatient care has not slowed since first described by these pioneers. Surgical innovation, new anesthetic drugs and techniques, and changes in insurance carrier demands have increased the type and number of procedures performed at ambulatory care centers or traditional hospital operating rooms. Within the United States, outpatient procedures at freestanding centers increased nearly 300% between 1996 and 2006. An estimated 35 million outpatient surgical procedures were performed in 2006. The most common ambulatory procedures included myringotomy and tonsillectomy for patients under 15 years of age, large intestine endoscopy and therapeutic injection for patients aged 15 to 44 years, and intraocular lens extraction for patients 75 years or older. Currently, 64% of all elective procedures are performed on an outpatient basis.³ In addition, difficult procedures performed even on patients with complex medical conditions are more routinely being performed on an outpatient basis. It is the responsibility of the attending anesthesia provider to ensure that these complex medical conditions are managed optimally before, during, and after the procedure.

It is expected that the patient will enter the outpatient surgical care facility, undergo the procedure, and then be released without

needing an overnight stay. Outpatient surgery, in addition to office-based and free-standing ambulatory surgery centers, includes the “23-hour observation” patient, who may be admitted to the inpatient or overnight facility yet is discharged before staying in the hospital 24 hours. Surgical procedures requiring the expertise of an anesthesia provider in the office setting are becoming increasingly popular. Office-based surgery can be performed more efficiently and at a lower cost than surgery performed in the hospital.⁴ Presently, 12 million operations annually, representing approximately 17% to 24% of all outpatient procedures, are performed in an office-based setting.^{5,6} Optimal anesthesia and surgical techniques for office-based surgery are similar to ambulatory procedures performed at traditional ambulatory surgical centers. Although office-based surgery can be performed safely, it is not without risk. Current issues of discussion include patient and procedure selection, recovery, complication management, perioperative management, and facility requirements.⁷ Office-based anesthesia practice standards and guidelines have been developed by the American Association of Nurse Anesthetists (AANA),⁸ the American Society of Anesthesiologists (ASA),⁹ and the Joint Commission.¹⁰

Features of Outpatient Surgery

Advantages

Financial

An advantage of ambulatory surgical settings has been the economic benefit for consumers, third-party payers, and medical facilities. Patients may benefit not only from reduced medical cost but also from minimized costs of outside child care and from resumption of normal living activities at an earlier time. Third-party payers concerned about cost containment are increasingly identifying procedures that may be performed only in the outpatient setting. Cost savings exceeding 50% have been reported for selected surgeries (e.g., laparoscopic cholecystectomy) performed on an outpatient basis.¹¹ Ambulatory centers, secondary to their design, facility layout, and patient selection, tend to operate more efficiently than hospital-based operating theaters in regard to surgical volume.

Medical

One medical advantage of ambulatory surgery is the increased availability of hospital beds for patients requiring hospital admission. For patients who are susceptible to infection (e.g., children, immunosuppressed patients, cancer patients, and transplant recipients), minimizing time and contact in the inpatient hospital setting may decrease the risk of nosocomial infections.¹²

Patient Satisfaction

Patients report greater satisfaction with outpatient procedures because of shorter waiting times and lower costs.^{13,14} Delays secondary to lack of available beds, as seen with inpatient facilities, are less likely to occur.

Social

Children benefit from outpatient surgery because it minimizes

separation from parents and causes less disruption in a child's feeding schedule. The continued presence of and care offered by the parents are especially beneficial for children with mental or physical impairments.¹⁵ Geriatric patients show better cognitive and physical capacity when separation from familiar surroundings and family is minimized. The elderly are better able to maintain their normal living routines (e.g., diet, medication, and sleep pattern). Postoperative cognitive dysfunction is decreased in geriatric patients undergoing outpatient procedures because they receive less medication and are returned to a familiar environment sooner than their inpatient counterparts.^{16,17}

Staffing

The ambulatory surgery setting is more convenient than the inpatient surgery setting for the staff because it offers more efficient use of time, uniform work schedules, and more predictable surgical outcomes.

Disadvantages

The outpatient setting may have several disadvantages:

- The degree of patient privacy is less than that in the inpatient setting.
- The patient may be required to make multiple trips to the physician's office or the ambulatory setting for evaluation and screening.
- Adequate home care must be ensured once the patient is discharged from the facility after surgery.
- Compliance and efficacy related to preoperative and postoperative instructions may not be as good as when the patient is admitted to the hospital before surgery.
- Because of the emphasis on efficiency, children have less time to adapt to the surgical setting than they would as inpatients.
- Observation time and monitoring for the occurrence of adverse events are decreased in the outpatient setting.
- Management of complications can be problematic at a free-

standing or office-based facility secondary to a lack of resources.

Demographic Considerations

Patient Age

Patients of any age can receive outpatient anesthesia; age should not be a limiting factor when determining appropriateness for ambulatory procedures. Approximately 6% of outpatients are younger than 15 years, and more than 14% are at least 75 years of age.³ More than 60% of all anesthesia administered for pediatric surgery is performed on an outpatient basis.¹⁵

Surgical Time

Earlier guidelines recommended limiting the amount of time of an outpatient surgery to less than 1.5 to 2 hours.¹⁸ The reasoning was that the longer surgery lasts, the more likely patients will experience severe pain or vomiting.^{19,20} Surgical time exceeding 2 hours was also thought to be a strong predictor for delayed discharge and unplanned hospital admission postoperatively.²¹ However, other factors such as the skill of the surgeon, the type of surgery performed, the patient's condition, and the anesthetic technique used must be considered. Arbitrarily limiting the length of surgery to less than 2 hours is no longer considered necessary; procedures exceeding 4 hours are routinely performed without complications in ambulatory centers.

Suitable Procedures

The list of procedures suitable for the ambulatory setting is constantly evolving. Endoscopy of the large and small intestine is the most common type of outpatient procedure, and ophthalmologic surgery is the second most common.³ The outpatient surgical procedure should not involve extensive blood loss or physiologic shifts of considerable fluid volumes because these processes necessitate protracted patient observation and hydration. In the past, the potential for blood transfusion implied the need for the procedure to be conducted at an inpatient facility. Now the increasing popularity of patient blood management for

decreasing possible transfusion needs has facilitated outpatient surgery.²²

The list of surgical procedures deemed acceptable for outpatient surgery is ever expanding; routinely included are surgeries such as laparoscopic cholecystectomy,²³ lumbar laminectomy,²⁴ cervical laminectomy and fusion,²⁵ thyroidectomy,²⁶ hysterectomy,²⁷ tonsillectomy,²⁸ total joint arthroplasty,²⁹ and select bariatric surgeries.³⁰ The norm regarding suitable outpatient procedures continues to be challenged, with the addition of more potentially higher-risk procedures, that is, craniotomy for unruptured cerebral aneurysm³¹ or tumor,^{32,33} and adrenalectomy.³⁴ Facilities with a 23-hour observation area designed for extended patient assessment are often the desired locations for outpatient tonsillectomy and higher-risk procedures.

Procedures requiring prolonged immobilization are best conducted on an inpatient basis. For procedures associated with postoperative discomfort, the appropriate inclusion of peripheral nerve block techniques, and arrangements for parenteral opioid therapy in the home may be made, provided that adequate pain relief can be achieved with safe doses of opioids.

Patient Selection

Proper patient selection minimizes the number of hospital admissions that follow outpatient surgery. Primary predictors of unanticipated hospital admission (0.08% of all ambulatory cases)³⁵ are related to the type of surgical procedure and subsequent complications, such as, nausea and vomiting, pain, or significant operative fluid shifts or blood loss. Evaluation of patients to determine who is appropriate for outpatient surgery and anesthesia requires consensus and cooperation between the surgical and anesthesia staff. Factors to consider in determining the suitability of a patient for outpatient surgery include the following:

- *The anticipated surgical procedure for the patient.* The proposed surgery should have an insignificant incidence of intraoperative and postoperative problems and should not require intense postoperative patient management.
- *The physical and psychosocial health of the patient.* The patient is ideally in his or her usual good health, or if ill, the condition should be well controlled. A reduction in postoperative complications has been shown if the patient's medical condition is stable for at least 3 months before surgery.³⁶ The patient and family should be receptive to the outpatient philosophy and the perioperative adaptations that will be required of them.
- *The surgeon's skills and cooperation.* Early referral to the anesthesia department for patients of questionable appropriateness helps streamline the outpatient process and minimize delays on the day of surgery.

Selection Criteria

Acute Substance Abuse

The patient with a history of substance abuse should be evaluated before the day of surgery. Counseling for such patients includes the warning that preoperative substance abuse will lead to cancellation of the surgery. A distinction between long-term and acute substance abuse must be made. A urinary drug screen should be

performed in patients suspected of substance abuse. The patient with signs of acute substance intoxication is an inappropriate ambulatory surgery candidate because of the increased likelihood of impaired autonomic and cardiovascular responses. The surgery should be rescheduled after the patient is detoxified and treated. Patient management strategies should emphasize methods of minimizing postoperative pain, because substance abusers are typically intolerant to pain. Regional or local anesthetic techniques, if their use is suitable to the surgeon and appropriate for the type of operation being performed, may be used if the patient wishes to abstain from sedatives and opioids. Postoperatively, pain may be minimized by using local wound infiltration, regional techniques, and the prophylactic use of nonsteroidal analgesics. Placing a catheter in the wound and instilling local anesthesia, either continuously or intermittently, has been shown to prolong pain relief and improve patient satisfaction and should be considered for this patient population.³⁷

Age

Patient age by itself should not be the deciding factor for outpatient suitability. Meridy³⁸ retrospectively examined the charts of patients ranging in age from 9 months to 92 years and noted that most perioperative complications occurred in the 20- to 49-year age group. Children less than 2 years have a higher unanticipated hospital admission rate following surgery.³⁹ Patients older than 85 years, who required multiple hospitalizations within 6 months of the surgery, have been shown to have an increased risk of unanticipated hospitalization and death after outpatient surgery.⁴⁰ Although multiple medications and preexisting comorbidities (i.e., hypertension, cardiac disease, and diabetes) are more likely in the elderly, there is a paucity of data supporting increased adverse outcome in these high-risk elderly patients.⁴¹

Premature Infant.

The premature infant (gestational age of 37 weeks or less at birth) is an inappropriate candidate for outpatient surgery because of potential physiologic aberrations. The premature infant may:

- Exhibit anemia
- Not have fully developed gag reflexes (and thus be more prone to aspiration of liquid or solid food)
- Have immature temperature control and be susceptible to the effects of hypothermia, which could contribute to postoperative apnea
- Demonstrate immature brainstem functioning, which predisposes the infant to pathologic respiratory conditions

The infant with a hemoglobin value less than the predicted normal value for that age will require additional evaluation before surgery. Hemoglobin values in the premature infant may drop to between 7 and 8 g/100 mL, 1 to 3 months after birth.⁴² The presence of anemia (hematocrit less than 30%) may increase the incidence of apnea in the newborn.⁴³ Some investigators have recommended delaying elective surgery until the hematocrit is increased to greater than 30% through supplementation of iron intake.⁴⁴

In the perioperative period, the preterm infant is at greater risk for developing respiratory complications, including apnea, than is the full-term infant.⁴⁵ The preterm infant is susceptible to short apnea (6 to 15 seconds), prolonged apnea (greater than 15 seconds), or periodic breathing (three or more periods of apnea of 3 to 15 seconds separated by less than 20 seconds of normal respiration). Short or prolonged apnea and periodic breathing predispose the infant to hypoxemia and bradycardia. An obstructive component that leads to quicker oxyhemoglobin desaturation appears to be part of postoperative apnea in these infants.⁴⁶ These infants have developed prolonged apnea as late as 12 hours after surgery.⁴⁵

The older the infant, the less likely that respiratory complications such as apnea will occur. In evaluating the suitability of a former preterm infant for outpatient surgery, conservative measures are best; inpatient status should be assigned if significant concerns exist. These patients benefit from the intensive monitoring available in the inpatient setting. Much discussion has been held as to the postgestational age (gestational age plus postnatal age) at which the former preterm infant may safely undergo outpatient anesthesia. Healthy former premature infants whose postgestational age is less than 50 to 60 weeks should be admitted to the hospital for extended

monitoring.^{47,48} Postoperative apnea has been described even in the full-term infant.⁴⁹ The ability to exactly predict the susceptibility of an infant to postoperative apnea is lacking.⁵⁰ Patients should be evaluated individually for appropriateness for outpatient surgery, and consideration should be given to growth and development, feeding problems, upper respiratory tract infections (URTIs), apneic history, and disorders of metabolic, endocrine, neurologic, or cardiac systems. All infants with a history of prematurity should be closely observed for signs of apnea and bradycardia. If any of these signs are evidenced in the postanesthesia care unit, patients should be admitted and observed. An infant with a history of apnea or bradycardia must be apnea free and without monitoring for at least 6 months to be considered for outpatient surgery.⁵⁰ Efforts should be made to schedule surgery for these patients as early in the day as possible to allow for extended observation time.

Beyond simply delaying surgery, attempts to minimize the likelihood of postoperative apnea in susceptible infants have been examined. Spinal anesthesia without sedation resulted in less prolonged apnea, oxyhemoglobin desaturation, and bradycardia than did general anesthesia or spinal anesthesia with ketamine sedation.⁴⁴ However, apnea and delayed respiratory failure have been reported in children who have had spinal or caudal anesthesia.⁵¹ Infants treated with endotracheal intubation or mechanical ventilation (or both) for respiratory distress syndrome at birth have been shown to have abnormal arterial blood gas values and abnormal pulmonary function results as late as 1 year after treatment.⁵² Infants exhibiting signs of bronchopulmonary dysplasia should not be considered for outpatient surgery,⁵³ as they are at risk of sudden infant death.⁵⁴

Infants with a history of apneic events or who have siblings who developed sudden infant death syndrome (SIDS) are at risk for SIDS. The greatest at-risk age for the development of SIDS is between 1 month and 1 year of age.⁵⁵ In infants who have lost a sibling to SIDS, the risk of dying from the same syndrome is four to five times that of the general population.⁵⁶ Patients at risk for the development of SIDS should not be considered for outpatient surgical procedures until they are at least 6 months to 1 year of age.⁵⁷

Full-Term Infant.

Healthy, full-term infants (older than 37 weeks gestational age at birth) can be considered for minor outpatient surgery. Full-term infants with histories of apneic episodes, failure to thrive, and feeding difficulties are not suitable candidates for outpatient surgery. Infants with a history of respiratory difficulties at birth are not suitable outpatient candidates unless they are free of respiratory symptoms at the time of surgery and at the time of hospital discharge.⁵⁷ There are no formal practice guidelines from major anesthesia or pediatric organizations regarding outpatient surgery in infants. However, individual hospitals frequently establish a cutoff age of 50 to 56 weeks of postconceptual age in infants born before 37 weeks, and also consider factors such as anemia, prior apnea, and coexisting disease. Postoperative monitoring recommendations range from 12- to 24-hour admission for cardiorespiratory monitoring. Some facilities also restrict day surgery procedures for term infants to only those infants older than 44 to 46 weeks of postconceptual age, or the facilities require a longer observation period (e.g., 4 hours) in phase II recovery.⁵⁸ Some evidence-based suggested guidelines are listed in [Box](#)

[Box 42.1](#)

Suggested Guidelines for Outpatient Surgery in Infants

- Appropriate short-acting anesthetic agents may facilitate emergence and discharge.
- Where possible, regional anesthetic techniques and nonopioid analgesics should be used instead of opioids.
- A loading dose of caffeine citrate 20 mg/kg may decrease postoperative apnea in former premature infants.
- If the surgical procedure is suitable, consider spinal anesthesia without sedation in former premature infants; however, postoperative monitoring is still recommended in the at-risk age range.

- Former premature infants should be admitted for observation unless they are over 55 to 60 weeks of postconceptual age (depending on degree of prematurity) and are without anemia, ongoing apnea, or other significant medical problems. Infants meeting these criteria also need to have had an uneventful anesthetic and recovery room course before consideration of discharge. Full-term infants younger than 44 weeks postconceptual age who exhibit any respiratory abnormality should be observed overnight, as well as certain children with sleep apnea following a tonsillectomy.
- Term infants are acceptable for outpatient procedures providing they are otherwise healthy, the procedure is not likely to result in significant physiologic changes or postoperative pain requiring opioid medications, and the anesthetic proceeds uneventfully. It may be prudent to monitor these patients in the recovery area for several hours postoperatively.
- All infants should be cared for in a facility with adequate and appropriately sized equipment, and medical and nursing staff with appropriate expertise and adequate ongoing experience in caring for this age group.

From Everett LL. How young is the youngest infant for outpatient surgery? In Fleischer LA, ed. *Evidence-Based Practice of Anesthesiology* 3rd ed. Philadelphia: Elsevier Saunders; 2013:523–528; August DA, Everett LL. Pediatric ambulatory anesthesia. *Anesthesiology Clin*. 2014;32:411–429; Johr M, Berger TM. Anaesthesia for the paediatric outpatient. *Curr Opin Anesthesiol*. 2015;28:623–630.

Geriatric Patients.

The decision of whether to perform ambulatory surgery on a geriatric patient (age 65 years or older) should be individualized and based on physiologic age rather than on chronologic age. Existing medical problems are a concern when considering the geriatric patient for outpatient surgery. There are more concomitant age-related diseases that should be optimally treated preoperatively in this group of patients. Patient age exceeding 80 years is a predictor of hospital admissions after outpatient surgery.^{61,62} Thoughtful preoperative planning for the elderly patient's postdischarge care is paramount to ensure a safe and successful

outpatient experience. The elderly population presenting for outpatient surgery has increased dramatically and will continue to increase as the population ages.⁶³ Appropriate home care and transportation to and from the outpatient center with a responsible caregiver must be ensured.

Special Considerations

Convulsive Disorders.

Surgery for patients with seizure disorders should be scheduled early in the day so patients can be observed for 4 to 8 hours after the operation before they are discharged. It is important to establish the patients' ability to maintain their schedule for anticonvulsant medications. Patients with uncontrolled seizure activity are not deemed appropriate for outpatient surgery by most institutions.

Cystic Fibrosis.

The extent of pulmonary involvement is the primary determinant of appropriateness for ambulatory surgery in patients with cystic fibrosis. Such patients should be evaluated several days before the proposed surgery; patients with symptomatic respiratory distress are better treated in an inpatient setting, where appropriate respiratory-care management and hydration can be administered.⁶⁴ Protective airway measures should be instituted in the cystic fibrosis patient secondary to an increased risk of gastroesophageal reflux disease and pulmonary aspiration.⁶⁵

Malignant Hyperthermia Susceptibility.

Malignant hyperthermia susceptibility is impossible to predict because it occurs in phenotypically normal individuals.⁶⁶ A malignant hyperthermia (MH)–susceptible patient is defined as having one or more of the following^{67–73}:

1. A previous episode of MH
2. Masseter muscle rigidity with previous anesthesia
3. A first-degree relative with history of an MH episode or positive

muscle biopsy

4. Diseases with known mutations on chromosome 19; these may include, but are not limited to, central core myopathy, King-Denborough syndrome, Native American myopathy, and hypokalemic periodic paralysis

5. Patients with heat-induced rhabdomyolysis

Diseases not associated with MH susceptibility include mitochondrial myopathies, Noonan syndrome, osteogenesis imperfecta, and neuroleptic malignant syndrome.⁶⁶

The MH-susceptible patient who has received a trigger-free uneventful anesthetic does not require overnight hospitalization based exclusively on being MH susceptible. The ambulatory facility should have a fully stocked emergency MH cart, the requisite monitoring and resuscitation capabilities, including a minimum of 36 vials of dantrolene, for managing the MH patient.⁷³ The busy ambulatory surgery practice will find the activated charcoal filter system (Vapor Clean), designed to reduce the volatile anesthetic concentration to less than 5 parts-per-million (ppm) in as little as 2 minutes of anesthesia machine preparation, beneficial from a time-saving perspective.^{74,75} A point-of-care monitor (capable of measuring blood gases and electrolytes) and urinalysis with a dipstick (to detect myoglobinuria) are recommended monitoring devices used in the free-standing ambulatory center should symptoms of an MH event present.⁷⁶ The patient should be scheduled as early in the day as possible to allow for extended patient observation for at least 1 hour in the postanesthesia care unit (PACU) plus an additional hour in phase 2 recovery, and the lack of symptoms of MH should be ensured before discharge is considered.⁷⁷ A patient who exhibits marked rigidity of the jaw muscles should not be discharged. Overnight observation is required for temperature rise, myoglobinuria, elevated creatine kinase levels, or progression to an MH episode. Patients who experience milder increases in jaw tension should be observed for signs and symptoms of MH for at least 12 hours. If there is evidence of myoglobinuria (i.e., dark, cola-colored urine), elevated temperature and pulse rate, or abnormality of acid-base balance,

the patient should be emergently transferred and admitted to the nearest full service facility and observed overnight.^{75,77} Written discharge instructions should include: (1) how to monitor the patient's temperature at home, (2) how to recognize the signs and symptoms of MH, and (3) contact information if emergency medical advice is required.⁷⁸

Morbid Obesity.

The uncomplicated morbidly obese patient is an appropriate candidate for select outpatient surgery.⁷⁹ The morbidly obese patient with significant preexisting cardiac, hepatic, pulmonary, or renal disease must be evaluated on an individual basis and may best be managed as an inpatient. Late problems are more likely to occur when the body mass index (BMI) reaches 35 to 40 kg/m²; this was once considered to be the cutoff point for ambulatory surgery. With the introduction of select bariatric procedures into the outpatient setting, this exclusionary criterion has been reevaluated. A higher incidence of postoperative hypoxemia has been observed in patients with a BMI of 35 kg/m² or higher.⁸⁰ However, no increase in adverse postoperative outcomes, delayed discharge, or unanticipated hospital admission after ambulatory surgery was observed in obese patients with an average BMI of 44 kg/m².^{81,82} The super morbidly obese patient (BMI ≥ 50 kg/m²) is at increased risk of exhibiting perioperative complications and should be considered with caution for ambulatory surgery.⁷⁹ The laparoscopic adjustable gastric banding procedure has opened the door for bariatric surgery to be performed on an outpatient basis, because this procedure does not open the digestive tract.⁸³⁻⁸⁵ Initial reports of outpatient laparoscopic Roux-en-Y procedures are being investigated for safety and appropriateness.⁸⁶ The ability to sufficiently manage postoperative pain and address postoperative ambulation should be discussed preoperatively by the surgeon and anesthesia provider. The morbidly obese patient is at risk for persistent hypoxemia in the PACU, which may necessitate overnight supplemental oxygen therapy.

Preoperative airway evaluation (e.g., Mallampati classification, nuchal girth, redundant pharyngeal tissue) is especially important. A high Mallampati airway classification, reduced thyromental

distance, and restricted mandibular mobility were predictive of difficult endotracheal intubation, yet an increasing BMI was not associated with difficulty.⁸⁷

Obstructive Sleep Apnea.

Morbid obesity is associated with an increased risk of obstructive sleep apnea (OSA); many obese patients present for ambulatory surgery with classic signs of OSA yet without formal sleep studies.⁸⁸ An assessment of intubating conditions in the patient with OSA found a 22% incidence of difficult endotracheal intubation.⁸⁹ The likelihood of a difficult airway must be assessed preoperatively, and the ability to manage the difficult airway must be ensured.⁹⁰

If continuous positive airway pressure (CPAP) is part of the patient's management of OSA, the patient, undergoing general anesthesia, should be instructed to bring his or her CPAP machine into the surgery center for use in the immediate postoperative recovery phase. Intraoperative benzodiazepine⁹¹ and opioid usage, out of concern for worsening airway obstruction, should be minimized or avoided in these patients, and pain should be controlled with alternative techniques (e.g., nonopioid analgesics, regional anesthesia techniques, local wound infiltration with local anesthesia) when possible.⁹² Moderate to severe OSA patients requiring postoperative opioids should not undergo ambulatory surgery.⁹³

No increase in morbidity and mortality or unanticipated hospitalizations has been shown in OSA patients who are appropriately screened and deemed eligible to undergo ambulatory surgery.^{16,94} The decision concerning whether to provide for the patient with OSA in the ambulatory setting should be contingent on certain criteria being met. The Society for Ambulatory Anesthesia has released a consensus statement on preoperative selection of adult patients with OSA scheduled for ambulatory surgery.⁹⁵ Patients with a known diagnosis of OSA and optimized comorbid medical conditions can be considered for ambulatory surgery if they are able to use a continuous positive airway pressure device in the postoperative period. Patients with a presumed diagnosis of OSA, based on screening tools such as the STOP-Bang questionnaire, with optimized comorbid conditions, can be

considered for ambulatory surgery if postoperative pain can be managed predominantly with nonopioid analgesic techniques or with regional anesthesia techniques. On the other hand, OSA patients with nonoptimized comorbid medical conditions may not be good candidates for ambulatory surgery. All obese patients should be assessed with the STOP-Bang questionnaire as part of the preoperative evaluation (see [Box 20.10](#)). A score greater than 3 indicates a high suspicion for OSA. As noted previously, unless the patient's comorbid conditions are optimized and they are able to use CPAP after discharge and achieve postoperative pain relief without opiates, they are not candidates for outpatient surgery ([Box 42.2](#)).⁹⁵ Strict adherence to preoperative eligibility requirements and home care protocols is essential.⁹⁶ Consideration should be given to scheduling these patients early in the day to allow for prolonged observation of an additional 3 hours prior to discharge.⁹⁷ Three hour observational time may not be necessary for patients with OSA receiving only moderate sedation.¹⁶ Patients with obstructive sleep apnea may be considered for discharge home if they are without (1) signs of moderate to severe OSA; (2) recurring PACU respiratory issues, that is, apnea, bradypnea, oxyhemoglobin desaturation; and (3) potent postoperative opioids for analgesia.⁹⁸ A complete discussion of anesthesia and obesity can be found in [Chapter 48](#).

The Society for Ambulatory Anesthesia Consensus Statement on Preoperative Selection of Adult Patients With Obstructive Sleep Apnea Scheduled for Ambulatory Surgery

- Patients with known OSA whose comorbid conditions are optimized and are who are able to use CPAP after discharge are candidates for ambulatory surgery.
- Patients with known OSA whose comorbid conditions are not optimized are not candidates for ambulatory surgery and may benefit from further treatment.

- Patients with a presumptive diagnosis of OSA, optimized comorbid conditions, and postoperative pain that can be managed with nonopioid analgesics are candidates for ambulatory surgery.
- Patients with a presumptive diagnosis of OSA and nonoptimized comorbid conditions are not candidates for ambulatory surgery and may benefit from further treatment.

All obese patients should be assessed via the STOP-Bang method for presumptive OSA (see [Box 20.10](#)).

Comorbid conditions include hypertension, arrhythmias, heart failure, cerebrovascular disease, and metabolic syndrome.

CPAP, Continuous positive airway pressure; *OSA*, obstructive sleep apnea.

Adapted from Joshi GP, et al. Society for Ambulatory Anesthesia consensus statement on preoperative selection of adult patients with obstructive sleep apnea scheduled for ambulatory surgery. *Anesth Analg*.2012;115(5):1060–1068.

Reactive Airway Disease.

Before surgery is performed, the severity of reactive airway disease must be assessed, and optimal disease management should be achieved. A chest radiograph is indicated only if the patient is suspected of having an acute infiltrative process or if deterioration in the patient's physical condition has occurred. Likewise, arterial blood gases are indicated when signs and symptoms of chronic respiratory insufficiency are suspected. The patient may be best managed as an inpatient if indications for a chest radiograph or arterial blood gases are met. Consultation with the patient's internist may help in formulating therapeutic modalities and establishing baseline conditions for this patient. Patients receiving long-term medication therapy should continue to take their medications until the time of surgery. All parties involved must anticipate the possibility of admitting the patient to the hospital if the symptoms of the disease become exacerbated.

Sickle Cell Disease.

The possibility of sickle cell hemoglobinopathy should be

considered in every African American when obtaining the preoperative medical history. If individual or family history is suggestive of the disease, a Sickledex may be obtained in children 6 months of age and older to determine the presence of sickle-shaped red blood cells.⁹⁹ The patient with sickle cell disease is at risk for crisis development if acidosis, dehydration, or hypoxia occur. These patients often present for cholecystectomy because cholelithiasis is a well-recognized complication of chronic hemolysis.¹⁰⁰

The select patient diagnosed with sickle cell disease is an acceptable outpatient candidate, but this patient is not without risk.¹⁰¹ Sickling of the red blood cells may occur when the patient with this trait is subjected to hypoxia.¹⁰² If the patient with sickle cell anemia is to be cared for in the ambulatory setting, certain criteria must be satisfied:

1. The patient should have no major organ disease as a result of the sickle cell disease.
2. The patient should not have had a sickle cell crisis for at least 1 year.
3. The patient should be compliant with the prescribed medical care.
4. On discharge, the patient should be within 15 minutes' travel time to a facility prepared to care for him/her.
5. The patient should receive close follow-up postoperative care.

The procedure should not be a prolonged surgery that is associated with blood loss. The patient should arrive earlier than normal so adequate intravenous hydration can be established. The patient's surgery should be scheduled early in the day to allow for extended postoperative monitoring before he/she is discharged from the ambulatory center.

Social Considerations

Factors other than physical condition must be weighed in considering a patient for outpatient surgery ([Box 42.3](#)). The lack of

appropriate home conditions and care makes the outpatient option less desirable.

Social Considerations in Ambulatory Surgery

- Patient compliance
- Presence of responsible caregiver
- Discharge accommodations
- Access to assistance
- Financial and insurance considerations

Unacceptable Patient Conditions for Ambulatory Surgery

Certain situations make ambulatory surgery impractical. Each patient must be considered individually for acceptability as an outpatient surgical candidate. Patients believed to be at increased risk for outpatient surgery and to be unacceptable candidates for such surgery are those with any of the following³⁶:

- Unstable ASA physical status classification III or IV (e.g., cardiac, renal, endocrine, pulmonary, hepatic, or cancer diagnoses)
- Active substance/alcohol abuse
- Psychosocial difficulties, that is, responsible caregiver not available to observe the patient on the evening of surgery (see [Box 42.3](#))
- Poorly controlled seizures
- Morbid obesity with significant comorbid conditions, that is, angina, asthma, OSA
- Previously unevaluated and poorly managed moderate to severe OSA
- Ex-premature infants younger than 60 weeks postconceptual age requiring general anesthesia with endotracheal intubation

- Uncontrolled diabetes
- Current sepsis or infectious disease necessitating separate isolation facilities
- Anticipated postoperative pain not expected to be controlled with oral analgesics or local anesthesia techniques

Patient Evaluation and Preparation

To recognize anesthetic risks and determine the patient's suitability for the planned procedure, preoperative evaluation is mandatory for all patients preparing to undergo outpatient anesthesia and surgery. Challenges for the outpatient team will be organizing and accomplishing all the necessary tests and evaluations while causing the least inconvenience to the patient and maintaining an expedient surgical process. The preoperative interview elicits pertinent patient information and clarifies risk factors that may affect surgery and outcome. Additionally, by obtaining a thorough current and past medical history, including a personal and family anesthetic history, the staff may determine what further patient workup is required before surgery. A formalized preanesthesia assessment clinic is the most comprehensive and cost-effective process for preoperative evaluation and preparation.¹⁰³ Preoperative screening also allows the staff to communicate what will be expected of the patient in the perioperative phases.

Consultations, laboratory tests, and diagnostic procedures should be performed based on clinical findings rather than on a preestablished regimen of “standard” tests. Without any discoveries from the medical history and physical examination, the probability of observing a significant abnormality is negligible in diagnostic procedures, including electrocardiogram, chest radiograph, and laboratory tests. Abnormal test results obtained from routine testing potentially alter patient care only 0.22% to 0.56% of the time.¹⁰⁴ Routine preoperative laboratory screening is neither cost-effective nor predictive of postoperative complications.¹⁰⁵⁻¹⁰⁷

Patient Interview

Patient screening should take place sufficiently in advance of the scheduled surgery to allow time for necessary risk assessment, preoperative testing, specialty consultations, and adjustments in patient care. Proper timing of the patient assessment, particularly for the patient with complex medical conditions, minimizes surgical

delays and cancellations. The high-risk patient should be evaluated at least 1 week before the scheduled procedure. With respect to client convenience, the otherwise healthy individual who does not have the opportunity to visit the clinic can be evaluated on the day of surgery. In this circumstance, there is a higher potential for surgical postponement or cancellation with last-minute discovery (e.g., inappropriate fasting, suspected difficult airway).

Patient Orientation

The preoperative interview allows the staff to convey what is expected of the patient and what the patient can expect perioperatively. Providing instructions to the patient, verbally and in writing, results in improved patient compliance. An information packet given to the patient at the interview is beneficial. It should detail specific instructions and concerns related to the procedure ([Box 42.4](#)).

Preoperative Patient Instructions

Preoperative Instructions

- Tell the patient when and where laboratory tests, consultations, and diagnostic procedures will be completed.
- Clarify the appropriate time for the patient to be without food and drink.

Registration on the Day of Surgery

- Tell the patient the time to report for surgery, and mention that a wait can normally be expected.
- Describe the location of the parking areas.
- Tell the patient where to report for surgery.

Ambulatory Center Policies

- Inform the patient and family about expected conduct.

- Explain the ambulatory facility policies to the patient and family.
- Describe the family waiting area and services (e.g., dining areas).
- Review advance-directive information as required by law in some states.
- Review the patient's right-to-privacy policies.
- Outline the facility's cancellation policies: late arrival, nonadherence to fasting guidelines, inappropriate transportation home, lack of responsible person to help patient postoperatively, interim changes in patient's health status (e.g., URTI).

Personal Considerations

- Tell patient to wear comfortable, loose-fitting clothing that may be easily stored.
- Instruct patient to wear no jewelry or makeup (remove nail polish from at least one nail).
- Instruct patient to bring personal toilet items (e.g., comb, brush, toothbrush) as required.
- Caution patient to leave valuables at home.
- Tell caregiver to bring child's favorite toy, comforter, or pacifier, or light reading material for the older patient.

Postoperative Considerations

- Inform patient and family of the discharge time, including the time spent in the postanesthesia care unit and the customary length of stay until discharge.
- Instruct patient in the manner of discharge, the appropriate transportation arrangements, and the necessity for the presence of a responsible caregiver.

- Give the patient postoperative instructions: no driving, alcohol, or major decisions postoperatively for at least 24 to 48 hours after anesthesia (see [Box 42.12](#) for additional information).
- Inform the patient where, how, and to whom complications should be reported. Supply telephone numbers.
- Indicate the possibility of hospital admission.

Considerations if the Patient's Physical Condition Changes

- Tell the patient to contact the surgeon.
- Tell the patient to contact the anesthetist.
- Tell the patient to call regarding cancellations or physical condition changes (e.g., URTI).

Patients and family members should have the opportunity to become acquainted with the ambulatory surgery facilities and the anticipated sequence of events. This includes orientation to the laboratory and procedure areas, changing areas, waiting room, play areas, and the short-stay area, where the patient remains after surgery until discharge. This orientation is designed to reduce patient and family fear by providing relevant perioperative information (e.g., directions, anticipated schedule, instructions for physiologic preparation of the child, expected postoperative course, and discharge instructions), offering reassurance, and enhancing coping skills through familiarity. A variety of techniques may be incorporated to prepare the child for the operative procedure. Children can be oriented to equipment that is commonly used in the perioperative setting (e.g., anesthetic mask, intravenous therapy equipment, the anesthesia machine and circuit, blood pressure cuff, thermometer, and postoperative oxygen therapy devices). Children can be told when and where they will be reunited with their parents after surgery.

History and Physical

Results of a thorough medical history and physical examination performed by a member of the medical staff should be available in the patient's chart before the surgery is performed. A separate anesthesia history should be incorporated into a questionnaire specifically designed for preanesthetic evaluation; the anesthesia provider should review this history with the patient.

Such a review may be accomplished in a written format and would include a general review of the major systems, history of allergies, current medications, past and present medical problems, laboratory and diagnostic test results, and patient and family response to previous anesthetics. Prior anesthesia records should be examined for complications, response to anesthesia, and postoperative course. Patient evaluation should be conducted within 30 days of the scheduled surgery for medically stable patients and within 72 hours of the scheduled surgery for high-risk patients. The clinician should determine whether any changes might have occurred since the original history and physical examination were performed, and an update note should be made on the day of the procedure. A review of current vital signs, laboratory test results, diagnostic reports, and fasting status should be made.

Laboratory Evaluation

Each ambulatory center should have a consensus regarding the minimum testing requirement for surgery. These testing criteria depend on the proposed surgical procedure, the patient's medication history, and the patient's physical condition. Some states and regions have established minimum testing requirements. However, conducting a battery of preoperative laboratory tests without specific indications that they are needed has not been shown to reduce patient morbidity,¹⁰⁵ is not cost effective, and may even place the patient at increased risk.¹⁰⁶ Discriminate laboratory testing, based on findings from the history and physical examination and primarily designed to evaluate a patient's chronic comorbidities and surgical risk, seems to be indicated. Normal laboratory test and diagnostic procedure results are deemed current

if the tests are performed within 6 months of surgery if the patient's physical condition remains stable.^{107,108} Exceptions include serum potassium level determinations, which should be obtained within 7 days of surgery for patients receiving diuretics or digitalis, and blood glucose level determinations, which should be obtained on the same day of surgery for patients with diabetes controlled by medication. Physical conditions and systemic illnesses in which preoperative laboratory testing is appropriate are listed in [Table 42.1](#).

TABLE 42.1

Summary of Tests and Their Indications for Ambulatory Surgery (Low-Risk Surgery)

Test	Indicated	Guidelines	Exceptions
EKG	No	Class 3 AHA	—
Complete blood count	No	—	Anemia Anticipated blood loss Premature infants
bHCG	Yes, by history	Institution specific	—
Coagulation studies/platelets	No	—	Personal/family history of bleeding diathesis Anticoagulants Liver disease Tonsillectomy and neurosurgery (controversial)
Liver function tests	No	—	Risk assessment—cirrhosis Acute history
Pulmonary Functions	No	—	Only as part of routine management of asthma
Arterial blood gases	No	—	—
UA	No	—	Insertion of hardware
PSG	No	ASA practice advisory	Diagnosis of severe obstructive sleep apnea (OSA) will change venue
CXR	No	—	—
Type and screen	—	—	Anticipated blood loss > 500 cc Rhogam
Electrolytes	No	—	Recent change in medications affecting potassium/electrolytes
Creatinine	No	—	Contrast dye study
Glucose	No	—	Morning of surgery

Pregnancy Testing

The medical facility should have established guidelines delineating when testing for pregnancy is appropriate and informed consent must be obtained. Anesthetic concerns include the effect of surgery and anesthesia on the developing fetus and the potential to trigger preterm labor. If the medical history and physical examination indicate that the patient may be pregnant, or if pregnancy might complicate the surgery, then pregnancy testing should be performed. It is important that the patient be educated as to the potential risks of exposing a fetus to an anesthetic. Whenever possible, especially in the adolescent population, a female staff member should question the patient in the absence of family members.¹⁰⁹ Suggested pregnancy testing guidelines are given in [Table 42.2](#).

TABLE 42.2

Recommendations for Preoperative Pregnancy Testing

Population Type	Recommendations
Menstruating females under 13 years of age	No pregnancy test unless history is either indicative of sexual activity or is inconclusive.
Patients of childbearing age (over 13 years of age until 1 year after last reported menses)	Preoperative pregnancy test should be offered to all patients regardless of history, except in patients with a history of hysterectomy or bilateral salpingo-oophorectomy.
Testing on the day of surgery	Urine pregnancy test is sufficient.
Testing within 1 week of surgery	Serum pregnancy test is preferable.
All patients	Well-documented informed consent must be obtained from patients or their guardians.
All patients	There must be an established system involving an obstetric/gynecologic consultation for disclosing an unexpected positive result to the patient.
All patients	A thorough and detailed history should be obtained from all patients.

From Molov JL, Twersky RS. Is routine preoperative pregnancy testing necessary? In Fleischer LA, ed. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia: Elsevier; 2013:26–30.

Diagnostic Procedures

Chest Radiography.

Performing routine preoperative chest radiography is not recommended without specific indications for the necessity of the

test from the history and physical examination. Clinical findings obtained from the history and physical are as efficient as a chest radiograph. A chest radiograph should be considered preoperatively if the patient (1) presents with new pulmonary signs or symptoms, (2) has end-stage renal disease, or (3) has decompensated heart failure, and only if the test might change patient management or outcome. Patients with these symptoms might not be suitable candidates for ambulatory surgery, except for brief, minor procedures (e.g., ophthalmologic surgery).¹⁰⁷

Electrocardiography.

Few data support the routine performance of 12-lead electrocardiographic screening before elective surgery, because it has not been shown to be cost effective, is a poor predictor of perioperative complications, and is of limited value in detecting ischemia in asymptomatic individuals. It has been proposed that routinely acquiring a preoperative electrocardiogram is not indicated in the patient undergoing ambulatory surgery.¹⁰⁸

Fasting Status and Aspiration Risk

Part of the preoperative evaluation process identifies patients at risk for aspirating gastric contents into the lungs and developing aspiration pneumonitis. Factors associated with an increased risk of pulmonary aspiration of gastric contents are listed in [Box 42.5](#).

Recent ingestion of food and liquid before surgery contributes to an increased risk of aspiration. Solid foods must be digested to a bolus diameter of less than 2 mm before the food can pass through the pylorus. This process normally takes several hours for solids, whereas liquids pass through the pylorus in 1 to 2 hours.

Historically, patients have been required to fast for extended periods to ensure an empty stomach. However, sustained fasting does not ensure that the stomach will be empty at the time of surgery. The traditional policy of fasting after midnight fails to address several variables that influence gastric emptying for

Box 42.5

Risk Factors for Pulmonary Aspiration

- Age extremes (younger than 1 year or older than 70 years)
 - Anxiety
 - Ascites
 - Collagen vascular disease (e.g., scleroderma)
 - Depression
 - Esophageal surgery
 - Exogenous medications (opioids or premedications [e.g., barbiturates] and anticholinergics)
 - Failed intubation or difficult airway history
 - Gastroesophageal junction dysfunction (e.g., hiatal hernia)
 - Mechanical obstruction (e.g., pyloric stenosis, duodenal ulcer)
 - Metabolic disorders (e.g., hypothyroidism, chronic diabetes, hepatic failure, hyperglycemia, obesity, renal failure, and uremia)
 - Neurologic sequelae (e.g., developmental delays, head injury, hypotonia, seizures)
 - Pain
 - Pregnancy
 - Prematurity with respiratory problems
 - Smoking
 - Type and composition of gastric contents (e.g., solid foods, milk products)
- The time of the scheduled surgery
 - The time at which the patient retired for the night

- The variability of gastric emptying for solids and fluids across individuals

Several problems have been associated with prolonged fasting:

- Dehydration
- Hypoglycemia
- Hypovolemia
- Increased irritability
- Enhanced preoperative anxiety
- Reduced compliance with preoperative fasting orders
- Thirst and related discomfort (e.g., hunger, headache, unhappiness)

Data suggest that liquids (e.g., clear apple juice, clear broth, coffee, gelatin, Popsicles, pulp-free orange juice, water, and weak tea) may be given to healthy, unpremedicated patients up to 2 hours before surgery without placing them at increased risk for aspiration. There is no increase in gastric volume, nor is there a decrease in gastric pH, at the time of elective surgery. The studies that allowed patients to consume clear liquids until 2 to 3 hours before surgery demonstrated that although the patients appeared to be at no greater risk of aspirating gastric contents, the pH of the stomach contents remained less than 2.5. In light of these findings, recommended fasting guidelines for the otherwise healthy individual have been liberalized ([Table 42.3](#)).¹¹⁰

TABLE 42.3
Preoperative Fasting Recommendations

Ingested Materials	Minimum Fasting Period* (hr)
Clear liquids [†]	2
Breast milk	4
Infant formula	6
Non-human milk [‡]	6
Light meal [§]	6
Heavy meal; fried or fatty food	8

*The fasting periods noted above apply to all ages.

[†]Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

‡Because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.

§A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

From American Society of Anesthesiologists Committee. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2011;114:495–511.

Special Considerations

Daily Medications

Patients should continue to take their prescribed cardiopulmonary medications on the morning of the surgery. The medications may be taken with a minimum of water (up to 150 mL in adults and up to 75 mL in children) up to 1 hour before anesthesia.

Warfarin Sodium.

An early decision regarding whether the administration of warfarin sodium should be (1) continued, (2) discontinued, or (3) interrupted and bridging anticoagulation be accomplished with subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin be initiated must be made in consultation with the surgeon and the patient's internist. The question of whether the disadvantages of stopping the administration of this medication before surgery outweigh any advantage must be addressed. If the decision to withhold warfarin is made, the drug should be discontinued approximately 5 days before the scheduled surgery, and an international normalized ratio (INR) should be determined on the day of surgery. With adequate hemostasis, warfarin should be resumed 12 to 24 hours after surgery.¹¹¹ A complete discussion on the perioperative management of anticoagulants can be found in [Chapter 38](#).

Diabetes

Recommended care for the diabetic patient who is undergoing ambulatory surgery is a subject of debate and lacks clear guidelines. Optimal goals for glucose level management and consensus guidelines are currently lacking.⁹⁴ The patient with diabetes is at increased risk for cardiovascular, pulmonary, and neurologic events and should receive an early and thorough preoperative evaluation, including electrocardiography, history, physical examination, and indicated laboratory analysis. The patient with insulin-dependent diabetes whose diabetes is not well controlled and whose serum glucose levels are prone to wide fluctuations may be best treated in the inpatient setting depending on the type of surgery. Considerations for care of the patient with diabetes who is undergoing ambulatory surgery include the following¹¹²⁻¹¹⁵:

- Schedule the patient's surgery for early in the day.
- Obtain baseline information regarding the patient's glycemic control (i.e., the frequency and severity of hypoglycemia, the blood glucose level when the patient becomes symptomatic and the manifestations, and whether they are hypoglycemic unaware).
- If available, review previous 3- to 4-month trend for blood glucose and glycosylated hemoglobin A1c (HbA1c) to assess glycemic control. Patients with an HbA1c greater than 6.9 mmol/L and those with significant comorbidities should receive consultation with the patient's internist for optimization prior to surgery.
- Determine type (e.g., oral antidiabetics and insulin), dose, and schedule of antidiabetic therapy.
- Obtain hospitalization history related to glycemic control issues.
- Instruct the patient to have nothing to eat or drink after midnight the night before surgery if the procedure is scheduled for early in the day. Reinforce that the patient is knowledgeable regarding the symptoms of hypoglycemia.
- Monitor the patient's blood or serum glucose levels on arrival to the ambulatory center by use of a capillary test strip or laboratory analysis.
- Prevent hypoglycemia while maintaining blood glucose levels at less than 180 mg/dL.

- Manage preoperative oral antidiabetic and noninsulin injectable therapy.
- Continue usual routine prior to day of surgery.
- Withhold therapy on the day of surgery.
- Manage preoperative insulin therapy (Table 42.4).

TABLE 42.4

Patient Instructions for Preoperative Insulin and Noninsulin Administration

Insulin Regimen	Day Before Surgery	Day of Surgery	Comments
Insulin pump	No change	No change	Use “sick day” or “sleep” basal rates
Long-acting, peakless insulins	No change	75%–100% of morning dose	Reduce nighttime dose if history of nocturnal or morning hypoglycemia; on the day of surgery, the morning dose of basal insulin may be administered on arrival to the ambulatory surgery facility
Intermediate-acting insulins	No change in the daytime dose; 75% of dose if taken in the evening	50%–75% of morning dose	See comments for long-acting insulins
Fixed combination insulins	No change	50%–75% of morning dose of intermediate-acting component	Lispro-protamine only available in combination; therefore, use NPH instead, on day of surgery
Short- and rapid-acting insulin	No change	Hold the dose	
Noninsulin injectables	No change	Hold the dose	

NPH, Neutral protamine Hagedorn.

Adapted from Joshi GP, et al. Society for Ambulatory Anesthesia consensus statement on perioperative blood glucose management in diabetic patients undergoing ambulatory surgery. *Anesth Analg*. 2010;111:1378–1387; Kadoi Y. Anesthetic considerations in diabetic patients. Part 1: preoperative considerations of patients with diabetes mellitus. *J Anesth*. 2010;24:739–747; Sebranek JJ, et al. Glycaemic control in the perioperative period. *Br J Anaesth*. 2013;111(Suppl 1):i18–34.

- Return the patient to preoperative activities of daily living (e.g., baseline activity status, nutrition habits) as soon as possible.
- Make the patient aware that admission to the hospital is likely if persistent nausea and vomiting prevent resumption of normal

dietary intake.

Heart Murmur

The surgical patient with a heart murmur requires further workup if the condition was previously undetected. Heart murmurs are categorized as innocent or pathologic. Pathologic murmurs may be due to complex congenital malformations or heart disease and have accompanying physical dysfunction, whereas with innocent murmurs, the patient may be completely asymptomatic. Whether the murmur is benign, functional, or caused by organic heart disease, cardiologic assessment should be obtained before the induction of anesthesia.¹¹⁶

Rhinorrhea

Twenty percent to thirty percent of all children display symptoms of rhinorrhea for a good portion of the year. Children younger than 2 years of age are prone to 5 to 10 viral respiratory infections annually.¹¹⁷ For the child undergoing ambulatory surgery, individual patient evaluation is required for a runny nose. Both the history and physical examination are beneficial in determining the cause. The differential diagnosis of rhinorrhea should include the following:

- Allergic (seasonal) rhinitis
- Bacterial infection (early stages)
- Flu syndrome
- URTI
- Vasomotor rhinitis
- Nothing found

The clinician obtaining the patient history should try to ascertain the allergic or acute nature of the runny nose and determine whether it is normal for the child or an illness has recently developed and worsened. Recently acquired (within 12 to 24 hours of surgery) rhinorrhea or chronic rhinorrhea in the otherwise fit child is not a contraindication to surgery. The differentiation between a noninfectious and an infectious runny nose might

influence the decision of whether the procedure should be delayed (Box 42.6). Surgery might be delayed for only 2 weeks in the child with localized infectious rhinorrhea.^{118,119}

Differential Diagnosis of Rhinorrhea

Noninfectious Runny Nose

- Allergic rhinitis
- Seasonal
- Perennial
- Vasomotor rhinitis
- Emotional (crying)
- Temperature

Infectious Runny Nose

- Viral infections
- Nasopharyngitis (common cold)
- Contagious disease (e.g., chickenpox, measles)
- Acute bacterial infections
- Streptococcal tonsillitis
- Meningitis

Considerations for Postponing Surgery

Lack of Drug Compliance

The patient with uncontrolled hypertension or diabetes who has wide swings in blood pressure or blood glucose levels may not be suitable for outpatient surgery; such conditions should be optimally

managed before outpatient surgery and anesthesia are performed.

Fasting Status

For safety reasons, the patient not adhering to the fasting guidelines should not undergo surgery, and the rationale of not eating before surgery should be reinforced.

Suspicion of Pregnancy

If the patient responds that she may be pregnant or if clinical signs are indicative of pregnancy, surgery should be delayed until determination of whether the patient is pregnant can be made. Decisions about whether surgery should be performed and what type of anesthesia should be used can be based on pregnancy test results.

Upper Respiratory Tract Infection

Acute respiratory infections are one of the leading medical causes for surgery cancellation in children. In patients with an acute infection, differentiating between a bacterial infection as causative of the upper respiratory tract infection (URI) or lower respiratory tract infection (LRI) and other causes—such as uncomplicated viral infection (afebrile, clear secretions) or allergic conditions—is important. Differentiating between a noninfectious process and an infectious process is paramount in the decision regarding whether the procedure should be performed. This differentiation may be difficult to make early in the course of the disease. Symptoms of URI include the following:

- Elevated white blood cell count (greater than 12,000 with a left shift)
- Mucopurulent nasal secretions
- Inflamed and reddened mucosa (nasopharyngeal and oropharyngeal) (with allergic rhinitis, e.g., nasal mucosa is ashen and boggy)
- Positive chest findings (e.g., congestion, rales)
- Temperature of 37.5°C to 37°C (greater than 37°C usually)

associated with lower respiratory tract involvement)

- Tonsillitis
- Viral ulcers in the oropharynx

Other accompanying symptoms may include conjunctivitis, coughing (nonproductive), fatigue, itching, laryngitis, malaise, myalgia, sneezing, and sore throat. Laboratory and diagnostic testing in children with suspected URI includes nasal or throat cultures if signs of an infectious process are observed. A chest radiograph is not warranted, especially if chest sounds are clear. Similarly, the value of obtaining a white blood cell count has been challenged because the results may be normal and typically do not influence whether to proceed with the surgery.¹²⁰

Anesthetizing the patient who has a URI or LRI has been shown to increase the incidence of respiratory-associated complications two- to sevenfold. Bronchial reactivity may persist for 6 to 8 weeks after a viral LRI. The anesthetized patient with a respiratory tract infection is more prone to experience breath holding, bronchospasm, coughing, hypoxemia, increased secretions, laryngospasm, pneumonia, atelectasis, croup, and stridor. Risk factors for the development of perioperative adverse respiratory events include endotracheal intubation (less than 5 years of age), history of prematurity, history of reactive airway disease, exposure to secondhand smoke, surgery involving the airway, the presence of copious secretions, and nasal congestion.

A minimum of 4 hours of postoperative observation is appropriate before the patient is considered for discharge from the ambulatory setting. Each case should be reviewed individually. The decision to operate frequently depends on the urgency of the surgery, the duration and complexity of the surgery, and the need for instrumentation of the airway. Children with uncomplicated respiratory infection may undergo elective procedures without significantly increasing anesthesia complications.¹¹⁹⁻¹²¹ Guidelines for assessment and anesthetic management of children with respiratory infections are given in [Fig. 42.1](#).¹²⁰ Further discussion on the management of children with respiratory infection is in [Chapter 53](#).

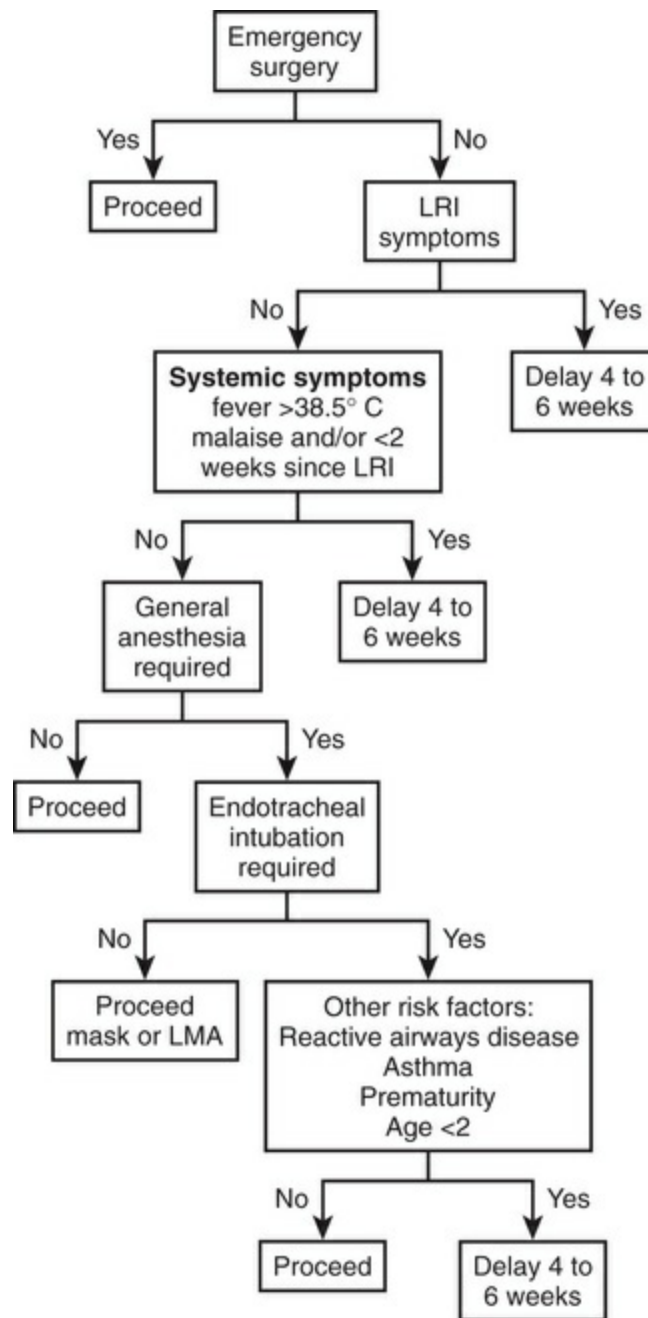

FIGURE 42.1 Clinical decision tree for proceeding with surgery in children with respiratory tract infections. *LMA*, Laryngeal mask airway; *LRI*, lower respiratory tract infection. (From McKee CT, et al. Should a child with a respiratory tract infection undergo elective surgery. In Fleischer LA, ed. *Evidence-Based Practice of Anesthesiology*. Philadelphia: Elsevier; 2013:534.)

Each case must be reviewed individually and consideration given to the urgency of the surgery, the duration and complexity of the surgery, the number of times the procedure has been canceled, and the wishes of the family and patient.

Premedication

Premedicating the ambulatory surgery patient with sedative agents is done on an individual basis and with minimally effective doses. The concern about giving anxiolytic and sedative medications is related to their potential to prolong the patient's stay. Prophylactic drugs for postoperative nausea and vomiting (PONV) are commonly used in patients at risk. Nonsteroidal antiinflammatory drugs (NSAIDs) given orally, when indicated for analgesia, should be considered preoperatively.¹⁹ Preemptive analgesia may reduce postoperative pain by preventing surgically induced peripheral and central sensitization.¹²² Lower postoperative pain scores and less opioid use have been seen when NSAIDs were given prior to surgery.¹²³ However, the use of premedication should not become routine; rather, the decision to administer these agents should be based on individual need and desired benefit.¹²⁴ Common indications for preoperative medication are as follows:

- To decrease patient anxiety and fear
- To facilitate smooth induction and emergence from anesthesia
- To supplement anesthesia and reduce the need for general anesthetic agents
- To reduce the volume and acidity of gastric contents
- Prophylaxis for PONV
- To provide a more pleasant stay in the PACU

Pulmonary Aspiration Prophylaxis

Patients at higher risk for aspirating gastric contents should be given medications before surgery to raise gastric pH and lower gastric volume, with the hope of minimizing their risk for pulmonary aspiration. Pulmonary aspiration prophylaxis in the patient not at risk is not recommended.¹¹⁰

Antacids

The value of oral antacids lies in their ability to rapidly reduce

gastric acidity; they are effective in raising pH in 15 to 20 minutes.¹²⁵ This characteristic is useful in emergency situations, but it is of limited application in the ambulatory setting. Although oral antacids raise gastric pH, they have the disadvantage of increasing gastric volume. Clear, nonparticulate oral antacids (e.g., two tablets of Alka-Seltzer Gold in 30 mL of water; 30 mL [0.4 mL/kg pediatric dose] of 0.3 M sodium citrate [Bicitra]) are preferred over particulate antacids, such as Maalox or Mylanta, because particulate antacids may produce pulmonary injury if aspirated.¹²⁶

Gastrokinetics

Reducing the volume of gastric fluid with the gastrokinetic agent metoclopramide (Reglan) helps minimize the risk of aspiration. Metoclopramide has been demonstrated to decrease gastric fluid volume by reducing gastric emptying time without increasing pH in adults and in children. Metoclopramide may also reduce the risk of pulmonary aspiration by increasing lower esophageal sphincter tone. It appears to exert a central antiemetic effect via dopamine receptor blockade of the chemoreceptor trigger zone.¹²⁷ The combination of metoclopramide with a histamine₂ (H₂)-receptor antagonist has been shown to be effective in raising gastric volume pH and decreasing gastric volume content.¹²⁸

The intramuscular dose is 10 mg for adults (0.1 mg/kg for children) given at least 45 minutes before surgery. The intravenous dose is 10 to 20 mg for adults (0.15 to 0.2 mg/kg for children) given over the course of 3 to 5 minutes at least 30 minutes to 45 minutes before surgery. These regimens allow sufficient time for the desired results to be achieved. The oral dose, 10 mg for adults (0.1 mg/kg for children), achieves peak plasma concentrations 40 to 120 minutes after administration.³⁶

H₂-Receptor Antagonists

Selective and competitive H₂-receptor antagonists, such as cimetidine (Tagamet), famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid), block hydrogen ion release by gastric parietal cells. These drugs do not alter the pH of gastric fluid already present in the stomach. All are available over the counter. These

medications may be administered the night before surgery, on the day of surgery, or both, to reduce gastric acidity. Famotidine and ranitidine have longer durations of action, are more potent, and exhibit a lower potential for side effects than cimetidine.¹²⁹

Cimetidine.

In one study, an intravenous adult cimetidine dose of 300 mg helped reduce the risk of pulmonary aspiration. The oral dose is 300 mg (3 to 4 mg/kg) for adults and 7.5 mg/kg for children, given from 1.5 to 3 hours before surgery. This is effective in reducing the risk of chemical pneumonitis if pulmonary aspiration occurs.¹²⁹

Famotidine.

The intravenous dose of famotidine is 20 mg for adults, given 15 to 30 minutes before surgery; this is effective in increasing gastric pH. When given electively, oral famotidine (40 mg) is given the night before surgery and on arising the morning of surgery. When compared with ranitidine, famotidine was slower in raising the gastric pH to safe levels.¹³⁰

Ranitidine.

The intravenous dose of ranitidine is 50 to 100 mg or 1 to 2.5 mg/kg. This drug decreases the risk associated with pulmonary aspiration. The oral dose of 150 to 300 mg for adults (2.5 mg/kg for children), given 1 to 3 hours before surgery, increases gastric pH, whereas gastric fluid volume may not be less than 25 mL. Comparable results were noted when ranitidine (150 mg) was given at bedtime and again on arising on the morning of surgery or when it was given orally 1 to 2 hours before surgery.¹²⁹

Gastric Proton-Pump Inhibitors

Omeprazole.

Omeprazole (Prilosec) causes dose-dependent intracellular inhibition of gastric acid secretion in humans without affecting gastric volume. Omeprazole has a longer duration of action than the H₂-receptor antagonist agents in suppressing gastric acid secretion and appears to cause no significant side effects.

The intravenous dose of omeprazole is 40 mg, administered after the induction of anesthesia. This is as effective as ranitidine in raising gastric pH above 2.5.

The oral dose is 80 mg, given the evening before surgery. This has increased mean gastric pH to 4.56, compared with the pH of 2.05 that was achieved with the administration of a placebo. Orally administered omeprazole 40 mg was not found to be as effective as either famotidine 40 mg or ranitidine 300 mg in protecting against pulmonary aspiration in parturients.¹²⁹

Lansoprazole, Rabeprazole, and Esomeprazole.

Orally administered lansoprazole (Prevacid), 30 mg, rabeprazole (Aciphex), 20 mg, or esomeprazole (Nexium) given the day prior to surgery and on the morning of surgery were not as effective in raising pH and lowering gastric volume as a single morning-of-surgery dose of ranitidine 150 mg. Intravenous preparations of esomeprazole (20 and 40 mg) and lansoprazole (30 mg) are available.¹³¹

Pantoprazole.

Pantoprazole (Protonix) is marketed as both an intravenous solution and as tablets, which may prove useful for perioperative use. Intravenously administered pantoprazole 40 mg was comparable with ranitidine 50 mg in increasing pH and reducing gastric fluid volume.¹³²

A complete list of the proton pump inhibitors and their doses are listed in [Table 33.10](#).

Anesthetic Considerations

Anesthetic techniques suitable for outpatient surgery include general anesthesia, regional anesthesia, and monitored anesthesia care. The goals for outpatient anesthesia, regardless of the type administered, are listed in [Box 42.7](#), and factors influencing the choice of anesthesia are shown in [Box 42.8](#). The ideal anesthetic agent for ambulatory anesthesia—whether it is administered inhalationally, intravenously, locally, or regionally—is one with the appropriate pharmacokinetic traits (i.e., rapid onset and offset, [Box 42.7](#) short duration, inert metabolites, and insignificant side effects).

Goals of Outpatient Anesthesia

- Minimize the physiologic changes associated with anesthesia.
- Provide a fast, smooth onset of anesthetic action.
- Promote intraoperative amnesia and analgesia.
- Afford suitable operating circumstances.
- Minimize perioperative anesthetic side effects.
- Allow rapid offset of anesthetic influence while maintaining patient comfort.

Box 42.8

Considerations for Choice of Anesthetic

- Surgical requirements
- Skill of anesthesia provider
- Patient choice
- Patient age

- American Society of Anesthesiologists physical status classification
- Level of care available once patient is discharged from outpatient facility
- Risk of postoperative nausea and vomiting
- Postoperative analgesia requirements

General Anesthesia

General anesthesia is the most widely used anesthetic technique for ambulatory surgery. General anesthesia should be achieved with the less-soluble inhalation agents or with short-acting intravenous agents that have the capability of reversal if required. A combination of potent rapid-onset and rapid-offset inhalation agents (e.g., desflurane, sevoflurane), along with intravenous agents (e.g., propofol, intravenous opioids, short-acting muscle relaxants, NSAIDs, and dexmedetomidine), comprise general anesthesia in contemporary practice. The popularity of general anesthesia in the ambulatory setting is related to its acceptance by the patient, the anesthesia provider, and the surgeon, and to the consistent pace that can be maintained with regard to achieving a satisfactory state of anesthesia.

Depth-of-Anesthesia Monitoring

Advances in depth-of-anesthesia monitoring technology have made their mark in ambulatory anesthesia. The data indicating that the routine use of bispectral index monitoring (BIS) during outpatient anesthesia improves outcomes is mixed. Some of the purported advantages of BIS monitoring in the outpatient setting include reducing the amount of anesthetic agent required, faster emergence from anesthesia, and a reduction in phase II vomiting.¹³³⁻¹³⁸

Airway Management

Issues regarding the use of general anesthesia with a facemask, a laryngeal mask airway (LMA), or an endotracheal tube in patients

undergoing outpatient surgery are the same as those in patients undergoing inpatient surgery. The indications for intubating the trachea depend on the constraints of the surgery and the individual patient concerns (e.g., risk of regurgitation and aspiration, hypoventilation, access to the airway, use of muscle relaxants, and airway obstruction).

Drawbacks to endotracheal intubation specific to the outpatient setting must be considered. Irritation and trauma to the upper airway and trachea are a concern, especially in children. The development of postextubation croup is rare (0.1%), but the potential for its occurrence must be considered in the plan for discharging the patient.¹³⁹ Paying careful attention to minimizing intubating trauma, ensuring that an air leak is present at less than 40 cm H₂O, and avoiding large-diameter endotracheal tubes helps reduce the incidence of postextubation croup in children.¹⁴⁰

The LMA has proven to be a popular and cost-effective airway management tool in the ambulatory setting. Patients tolerate LMAs at a lower dose of anesthetic than that needed for an endotracheal tube. Neuromuscular blocking agents are rarely necessary for airway management, and the incidence of airway morbidity such as coughing and sore throat is lower with LMAs than with endotracheal tubes. These advantages may facilitate faster recovery and earlier discharge of patients. Limitations include incomplete protection against aspiration of gastric contents and inadequate delivery of positive pressure ventilation.^{141,142}

Intravenous Fluid Therapy

Debate exists over whether all patients undergoing brief (less than 15 minutes) anesthesia require intravenous cannulation for uncomplicated surgery in which rapid recovery is expected. If an intravenous catheter is not inserted in children undergoing general anesthesia, the equipment and personnel trained in intravenous line placement should be immediately available in case they are needed.

The optimum amount of perioperative fluid therapy remains unclear. The three most common total fluid regimens include restrictive, liberal, and hemodynamic goal directed. Each technique has its proponents.¹⁴³⁻¹⁴⁶ Benefits of liberal fluid therapy include less

thirst postoperatively, a lower incidence of sore throat; and a lower incidence of dizziness, drowsiness, and faintness on standing compared with patients for whom fluids were withheld perioperatively. Less PONV also has been reported.¹⁴⁷ Fluid restriction has been used as part of fast-track surgery to reduce the length of stay compared to application of liberal fluids.¹⁴⁶ Authors of a 2012 large-scale meta-analysis noted that outcomes favored a goal-directed therapy rather than liberal fluid therapy without hemodynamic goals. Whether goal-directed therapy is superior to a restrictive fluid strategy remains uncertain.¹⁴³

Intravenous cannulation should be used, and perioperative fluid should be administered in the following situations:

1. *Procedures lasting longer than 30 minutes.* Longer surgical times increase the risk of hypothermia, increase the amount of anesthetics delivered to the patient, and result in a delay of resumption of normal diet.
2. *Procedures with an increased incidence of PONV.* Intravenous access permits the administration of antiemetic medications and allows hydration.
3. *Procedures associated with postoperative discomfort.* If anticipated postoperative pain is unlikely to be controlled by nonintravenous means, an avenue should be established for the administration of intravenous analgesics.
4. *Prolonged fasting before surgery.* If the child has been fasting for more than 15 hours, intravenous hydration is desirable for the maintenance of fluid and glucose homeostasis.
5. *Procedures associated with intraoperative and postoperative bleeding.*
6. *Procedures associated with the use of perioperative antibiotics or patients who require the perioperative administration of antibiotics.*

Regional Anesthesia

The use of regional anesthesia in the ambulatory setting is well established. Regional anesthesia improves pain scores, decreases

opiate use, lowers the incidence of PONV, shortens the recovery period, and reduces PACU stay.⁹⁴ Thus more patients can be discharged home in less time with high satisfaction.¹⁴⁸ The provider should assess the patient's appropriateness for regional anesthesia, which includes current medications, comorbidities, patient desire, and surgeon preference.

Local wound infiltration, peripheral nerve block, intravenous regional anesthesia, ophthalmic blocks (e.g., retrobulbar or periorbital), brachial plexus anesthesia, spinal anesthesia, and epidural anesthesia are all successfully used for outpatient surgery. The proper application of outpatient regional anesthesia requires knowledge of the anticipated surgical procedure, anesthesia requirements, length of procedure, and appropriate patient selection. The shortest-acting agent capable of providing satisfactory central neuraxial blockade, in combination with a potent opiate (i.e., fentanyl) should be used in the ambulatory setting if unreasonable delays in discharge are to be avoided. Lidocaine is a good agent for short procedures, yet some clinicians avoid its use secondary to concerns over transient neurologic symptoms (TNS). Low-dose bupivacaine (less than 6 mg) provides a low risk of TNS with the potential of a short discharge time, but with a high degree of variability and a limitation of adequate surgical anesthesia to the lower extremity and rectal area at the lower doses. The recovery from bupivacaine at doses of as little as 4 mg may take up to 240 minutes before discharge readiness is reached.¹⁴⁹ Prilocaine and preservative free 2-chloroprocaine are popular short-acting agents approved for neuraxial use outside of the United States^{149,150} It is crucial to weigh the potential risks and benefits of neuraxial agent selection in the outpatient setting.

Ultrasound guided single shot peripheral nerve blockade with longer-acting local anesthetics can provide up to 24 hours of analgesia postoperatively. The use of ultrasound guidance for peripheral nerve block placement has been shown to decrease the length of time to place the block and decrease the number of incomplete or failed blocks.¹⁵¹ Peripheral nerve block in conjunction with general anesthesia has been found to reduce the incidence of unanticipated hospital admissions.¹⁵²⁻¹⁵⁴ Continuous peripheral nerve blocks may provide extended postoperative pain relief for

outpatients for up to 7 days.¹⁵⁵ Continuous peripheral nerve blocks are also appropriate in pediatric and adolescent patients in the outpatient setting. Additional education and resources are required for patients that go home with continuous blocks.¹⁵⁶ Regional techniques are not as reliable as general anesthesia and may further delay surgery. There is also the issue of postoperative complications, including postspinal headache, transient neurologic symptoms (TNS) after spinal anesthesia, and urinary retention.¹⁵⁷ The advantages and disadvantages of the use of outpatient regional anesthesia are listed in [Box 42.9](#).¹⁵⁸

Advantages and Disadvantages of Outpatient Regional Anesthesia

Advantages

- Peripheral nerve block recovery times are shorter than those of general anesthesia.
- Unanticipated admission to the hospital is reduced.
- Phase I recovery bypass (fast-track) eligibility is high.
- Provides excellent immediate postoperative pain relief.
- Results in better postoperative pain scores than general anesthesia.
- Common side effects associated with general anesthesia (e.g., airway trauma, dizziness, “hangover,” myalgia, nausea and vomiting, pharyngitis) are minimized.
- The patient who fears general anesthesia or “loss of control” has a satisfactory alternative.

Disadvantages

- Cooperation of the patient and the surgeon is required.
- Regional anesthesia may require more time to provide than

general anesthesia. In an ambulatory setting, where surgeries and patient stays tend to be of short duration, regional anesthesia may not be as well received. If a team approach is used, patient stays may be minimized by early placement of the proposed regional anesthetic if appropriate.

- Inherent problems associated with regional anesthesia, regardless of inpatient or outpatient status, include the sympathetic block associated with spinal and epidural anesthesia, potential nerve injury, pneumothorax associated with interscalene and paravertebral blocks, fall risk with lumbar plexus blocks, as well as respiratory compromise that can come with phrenic nerve blockade.¹⁵⁸
- Time to discharge may be delayed for slow recovery of neuraxial block.
- Additional education and resources may be necessary if patient is discharged following a single shot or continuous catheter peripheral nerve block.

Recommendations for the safe and effective use of regional anesthesia in outpatient surgery are noted in [Box 42.10](#). Specific regional techniques are discussed in detail in [Chapters 49](#) and [50](#).

Recommendations for the Use of Regional Anesthesia in Outpatient Surgery

- Local anesthesia is ideal and should be used whenever possible as the sole anesthetic regimen, or be included for postoperative analgesia after any technique.
- Peripheral nerve blockade is highly effective in providing postoperative analgesia and rapid discharge when used for upper or lower extremity surgical procedures. It is also effective for truncal operations such as hernia repair. The use of continuous catheter techniques provides maximum benefit.
- Performance of a block in a separate induction room may reduce

the additional time otherwise required for regional anesthesia.

- If neuraxial blockade is chosen, spinal anesthesia has the advantages of rapid onset and high reliability. Unfortunately, there appears to be a persistent risk of transient neurologic symptoms (TNS) with the current agents. Low-dose bupivacaine (less than 6 mg) provides a low risk of TNS with the potential of a short discharge time, but with a high degree of variability and a limitation of adequate surgical anesthesia to the lower extremity and rectal area.
- Performance of an epidural anesthetic provides a more rapid discharge than with most of the current spinal techniques, and it provides the added advantage of flexibility in duration and extent of blockade if a catheter is placed.
- Excessive sedation must be avoided if the advantage of a high degree of alertness and rapid discharge is to be maintained.
- Discharge times after spinal anesthesia also require careful selection of drug and dose. The addition of epinephrine to subarachnoid local anesthetics increases the potential for urinary retention and for prolonged discharge times. The use of fentanyl may be a better choice for intensifying local anesthetic effect without prolonging discharge due to urinary retention.
- Urinary retention after a short-acting spinal anesthetic in low-risk patients is not any more frequent than with general anesthesia, and these patients can be discharged without mandatory voiding.

Adapted from Alley EA, Mulroy MF. Is regional anesthesia appropriate for outpatient surgery. In: Fleischer LA, ed. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia: Elsevier; 2013:404–409.

Postoperative Considerations

After the surgical procedure, care is provided in either the PACU (phase I) or the short-stay unit (phase II) until the patient is ready for discharge from the ambulatory setting. The location and the level of nursing care required vary according to the patient undergoing the procedure, the type of anesthesia used, and the surgical procedure. Properly addressing potential or realized complications in the most efficient manner possible expedites patient management and promotes a timely discharge process. Complications that might delay the patient's departure from the ambulatory facility include nausea, vomiting, and pain.³⁵ Each outpatient facility has specific criteria for discharge that should be met before the patient is released from the facility.¹⁵⁹ A thorough discussion of the current practices in postanesthesia recovery is provided in [Chapter 55](#).

Postoperative Complications and Management

With today's standard of anesthesia care, major morbidity and mortality after ambulatory surgery are extremely rare; however, a variety of adverse postoperative events may lead to unplanned hospital admission ([Box 42.11](#)).¹⁶⁰ PONV and pain are the most common reasons for hospitalization after ambulatory surgery. Certain procedures (e.g., laparoscopic sterilization; laparoscopic inguinal herniorrhaphy; head and neck; ear, nose, and throat; urologic; orthopedic) are also associated with a higher incidence of unplanned hospital admissions. The hospital admission rate after ambulatory surgery is less than 2%.¹⁶¹

Risk Factors and Predictors for Unanticipated Hospital Admission

Surgical

- Pain
- Bleeding

- Extensive surgery; prolonged length > 3 hours
- Surgical complications and unanticipated operative events
- Abdominal surgery
- General and urologic surgery

Anesthesia

- ASA 2–4
- Mallampati 2
- Nausea and vomiting
- Somnolence
- Aspiration

Social

- Discharge without escort

Medical

- Medical complications related to DM, IHD, and sleep apnea
- Medication error
- Increased BMI
- Advanced age > 80 years

ASA, American Society of Anesthesiologists; DM, diabetes mellitus; ENT, otorhinolaryngology; IHD, ischemic heart disease.

Adapted from Shnaider I, Chung F. Outcomes in day surgery. *Curr Opin Anaesthesiol.* 2006;19:622–629; Whippey A, et al. Predictors of unanticipated admission following ambulatory surgery: a retrospective case-control study. *Can J Anaesth.* 2013; 60(7):675–683.

Nausea and Vomiting

Persistent nausea and vomiting are responsible for delays in discharge and for increases in patient cost and are a common factor in unanticipated hospital admission after outpatient surgery. The reported incidence of PONV is approximately 30% on average and as high as 80% in high-risk patients.¹⁶² Postdischarge nausea and vomiting (PDNV) has been reported to occur in 37% of patients.¹⁶³ Many anesthetic- and nonanesthetic-related factors affect the susceptibility of patients to postoperative nausea and emesis. A complete discussion of postoperative and post-discharge nausea and vomiting and the antiemetic drugs can be found in [Chapter 14](#).

Postoperative Pain

Appropriate postoperative pain management helps minimize the stress of surgery, thereby fostering a quicker convalescence. Uncontrolled postoperative pain causes triggering of the stress response, patient uneasiness, and neurohumoral responses, and increases nausea and vomiting, psychologic distress, discharge delays, and unanticipated hospital admission. Nearly 12% of all ambulatory surgery cases reported inadequate pain control, with ophthalmology reporting the highest incidence of 19%.⁴⁰ Pain management should begin with the use of wound infiltration with local anesthesia such as bupivacaine or bupivacaine liposomes (Exparel), the use of peripheral or regional nerve block, perineural, incisional, or intraarticular local anesthesia catheters, and the administration of opioid and nonopioid (i.e., NSAIDs) analgesics preoperatively or intraoperatively, particularly in procedures associated with discomfort after emergence from anesthesia. These practices decrease analgesic requirements in the immediate recovery period, resulting in reduced pain scores and decreased PONV.¹⁶⁴

The severity and onset of postoperative discomfort are influenced by previously administered analgesics. Immediate control of pain in the PACU can be achieved by incremental titration of small intravenous doses of a short-acting opioid analgesic such as fentanyl (12.5 to 75 mcg) or alfentanil (50 to 300 mcg) every 2 to 3 minutes until nociceptive pain relief has been achieved. Nonopioid

analgesics should be considered to treat inflammatory pain or neuropathic pain. They have the advantage of improving overall analgesia, promoting early mobilization, and minimizing opioid-related side effects. Once patient discomfort has been controlled and the patient is tolerating oral fluids, early management of pain with oral analgesics (similar to those the patient will be taking after discharge) should be considered. This allows for evaluation of the analgesic's effect on pain alleviation, and the patient's mental condition and respiratory drive. The outpatient's analgesic medication should be safe and easily managed by the patient or caregiver once the patient is discharged from the facility.

Discharge Criteria

Before the patient is discharged from the ambulatory facility, he or she must meet certain physiologic criteria-based scores of recovery from the effects of surgery and anesthesia. A consistent method of evaluating the patient for discharge readiness offers the advantages of reproducibility, standardization, and objectivity; however, no single universally accepted standard exists for determining discharge readiness. For discharge to occur, the patient must be clinically stable and able to continue the recovery process at a remote recovery location. The decision to discharge is best made on objective criteria outlined in the policies of each ambulatory surgical facility. Distinct objective discharge criteria must be addressed when assessing home readiness of the patient. (Note: Before discharge from phase I, the patient's vital signs will be stable, there will be no respiratory impairment, protective reflexes of swallow and cough will be present, and the patient will be oriented to his or her preoperative level. It is assumed that the status of these parameters will not deteriorate during the patient's stay in phase I.) Individually, the following clinical markers should be evaluated in an organized, concise manner:

1. Vital signs should be stable and age appropriate.
2. The patient should be oriented to person, place, and time or at a level appropriate for the patient's developmental and preoperative status.

3. Ambulation can be affected by the surgical procedure and the patient's developmental level. If assistance to ambulate is required, the home caregiver must be able to meet this need.
4. There should be no respiratory distress.
5. Swallowing and coughing protective airway reflexes must be present.
6. Bleeding should be minimal or appropriate for the surgical procedure.
7. Pain should be minimal or controlled with an appropriate analgesic regimen.
8. Nausea and vomiting should be minimal.
9. Oral intake prior to discharge is not necessary unless crucial to the patient's continued convalescence at home (e.g., diabetic patient, patient requiring oral analgesics).¹⁶⁵
10. Voiding is not mandatory before discharge, except for patients at high risk for postoperative urinary retention (e.g., history of postoperative urinary retention, pelvic or urologic surgery, perioperative catheterization). In this high-risk population for urinary retention, a bladder-scan should be employed prior to discharge to assure overdistention is not an issue.¹⁶⁵
11. A responsible caregiver should be available.

A complete discussion of postanesthesia discharge criteria can be found in [Chapter 50](#).

Discharge Considerations

During the preparatory phase, the availability of a responsible person who will oversee the patient's care once the patient is discharged should be ascertained before surgery. In some cases, inpatient admission may be necessary if a responsible individual cannot be located. Postoperative care may be required for up to 48

hours in such cases, especially in elderly patients. The patient and responsible person should be provided with written instructions that are verbally reinforced before the patient is discharged. This information should include the physician's telephone numbers and steps to be taken if questions or complications arise. Once the patient has satisfied the criteria for discharge from the outpatient facility, certain discharge instructions should be reviewed to **Box 42.12** expedite and streamline the discharge process (**Box 42.12**).

Key Education Points for Discharge Instructions

Medications

- Detail the name, purpose, and dosage schedule for each medication. Emphasize the importance of following the directions on the label.
- The patient should resume medications taken before surgery per the physician's order.
- If pain medication is not prescribed, nonprescription, nonaspirin analgesics (e.g., acetaminophen, ibuprofen) may be effective to treat mild aches and pains.
- Additional pain medication may be ordered by the physician after surgery. The patient should take these medications as directed, preferably with food to prevent gastrointestinal upset.

Activity Restriction

- Caution the patient to take it easy for the remainder of the day following surgery. Postoperative dizziness or drowsiness is not unusual after surgery and anesthesia and may last several days.
- For the next 24 hours, the patient should not drive a vehicle, operate machinery or power tools, consume alcohol (including beer), make important personal or business decisions, or sign important documents.

- Describe the permissible activity level in specific behavioral terms (e.g., do not lift objects greater than 20 lbs); describe any limitation of activities.

Diet

- Explain any dietary restrictions or instructions.
- If no dietary restriction, instruct the patient to progress as tolerated to a regular diet.

Surgical and Anesthesia Side Effects

- Anticipated sequelae of surgery, such as bleeding and pain, should be delineated.
- Common side effects associated with anesthesia include dizziness, drowsiness, myalgia, nausea and vomiting, and sore throat.

Possible Complications and Symptoms

- Instruct the patient and responsible caregiver in pertinent signs and symptoms that could be indicative of postoperative complications.
- The patient should call his or her physician if any of the following develop:
- Fever greater than 38.3°C (greater than 101°F) orally
- Persistent, atypical pain
- Pain not relieved by pain medication
- Bleeding that does not stop or prolonged,

unexpected drainage from the wound

- Extreme redness/swelling around the incision, drainage of pus
- Urinary retention after 8 hours or as otherwise instructed
- Unremitting nausea or vomiting

Treatment and Tests

- Procedures the patient or responsible caregiver are expected to perform, such as dressing changes or the application of warm, moist compresses, should be described in detail.
- A complete list of necessary supplies should be included.
- If any postoperative tests are to be conducted, instructions as to the date, time, test location, and any pre-visit preparation should be listed.

Access to Postdischarge Care

- Provide the telephone number of the responsible and available physician.
- Provide the telephone number of the ambulatory center and the hours of operation.
- Provide the name, address, and telephone number of the appropriate emergency care facility.

Follow-Up Care

- Identify the date, time, and location of the patient's scheduled return visit to the clinic or surgeon.

The period of patient recovery after discharge from the ambulatory facility until resumption of normal activities is termed *phase III*. This is an important and often forgotten aspect of postoperative ambulatory care. Patient-care issues requiring attention continue to be important. It is important to convey to patients that it will take several days before they begin to feel as they did before surgery.

Summary

The numbers and types of surgeries performed on an ambulatory basis will continue to increase, as will the ability of facilities to appropriately treat these patients. As anesthetic techniques and agents are refined, thereby increasing the safety and efficiency of patient care and discharge, new groups of patients will be evaluated for their appropriateness for outpatient surgery. These new groups will continue to challenge our resources for providing ambulatory anesthesia.

Anesthesia for Ear, Nose, Throat, and Maxillofacial Surgery

Christopher J. Gill

The practice of anesthesia for the ear, nose, and throat (ENT) patient is both challenging and rewarding. The anesthesia practitioner is often required to make decisions regarding difficult airway management and must have the knowledge and skills to navigate abnormal and difficult anatomy. As a specialty, ENT presents specific concerns to the anesthetist in regard to the preparation and management of surgical procedures (Box 43.1). There are several essential goals when providing anesthesia for ENT and maxillofacial (i.e., plastics and dental) surgical

Box 43.1 Procedures:

Special Considerations for ENT Procedures

- Increased risk of unanticipated difficult airways
- Cannot intubate, cannot ventilate situation
- Use of specialized ventilation techniques
- Insufflation
- Intermittent apnea
- Apneic oxygenation
- Prevention of endotracheal tube fire
- Shared airway
- Surgical field avoidance

- Restricted use of nitrous oxide
- Restricted use of muscle relaxants
- Use of specialized equipment
- Laser
- High-frequency jet ventilation (HFJV)
- High percentage of pediatric patients
- Potentially undiagnosed obstructive sleep apnea
- Minimizing blood loss

ENT, Ear, nose, and throat.

1. Possessing a thorough knowledge of the airway anatomy and function
2. Selecting and preparing for appropriate technique(s) and approach for airway management
3. Preventing and managing potential airway complications
4. Producing profound selective muscle relaxation during periods of extreme stimulation, yet maintaining the potential for rapid recovery (e.g., suspension laryngoscopy)
5. Maintaining cardiovascular stability during periods of intense surgical stimulation
6. Omitting neuromuscular relaxation for surgical procedures that require isolation of nerves
7. Preventing or containing airway fires
8. Minimizing intraoperative and postoperative blood loss
9. Preventing adverse respiratory and cardiac responses resulting

from manipulation of the carotid sinus and body

10. Taking the appropriate postoperative measures to prevent and treat postsurgical airway obstruction

11. Avoiding or limiting the use of nitrous oxide (N₂O) during tympanoplasty or other closed-space grafting

Surgical intervention for ENT procedures uses a variety of specialty equipment, including lasers, endoscopes, and specialized endotracheal tubes (ETTs) (e.g., laser and microlaryngeal tube). The basis of many ENT and maxillofacial surgical procedures includes endoscopic examination of the sinuses; tissue tumors of the head, neck, and oral cavity; abscesses; surgery to the middle ear; papillomas of the airway; hypertrophic tonsils and adenoids; acute epiglottitis; thyroid disorders; and traumatic or congenital facial deformities. Most these procedures involve the nose, facial and frontal sinuses, larynx, oropharynx, nasopharynx, tongue, trachea, mandible, and maxilla, in addition to other supporting structures of the head and neck. These procedures necessitate sharing the airway with the surgeon and may lead to a tenuous airway and significant challenges perioperatively. Airway compromise in ENT patients may be subtle and can take several forms. Therefore good communication is essential in the preoperative period to ensure the safest approach to anesthesia.

This chapter describes the pertinent anatomy and physiology of the head and neck for the anesthetist, reviews specialized anesthetic considerations, reviews surgical and anesthesia equipment used during ENT procedures, analyzes some of the common pharmacologic agents used for ENT procedures, and discusses principles of anesthesia for ENT.

Functional Anatomy of the Head and Neck

A fundamental knowledge of the anatomic and physiologic function of the structures of the head and neck is essential for dealing with the myriad decisions arising perioperatively during these procedures. Commonly the ENT surgical procedure is being performed because the anatomic structures are abnormal, distorted, or deviated. Having a working knowledge of the structures and their relationships before subjecting the patient to respiratory changes produced by anesthesia is imperative.

The anatomic structures of the head and neck and their relationships are complex ([Fig. 43.1](#)). The sensory and motor supply of the upper airway originates from cranial nerves and includes the trigeminal, glossopharyngeal, facial, and vagus nerves. Understanding the sensory supply is required to provide sufficient local and regional anesthesia. Likewise, motor function evaluated during and after surgical procedures may indicate trauma or damage to muscles. A thorough knowledge of which nerves control muscle function is essential to preventing such trauma.

FIGURE 43.1 Anatomy of nasal cavity, oral cavity, nasopharynx, oropharynx, and hypopharynx. (From RD Miller, et al. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015:2524.)

The relationships of the oropharynx, nasopharynx, nasal chambers, sinuses, esophagus, and lower airway structures such as the larynx, cricoid, thyroid, and vocal cords provide a basis for directing and providing care for the patient receiving ENT surgery. The nose is a major anatomic structure that is responsible for warming, filtering, and providing humidity to the air taken in during inspiration. The structures of the nose include the external nose, the nasal cavity, and frontal, maxillary, and ethmoid sinuses. The nares or nostrils are separated by the septum. The lateral margins of the nares are cartilaginous structures and extend posteriorly over the hard palate leading to a confluence at the soft palate, oropharynx, and base of the tongue. The oropharynx rests superior to the epiglottis, vocal cords, larynx, and trachea.

The external nose is composed largely of cartilage supported primarily by soft connective tissue and delicate mucous membranes, as is the nasal septum. The nasal cavities are hollow structures formed by a floor, roof, lateral wall, and the septum. The lateral aspects of the nasal cavities contain concha, or turbinates. The turbinates are highly vascular and are divided into three

separate compartments: the superior, middle, and inferior. The turbinates greatly increase the surface area of the nasal cavities, aiding in filtration and humidification of inspired gases.

The extensive vascular supply of the turbinates may lead to severe bleeding if the nasal airway or nasoendotracheal tube is not inserted along the superior margin of the hard palate. Congestion of the mucosal veins in the turbinates of the nose causes swelling of these tissues, reducing the size of the nasal cavity (most notably, the paranasal sinuses), and thus creating the feeling of “congestion” during respiration. Inadvertent palatine submucosal insertion of the nasoendotracheal tube can lead to severe bleeding or infection in the perioperative period if entry of the tube is forced or tissues are engorged. These paired sinuses include the sphenoid, ethmoid, frontal, and maxillary sinuses. They not only serve as resonators for the voice but also filter, humidify, and warm the air during inspiration. These hollow structures are formed of low-density bone and are lined with a thin layer of mucous membranes, reducing the weight of the skull but making these bones more susceptible to fractures and cerebral spinal fluid leak secondary to facial trauma.¹⁻³

The pharynx is composed of the terminal end of the nasopharynx, the oropharynx, and laryngopharynx or hypopharynx extending to the sixth cervical vertebra. The medulla inhibits respiration with swallowing; the pharynx then serves as a muscular tube that constricts, allowing the passage of food. The pharynx allows the smooth passage of air and functions as a modulator for the voice. The nasopharynx is continuous with the internal nasal cavities and extends to the soft palate. The nasopharynx communicates with the oropharynx and forms the posterior aspect of the throat. Major structures of the oropharynx include the base of the tongue, soft palate, uvula, and lymphatic structures (tonsils). The tonsils are the most sensitive areas of the oropharynx. Beginning with the anterior margin and progressing bilaterally and posteriorly, the oropharynx is defined by the soft palate, base of the tongue, uvula, palatine tonsils, and adenoids, forming Waldeyer tonsillar ring.¹⁻³

Hypertrophy of the palatine and adenoid tonsils (exaggerated many times by chronic infection) and of the soft palate and uvula

can pose serious airway compromise, particularly in young children. The generous blood supply to the tonsils from branches of the external carotid, maxillary, and facial arteries, and their close proximity to the facial and internal arteries, are matters of concern regarding potential bleeding during “routine and simple” tonsillectomy. The laryngopharynx includes the epiglottis, which provides protection for the vocal cords, and is the region shared by the esophageal orifice and larynx.

The complexity of the neuromuscular system, which controls the epiglottis, allows the isolation of the trachea from the esophagus during swallowing. Any interruption of this coordinated neuromuscular function of the epiglottis or of any other protective reflexes can provide a dangerous opportunity for the entrance of food or liquid into the larynx and lower airway. As food is squeezed posteriorly an automatic swallowing reflex is initiated. The larynx is pulled superiorly allowing the epiglottis to cover and protect the opening of the larynx.¹ The epiglottis does not operate as a movable lidlike structure that falls to close the larynx during swallowing, as is often claimed. Passage of food into the trachea can occur if the muscles and protective elevation of the larynx become rigid or are changed because of nerve interruption. A series of reflex and involuntary processes mediated by the superior laryngeal, recurrent laryngeal, and glossopharyngeal nerves coordinates and regulates glottic closure during swallowing.¹⁻³

The larynx is a rigid organ composed of three paired and three unpaired cartilages (arytenoid, corniculate, and cuneiform; and thyroid, cricoid, and epiglottis, respectively) and is supported by the hyoid bone. This hollow structure forms a reservoir distal to Waldeyer tonsillar ring and provides the connection of the oropharynx to the trachea (Fig. 43.2). The primary functions of the larynx are vocalization and articulation; secondarily, it provides protection of the airway and allows respiration.¹ In the adult, the area of the vocal cords, or rima glottidis, is the narrowest portion of the larynx. In children, the cricoid ring has traditionally been regarded as the narrowest portion of the airway until approximately 10 years of age. Cuffed tubes were then generally recommended for those older than 8 to 10 years of age to allow for a better seal of the airway, prevent subglottic edema, and reduce the

incidence of postoperative airway compromise.⁴

FIGURE 43.2 Laryngeal cartilages. Some softer tissues of the larynx and surrounding structures have been removed to make it possible to see the cartilages of the larynx. Note the position of the nearby thyroid gland. **A**, Anterior view. **B**, Posterior view. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 9th ed. St. Louis: Elsevier; 2016:805.)

However, more recent studies (2013) have indicated no difference in the rate of postoperative complications, such as postintubation croup, between the use of cuffed and uncuffed ETTs. These studies instead support the use of a newer pediatric low pressure cuffed tube called the *Microcuff ETT* (Microcuff GmbH, Weinheim, Germany, distributed by Kimberly-Clark USA).⁵

Specific nervous structures of the head and neck are noteworthy because of their superficial location or proximity to operative sites. Surgeons may use audible or visual nerve-locating devices to find these nerves and their appropriate branches. To accurately locate these nerves, neuromuscular blocking agents may need to be avoided during the maintenance of certain general anesthetics.

The facial nerve (VII) has six major branches: four anterior (temporal, zygomatic, buccal, and mandibular), one inferior (cervical), and one posterior (posterior auricular) branch. The facial nerve located at the tragus of the ear is the motor and sensory supply to the muscles for facial expressions. The zygomatic branch

leaves the skull via the stylomastoid foramen and advances anteriorly over the maxilla. The chorda tympani branch of the facial nerve conveys taste from the anterior two-thirds of the tongue, and the more superficial tribranched facial nerve controls facial expression. The trigeminal nerve begins at the gasserian ganglion and divides into three branches; they are the ophthalmic (the first division, V_1), maxillary (the second division, V_2), and mandibular (the third division, V_3). All three divisions provide sensory and motor innervation to the nose, sinuses, palate, and tongue. They aid in the motor control of the face and in mastication.¹⁻³

The glossopharyngeal nerve provides motor and sensory innervation for the base of the tongue and nasopharynx and oropharynx. The glossopharyngeal nerve is responsible for eliciting the gag reflex during instrumentation of the posterior pharynx and vallecula.

The superior laryngeal nerve and recurrent laryngeal nerve (RLN) are both branches of the vagus (X). The superior laryngeal nerve descends to the hyoid bone and then branches into the internal laryngeal nerve, which passes through the thyrohyoid membrane, and the exterior laryngeal nerve, which descends over the lateral thyroid cartilage to the distal trachea. The RLN ascends from the vagus up the distal trachea, passing through the cricothyroid ligament into the proximal trachea and vocal cords. The RLN lies between the trachea and esophagus and supplies sensory innervation to the trachea and vocal cords. This branch of the vagus nerve also affects vocal cord closure and sensory function up to the inferior aspect of the epiglottis. Stimulation of the epiglottis with the tip of a straight laryngoscope, blades, suction catheters, and placement of an ETT in the trachea can produce a vagal response.³ The paired and unpaired cartilages of the larynx are listed in [Table 43.1](#). Nerve supply to the larynx is given in [Table 43.2](#). The intrinsic muscles of the larynx, their nerve supply, and function are listed in [Table 43.3](#). The extrinsic muscles of the larynx, their nerve supply, and function are listed in [Table 43.4](#).¹⁻⁶

TABLE 43.1**Paired and Unpaired Cartilages of the Larynx**

Paired	Unpaired
Arytenoid	Thyroid
Corniculate	Cricoid
Cuneiform	Epiglottis

TABLE 43.2

Nerve Supply of the Larynx

Nerve	Innervation
Sensory Nerves	
Superior laryngeal n. internal branch (vagus)	Laryngeal mucosa above vocal cords (inferior epiglottis)
Recurrent laryngeal	Laryngeal mucosa below vocal cords
Glossopharyngeal	Superior aspect of epiglottis and base of tongue
Motor Nerves	
Recurrent laryngeal	All intrinsic muscles except cricothyroid
Superior laryngeal n. external branch	Cricothyroid muscles

n, Nerve.

TABLE 43.3

Intrinsic Muscles of the Larynx

Muscle	Innervation	Function
Cricothyroid	Superior laryngeal nerve	Tension and elongates vocal cords
Thyroarytenoid	Recurrent laryngeal nerve	Relaxes vocal cords
Vocalis	Recurrent laryngeal nerve	Relaxes vocal cords
Posterior cricoarytenoid	Recurrent laryngeal nerve	Abducts vocal cords
Lateral cricoarytenoid	Recurrent laryngeal nerve	Adducts vocal cords
Transverse arytenoid	Recurrent laryngeal nerve	Adducts vocal cords
Aryepiglottic	Recurrent laryngeal nerve	Closes glottis
Oblique arytenoid	Recurrent laryngeal nerve	Closes glottis; approximates folds

TABLE 43.4

Extrinsic Muscles of the Larynx

Muscle	Innervation	Function
Sternohyoid	Cervical plexus; C1, C2, C3	Draws hyoid bone inferiorly
Sternothyroid	Cervical plexus; C1, C2, C3	Draws thyroid cartilage caudad
Thyrohyoid	Cervical plexus; hypoglossal nerve; C1 and C2	Pulls hyoid bone inferiorly
Thyroepiglottic	Recurrent laryngeal nerve	Inversion of aryepiglottic fold
Stylopharyngeus	Glossopharyngeal	Folds thyroid cartilage
Inferior pharyngeal constrictor	Pharyngeal plexus; vagus	Aids swallowing

Preparation and Considerations for Ear, Nose, and Throat Procedures

The Shared Airway and Considerations for Positioning

Operative procedures involving the airway, mouth, or bony structures of the face involve a true sharing of the airway between the surgeon and the anesthetist. Therefore proper preparation requires planning and communication between the surgeon, surgical personnel, and the anesthetist prior to the surgical procedure. Sharing the airway with the surgeon also requires preparing and planning the use of the appropriate equipment. For example, during laryngoscopy the ETT may have to be smaller in diameter and moved to one side of the oropharynx to allow the surgeon to work around the tube and to facilitate the surgery. The head of the table is often rotated 90 to 180 degrees away from the anesthetist, resulting in a vulnerable airway to which the anesthetist may have little or no access. Particular concerns are the maintenance of adequate ventilation, and patency of the anesthesia circuit and ETT. Extubation, disconnects, and leaks must be prevented. Adequacy of ventilation is constantly assessed by observing chest movement, auscultation, pulse oximetry, end-tidal CO₂, and blood gas analysis. A sudden loss of breath sounds, rising inspiratory pressures, or a reduction in end-tidal CO₂, particularly in the presence of a sharp reduction in inspiratory effort, may be caused by a deflation of the ETT cuff, obstruction of the ETT, dislodgment of the ETT, a disconnection of the anesthesia circuit, or severing of the ETT during surgical dissection.⁶ When coupled with vigilance, the precordial or esophageal stethoscopes are simple devices that should not be overlooked; these devices, in addition to more sophisticated mechanical devices, help the anesthetist maintain assessment of the airway.

Assessment of the airway prior to induction is critical in most ENT patients. Although the induction of anesthesia and securing of the airway are performed in the usual manner (with the anesthetist

at the head of the table), the management of the airway can become questionable and difficult while at a distance. Obtaining a thorough history and performing an extensive evaluation of the airway for the ENT patient is crucial. A good examination of the airway will (1) allow for a careful and deliberate approach to airway management, (2) aid in evaluating the need for additional equipment and assistance, and (3) include alternative approaches for the difficult airway if the initial plan proves not to be successful. Once the induction is complete and the airway established, the anesthetist must be prepared to provide adequate ventilation, deliver necessary anesthetic and adjunct agents, place invasive lines, and safely monitor the patient while remaining at a distance and isolated from the airway.

Orchestrating how the patient is turned so that the patient's head is away from the anesthetist demands clear planning. The ETT should be secured with tape or suture to prevent removal. The invasive line tubing, intravenous (IV) access lines, monitoring devices, and breathing circuit require added length to extend to the patient without creating tension at the site before induction. In addition to increasing line and tubing length additional thought must be given to padding areas of pressure on the patient's body. The patient's entire head is frequently draped and prepped into the surgical field limiting access to the ETT and breathing circuit connections (Fig. 43.3).

FIGURE 43.3 Illustration of secured airway for a patient

undergoing face, neck, or maxillofacial surgical procedures. Note that the tube is positioned to prevent pressure on the lip, nose, or forehead and secured with tape to prevent movement during surgery. The connection is covered by sterile surgical drapes and allows only limited access during the surgical procedure.

When repositioning of the head is necessary, communication between the surgeon and anesthetist is important to reduce the possibility of extubation, position change, or occlusion of the ETT. Signs of air leaks around the ETT (e.g., bubbling, the sound of air escaping, or the smell of anesthetic agent from the patient's mouth) may well be more sensitive indicators than mechanical airway monitors. Occlusion of the ETT is best prevented but can be determined by good auscultation, watching chest wall motion, and monitoring inspiratory pressures and morphology of CO₂ waveforms. The surgeon must communicate any changes in the surgical field, such as changing the position of a suspended or fixed laryngoscope, dark blood, manipulation of carotid bodies, or the need for a change in the patient's head position.⁷ Increased inspiratory pressures or a rapid loss of inspiratory pressure, decreased oxygen saturation, changes in end-tidal CO₂ measurements, or diminished breath sounds should, in turn, be communicated to the surgeon so that inspection of the airway and anesthesia circuit may be undertaken. If unable to arrive at a cause, undraping the patient may become necessary for a thorough examination of tube placement and connections, or to find a leak in the anesthesia circuit that could compromise patient ventilation.

Procedures of the head and neck typically require access to all planes of the head by several members of the surgical team.⁸ Because several problems can be encountered with the intubated patient during the surgical procedure, the surgeon may elect to perform a tracheostomy, then place and suture a flexible ETT in a fixed position during the procedure. A heightened state of vigilance must be maintained for occlusions from mucous plugs or blood, disconnects, ETT fires, and other problems that may arise during the anesthetic. During some ENT procedures the surgical team also may need access to the chest and abdomen for securing grafts for the esophagus or oral cavity. Often this requires the anesthetist to

take residence at either the side of the patient or at the foot of the operating table (Fig. 43.4). Providing a smooth transition with protection of the established airway and prevention of hypoxia are the primary concerns during movement of an operating table with an anesthetized patient.

FIGURE 43.4 Position of the anesthetist for surgery of the head and neck. The anesthetist is positioned at the side of the table and using a standard circle circuit (*left*). The anesthetist is positioned at the foot of the bed and using a coaxial (Bain) circuit (*right*). ESU, Electrosurgical unit. (From Phillips N. Berry & Kohn's *Operating Room Technique*. 13th ed. St Louis: Elsevier; 2017:840.)

The anesthesia circuit and other monitors should be temporarily and briefly disconnected before the bed is turned. This will prevent undue tension on the circuit and other lines that could lead to traumatic extubation or loss of access. Ventilation of the patient with 100% oxygen and adequate tidal volumes for 3 to 5 minutes before disconnection will denitrogenate the functional residual volume and provide an extra reservoir of oxygen during the turn, preventing even a short period of hypoxia. However, if a volatile agent is the primary source of anesthesia, the addition of IV anesthesia during this preoxygenation is necessary to maintain an adequate level of anesthesia and/or amnesia during this period. A saturation of 100% is a reasonable goal before the disconnection and table movement.

The degree of table movement should be discussed with the surgeon before any interruption in the anesthesia or the breathing circuit takes place. Turning of the operating table should be a well-organized procedure, understood by all members of the surgical team, and one that takes a minimum amount of time. After relocking the bed, reconnection of the anesthesia circuit must be immediate to reestablish oxygenation and/or anesthesia. Reevaluation and assessment of the tube placement, breath sounds, chest expansion, oxygen saturation, anesthetic level, line and IV access, and end-tidal CO₂ should be performed *before* prepping and draping is begun and throughout the case. Once adequate ventilation is established, the use of a heat moisture exchanging (HME) device or airway humidifier will help in decreasing insensible losses from the respiratory system during long periods of anesthesia.

Attention to simple practical points may prevent airway mishaps. At least one large-bore IV line, in addition to arterial and central venous pressure lines, should be started on the nonoperative side, if possible on the side of the patient that will be nearest to the anesthetist during the procedure. This will prevent obstruction of flow caused by the surgical procedure, afford easier access for drug administration and blood sampling, facilitate the manipulation or maintenance of lines during surgery, and allow the surgeon easy access to the operative field. If such lines must be placed on extremities opposite the anesthetist, adequate extensions should be placed before a change in position of the table to reduce the chance of lines being removed, infiltrated, or disconnected during movement. The calf of the leg may be used for noninvasive blood pressure measurements to prevent dampening of IV fluid flows in the upper extremities. Care must be taken to ensure that the measurement of the blood pressure takes into account variations in table changes from the horizontal position to prevent hypotension to vital organs. Monitoring of neuromuscular relaxation may be performed at locations other than the adductor pollicis. Stimulation of the tibial nerve produces flexion of the big toe and is similar to that of the adductor pollicis.⁹ Because ENT procedures may take more than 3 hours and can require significant fluid administration, monitoring urinary output with a Foley catheter may be included in

the plan.

Specialized Equipment for Ear, Nose, and Throat Procedures

Endotracheal Tubes Designed for ENT Surgery

Several ETTs are available for securing an airway. Standard ETTs equipped with flexible or straight connectors are appropriate for many ENT procedures. The diameter and length of the ETT will affect ventilation and seal of the airway. Using a small-diameter ETT in a large adult airway will not only lead to less ventilation through increased resistance, but also will allow only a small portion of the cuff to contact the trachea. Using specialized tubes with small diameters allows more even distribution of the cuff over the trachea during inflation. Several of these specially designed ETTs have found wide acceptance in ENT anesthesia. A variety of designs are used to limit encroachment of the ETT into the surgical field, prevent kinking of the ETT when severe angles are necessary, prevent fires in the airway during laser therapy, and provide maximal patient ventilation and safety.¹⁰

Several ETTs have been introduced for use in ENT anesthesia. The purpose for the evolution of these various types of ETT cuffs was to reduce cuff pressure on the tracheal wall and allow for improved tracheal perfusion, reduced tracheal injury, and more convenient airway access. Preformed right-angled ETTs, in cuffed and noncuffed types, are available for either oral or nasal intubation of adults or children. Oral ring, Adair, and RAE tubes (named after inventors Ring, Adair, and Elwyn) are an excellent choice for cleft palate repair, tonsillectomy, uvulopalatopharyngoplasty, and procedures of the eye or upper face. Nasal RAE tubes are particularly well suited to maxillofacial surgery that does not allow for oral intubation. The nasal RAE can be used for cosmetic procedures of the face, surgical procedures of the oral cavity and mandible, or to correct malocclusion. However, although the preformed bend in the RAE tube prevents the ETT from kinking in many instances, it may be too distal or proximal for an individual

patient's airways. This then allows the tip of the ETT to rest well below or above the carina. A careful check of the breath sounds and inspiratory pressures is imperative after intubation with the RAE to ensure proper positioning. Nasal intubation and placement of a nasogastric tube in the unconscious patient with facial trauma is best avoided to prevent possible penetration of the brain.^{11,12}

Anode, armored, reinforced, and Kant Kink tubes all have an embedded coiled wire or plastic coil strand to produce a tube with greater flexibility and memory. Armored tubes for oral or nasal intubation resist kinking and retain their original integrity. They are useful when acute neck flexion or severe angles of the ETT are required, as in procedures involving the base of the skull or posterior aspect of the neck. However, several reports suggest that even the edentulous patient can on occasion occlude a reinforced ETT.¹³ Several varieties of metal-impregnated tubes are available for use with laser surgery; these are designed to reduce the occurrence of an airway fire (Figs. 43.5 and 43.6). The cuff of the laser tube is usually filled with saline to dampen or prevent ignition. In addition, it is recommended that the cuff be filled with methylene blue-dyed saline so that a cuff perforation is easily detected. Wrapping a standard ETT with reflective tape is not an adequate alternative to these commercially prepared tubes because the wrapped standard ETT will dry and lead to greater flammability.¹⁴

FIGURE 43.5 Endotracheal tubes for laser surgery of the airway.

FIGURE 43.6 The Laser Flex endotracheal tube comes with a double cuff or no cuff. The double cuff is typically filled with normal saline or blue dye to easily visualize cuff rupture. (Reprinted by permission from Nellcor Puritan Bennett LLC, Boulder, Colorado, part of Covidien.)

Although not classified as an ETT, the laryngeal mask airway (LMA) and intubating laryngeal mask airway may be used to facilitate intubations, as well as control the airway. The LMA does not produce tracheal stimulation, which can be a considerable advantage in ENT procedures. The incidence of coughing on emergence is lower with the LMA than with the ETT. Another advantage of the LMA is the ability to insert the device without the use of neuromuscular blocking agents, or for airway rescue situations. Although LMA is contraindicated in some patients with laryngeal pathology, it is often the airway of choice when dealing with patients with pharyngeal pathology. Indications for LMA use in ENT surgery include a conduit for surgical access to the glottis and trachea, an aid to neurologic monitoring to avoid relaxant use, and as a means of isolating the glottis from bleeding from pharyngeal sources.¹⁵

Special Considerations for Ear, Nose, and Throat Procedures

Pharmacologic Considerations

The use of local anesthetics is particularly prevalent during nasal and sinus surgery. The most commonly used local anesthetics for ENT surgery include the amide-based drugs. Many procedures are performed using topical and local anesthesia as the sole agent in combination or supplemented with monitored anesthesia care, IV sedation, or general anesthesia. [Table 43.5](#) gives some topical local anesthetics commonly used in ENT surgery. Determination of doses of local anesthetics administered by injection and topically must be carefully calculated because more than one agent in various combinations is commonly used.

TABLE 43.5
Topical Anesthetic Drugs

Drug	Concentration	Dose	Notable Features
Cocaine	4%	3 mg/kg	Only local anesthetic with vasoconstrictive ability; blocks reuptake of norepinephrine and epinephrine at adrenergic nerve endings
Lidocaine	2% and 4% solution; 2% viscous solution; 10% aerosol; 2.5% and 5% ointment; 10%, 15%, 20% cream	4 mg/kg plain; 7 mg/kg epinephrine 250–300 mg	Rapid onset; suitable for all areas of the tracheobronchial tree
Benzocaine	<i>Cetacaine contains:</i> 14% benzocaine, 2% butamben, and 2% tetracaine		Short duration of action (10 min); can produce methemoglobinemia
Bupivacaine	0.25%, 0.5%, 0.75%	2.5 mg/kg plain	Slow hepatic clearance; long duration of action
Mepivacaine	1%, 2%	4 mg/kg	Intermediate potency with rapid onset
Dyclonine	0.5%, 1%	300 mg maximum	Topical spray or gargle; frequent use for laryngoscopy; absorbed through skin and mucous membranes

Additional information regarding local anesthetics for injection and topical use can be found in [Tables 10.7](#), [10.9](#), and [10.10](#).

Vasoactive Drugs

The duration of action of a local anesthetic is proportional to the

time the drug is in contact with nerve fibers. For this reason, epinephrine in varying concentrations (1 : 200,000 or 5 mcg/mL; 1 : 100,000 or 10 mcg/mL; and 1 : 50,000 or 20 mcg/mL) may be added to local anesthetic solutions to produce vasoconstriction. Vasoconstriction limits systemic absorption and maintains a higher drug concentration in the vicinity of the nerve fibers to be anesthetized, thus extending the effects of the local anesthetic. Addition of epinephrine to a local anesthetic prolongs the duration of blockade and decreases systemic absorption and plasma concentrations, thus decreasing toxicity.¹⁶

It is estimated that in the United States, topical cocaine (4% to 10% solution) anesthesia is used in more than 50% of ENT procedures performed annually, specifically rhinolaryngology procedures.¹⁶ Cocaine is a naturally occurring ester of benzoic acid that is hydrolyzed by plasma cholinesterase. Applied topically it is an excellent local anesthetic and vasoconstrictor. The duration of action is approximately 45 minutes.¹⁷ Cocaine produces vasoconstriction by blocking catecholamine reuptake into the adrenergic nerve ending resulting in vasoconstriction and shrinking of the mucosa. Epinephrine is also injected for ENT procedures and is usually injected shortly after the application of cocaine. This combination of cocaine and epinephrine sets the stage for a significant interaction. Because cocaine that is absorbed into the plasma can block the uptake of epinephrine systemically, a toxic effect of epinephrine can result from the injection. This interaction can result in severe headaches, hypertension, tachycardia, and dysrhythmias.¹⁸

Anticholinergics

Anticholinergics were used liberally in the early days of anesthesia predominantly because of the excessive secretions caused by older volatile inhalation agents. With the advent of newer anesthetic agents excessive secretions are not an issue, and the routine use of anticholinergics has diminished. The antisialagogue effects, however, may still be useful in certain intraoral procedures that require a drier operative field. Glycopyrrolate may be a better choice than atropine because it produces less tachycardia in comparison to atropine. Glycopyrrolate also does not readily cross

the blood-brain barrier and thus lacks sedative effects.

Corticosteroids

Glucocorticoids may be administered preoperatively and intraoperatively to decrease laryngeal edema formation, reduce nausea and vomiting, and prolong the analgesic effects of local anesthetics. They should be administered as early as possible in the perioperative period to reach their peak effect prior to initiating surgery. The use of steroids may reduce the nausea and vomiting experienced after surgery. Dexamethasone was also reported to prolong the analgesic effects of local anesthetics.¹⁹ It has been postulated that prostaglandins, histamine, and other mediators increase the permeability of local vessels, which changes nociception at the site of trauma, and leads to the sensation of pain. Steroids inhibit the production of prostaglandins and therefore reduce pain. Although the use of steroids may be beneficial, they can also create sufficient immunosuppression to mask inflammation or infection.

Postoperative Nausea and Vomiting

All patients are at risk for postoperative nausea and vomiting (PONV). ENT procedures, particularly of the middle ear, are associated with a high incidence of PONV.²⁰ Patients experiencing PONV are uncomfortable after surgery, their discharge may be delayed from the postanesthesia care unit (PACU), or they may have an unscheduled hospital admission. The accumulation of blood in the posterior oropharynx, which may drain into the stomach or be swallowed during the postoperative period, can lead to PONV. This frequently occurs during throat procedures such as tonsillectomy. Packing the back of the throat with surgical packs during the procedure can prevent some drainage into the stomach. Care must be taken that the patient is awake, all surgical packs are removed, and suctioning of the airway precedes the extubation process, producing a clear airway, and ensuring the control of protective airway reflexes. A multimodal approach is advocated to attenuate PONV in ENT patients.^{21,22} Anti-emetic drugs are discussed in [Chapter 14](#).

Special Anesthetic Techniques Associated With ENT Procedures

Deliberate Controlled Hypotension

Extensive dissection is required for many head and neck tumors with operative times extending to 12 or more hours. Considerable fluid replacement, blood loss, electrolyte imbalances, and cardiovascular and respiratory changes may occur during surgery. The surgeon may request deliberate controlled hypotension to reduce blood loss. Patients must be individually evaluated prior to controlled hypotension to determine a safe mean pressure. The effects of common IV controlled hypotensive techniques are compared in [Table 43.6](#).^{23,24} The practice of controlled hypotension focuses on reducing the mean arterial pressure (MAP) to some predetermined level related to the limits of cerebral and systemic autoregulation. Although the research is conflicting as to what values are best practice, the author's practice is to not allow the mean pressure to fall below 50–60 mm Hg or a greater than 20% decrease of baseline MAP. Controlled hypotension requires achieving numerical goals while maintaining cerebral and renal autoregulation, in addition to adequate coronary artery blood flow. Patients with chronic hypertension may require a higher mean pressure to maintain adequate perfusion.²⁴ Regardless of the technique or medication chosen, it is imperative that urine output, mean arterial blood pressure, cerebral and cardiac perfusion pressure, and arterial blood gases be closely monitored and maintained. When using hypotensive anesthesia, an arterial line is required. Hypotensive techniques are also used with endoscopic sinus surgery. It has been noted that better operating conditions are achieved when moderate hypotension is produced with a vasoconstrictor such as a β -blocker than when vasodilating agents are used.²⁵

TABLE 43.6

Common Intravenous Agents for Hypotensive Techniques

Drug and Dosage	Advantages	Disadvantages
Sodium nitroprusside: Variable	Potent; reliable; rapid onset and	Reflex tachycardia;

age- and anesthetic-dependent effects; <i>Young adults</i> : 1–5 mcg/kg per min; <i>Children</i> : 6–8 mcg/kg per min	recovery; cardiac output well preserved	rebound hypertension; pulmonary shunting; cyanide toxicity possible
Dexmedetomidine: 1 mcg/kg over 10 min then 0.2–0.7 mcg/kg per hr	Dose dependent sedation and analgesia with associated hypotension; decreases intravenous/inhalational anesthetic requirements; smooth emergence	Bradycardia and hypotension most often seen with bolus; heart block
Esmolol: 200 mcg/kg per min to achieve 15% reduction of mean arterial pressure	Particularly useful to control tachycardia	Potential for significant cardiac depression
Nitroglycerin: <i>Adults</i> : 125–500 mcg/kg per min; <i>Children</i> : 10 mcg/kg per min	Preserves myocardial blood flow; reduces preload; preserves tissue oxygenation	Increases intracranial pressure; highly variable dosage requirements
Nicardipine: 5 mcg/kg per min	Ca ⁺⁺ channel blocker Preserves cerebral blood flow	
Remifentanil with propofol Remifentanil: 1 mcg/kg IV then continuous infusion 0.25–0.5 mcg/kg per min Propofol: 2.5 mg/kg IV, then infusion of 50–100 mcg/kg per min	Remifentanil reduces middle ear blood flow, creating a dry surgical field for tympanoplasty Propofol may help reduce PONV	No analgesic effect once remifentanil infusion discontinued; postoperative secondary hyperanalgesia

Select Techniques Commonly Used in Ear Nose and Throat Procedures

Laser Surgery

Anesthesia and laser surgery is also discussed in [Chapter 47](#); however, some specific issues concerning lasers are relevant to ENT surgery. Laser technology has been used in medicine for more than 30 years. The two most common lasers used in ENT surgery are the CO₂ and Nd:YAG (neodymium-doped yttrium aluminum garnet); recently the argon laser has also become a popular choice.²⁶ Laser light is different from standard light. Standard light has a variety of wavelengths, whereas lasers have only one wavelength (monochromatic). Laser light oscillates in the same phase, or all the photons are moving in the same direction (coherent) and its beam is parallel (collimated). The wavelength of the Nd:YAG laser beam is shorter as it passes through the garnet than that of the CO₂ laser. The shorter wavelength allows less absorption by water and therefore less tissue penetration. For example, the shorter wavelength of the Nd:YAG allows the laser light to pass through the cornea, whereas the longer wavelength of the CO₂ laser would burn the cornea. Laser light emits a small amount of radiation and can be infrared, visible, and ultraviolet in the spectrum. Lasers enable very precise excision, produce minimal edema and bleeding, and are favored by surgeons for resection of tumors and other obstructions of the airway. For operations in and around the larynx the CO₂ laser is frequently used because of its shallow depth of burn and extreme precision.¹⁴ The CO₂ laser produces a beam with a relatively long wavelength that is absorbed almost entirely by the surface of these tissues, vaporizing cellular water. Intermittent bursts of the CO₂ laser produce intense, precisely directed energy that results in a clean cut through the target tissue with a minimal amount of penetration of surrounding tissue. A low-energy helium-neon laser is commonly used to aim or direct CO₂ laser beams.

The holmium: yttrium-aluminum-garnet (Ho:YAG) laser is a relatively new laser. The Ho:YAG laser has a pulsed infrared output

with a wavelength of 2.1 mm. The laser has excellent absorption in water-rich tissues, and in otolaryngology it has been used for nasal surgeries and for tonsillectomies.

Laser light beams are primarily used for their thermal effect and can be used to cut, coagulate, or vaporize tissues. The exact tissue interaction of a laser is dependent on several variables, including the types of tissues being irradiated, the wavelength of the emitted beam, and the power of the beam.

Most surgical fires occur during head and neck surgery. This is caused by the presence of oxygen and the extensive use of lasers. The use of laser technology mandates taking measures to ensure the safety of the patient and operating room personnel (Box 43.2). Specific concerns include eye protection with appropriate colored glasses, avoidance of the dispersion of noxious fumes, and fire prevention. Stray or reflected beams of the Nd:YAG laser are capable of traversing the eye to the retina; therefore, green-lensed eye protection for all personnel is mandatory during use of the Nd:YAG laser. All persons in the operating room must wear goggles specifically designed to absorb Nd:YAG laser beams. The required protective eyewear for CO₂ lasers can be any clear glass or plastic that surrounds the face. Orange-red eye protection is required for the potassium titanyl-phosphate (KTP) laser, and orange glasses are required for the argon laser.

General Safety Protocol for Surgical Lasers

- Post warning signs outside any operating area: "WARNING: LASER IN USE."
- Patient's eyes should be protected with appropriate colored glasses and/or wet gauze.
- Matte-finish (black) surgical instruments reduce beam reflection and dispersion.
- Use the lowest concentration of oxygen possible.
- Avoid using nitrous oxide (N₂O), because it supports combustion.

- Lasers should be placed in STANDBY mode when not in use.
- Use an endotracheal tube specifically prepared for use with lasers.
- Inflate cuff of laser tube with methylene blue dyed saline so that a cuff perforation is easily detected.
- All adjacent tissues should be shielded by wet gauze to prevent damage by reflected beams.
- Plume should be suctioned and evacuated from the surgical field.

When tissues are cut by a laser, the smoke and vapors that are formed are called *laser plume*. This plume is an environmental concern and potentially toxic to operating room personnel. When the tissues vaporized by the laser are malignancies or viral papilloma, the concern arises as to whether these vapors are even more dangerous to operating room personnel if not removed from the environment. Current evidence shows that although actual environmental transmittance of these pathogens is low, the risk still exists, and encourages use of smoke evacuators at the site of laser vaporization.²⁷

The prevention of combustion within the airway is of primary concern. Fire in the airway is relatively uncommon (0.4%), and it is usually the result of penetration of the laser through the ETT, which exposes the beam to a rich oxygen supply. N₂O, although not flammable, also supports combustion and can propagate the flame.²⁸ Positive pressure ventilation in the presence of intraluminal combustion produces a blowtorch effect that causes serious damage to the respiratory tract of the unfortunate patient.²⁹ Many important steps should be taken to minimize the risk of laser fires.³⁰ [Box 43.3](#) lists safety measures for preventing fires during ENT procedures.¹⁴ [Box 43.3](#) Operating room fires are discussed further in [Chapters 47](#) and [59](#).

Safety Measures for Preventing Fires During Ear, Nose, and Throat Procedures

- Use only air for open delivery to the face if the patient can

maintain a safe blood O₂ saturation without supplemental.

- If the patient cannot maintain a safe blood O₂ saturation without extra O₂, secure the airway with a laryngeal mask airway or tracheal tube.
- *Exceptions:* When patient verbal responses may be required during surgery (e.g., carotid artery surgery, neurosurgery, pacemaker insertion) and when open O₂ delivery is required to keep the patient safe, do the following:
 - Deliver the minimum O₂ concentration necessary for adequate oxygenation at all times.
 - Begin with a 30% delivery O₂ concentration and increase as necessary.
 - For unavoidable open O₂ delivery above 30%, deliver 5 to 10 L/min of air under drapes to wash out excess O₂.
 - Stop supplemental O₂ at least 1 minute before and during use of electrosurgery, electrocautery, or laser, if possible. Surgical team communication is essential for this recommendation.
 - Use an adherent incise drape, if possible, to help isolate the incision from possible O₂-enriched atmospheres beneath the drapes.
 - Keep fenestration towel edges as far from the incision as possible.

- Arrange drapes to minimize O₂ buildup underneath.
- Coat head hair and facial hair (e.g., eyebrows, beard, moustache) within the fenestration with water-soluble surgical lubricating jelly to make it nonflammable.
- For coagulation, use bipolar electrosurgery, not monopolar electrosurgery.

During Oropharyngeal Surgery (e.g., Tonsillectomy)

- Scavenge deep within the oropharynx with a metal suction cannula to catch leaking O₂ and nitrous oxide (N₂O).
- Moisten gauze or sponges and keep them moist, including those used with uncuffed tracheal tubes.

During Tracheostomy

- Do not use electrosurgery to cut into the trachea.

During Bronchoscopic Surgery

- If the patient requires supplemental O₂, keep the delivered O₂ below 30%. Use inhalation/exhalation gas monitoring (e.g., with an O₂ analyzer) to confirm the proper concentration.

From Sheinbein DS, Loeb RG. Laser surgery and fire hazards in ear, nose, and throat surgeries. *Anesthesiol Clin*. 2010;28(3):485–496.

The “perfect” ETT for use with lasers remains a major discussion. However, several manufacturers have attempted to produce a laser-

compatible ETT that allows for adequate ventilation during the laser procedure, but reduces the risk of airway fire injury. A few generalizations can be made. The necessity of an inflatable cuff is a point of debate, although the ability to better ventilate the patient and keep the field free of combustible gases is an advantage. When filled with air, the cuff becomes a generous reservoir of combustion-supporting gas. If a cuffed tube is used, inflation with methylene blue–tinged normal saline is encouraged to make it possible to detect penetration. If a laser beam contacts the cuff, the colored liquid will absorb and disperse heat, alerting the operating team to the penetration; the liquid also will reduce combustion.³¹

Fire safety policies, procedures, and practice guidelines are now routine and observed in every modern operating room.³² A further discussion of laser surgery and anesthesia is in [Chapter 47](#).

Endoscopy

Endoscopic surgery includes panendoscopy, laryngoscopy, microlaryngoscopy (laryngoscopy aided by an operating microscope), esophagoscopy, and bronchoscopy. All these procedures can be performed using a rigid or flexible endoscope. If the rigid laryngoscope is used, the laryngoscope may be suspended from an arching support anchored to the patient's abdomen/chest, or from a Mayo stand over the patient. One of the most common endoscopic procedures performed is the endoscopic sinus surgery. Over 250,000 endoscopic sinus surgeries are performed yearly in the United States alone.^{32,33} Endoscopic sinus surgery is often associated with recurrent and seasonal allergies leading to polyps. Patients undergoing endoscopic surgery are often also being evaluated for pathology responsible for hoarseness, stridor, or hemoptysis. Other possible reasons for endoscopic examination include foreign-body aspiration, papillomas, trauma, tracheal stenosis, obstructing tumors, or vocal cord dysfunction. Several complications can arise with endoscopic surgery: eye trauma, epistaxis, laryngospasm, and bronchospasm; excessive plasma levels of local anesthesia and epinephrine have also been reported. Preoperatively the patient should be examined for any signs of airway obstruction, and proper measures should be taken to ensure safe and controlled airway management. Knowledge of the location

and size of a mass is important, and discussion with the surgeon about chest radiography, magnetic resonance imaging (MRI), and computed tomography (CT) scan results can be invaluable.³⁴

Special consideration should be given to whether administration of routine anxiolytic premedication is necessary in older children and adults with airway pathology as they may experience respiratory depression and worsening of airway obstruction. The airway must be protected from aspiration of gastric contents especially during prolonged airway manipulation and deeper sedation. Premedication with an antisialagogue to dry secretions and a full regimen of acid aspiration prophylaxis in aspiration-prone patients may be indicated. An awake oral or nasal intubation with minimal sedation and topical anesthesia of the oral cavity, pharynx, larynx, and nasopharynx is common. In rare circumstances an awake tracheostomy with local anesthesia may be safest. For shorter ENT procedures, anesthesia should be maintained with short-acting inhalation and IV agents to: (1) avoid patient movement and vocal cord movement, and (2) control sympathetic nervous system response to brief periods of extreme stimulation, as in laryngoscopy.

Good muscle relaxation of the vocal cords is an essential part of anesthesia management for microsurgery of the larynx. A single-dose short-acting relaxant such as succinylcholine may be considered for brief cases. If the procedure is expected to last 30 minutes or more, use of an intermediate-duration neuromuscular-blocking drug such as vecuronium, cisatracurium, or rocuronium for the initial tracheal intubation allows the return of muscle strength and spontaneous respiration to meet extubation criteria at the end of the surgical procedure. In instances where the surgeon requests vocal cords immobility without neuromuscular blocking agents, use of remifentanyl for the induction and maintenance may be useful. Emergence should include adequate oropharyngeal suctioning, humidified oxygenation, and observation in the PACU for laryngeal spasm, or postextubation croup or stridor.

One of the greatest management challenges during endoscopic procedures is that of sharing the airway continuously with the surgeon. Several methods have been used to provide oxygenation and ventilation during the procedures. One method is to control the

airway by using a small cuffed ETT (5.0 to 6.0 mm for an adult). Because the 5.0- and 6.0-mm ETTs are designed for smaller patients, a better ETT selection might include the microlaryngeal endotracheal tube (MLT). The MLT in similar sizes (5.0 to 6.0 mm) has a cuff that is larger than the small standard ETTs (5.0 to 6.0 mm) allowing for a larger cuff distribution across the surface of the trachea and creating a wider field of pressure on the tracheal surface. Distinct advantages of an ETT include a secure airway with easily controlled ventilation, a cuff to protect the lower airway from debris, monitoring of end-tidal CO₂, and the ability to administer inhalational anesthetics. Several drawbacks include the potential for extubation and loss of airway, complications during laser surgery, and interference with the operative field by the ETT.

Intermittent apnea is also used as a technique to ventilate patients in this shared space. The anesthetist or the surgeon repeatedly removes the ETT, operates during a brief period of apnea, and then allows the anesthesia provider to reintubate and ventilate the patient. One advantage of the technique is that no special equipment is needed to ventilate the patient. Many patients undergoing these procedures have a long history of heavy smoking and alcohol use, which predisposes them to cardiovascular disease and labile vital signs. Some of the disadvantages of this approach include difficulty in reintubation and the time allotment between ventilations while preventing desaturations. The procedure must be interrupted frequently to ventilate the patient, and the airway is unprotected while the ETT is removed. During this technique, the blood pressure and heart rate tend to fluctuate widely. The procedure resembles a series of stress-filled laryngoscopies and intubations, separated by varying periods of minimal surgical stimulation. IV administration or topical application of agents such as lidocaine; small doses of alfentanil, remifentanil, sufentanil, or fentanyl; and/or adrenergic receptor–blocking drugs such as esmolol or dexmedetomidine may help moderate the sympathetic response.³⁵

Jet Ventilation

Jet ventilation has been used extensively for laryngeal surgery.

When the trachea is not intubated, a metal needle mounted in the operating laryngoscope or passed through the cords can be used for jet ventilation. Jet ventilation may be performed manually, using a simple hand valve attached to an appropriate oxygen source, or together with various mechanical devices that allow for adjustment of rate and oxygen concentration. Because oxygen can support combustion, the lowest concentration of oxygen possible should be used. Many patients will tolerate a fraction of inspired oxygen (FiO_2) of 30% or less; however, oxygen requirements for each patient should be considered for his or her individual needs. Using lower levels of oxygen will decrease the likelihood of an airway fire.

High frequency is useful when access to the airway by the surgeon is limited by the ETT or the surgeon might interfere or ignite the tube. Jet ventilation does not require an ETT and requires only a narrow catheter with resistance to laser beams. There is no absolute contraindication to high-frequency jet ventilation (HFJV); however, it can be difficult maintaining oxygenation and/or CO_2 elimination in certain patients. These include patients who are morbidly obese, have a stiff thorax, or advanced forms of restrictive and/or obstructive lung disease, lung fibrosis, and reduced alveolar-capillary diffusion capacity, such as with pulmonary edema. Jet ventilation should be avoided in any situation in which an unprotected airway is a concern (e.g., full stomach, hiatal hernia, or trauma).³⁶

Common types of HFJV include supraglottic, infraglottic, transtracheal, and via a rigid bronchoscope.³⁷ Fig. 43.7 shows the commonly used rigid bronchoscope technique. HFJV was originally used as a technique to provide adequate oxygenation and alveolar ventilation for rigid bronchoscopy and laryngeal surgery. HFJV is ventilation at low tidal volumes with high respiratory rates. A needle connected to a high-pressure hose with a regulator to adjust rate and volume is used to deliver the ventilation. With the tip of the needle either above or below the glottis, the anesthetist directs a high-velocity jet stream of oxygen into the airway lumen. The lungs are ventilated as the mixture of oxygen forces air into the lumen. Introduction of high-pressure (up to 60 psi) jet-injected oxygen entrains room air into the lung, allowing the jet stream of gases into the airway for ventilation.³⁷ Inspiration is accomplished by HFJV

pressurizing gas into the airway, whereas the expiration is passive and adequate exhalation should be constantly assessed both visually and mechanically. Some pauses in ventilation may be necessary to provide adequate time for expiration, particularly in patients with severe respiratory disease.

FIGURE 43.7 Rigid bronchoscope connected at its proximal end through an oblique side port to the jet line of the ventilator. (From Biro P. Jet ventilation for surgical interventions in the upper airway. *Anesthesiol Clin.* 2010;28(3):397–409.)

If an airway mass lies above the level of delivery of the gas jet, it may be easy to force the gas down the trachea during inspiration, but the gases will be trapped during expiration. This air trapping can lead to increased airway pressure, subcutaneous emphysema, and pneumothorax, particularly in patients with bullae. The anesthetist or surgeon also may find it difficult to aim the jet into the airway lumen, leading to hypoxia. If the jet is not accurately aimed, gastric distention, subcutaneous emphysema, or barotrauma may result. Patients with decreased pulmonary compliance or increased airway resistance from bronchospasm, obesity, or chronic obstructive pulmonary disease (COPD) are at high risk for hypoventilation with jet techniques. Adequacy of ventilation is assessed by observing chest movement, auscultation with the precordial stethoscope, and a pulse oximeter. IV anesthetic techniques are used with HFJV, because environmental contamination by leaking volatile agents is a concern.³⁶

Foreign-Body Aspiration

Aspiration of foreign bodies is a common problem that carries high morbidity and mortality, particularly in children. Asphyxiation by an inhaled foreign body is a leading cause of accidental death among children younger than 4 years. Some common aspirants include peanuts, popcorn, jelly beans, coins, bites of meat, and hot dogs. Most aspirated items are food particles, with nuts and seeds being the most common. Aspiration of beads, pins, and parts of small toys are also not unusual. A common site of foreign body aspiration is the right bronchus. If the patient is supine when the aspiration occurs, the object will most likely be found in the right upper lobe. If the patient is standing, the right lower lobe is most likely to be affected. Signs of aspiration include wheezing, choking, coughing, tachycardia, aphonia, and cyanosis. These signs indicate an obstructive, severe irritation, and swelling in the airway. As a result of the swelling, air may be trapped in the lungs, not allowing adequate expiration. Although rigid bronchoscopy has been the traditional diagnostic gold standard, the use of CT, virtual bronchoscopy, and flexible bronchoscopy is increasing. Reported mortality during bronchoscopy is 0.42%. Although asphyxia at presentation or initial emergency bronchoscopy causes some deaths, hypoxic cardiac arrest during retrieval of the object, bronchial rupture, and unspecified intraoperative complications in previously stable patients constitute most in-hospital fatalities. Major complications include severe laryngeal edema or bronchospasm requiring tracheotomy or reintubation, pneumothorax, pneumomediastinum, cardiac arrest, tracheal or bronchial laceration, and hypoxic brain damage.³⁸

Anesthetic management depends on the location of the airway obstruction, the size and location of the object, and the severity of the obstruction. If the foreign body is located at the level of the larynx, a simple laryngoscopy with Magill forceps should allow for easy removal of the object. Care must be taken not to dislodge the object and allow it to fall deeper into the airway. If the foreign body is in the distal larynx or trachea, the patient should have an inhalation induction performed in the operating room, maintaining spontaneous respiration. With the patient spontaneously breathing, the surgeon will most likely use a rigid bronchoscope for extraction

of the foreign body. Usually a gentle mask induction without cricoid pressure or positive pressure ventilation is the preferred induction technique.³⁹ Attempts to assist respirations should not be made because that might cause the object to move farther into the airway and compromise ventilation with occlusion. Patients should be placed in the sitting position because it is known to produce the least adverse effect on airway symptoms. An antisialagogue, H₂ antagonist, and metoclopramide are often administered intravenously to decrease secretions and promote gastric emptying; the secretions may obscure the view through the bronchoscope. Patients with full stomachs who are induced with a rapid sequence must be prepared for complete occlusion of the airway.

Direct and sometimes rigid laryngoscopy is typically performed. A rigid bronchoscope is also used and passed through the vocal cords into the trachea. Ventilation is accomplished through a side port of the laryngoscope or bronchoscope that can be attached to the anesthesia circuit. If a foreign body is present, the telescope eyepiece within the bronchoscope is removed and optical forceps are inserted through the bronchoscope for retrieval of the item. When the telescopic eyepiece is being changed a leak is present in the ventilation system, and protracted periods can lead to hypoxia. When an anesthesia gas machine circuit is used, high fresh gas flow rates, large tidal volumes, and high concentrations of inspired volatile anesthetic agents are often necessary to compensate for leaks around the ventilating bronchoscope. Coughing, bucking, or straining during instrumentation with the rigid bronchoscope may cause difficulty for the surgeon and result in damage to the patient's airway; these must be avoided. The best anesthesia technique for rigid laryngoscopy and bronchoscopy is total IV anesthesia, allowing greater control of cardiovascular stability and relaxation for short periods, as well as ventilation with 100% oxygen allowing longer periods of hypoventilation without hypoxia.

A rigid bronchoscopy can lead to several complications including damage to dentition, gums, upper lips, and chipped or damaged teeth, all of which can be prevented to some degree with the use of a mouth guard and vigilance. A good range of motion of the cervical vertebra is also evaluated and necessary for insertion of the

rigid scopes. Vagal stimulation may be noted from the extreme head extension, and tracheal tears can occur with the introduction of the bronchoscope. Inadequate ventilation manifests as hypoxemia, hypercarbia, barotrauma, and dysrhythmias. The surgeon must be prepared to perform an emergency tracheotomy or cricothyrotomy if partial obstruction suddenly becomes complete.

At the end of the procedure patients can be intubated to provide ventilation until returning to consciousness. Allow the patient to return to consciousness as quickly as possible, with airway reflexes intact prior to extubation. Laryngeal and subglottic edema may occur for 24 hours after removal of a foreign body. To check for airway edema, the cuff of the ETT can be deflated, if not contraindicated, and the lumen of the ETT should be occluded for one or two breaths during inspiration and expiration while listening for air movement around the tube. If there is no air escaping around the ETT, postoperative sedation and ventilation might be considered. Close observation and use of humidified oxygen are suggested during the recovery period. Some additional supportive measures that can alleviate some of the postoperative complications that occur include racemic epinephrine, bronchodilators, and steroids.

Procedures Involving the Face, Ear, Head, and Neck

Some of the common surgical procedures for the ear and face include myringotomy with insertion of tubes, mastoidectomy, acoustic neuroma, stapedectomy, and tympanoplasty. During ear surgery the anesthetist must be concerned with four major issues: (1) nerve preservation, (2) the effect of N₂O on the middle ear, (3) control of bleeding, and (4) PONV.

Nerve Preservation During Surgical Procedures

Surgical procedures of the ear and face require meticulous identification and preservation of the facial nerve and other cranial nerves especially during resection of a glomus tumor or an acoustic neuroma. Intraoperative neuromonitoring is a relatively recent advance in electromyography (EMG) applied to head and neck surgery. Its purpose is to allow real-time identification and functional assessment of vulnerable nerves during surgery. The nerves most often monitored in head and neck surgery are the motor branch of the facial nerve (VII), the recurrent or inferior laryngeal nerves (X), the vagus nerve (X), and the spinal accessory nerve (XI), with other lower cranial nerves monitored less frequently. Morbidity from trauma to these nerves is significant and obvious, such as unilateral facial paresis. Although functional restorative surgery can be performed, the importance of preventing nerve injury in head and neck surgery is obvious.

The identification of these nerves requires the surgeon to isolate and verify function by means of an electrical stimulation. One method used for nerve isolation is the brainstem auditory evoked potential and electrocochleogram monitoring. [Table 43.7](#) lists several types of intraoperative neurophysiologic monitoring used during ENT procedures and the effects of various anesthetic drugs on the monitoring modality.⁴⁰

TABLE 43.7

Types of Intraoperative Neurophysiologic Monitoring and the Effects of Various Anesthetic Drugs

Type or Modality of Neurophysiologic Monitoring	Surgery Examples	Region	Volatile Agents (e.g., Isoflurane)	Neuromuscular Blocking Agents*	Total Intravenous Anesthesia	
					Opioids	Propofol
Brainstem auditory evoked response	Acoustic neuroma, trigeminal neuralgia, facial nerve decompression, endolymphatic sac	Cerebellopontine angle, mastoid region, middle ear	1	0	0	1
Cortical somatosensory evoked potentials	Spinal fusion, tumor, decompression	Spine (posterior columns)	2 (affect amplitude and latency of waveforms)	0	0	0
Neuromuscular junction monitoring	Neuromuscular blockade in anesthesia	Ulnar nerve, facial nerve, posterior tibial nerve	0	2	0	0
IONM: spontaneous EMG†	Thyroid, parathyroid, parotid, neck dissection, skull base	Facial, vagal, recurrent laryngeal, other cranial nerves	0	2	0	0
IONM: evoked EMG†	Thyroid, parathyroid, parotid, neck dissection, skull base	Facial, vagal, recurrent laryngeal, other cranial nerves.	0	2	0	0
MEP	Spinal fusion, tumor, decompression	Spine (anterior columns)	2	2	0	0
EEG† (BIS)	All	All	2	0	1	2
EEG†	Carotid endarterectomy	Carotid	2	0	2	2

*The two classes of drug to be avoided during monitoring of facial, recurrent laryngeal, vagal, and other cranial motor nerves are neuromuscular blocking agents and local anesthetics. Both may increase latency, decrease amplitude, and increase stimulus threshold of the evoked response, or may decrease the sensitivity of EMG to nerve injury.

†A conventional balanced anesthetic (opioid, nitrous oxide/oxygen, volatile agent) is suitable for surgery using EMG and EEG.

Scale: 0 = insensitive; 1 = somewhat sensitive; 2 = very sensitive.

BIS, Bispectral electroencephalogram; *EEG*, electroencephalogram; *EMG*, electromyogram; *IONM*, intraoperative nerve monitoring; *MEP*, motor evoked potentials.

From Dillon FX. Electromyographic (EMG) neuromonitoring with otolaryngology-

head and neck surgery. *Anesthesiol Clin*. 2010;28(3):434–442.

Patient movement during neck dissection and skull base surgery must be prevented, especially if a positioning device is used for craniotomy. Muscle relaxants should only be used at induction and intubation to prevent interference with the nerve monitoring. The use of local anesthetics is also contraindicated because of their suppressant effects on muscle action potential amplitudes and muscle movement. Hemostasis during neck dissection is not as critical as during otologic or skull base neurosurgery, but the use of a short-acting opioid infusion such as remifentanyl or sufentanyl will help control blood pressure and aid hemostasis. The use of volatile anesthetic agents and N₂O is acceptable only if the N₂O is discontinued well before closing any cavity. Common anesthetic techniques include the use of remifentanyl with short-acting volatile anesthetic agents with or without N₂O. Midazolam preoperatively helps assure amnesia and rapid emergence. Selected use of deep extubation helps prevent straining during emergence, as straining increases postoperative bleeding and may necessitate reexploration.⁴¹

Middle Ear Procedures

Middle ear procedures require a bloodless surgical field, specific head positioning, facial nerve monitoring, and management of PONV. The term *middle ear* refers to the air-filled space between the tympanic membrane and the oval window. It is connected to the nasopharynx by the eustachian tube and is in close proximity to the temporal lobe, cerebellum, jugular bulb, and the labyrinth of the inner ear. The middle ear contains three ossicles—the malleus, incus, and stapes—which transmit sound vibration from the eardrum to the cochlea. This air-filled cavity is traversed by the facial nerve before it exits the skull via the stylomastoid foramen. The facial nerve provides motor innervation to the muscles of facial expression. Common surgeries in adults include tympanoplasty (reconstructive surgery for the tympanic membrane, or eardrum), stapedectomy or ossiculoplasty for otosclerosis, mastoidectomy for removal of infected air cells within the mastoid bone, and removal of a cholesteatoma. Common middle ear surgery in children

includes tympanoplasty, mastoidectomy, myringotomy, grommet insertion, and cochlear implantation.⁴²

Middle ear surgery can be done with either local or general anesthesia depending on the patient's ability to cooperate. Local anesthesia with sedation requires the patient to remain still under surgical drapes for extended periods. The main advantages of performing middle ear surgery under local anesthesia are the ability to test hearing during surgery, and less bleeding. Most middle ear procedures can be performed as outpatient surgery; thus, rapid recovery, good analgesia, and avoidance of nausea and vomiting are essential. Pain is a primary problem at the beginning of surgery when multiple injections of local anesthetic with epinephrine are given. The use of a topical application of lidocaine and prilocaine (eutectic mixture of local anesthetics [EMLA]) may increase patient comfort. A bloodless surgical field is mandatory in microsurgery. A combination of physical and pharmacologic techniques is used to minimize bleeding. The patient's head is positioned to avoid venous obstruction and congestion.^{42,43}

When general anesthesia is chosen, the airway can be maintained with an LMA or endotracheal intubation. Intubation may be more appropriate if extreme neck extension or rotation is required. A nerve stimulator is often employed for intraoperative monitoring of evoked facial nerve electromyographic activity to aid preservation of the facial nerve. Muscle relaxants are therefore avoided after intubation. A smooth recovery without coughing or straining is important to prevent prosthesis displacement, especially in patients who have undergone reconstructive middle ear surgery.

PONV, a common problem after middle ear surgery, can be minimized by the appropriate choice of anesthetic technique and antiemetic prophylaxis.⁴⁴ As noted previously, a bloodless operative field is essential. Physical and pharmacologic techniques are used to minimize bleeding. They include a head-up tilt of 15 to 20 degrees, avoidance of venous obstruction, normocapnia, and controlled hypotension. An ideal systolic blood pressure range is 80 to 90 mm Hg or a reduction of MAP to 20% of baseline in patients with hypertension. A slightly elevated position of the head reduces arterial and venous pressures in areas above the heart; however, it increases the risk of air embolism.

Pharmacologic agents used for controlled hypotension in ear, nose, and throat surgery include inhalation anesthetics, β -adrenoceptor antagonists (labetalol and esmolol), α_2 -adrenergic agonists (dexmedetomidine), opioids (remifentanyl), and more recently magnesium sulfate.^{41,45} Dexmedetomidine has several advantages as an adjunct to lower blood pressure. It produces sedation, analgesia, and a modest reduction in heart rate and blood pressure without respiratory depression. Dexmedetomidine has been used successfully to lower blood pressure during general anesthesia or as the primary sedative with supplementary low-dose propofol and midazolam for IV sedation.^{46,47} At the completion of the surgical procedure the patient's head is lifted and usually wrapped with a bandage. The anesthetist will want to avoid excessive coughing and bucking of the patient during this period. Therefore using a technique that limits coughing is desirable. Provided there are no contraindications, a deep extubation might be considered.

Nitrous Oxide and Middle Ear Surgery

N_2O is 34 times more soluble than nitrogen in blood, and enters the middle ear cavity more rapidly than nitrogen leaves causing an increase in middle ear pressure if the eustachian tube is obstructed. Normally pressure increases in the middle ear are vented via the eustachian tube into the nasopharynx. Yawning and swallowing actively open the eustachian tubes, but these equalizing maneuvers cannot occur in anesthetized patients. Additionally, pressure also may be increased in the middle ear with positive pressure ventilation by forcing air into the compartment through the eustachian tubes. During tympanoplasty the middle ear is open to the atmosphere; thus, there is no build-up of pressure, but once a tympanic membrane graft is placed, the continued use of N_2O might cause displacement of the graft. At the end of surgery, when N_2O is discontinued, the remaining N_2O is rapidly absorbed, which may then result in negative pressure. This negative pressure may result in graft dislodgement, serous otitis media, disarticulation of the stapes, or impaired hearing. Some clinicians feel that discontinuation of the N_2O at least 15 minutes before closure of the

middle ear is sufficient to ameliorate these adverse effects. Because N₂O is only a supplement to general anesthesia, avoiding it altogether during tympanoplasty is more reasonable. N₂O also may increase PONV, and its use in middle ear surgery may further increase the incidence of PONV above that already associated with this type of surgery.⁴¹

Myringotomy and Tube Placement

Most often patients scheduled for myringotomy are young, healthy patients. A myringotomy allows the pressure to equalize between the middle ear and the atmosphere, reducing the pressure in the middle ear compartment. Simple tubes with a lumen (grommets) are placed through the patient's tympanic membrane to alleviate the pressure created in the middle ear usually seen with chronic serous otitis media or recurrent otitis media. Chronic otitis media is manifested as fluid in the middle ear. Recurrent otitis media, a common pediatric disorder, is defined as either three or more acute infections of the middle ear cleft in a 6-month period or at least four episodes in 1 year. Untreated otitis media may lead to permanent middle ear damage and hearing loss; therefore appropriate treatment is necessary. Children with chronic otitis frequently have accompanying recurrent upper respiratory infections (URIs). Intervals between URIs may be brief, and the patient is usually on a regimen of antibiotics. Scheduling surgery during these interludes is often impractical. Frequently the eradication of middle ear fluid and inflammation resolves the URI; therefore surgery should not be delayed.

Bilateral myringotomies with tube insertions are typically very short operations. Sedative premedications may outlast the procedure and are usually not necessary. Mask or IV induction and maintenance using oxygen, N₂O, and a volatile inhalation agent such as sevoflurane is routine. If IV access is established, it is usually done after mask induction in children and may include fluid therapy or an injection cap for temporary access and administration of drugs. IVs are not usually necessary unless another procedure is performed at the same time.^{48,49} N₂O is often avoided in surgeries that involve the middle ear, but given that the

myringotomy surgical procedure is relatively short, and a tube will be placed through the tympanic membrane into the middle ear to relieve pressure, the effects of N₂O are not relevant. For bilateral procedures, the inhalation anesthetic is discontinued during the second myringotomy to facilitate prompt emergence. N₂O is continued until the completion of the surgery. Intubation is performed only if airway difficulties are anticipated or encountered, but airway equipment is always prepared and available. The procedure is typically without much risk of bleeding, but the patient's head must be held still, particularly when the myringotomy knife is being used.

The patient is supine with the head turned to expose the ear to the microscope. An ear speculum is inserted into the ear canal, cerumen is removed, and an incision is made in the tympanic membrane. Fluid is sometimes suctioned from the middle ear, and then a tympanostomy tube is inserted through the incision into the middle ear, straddling the tympanic membrane. Antibiotic and steroid eardrops are frequently inserted into the external auditory canal and mild pain medications given rectally, orally, or intravenously are administered in the perioperative period. The surgeon moves to the other side of the table, the microscope is repositioned, the head is turned, and the procedure is repeated in the other ear.^{50,51}

Tonsillectomy and Adenoidectomy

The frequency of adenotonsillectomy in the United States has declined, although it remains the most common pediatric surgery.⁵² The lateral tonsils, tonsillar tissue at the base of the tongue, and adenoids form a tonsillar “ring” around the oropharynx that can lead to significant airway challenges after surgical intervention. An adenotonsillectomy, although often considered a simple procedure, has the potential for significant airway challenges. Considerations of airway obstruction, shared airway, mechanical suspension of the airway, management of intubation and extubation, pain management, and the desire for a rapid awakening are all subtleties of anesthesia for this procedure. In adult patients, a tonsillectomy may also accompany a uvulopalatopharyngoplasty (UPPP) for

Pickwickian syndrome or obstructive sleep apnea (OSA). OSA is typically seen with obesity and redundant pharyngeal tissue. OSA patients can also present with significant comorbid conditions.^{53,54}

The patient undergoing a tonsillectomy and/or adenoidectomy will probably have a higher incidence of airway obstruction because of the hypertrophied tissues. Chronic obstruction and infections of the tonsils can lead to systemic involvement producing additional cardiac and respiratory anomalies. In the case of suspected airway obstruction, the clinician must choose wisely among routine IV induction, inhalation induction, awake intubation, or fiberoptic-assisted intubation before induction. Adult patients with severe OSA may require awake intubation before the induction of general anesthesia. Surgical approaches to tonsillectomy include coblation, cold steel, snare, monopolar cautery, and hot knife techniques. Techniques differ with respect to operative times, intraoperative blood losses, postoperative pain scores, or time to resumption of oral intake.⁵⁵

In children anesthesia is induced with propofol or sevoflurane, oxygen, and N₂O by mask depending on the age of the child and IV access. Some institutions allow parental presence in the operating room during induction to prevent separation anxiety in the child. LMA and ETT may both be used depending on the experience of the operating team.⁵⁶ A 2010 review noted that the use of the LMA during pediatric tonsil surgery does not appear to have any major disadvantages compared with use of the ETT. Analysis of safety, comfort, complications, and postoperative problems suggests that LMA may be superior for some outcome variables such as coughing and gagging. Use of spontaneous ventilation is more common among LMA patients.⁵⁷

A cuffed tube is recommended in those older than 8 to 10 years of age,^{4,5} with continued attention given to inflation pressures of the cuff. A properly sized pediatric ETT should allow a leak at 20 cm H₂O airway pressure, which reduces the likelihood of postoperative croup and edema. After the airway is secured, the mouth gag is inserted by the surgeon. An adequate depth of anesthesia is needed to facilitate gag insertion. The gag, designed to maintain an open mouth and tongue retraction, is equipped with a groove for the ETT or LMA to rest in (Fig. 43.8). The airway should be reevaluated at

the time the gag is placed to ensure that the tube has not been moved from its original position and that occlusion of the tube has not occurred as a result of compression from the gag. The table is frequently turned 45 to 90 degrees away from the anesthetist just prior to incision.

FIGURE 43.8 Superior view of the suspension technique for tonsillectomy using the Crowe-Davis mouth gag. Note use of preformed RAE (Ring, Adair, and Elwyn) orotracheal tube.

The choice of maintenance techniques for anesthesia varies. Several goals need to be considered when choosing an anesthetic: (1) provide a depth of anesthesia adequate to blunt strong reflex activity elicited by the procedure, (2) a rapid return of protective airway reflexes, (3) good postoperative analgesia, (4) reduced postoperative bleeding, and (5) minimal PONV. The use of intermediate-acting muscle relaxants is acceptable; however, they are often unnecessary. Judicious narcotic supplementation will reduce the total amount of inhalation agent required and provide analgesia with minimal postoperative respiratory depression. Disadvantages of opiates include increased sensitivity, desaturation in sleep apnea patients, and PONV. Suggested techniques include modest opioids and IV acetaminophen doses for analgesia, dexamethasone and ondansetron for antiemetic prophylaxis, and deep extubation of the trachea to minimize coughing and airway

stimulation when prudent.⁵⁷ Although an increase in postoperative bleeding has historically been a concern with the use of nonsteroidal antiinflammatory drugs (NSAIDs), a 2013 Cochrane review found that there was insufficient evidence to state whether NSAIDs increased bleeding risk post tonsillectomy. The review did note there was significantly less nausea and vomiting compared to use of opioid analgesics.^{58,59}

Blood loss during tonsillectomy is difficult to assess but has been estimated to average 4 mL/kg or 5% of blood volume.⁸ Average blood loss during UPPP is slightly higher because the procedure is frequently performed in conjunction with adenotonsillectomy. Although younger, healthier patients can tolerate greater volumes of blood loss, transfusion should be considered if blood loss, laboratory values, and patient factors indicate the need.

At the end of the surgical procedure the surgeon may release tension on the mouth gag to ensure that all bleeding has been controlled. The insertion of an orogastric tube and some irrigation may be used to remove blood and secretions from the stomach and oropharynx. This is thought to reduce the incidence of PONV. Suctioning of the oropharynx and nares should be done very gently and briefly, avoiding the surgical beds to prevent disruption and mucosal bleeding. Vigorous suctioning may induce laryngospasm and bronchospasm.

During emergence from anesthesia after tonsillectomy or UPPP the anesthetist should ensure that all protective reflexes have returned, the airway is free of blood and debris, and an adequate breathing pattern is present before the removal of the ETT. A topical spray of 2% lidocaine (maximum 3 mg/kg) on the glottic and supraglottic areas before intubation prevents postextubation stridor and laryngospasm after adenotonsillectomy. This approach has proved as effective as administering lidocaine (1–2 mg/kg IV) before extubation.⁶⁰

The postoperative tonsillectomy patient should be transported to the recovery in the “tonsil position” — that is, on one side with the head slightly down. This allows blood or secretions to drain out of the mouth rather than flow back onto the vocal cords. Adults, however, frequently prefer a middle- or high-Fowler position after UPPP. This position aids in ventilation and lessens the feeling of

asphyxiation in the immediate postoperative period. The patient must be awake enough to manage his or her own airway. To hydrate the airway, 100% oxygen with a high-humidity mist is given by facemask or face tent. The pharynx should be rechecked directly for bleeding and edema before discharge.

Routine tonsillectomy is generally performed as an outpatient procedure. A small subset of children are observed overnight if there are sufficient age, comorbidity, or perioperative concerns. Although postoperative bleeding is the most serious complication, persistent vomiting, poor oral intake, and persistent desaturation are the most common reasons for unscheduled overnight admission after ambulatory surgery. The incidence of PONV can be as high as 70% during the first 24 hours after tonsillectomy.⁶¹ This is the result of swallowed blood, opioid administration, or pharyngeal stimulation, and significantly increases the risk of overnight admission, delayed oral intake, and lower patient satisfaction.^{54,60,61} As discussed previously, it is important to develop anesthetic techniques that incorporate the use of antiemetics to minimize episodes of nausea and vomiting. Codeine for postoperative pain is contraindicated because of the potential for metabolic conversion to high levels of morphine in ultra-rapid metabolizers (see [Chapter 11](#)).

Bleeding Tonsil

Post tonsillectomy hemorrhage (PTH) is the most common emergency pediatric airway surgery. PTH rates are between 0.5% and 7.5% and are most common in patients more than 15 years of age, boys, patients with frequent infectious tonsillitis, and after hot (electrocautery) versus cold (scalpel) techniques. Approximately 75% of the postoperative tonsillar hemorrhages that occur are within 6 hours of the surgical procedure. The remaining 25% of the postoperative bleeds occur within the first 24 hours of surgery, although bleeding may be noted up until the sixth postoperative day.⁶²⁻⁶⁴ Slow oozing of the tonsillar bed is far more common than profuse bleeding. Patients may swallow large volumes of blood before bleeding is discovered. The patient may have signs of hypovolemia evidenced by tachycardia, hypotension, and agitation. If the blood is swallowed, the patient may have nausea and

vomiting. Appropriate laboratory tests including hemoglobin, hematocrit, and coagulation profile should be performed to determine patient status. Restoration of intravascular volume and/or blood based on the volume lost should precede induction. All patients should be assumed to have a significant amount of blood in the stomach and a rapid sequence induction is indicated. Care with laryngoscopy is necessary to prevent traumatic dislodgement of any clots. In some patients an awake intubation to maintain reflexes may be necessary. At induction of anesthesia an additional person should be available to provide suctioning of blood from the oropharynx. The patient should be placed in a slight head-down position to protect the trachea and glottis from aspiration of blood. Gastric decompression is performed to assess for occult blood loss and decrease the risk of subsequent pulmonary aspiration. The induction agent selected is based on the hemodynamics and condition of the patient. Emergence and extubation of the trachea should occur after return of protective laryngeal reflexes.⁵⁶

Thyroid Surgery

A thorough knowledge of the specific issues related to anesthesia case management for thyroidectomy is essential to provide high-quality care. Airway management may be difficult despite a normal airway examination because of impingement of a thyroid mass on the laryngeal and tracheal structures. Because sympathetic nervous system hyperactivity is associated with increased amounts of thyroid hormone, it is essential that all patients having an elective thyroidectomy be rendered euthyroid prior to surgery. There are multiple preoperative antithyroid medication regimens that effectively treat thyroid hormone hypersecretion. Although it is a rare event, thyroid storm can still occur during the perioperative period.

The thyroid gland is butterfly-shaped and composed of two lobes that are connected by a median tissue mass named the *thyroid isthmus*. It is located on the anterior and anterolateral aspect of the trachea immediately inferior to the larynx. The thyroid gland is the largest endocrine gland in the body weighing 20 g in the healthy adult. Its major blood supply arises from the superior and inferior

thyroid arteries, which are branches of the common carotid artery. Blood flow is approximately five times the weight of the gland, and therefore the thyroid receives one of the greatest blood supply per gram of tissue measures in the body.⁶⁵

Motor function associated with movement of the intrinsic muscles of the larynx that abduct, adduct, and tense the vocal cords is supplied by the RLN and the external branch of the superior laryngeal nerve. These nerves lie in close proximity to the lateral lobes of the thyroid gland. During surgical resection, if these nerves are temporarily or permanently damaged, then vocal cord movement can be adversely affected and may result in airway compromise after extubation. Anatomic representation of the thyroid gland and its associated structures is presented in [Fig. 43.9](#).

FIGURE 43.9 Thyroid gland and surrounding anatomic structures.

Pathophysiology

Thyroid dysfunction can be treated medically or surgically. A thyroidectomy is performed as definitive treatment for thyrotoxicosis or malignancy. Thyrotoxicosis refers to a condition in which excessive amounts of thyroid hormone are present in a patient's system, whereas hyperthyroidism (the most common cause of thyrotoxicosis) describes states in which the excessive thyroid levels are caused by a hyperactive thyroid gland.^{66,67} Malignancies of the thyroid gland are the most common malignancies of the endocrine system and have been associated

with prior exposure to radiation.^{67,68} Thyrotoxicosis is a rare (2%) occurrence in thyroid malignancies. Surgery is the principle treatment used to treat thyroid malignancies both for purposes of excision of the tumor, as well as staging. Most thyroid malignancies (greater than 90%) are considered well differentiated and are categorized as papillary thyroid cancer (PTC) or follicular thyroid cancer (FTC). PTC accounts for 70% to 80% of thyroid cancer, usually presents at an early stage, and has an excellent prognosis (greater than 95% 10-year survival). FTC accounts for 10% of thyroid cancer and tends to present at a later stage than PTC. The 10-year survival rate for FTC is 85%.⁶⁶

Preoperative Assessment and Preparation

The primary goals during preoperative assessment are ensuring that the patient is euthyroid, assessing the degree of end-organ complications, and determining the extent of airway involvement. Thyroid tumors or large goiters can impinge upon the tracheal cartilages and esophageal tissues resulting in tracheomalacia and airway compromise. Preoperatively the patient will be taking a combination of antithyroid medications to decrease the synthesis and release of thyroid hormone, and to treat the hyperdynamic state associated with hyperthyroidism. The patient may have taken or be currently taking glucocorticoids and thus require the administration of a steroid stress dose preoperatively or intraoperatively. Patients should continue their regimen of antithyroid medications and β -blockade through the morning of surgery. Preoperative use of antithyroid drugs has greatly decreased morbidity from thyroid surgery and rendered thyroid storm a rare event. The aim of preoperative management is to restore a normal metabolic state prior to surgical interventions. Patients with hyperthyroidism have increased T_3 and T_4 values and decreased or normal thyroid-stimulating hormone (TSH) levels. β -Blocking drugs are widely used as an adjunct to the antithyroid thionamides for symptomatic control. β -Blockers are generally continued throughout the surgical period and may be incrementally withdrawn postoperatively. Drugs that are used to treat hyperthyroidism are listed in [Table 43.8](#).⁶⁹

TABLE 43.8**Oral Drugs Used to Treat Hyperthyroidism**

Drug	Daily Oral Adult Dose	Comments
Thionamides		
Methimazole (generic)	<i>Starting:</i> 10–40 mg once or divided <i>Maintenance:</i> 5–15 mg once or divided	Methimazole is preferred because of ease of dosing and a better side effect profile; continue up to the morning of surgery
Propylthiouracil (PTU) (generic)	<i>Starting:</i> 100–450 mg divided bid or tid; <i>Maintenance:</i> 100–150 mg divided bid or tid	
Iodide		Iodide therapy added 1 week prior to surgery and continued through the day of surgery; decreases the production and release of thyroid hormone and reduces thyroid vascularity
SSKI	1–3 drops tid	
Lugol solution	5 drops tid (dissolve in a full glass of water)	
β -blockers		β -blockers without intrinsic sympathomimetic activity are preferred; also used in emergency thyroid surgery for adrenergic suppression
Propranolol (generic)	20–40 mg qid	
Propranolol (Inderal)—long acting	80–160 mg once	
Atenolol (generic and Tenormin)	25–100 mg once or bid	
Metoprolol (generic and Lopressor)	50–200 mg divided bid or tid	

bid, Twice a day; *tid*, three times a day; *qid*, four times a day; SSKI, saturated solution of potassium iodide.

Adapted from Elisha S, et al. Anesthesia case management for thyroidectomy. *AANA J.* 2010;78(2):151–160.

All routine airway assessments should be performed in addition to a full visualization and palpation of the patient's neck for a thyroid goiter. The patient's airway should be assessed in the supine position. If there is any indication for the potential for airway compromise, a chest radiograph and a CT scan of the neck and chest should be performed. Routine preoperative testing should include an electrocardiogram. Additional testing is dictated by the individual patient condition. Patients with hyperthyroidism have a higher incidence of myasthenia gravis and may present with skeletal muscle weakness and an increased sensitivity to muscle

relaxants.⁶⁹

Intraoperative Anesthetic Management

General endotracheal anesthesia is the technique of choice for thyroidectomy, and the standard induction and maintenance drugs are used. Paralysis may inhibit the surgeon's ability to assess the integrity of the RLN, and relaxation is avoided after intubation if nerve testing is planned. Succinylcholine is used for intubation because of its short duration. Intraoperative neural monitoring (IONM) during thyroid and parathyroid surgery has gained widespread acceptance as an adjunct to the gold standard of visual nerve identification. Neurophysiologic monitoring modalities and the effects of anesthetic drugs are given in Table 48.7.

A special ETT, Medtronic nerve integrity monitor (NIM) EMG endotracheal tube (NIM 3.0 ETT), is frequently used to assess recurrent laryngeal and vocal cord function during surgery.⁷⁰ Injury during surgical procedures can lead to hoarseness, aphonia, and (although rare) difficulty with ventilation as a result of permanent adduction of the cords. The major advantage of using the NIM 3.0 ETT is that it allows the surgeon the capability of identifying the muscles innervated by the RLN prior to traction or severing the nerve. The NIM 3.0 ETT is a flexible silicone elastomer ETT with an inflatable cuff. The tube is fitted with four stainless steel wire electrodes (two pairs) that are embedded in the silicone of the main shaft of the ETT and exposed only for a short distance, slightly superior to the cuff. The electrodes are designed to make contact with the patient's right and left vocal cords to facilitate electromyographic monitoring of the muscles innervated by the RLN when connected to a four-channel EMG monitoring device. If monitoring correctly, the EMG should show a consistent sound signal and an action potential tracing. The red wire pair of the NIM tube should contact the anterior and posterior portion of the right true vocal cord, and the blue wire pair should contact the anterior and posterior portion of the left true vocal cord as shown in [Fig. 43.10](#). Paralysis and laryngeal tracheal anesthesia with lidocaine both inhibit accurate EMG readings. Research is ongoing regarding the efficacy of EMG; however, some studies have shown no statistically significant difference in outcome between a standard

ETT and an NIM tube.^{69,70-72}

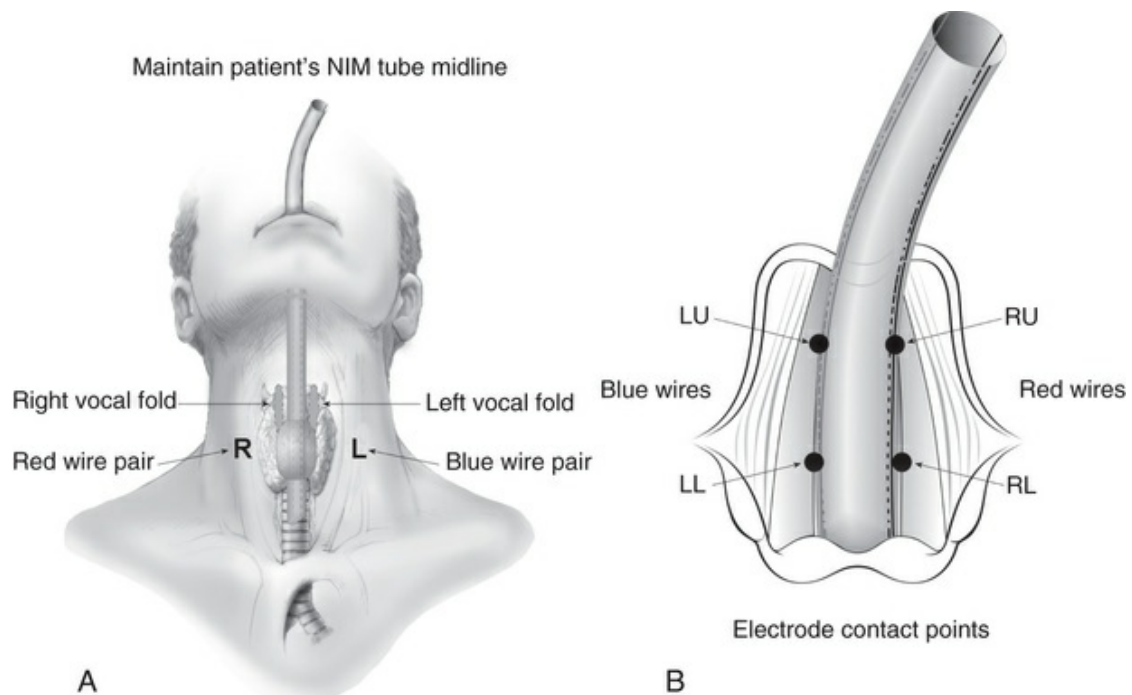

FIGURE 43.10 Nerve integrity monitor (NIM) endotracheal tube. **A**, Proper placement of the NIM endotracheal tube in relation to the thyroid gland. **B**, Four electrode contact points in relation to the vocal cords. *L*, left; *LL*, left lower; *LU*, left upper; *R*, right; *RL*, right lower; *RU*, right upper.

Maintenance of anesthesia can be provided by inhalational anesthetics with or without N₂O. A combined deep and superficial cervical plexus block can be considered for intraoperative and postoperative pain management.⁷³ The patient should be constantly monitored for an increase in core body temperature and hyperdynamic response. If hypotension occurs it is best treated with a direct-acting vasopressor (phenylephrine) rather than an indirect-acting vasopressor (ephedrine), which stimulates the release of catecholamines.⁶⁹ The patient is positioned supine with the head elevated 30 degrees and the neck extended using a roll behind the neck and shoulders (Rose position). The arms are tucked at the patient's sides with the ulnar nerves padded and protected. Hyperextension of the neck should be avoided in those patients with atlantoaxial joint instability and/or those with limited range of

motion. Because there is limited access to the face, special care should be taken to protect the eyes from injury, especially in patients with exophthalmos.

Postoperative Management

The most common postoperative complications include hypocalcemia, RLN damage, and hematoma at the surgical site. A complete list of the potential postoperative complications is presented in [Box 43.4](#). Postoperative hypocalcemia can result from hypoparathyroidism. The four parathyroid glands are located on the posterior aspect of the thyroid gland and produce parathyroid hormone, which increases serum calcium. Inadequate release of parathyroid hormone is caused by the inadvertent removal of the parathyroid glands during a total thyroidectomy. It can also occur secondary to parathyroid gland devascularization, injury, or [Box 43.4](#) "Securing" from dissection.^{69,74}

Complications Associated With Thyroidectomy

- Hypocalcemia-hypoparathyroidism
- Recurrent laryngeal nerve injury — unilateral or bilateral
- Neck hematoma
- Thyroid storm
- Superior laryngeal nerve injury
- Infection
- Pneumothorax
- Tracheomalacia

Adapted from Elisha S, et al. Anesthesia case management for thyroidectomy. *AANA J.* 2010;78(2):151–160.

Hypocalcemia causes neuronal excitability in sensory and motor nerves. Patients most commonly develop signs and symptoms associated with hypocalcemia 24 to 96 hours postoperatively. The degree of hypocalcemia coincides with the severity of the symptoms, which include perioral numbness and tingling, abdominal pain, paresthesias of the extremities, carpopedal spasm, tetany, laryngospasm, mental status changes, seizures, Q-T prolongation on the electrocardiogram, and cardiac arrest.^{66,69,74} Neuromuscular irritability also can be confirmed by assessing for Chvostek sign (i.e., facial contractions elicited by tapping the facial nerve in the periauricular area), and Trousseau sign (i.e., carpal spasm on inflation of a blood pressure cuff). In addition, monitoring postoperative ionized calcium levels is recommended because these values are reflective of the physiologically active form of calcium.

Treatment for severe symptomatic hypocalcemia includes the administration of calcium gluconate or calcium chloride (10 mL of 10% solution) intravenously given over several minutes, and followed by a continuous infusion (1–2 mg/kg per hr) until calcium levels normalize.⁶⁹

RLN damage is estimated to occur in up to 14% of cases. The surgical identification and preservation of the RLN is essential to avoid injury. RLN damage may be unilateral or bilateral; however, unilateral nerve injury is more common. Unilateral RLN damage causes the ipsilateral vocal cord to remain midline during inspiration resulting in hoarseness. Bilateral RLN injury results in dysfunction of both vocal cords, which remain midline during inspiration. After extubation, biphasic stridor, respiratory distress, and aphonia occur because of unopposed adduction of the vocal cords and closure of the glottic aperture. Unlike unilateral nerve injury, bilateral nerve injury necessitates immediate intervention requiring emergent reintubation or tracheotomy.⁶⁹

Postoperative bleeding of the surgical site results in a neck hematoma, which causes airway obstruction and asphyxiation. This complication represents a true surgical emergency. Common symptoms of neck hematoma include neck swelling, neck pain and pressure, dyspnea, and stridor. Initial treatment includes the emergent evacuation of the neck hematoma followed by airway

management.^{69,74}

Cleft Palate and Lip

Cleft Palate (Hard Palate and Soft Palate)

Cleft lip and palate is one of the most common craniofacial abnormalities, occurring in approximately 1 : 700 births.⁷⁵ During fetal development, the bones of the face develop between the fifth and ninth weeks, and the growth of the palatal bones between the sixth and eleventh weeks. A cleft develops when the bones of the nasal and maxillary or the palatal bones fail to fuse. A fetus can develop both a cleft lip and palate or either alone. Up to 30% of these newborns have other congenital anomalies such as Down syndrome, Pierre Robin syndrome, and Treacher Collins syndrome.

The timing for surgery remains controversial. Generally, cleft lip repair with primary tip rhinoplasty is performed at age 3 months. This will enable the baby to feed and demonstrate normal facial expressions. The next repair involves closure of the posterior hard palate and the soft palate before the development of speech and is usually at 5 to 8 months of age depending on the exact defects. The patient's overall health status and the presence of other congenital anomalies are also considerations. Widely followed preoperative guidelines include the rules of ten: weight at least 10 pounds, hemoglobin at least 10 g, white blood cell count less than 10,000/mm³, and age more than 10 weeks. Others advocate for earlier repair, and in utero techniques are under investigation.^{76,77}

Intubation may sometimes be difficult if the laryngoscope blade slips into the cleft. However, packing the cleft with gauze assists in preventing this from occurring. An oral RAE tube or flexible connector is used and secured at the midline of the lower lip. A specialized mouth gag is used to hold the mouth open and the ETT in place during cleft-palate surgery. All air bubbles should be carefully removed from IV lines to prevent air embolus because of the incidence of associated cardiac anomalies (e.g., atrioventricular defect) that may lead to air crossing from the venous to the arterial circulation. Congenital heart disease may influence which drugs are selected for maintenance of anesthesia and infiltration of the operative site, particularly if epinephrine is selected. Care must be

implemented to protect the child's eyes because accidental damage may occur during the surgical procedure. Before emergence, a suture is often placed through the tip of the tongue and taped to the cheek. This suture eliminates the need for an oral airway and prevents damage to the palatal repair. If soft-tissue obstruction occurs during emergence or recovery, traction on the suture can alleviate the problem. If edema occurs, a more aggressive and immediate airway management technique should be used. Copious secretions and blood may cause laryngospasm after extubation, and therefore a clear airway is imperative.

Cleft Lip

Management of unilateral cleft lip repair consists of routine induction followed by oral intubation using an RAE tube or a flexible connector. Secure the tube to the lower lip and midline via tape. To decrease tension on the surgical sutures at the end of the procedure, the surgeon may place a Logan bow across the upper lip of the patient.⁷⁸ When the Logan bow is placed, mask ventilation during emergence will become impaired or impossible. Extubation must be performed only with the patient fully awake and reflexes intact. The child's surgical site must also be protected from finger and hand manipulation. Some hospitals recommend the use of hand mittens or taping the extremities onto armboards during the postoperative period. Close monitoring of respiration should proceed into the postoperative period.

Dental Restoration Procedures

Dental restoration procedures are performed under general anesthesia for a multitude of reasons. These include rampant cavities, history of cerebral palsy or Down syndrome, and an uncooperative patient who would not be an appropriate candidate for local anesthetic and an office procedure.

Mentally disabled patients typically develop a close relationship with either a family member or their long-term health care worker. It is often suggested that this individual accompany the patient to decrease anxiety and communicate a health history to the anesthesia provider. A thorough airway assessment should be

performed before considering induction. Oral midazolam (0.5 mg/kg), or ketamine (3 to 4 mg/kg intramuscularly [IM]) is most effective in sedating children in the preoperative arena. Because many patients requiring dental restoration have congenital anomalies, it is not uncommon to find a small oropharynx, enlarged tonsils, a large tongue, and increased secretions. Atlantoaxial instability and congenital heart disease should also be considered in the preoperative preparation and anesthetic management.⁷⁹⁻⁸¹ Preparation and appropriate airway management must be planned and implemented for these patients. Patients who receive phenytoin to control seizures may have gingival hyperplasia. Because the gingiva is highly vascular, any surgical manipulation during restoration may lead to significant blood loss.

In patients with normal airways a standard induction is appropriate, and a nasal intubation usually facilitates the dental procedure. The application of a topical vasoconstrictive nasal spray during the preoperative period reduces or prevents bleeding during the insertion of the nasotracheal tube. Following loss of consciousness, lubricated intranasal trumpets may be inserted into the most patent nasal airway. Starting with a smaller nasal trumpet, several are placed in increasing sizes to dilate the airway. When full dilation of the nares has occurred, a well-lubricated ETT is passed through the nose into the trachea, either blindly or assisted by Magill forceps under direct laryngoscopy. The nasal ETT is preferably placed on the side opposite where the surgeon will be working. The ETT is often sewn to the nasal septum by the surgeon. Throat packs may be placed to prevent blood from entering the stomach and causing nausea and vomiting; monitoring their removal is essential to preventing respiratory obstruction after extubation.

Sinus and Nasal Procedures

Nasal and sinus procedures for drainage of chronic sinusitis, polyp removal, repair of a deviated septum, or closed reduction of fractures generally involves the young and healthy patient population. Many patients who undergo sinus and nasal surgery have chronic environmental and drug allergies; therefore, there is an increased incidence of reactive airway disease in these patients.

Nasal polyp removal, for example, may be necessitated by Samter syndrome. A patient with Samter syndrome or triad has nasal polyps, asthma, and an aspirin allergy. The nasal polyps, if symptomatic, are removed surgically. The use of fiberoptics or functional endoscopic sinus surgery for nasal and sinus surgery has become a popular treatment for chronic sinusitis.

Nasal surgery may be successfully accomplished with local anesthesia, local combined with IV sedation, or general anesthesia. All three methods of anesthesia require vasoconstriction. The mucous membranes of the sinuses and nose are highly vascular, and blood loss may be significant if vasoconstriction is not used. The surgeon may select to control vasoconstriction with epinephrine or cocaine. Al Haddad et al.⁸² found when comparing 4% cocaine and phenylephrine that using phenylephrine 0.5% was not different in the quality of vasoconstriction in septoplasty. A hypotensive technique or slight head elevation (i.e., 10 to 20 degrees) may be used during the procedure. Using general anesthesia has been associated with increased blood loss even with the use of an epinephrine injection. This exaggerated blood loss may be related to the vasodilatory properties of inhalation agents. Delivering general anesthesia for sinus surgery with propofol, as well as other IV anesthetic techniques for the maintenance of anesthesia, has been associated with less blood loss than occurs with the use of volatile agents for maintenance.⁸⁰ The placement of an oropharyngeal pack and light suctioning of the stomach at emergence may attenuate postoperative retching and vomiting. After all the packing is removed, extubation should be performed on the awake patient who has regained control of protective reflexes.⁸¹ The use of IV or topical lidocaine may reduce some of the coughing prior to extubation, leading to less bleeding in the postoperative period.

Trauma

Initial Assessment

Traumatic disruption of the bony, cartilaginous, and soft-tissue components of the face and upper airway require special consideration. It is imperative to create an anesthetic plan for

securing the airway without promoting further damage or compromising ventilation. Possible mechanisms by which the upper or lower airway may become obstructed include edema, bleeding from the oral mucosa and palate, intraoral fracture sites, distortion of the nasal passages, injury of the pharynx and sinuses, open lacerations, and the presence of foreign bodies such as avulsed teeth, blood clots, or bony fragments.⁸³

Initial management of the airway depends on the situation at hand. In the case of severe facial or neck trauma, alternative methods of tracheal intubation (e.g., fiberoptic laryngoscopy, retrograde wire placement, jet ventilation via cricothyrotomy, or emergent tracheostomy) may be necessary to secure the airway.⁸³

Injuries of the head and neck may include cervical spine or cranial injury. Although a complete evaluation of all cervical vertebrae is ideal, inspection of radiographs of the cervical spine is judicious to determine the presence or absence of dislocations and fractures. All seven cervical vertebrae must be visible in such studies. The seventh cervical vertebra is the most common site of traumatic fracture of the spine.⁸⁴ Vertebral artery injury must be suspected with a cervical injury, because these fractures can lead to vertebral artery tear or occlusion. If deteriorating respiratory function requires immediate airway management and intubation, the head should be maintained in a fixed position before any manipulation of the airway is performed. The use of manual axial in-line stabilization and/or a rigid cervical collar in place is recommended. The removal of the anterior segment of the collar can facilitate intubation and manipulation of the soft tissues of the neck.^{84,85}

Blunt trauma to the face or anterior neck may produce rapid airway occlusion secondary to soft-tissue edema or hematoma formation secondary to trauma of the vascular structures of the neck. The patient exhibiting smoke inhalation or blistering in the area of the mouth and nares or with a history of inhalation of toxic byproducts of combustion should be intubated immediately. Edema of the face and glottis, which may lack symptoms in the early stages, has the potential to produce serious airway compromise several hours after injury.

Maxillofacial Trauma and Orthognathic Surgery

Le Fort⁸⁶ determined the common fracture lines of the maxilla and face by experimentation on cadavers in 1901. The Le Fort classification is based on his finding that blunt trauma tends to cause fractures along three particular lines of the face. Fractures occurring in 21st-century, real-life situations (in particular in high-velocity motor vehicle accidents) often deviate from this classification system, and “pure” Le Fort fractures are rare. Nevertheless, the Le Fort classification system is widely known, and it provides a method for concise communication of fracture patterns between clinicians and radiologists.

The three types of Le Fort fractures, which describe a pattern of fractures involving multiple facial bones,^{87,88} are divided into Le Fort I, II, and III (Fig. 43.11). The Le Fort I fracture is a horizontal fracture of the maxilla extending from the floor of the nose and hard palate, through the nasal septum, and through the pterygoid plates posteriorly. The palate, maxillary alveolar bone, lower pterygoid plate, and part of the palatine bone are all mobilized. The Le Fort II fracture is a triangular fracture running from the bridge of the nose, through the medial and inferior wall of the orbit, beneath the zygoma, and through the lateral wall of the maxilla and the pterygoid plates. The Le Fort III fracture totally separates the midfacial skeleton from the cranial base, traversing the root of the nose, the ethmoid bone, the eye orbits, and the sphenopalatine fossa.^{86,89}

FIGURE 43.11 Examples of Le Fort I, II, and III facial fractures (*left to right*).

A Le Fort I fracture generally causes little difficulty for the anesthesia provider. Patients may be intubated orally or nasally and the airway secured without a problem. The Le Fort II and Le Fort III fractures are of particular concern when contemplating nasal intubation. In both these fractures, disruption of the cribriform plate may occur, opening the underside of the cranial cavity. The presence of cerebral fluid in the nose, blood behind a tympanic membrane, periorbital edema, or “raccoon-eyes” hematoma are indications that attempts to pass an ETT or nasogastric tube through the nares could lead to inadvertent intracranial placement.⁸⁹ Although the insertion of a nasal tube may aid the surgeon, an attempted nasotracheal intubation of a patient with a basal skull fracture involves the very serious risk of introducing the tube into the skull, bringing contaminated material into the subarachnoid space and causing meningitis. The tube may also inflict damage to the brain itself.⁹⁰

The forces required to produce facial fractures are considerable and may be associated with other trauma. It is important that cervical spine injury, subdural hematoma, pneumothorax, and intraabdominal bleeding be investigated. Soft-tissue injury to the airway and blood or debris in the oropharynx may make visualization impossible. If in doubt while in the emergency department, a tracheostomy under local anesthesia or an awake oral intubation with topical anesthesia should be considered. These patients should be treated with full stomach precautions.

As with any trauma victim, attention is first directed toward maintaining the ABCs: airway, breathing, and circulation. The repair of the facial fracture itself is not an emergency and may be carried out later. Once the patient arrives in the operating room for surgery, it may be challenging to open the patient's mouth for intubation because of edema, pain, or trismus. It is necessary to differentiate the cause of the small mouth opening because it may be pain related or mechanical in nature. The administration of a short-acting narcotic or midazolam will sometimes assist the anesthesia provider in determining the cause of the restriction, which greatly influences the induction chosen. In mandibular or maxillary fractures nasal intubation is usually best, because the patient's teeth are brought together via wires or rubber bands at the

conclusion of surgery (intermaxillary fixation). Anesthesia is induced with an IV agent and maintained with narcotics, muscle relaxants, and inhalation agents. Blood loss from facial fractures can be extensive. The patient's blood should be typed and crossmatched so that blood is immediately available. The fixation process closes the teeth in proper occlusion and prevents access to the oropharynx. Masking the patient at emergence requires that the patient be awake with intact reflexes at extubation. It also requires that wire cutters or scissors be available to cut the wire or rubber bands fixing the mandible to the maxilla in case an airway emergency occurs in the recovery area.⁹¹

Orthopedic orthognathic procedures often require sagittal splitting of the mandible to move the lower jaw either forward or back. A Le Fort I or Le Fort II osteotomy may be purposefully performed to move the maxilla in any direction to correct anomalies. Many of these patients have anomalies of the mandible and maxilla, small mouth openings, and appliances that make intubation difficult and airway management challenging. Because many of the malocclusions are treated orally, a nasal ETT is usually preferred over an oral intubation. Securing the nasotracheal tube away from the surgical field without causing necrotic injury of the nares is vital. Because blood loss during these procedures can be extensive, the patient is typed and crossmatched. Deliberate hypotensive anesthetic techniques are often used if the patient remains stable. Rigid metal or plastic external or internal fixation devices are used to maintain stability in both the mandible and maxilla postoperatively; therefore, the proper cutting tools should be at the patient's bedside for emergency airway issues. Edema will often be extensive and progress over the first 24 hours after orthognathic surgery. To prevent postoperative respiratory problems, the patient may remain intubated for several days. If extubation is necessary, it should be done only when the patient is awake, in full command of protective reflexes, and can be carefully monitored in the postoperative period.

Radical Neck Dissection

Radical neck dissection is required when cancerous tumors have invaded the musculature and other structures of the head and neck.

Neoplastic growths can occur anywhere within the upper airway and may achieve significant size with little evidence of airway penetration or obstruction. Such tumors are often friable and bleed readily. These patients are frequently heavy drinkers and smokers who have bronchitis, pulmonary emphysema, or cardiovascular disease. If the tumor interferes with eating, associated weight loss, malnutrition, anemia, dehydration, and electrolyte imbalance can be significant. Patients who have had radiation treatments of the neck and jaw prior to surgical intervention will have soft tissues that are less mobile, making intubation more difficult. Many of these patients are older and have the comorbidities associated with age.^{92,93} Attempted tracheal intubation can induce significant hemorrhage and edema, causing severe compromise of the airway.

Determining the appropriate techniques for airway management entails consultation with the surgeon as to the nature, extent, and location of the tumor; therapy administered (radiation or chemotherapy); CT results; history and physical examination; and relevant preoperative laboratory values.

Head and neck reconstruction is an integral part of surgical removal of head and neck tumors. Traditional methods of reconstruction include regional pedicle flaps with microvascular reconstruction. Flaps include the pectoralis major myocutaneous flap, trapezius flap, and local rotational flaps (e.g., forehead flap). Additionally, small bowel may be harvested to reconstruct the oropharynx and esophagus. Successful anesthesia plays an important role in maximizing the overall success rate of a free flap and microvascular flow of the flap.⁹⁴ The planned donor site should be determined to plan for any limitation on the available sites to place lines necessary for monitoring and venous access. Although the choice of monitoring is largely dependent on the general condition of the patient, the placement of a central venous pressure (CVP) line, a Foley catheter, and an arterial line (beat-to-beat and arterial blood gas trends) is suggested, particularly if deliberate hypotension during anesthesia is used. The internal jugular approach should be avoided because of proximity to the surgical site. Sites commonly used for the CVP placement when the internal jugular is not accessible are the subclavian and femoral veins respectively.

Maintenance of anesthesia is often performed with an inhalation agent and supplemental narcotics. The use of a nondepolarizing muscle relaxant must be discussed with the surgical team preoperatively because a nerve stimulator is frequently used (by the surgeon) to locate nerves distorted by the tumor during the procedure. Significant blood loss can be a problem; sometimes a controlled hypotension technique may be requested.^{92,93} At least one and preferably two large-bore peripheral IV lines (16 to 14 gauge) should be in place. An arterial line, hemodynamic monitor, and central line are often desirable. The patient's blood should be typed and crossmatched with blood readily available. It is important to replace blood loss but not to the point of fluid overload. Monitoring estimated blood loss and measuring the hematocrit may provide some guidelines for replacement of blood. A positive fluid balance in the postoperative phase can result in edema and congestion of the flap predisposing it to vascular compromise. Colloids may be used to help limit the amount of crystalloid required during the procedure. Patients undergoing a radical neck dissection are frequently hypovolemic and have electrolyte imbalances preoperatively. This requires judicious fluid replacement and electrolyte balance intraoperatively to maintain cardiovascular stability. Cerebral blood flow can be compromised by the tumor, retractors, or blood flow; therefore, it is important to maintain adequate perfusion.

In preparation for a tracheostomy or total laryngectomy to be performed during the surgical procedure, the patient should be well oxygenated. The trachea will be transected by the surgeon, which requires that the anesthesia provider suction the airway and remove the ETT only to a level above the tracheal incision. Once the tracheostomy tube has been placed by the surgeon and ventilation validated, the ETT can then be completely removed. A reinforced tube is usually placed in the distal airway by the surgeon and connected to the anesthesia machine. A reassessment of the ventilation should be performed, including the entire procedure of listening to bilateral breath sounds, observing chest excursion, and checking end-tidal CO₂ and positive inspiratory pressure, or negative inspiratory pressure. After the anesthesia provider has validated tube placement, the ETT is sutured to the chest wall for

the entire surgical duration. At the end of surgery, the reinforced tube may be switched for a tracheostomy cannula.

During radical lymph node dissection of the neck for carcinoma, manipulation of the carotid sinus may elicit a vagal reflex, causing bradycardia, hypotension, or cardiac arrest. Small doses of local anesthetic injected near the carotid sinus or administration of an anticholinergic may block vagal reflexes. Because of the long duration of the surgery and interruption of venous flow, venous thrombus is commonly seen in patients who are undergoing radical neck dissection. The head-up position and open neck veins during surgery may lead to venous air embolism. Careful monitoring with precordial Doppler sonography or transesophageal echocardiography provides the most precise detection of air embolism. Immediate removal of the air through the CVP is essential. Laryngeal edema, vascular occlusion, and obstruction can also occur as a result of the venous stasis that follows major disruptions in venous flow during surgery or with trauma. Continual review of complications and follow-up treatments are necessary.^{91-93,95}

Postoperative considerations consist of tracheostomy care, controlled ventilation, chest radiography (to rule out pneumothorax, hemothorax, pulmonary edema), and monitoring for laryngeal edema induced by thrombosis. Postoperative characteristics of various surgical laryngectomy procedures are given in [Table 43.9](#). It is suggested that these patients be admitted overnight to the intensive care unit because they have undergone major fluid and electrolyte shifts and altered ventilation-perfusion status and have spent an extensive time under the influence of anesthesia.^{96,97}

TABLE 43.9
Laryngectomy

Structures Removed	Structures Remaining	Postoperative Conditions
Total Laryngectomy		
Hyoid bone; entire larynx (epiglottis, false cords, true cords); cricoid cartilage; two or three rings of trachea	Tongue; pharyngeal wall; lower trachea	Loses voice; breathes through tracheostomy; no problem swallowing
Supraglottic or Horizontal Laryngectomy		
Hyoid bone; epiglottis; false vocal cords	True vocal cords;	Normal voice; may aspirate occasionally,

	cricoid cartilage; trachea	especially liquids; normal airway
Vertical (or Hemi-) Laryngectomy		
One true vocal cord; false cord; arytenoid one half thyroid cartilage	Epiglottis; one false cord; one true vocal cord; cricoid	Hoarse but serviceable voice; normal airway; no problem swallowing
Laryngofissure and Partial Laryngectomy		
One vocal cord	All other structures	Hoarse but serviceable voice; occasionally almost normal voice; no airway problem; no swallowing problem
Endoscopic Removal of Early Carcinoma		
Part of one vocal cord	All other structures	May have a normal voice; no other problems

Summary

Administering anesthesia for ENT and maxillofacial procedures requires knowledge in both basic and advanced anesthesia techniques. Using these techniques demands the best skills of even a seasoned and experienced clinician. The usual tenets of safe practice must often be adhered to while remaining at a distance from the airway. Good preparation remains imperative. Cooperation and communication between the surgeon and anesthetist maintain a vital link for all concerned, especially those patients in their charge.

Anesthesia for Ophthalmic Procedures

Randolf R. Harvey

Ophthalmic anesthesia continues to be an exciting and challenging segment of anesthesia practice. Ophthalmologists recognize the value anesthesia practitioners provide to their patients and practice. Phacoemulsification and advances in intraocular lens technology have led to smaller incision cataract surgery, which is generally tolerated well under topical and intraocular anesthesia. Anesthesia practitioners have also taken a leading role in advancing safer orbital regional needle block techniques. The reemergence of the intraconal Retrobulbar block technique is an example, as modifications to Atkinson's original technique have led to safer needle approaches to the intraconal space. The intraconal retrobulbar space remains the most effective area for anesthetic distribution throughout the orbit.¹ The extraconal peribulbar and the sub-Tenon's block techniques are also being used to meet the growing demand of ophthalmic surgical procedures. Advances in retinal surgical techniques have increased the demand by surgeons for orbital regional injection eye blocks for select surgeries, and replaced the use of general anesthesia except in rare circumstances. This trend is also growing for corneal transplants, adult eye muscle, and glaucoma procedures.

Today, more than one million ocular blocks are performed annually for surgical procedures. Thanks to ophthalmic anesthesia educational programs, safe ocular blocks are being administered, and more-efficient patient care is being provided. This new expertise in eye anesthesia has spurred a high demand for such services, in part because of the proliferation of ambulatory surgical centers (ASCs) to meet the increased demand for ophthalmic surgery.

Ophthalmic Anatomy

Extraocular Muscles

The eye is surrounded by six extraocular muscles ([Figs. 44.1](#) through [44.3](#)). The superior rectus muscle, located at the 12-o'clock position on the globe, moves the eye upward, or supraducts the eye. The inferior rectus muscle, located at the 6-o'clock position on the globe, moves the eye downward, or infraducts the eye. The medial rectus muscle, located 90 degrees medially to the 12-o'clock position on the globe, moves the eyeball nasally, or adducts the eye. The lateral rectus muscle, located 90 degrees laterally to the 12-o'clock position on the globe, moves the eyeball laterally, or abducts the eye. The superior oblique muscle, located on the superior aspect of the eye, rotates the eyeball on its horizontal axis toward the nose, or intorts the eye and depresses the eyeball. The inferior oblique muscle, located on the inferior aspect of the globe, rotates the eyeball on its horizontal axis temporally, or extorts the eye and elevates the eyeball ([Table 44.1](#)).

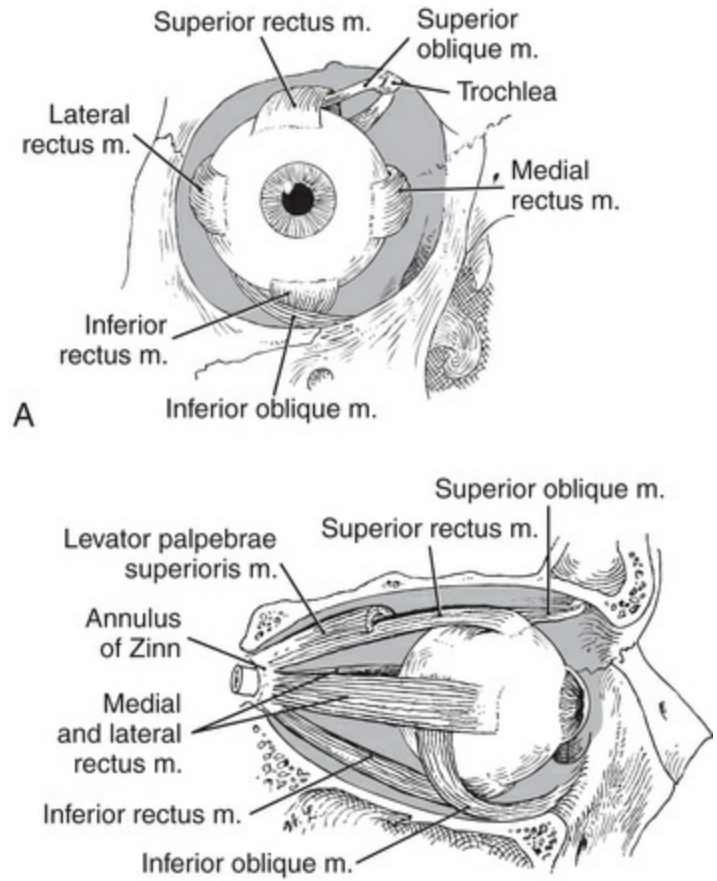

FIGURE 44.1 **A**, Frontal view of the orbit. **B**, Lateral view of the orbit. *m.*, Muscle.

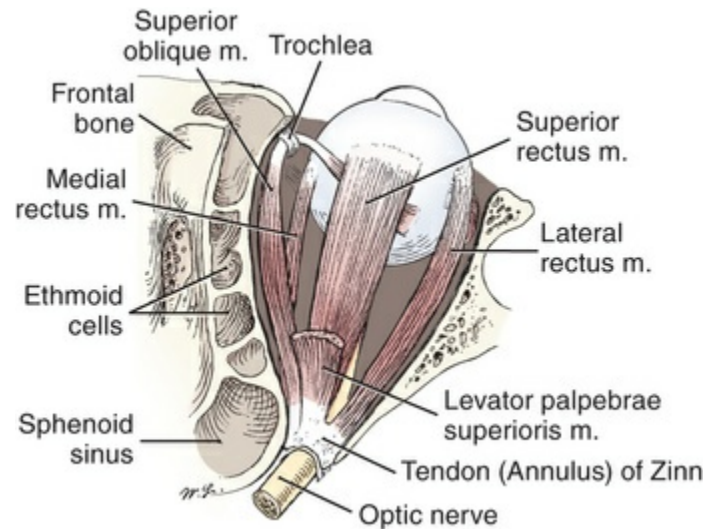

FIGURE 44.2 Superior view of the orbit. *m.*, Muscle.

FIGURE 44.3 Posterior view of the globe. *m.*, Muscle.

TABLE 44.1

Orbital Muscles and Innervation

Muscle	Function	Cranial Nerve
Superior rectus	Supraduction	III
Inferior rectus	Infraduction	III
Medial rectus	Adduction	III
Lateral rectus	Abduction	VI
Superior oblique	Intorsion-Depression	IV
Inferior oblique	Extorsion-Elevation	III

All the ocular muscles, except the inferior oblique, originate in the orbital apex around the annulus of Zinn (Fig. 44.4), which is a fibrinous ring that encircles the optic foramen. The four rectus muscles move forward in a conal pattern that forms the muscle cone around the globe. These muscles, which are approximately 40 mm long, insert into the globe just anterior to its equator.² The superior oblique muscle arises just superior to the annulus of Zinn and moves forward, becoming a tendon. This tendon passes through a cartilaginous ring called the *trochlea*, which is located on the medial supranasal orbital wall. After passing through the trochlea, the tendon is redirected in a posterolateral direction and inserts on the superolateral aspect of the globe under the superior rectus muscle. The inferior oblique muscle originates from the anterior nasal orbital floor and moves in a posterolateral direction along the globe, inserting inferior to the macula of the globe. The arching of both the inferior and the superior oblique muscles around the globe allows for the torsional movements of the eye.

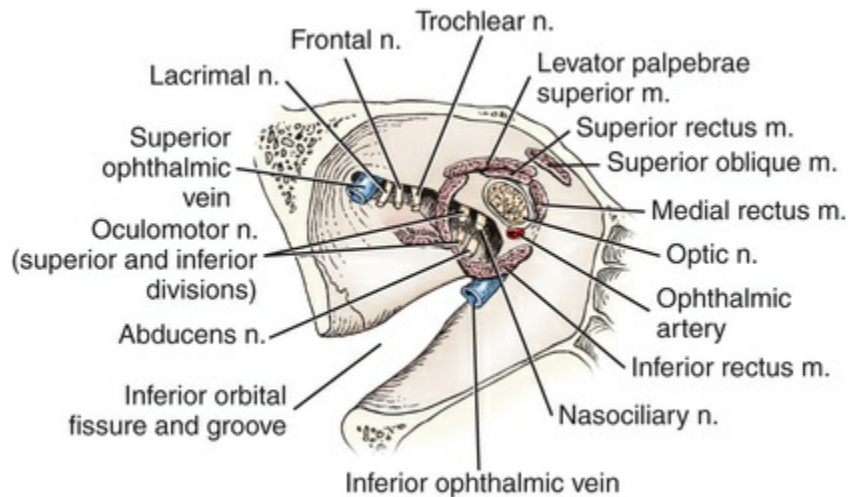

FIGURE 44.4 View of the orbital apex. *m.*, Muscle; *n.*, nerve.

Eyelid Muscles

The levator muscle of the upper eyelid is the primary muscle used for raising the upper eyelids. This muscle originates near the annulus of Zinn (see Fig. 44.1B). It moves forward just superior and slightly medial to the superior rectus muscle, inserting into the upper eyelid. Because the levator muscle only retracts and does not contract the eyelid, akinesia of this muscle is not necessary.

The orbicular muscle of the eye (Fig. 44.5) causes the eyelids to contract. This muscle has three divisions—orbital, palpebral, and tarsal—which are concentrically arranged around the eyelid. Akinesia of these muscles is generally desired for ocular procedures, because if the muscles were allowed to contract around the globe, intraocular pressure would increase. However, the recent success of cataract and glaucoma procedures performed with the use of topical and subconjunctival anesthesia has demonstrated that akinesia of the orbicular muscle of the eye is not always mandatory.

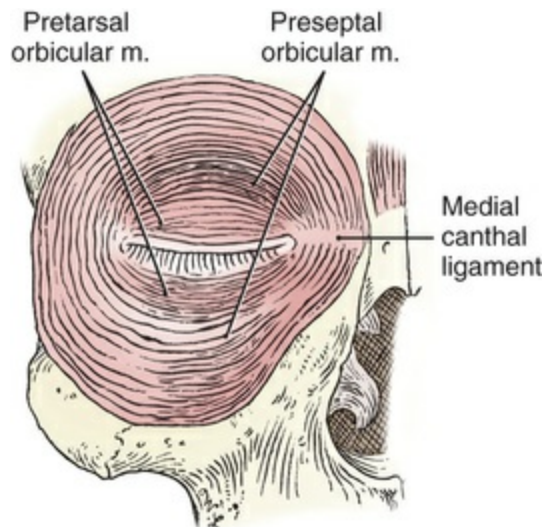

FIGURE 44.5 Orbicularis oculi muscles. *m.*, Muscle.

Cranial Nerves

The orbital portion of the optic nerve (cranial nerve II) (Fig. 44.6) is 25 to 30 mm long and travels posteriorly within the muscle cone, from the globe into the cranial cavity. The optic nerve is actually longer than the distance from the posterior pole of the globe to the orbital apex, giving the optic nerve an S-shaped configuration. This shape allows free movement of the nerve so that the many positions of the eye are accommodated. The optic nerve is myelinated and is approximately 4 mm in diameter.³ The optic nerve extends through the optic canal and continues until it meets the optic chiasm intracranially. The optic chiasm is the junction for both optic nerve tracts. Here, suspended in and surrounded by cerebrospinal fluid, the optic nerve fibers partially decussate, sending visual fibers to the contralateral eye.

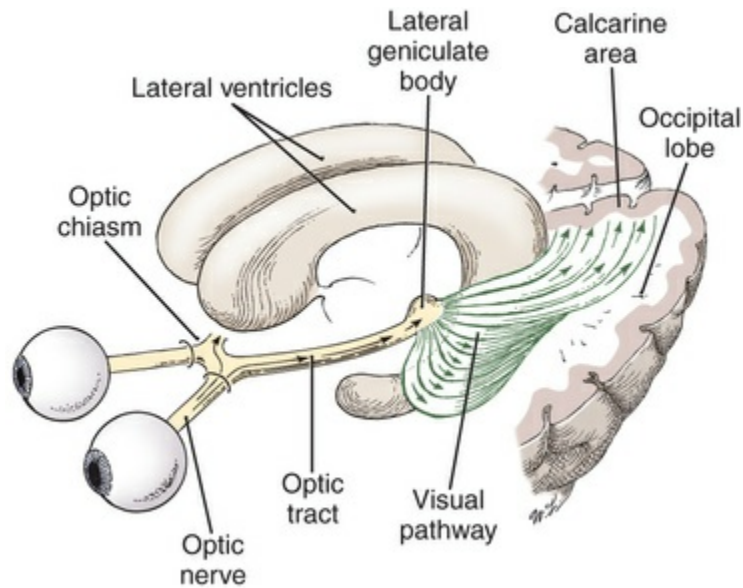

FIGURE 44.6 Intraorbital and intracranial view of the optic nerve.

The optic nerve is not a true cranial nerve but is actually an outgrowth of the brain.² As a result, the optic nerve is also covered by the meninges, the fibrous wrappings of the arachnoid, dura, and pia mater, which envelop the central nervous system (CNS). Therefore any anesthetic agent injected into the optic nerve sheath can find its way back to the midbrain through the cerebrospinal fluid, resulting in CNS depression and even leading to respiratory arrest. The optic nerve also carries the central retinal artery and vein into the globe. The central retinal artery and vein exit the optic nerve approximately 8 to 15 mm posterior to the globe.⁴

The oculomotor nerve (cranial nerve III) innervates the following muscles of the orbit: the superior rectus muscle, the inferior rectus muscle, the inferior oblique muscle, the medial rectus muscle, and the levator muscle of the upper eyelid. The oculomotor nerve is the primary motor nerve to the extraocular muscles of the orbit; this nerve branches superiorly and inferiorly (Fig. 44.7). The superior branch innervates the superior rectus muscle and the levator muscle of the upper eyelid. The inferior branch of the oculomotor nerve innervates the medial rectus muscle, the inferior rectus muscle, and the inferior oblique muscle. This nerve also sends parasympathetic fibers to the ciliary ganglion (Fig. 44.8), which is located adjacent to the optic nerve in the posterior portion of the orbit. The ciliary ganglion receives parasympathetic fibers from the

oculomotor nerve and sympathetic fibers from the carotid artery plexus and a sensory branch from the nasociliary nerve, a branch of the ophthalmic nerve. The parasympathetic fibers move forward from the ciliary ganglion to innervate the iris sphincter muscles, which cause constriction of the pupil. The sympathetic motor fibers move forward to control the radial muscle of the iris for pupillary dilation.²⁻⁴

FIGURE 44.7 Frontal view of the posterior orbit with its motor nerves and the extraocular muscles. *m.*, Muscle; *n.*, nerve.

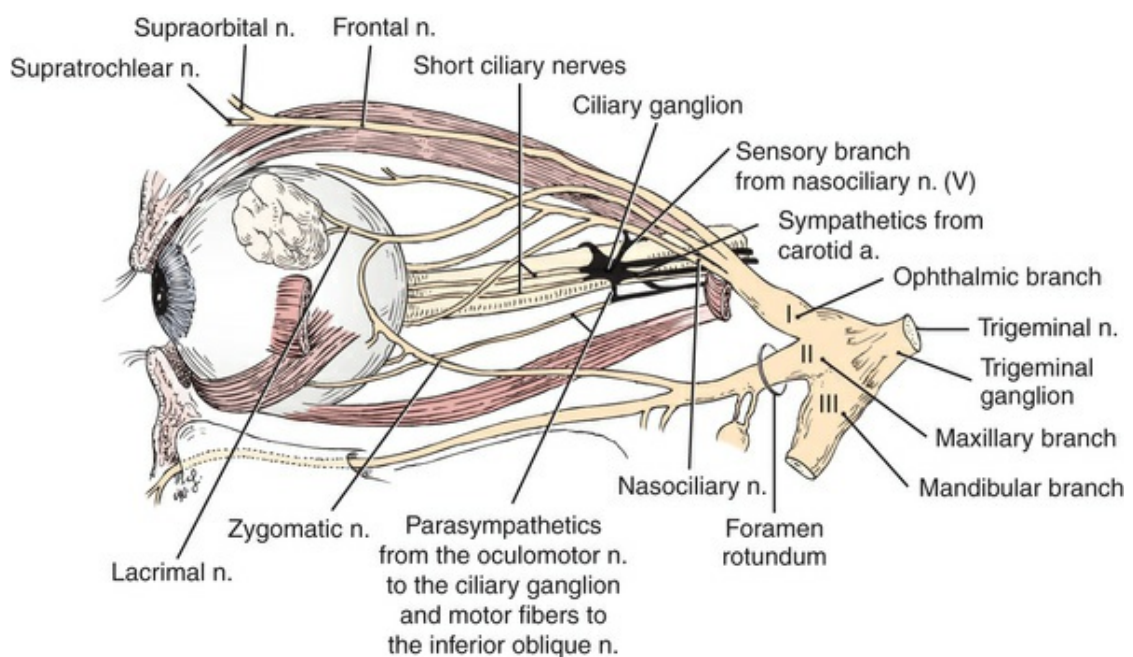

FIGURE 44.8 Lateral orbital view of sensory nerves and ciliary ganglion. *a.*, Artery; *n.*, nerve.

The trochlear nerve (cranial nerve IV) (see [Fig. 44.7](#)) provides the motor fibers for the superior oblique muscle. This nerve enters the orbit through the superior orbital fissure outside the muscle cone. It is the only orbital cranial motor nerve that enters the orbit from outside the muscle cone. Once inside the orbit, the nerve root moves in a medial direction to innervate the superior oblique muscle.

The trigeminal nerve (cranial nerve V) (see [Fig. 44.8](#)) has sensory and motor components. In ocular anesthesia, the sensory component is of primary importance. The intracranial portion of the nerve forms the trigeminal ganglion, which has three main divisions: the ophthalmic, the maxillary, and the mandibular nerves. The ophthalmic branch provides for the sensation of pain, touch, and temperature to the cornea, ciliary body, iris, lacrimal gland, conjunctiva, nasal mucosa, eyelid, eyebrow, forehead, and nose. The maxillary branch provides for the sensation of pain, touch, and temperature to the upper lip, nasal mucosa, and scalp muscles.⁵

The ophthalmic nerve has three main branches: lacrimal, frontal, and nasociliary. The lacrimal nerve branch innervates the lacrimal gland in the superior lateral aspect of the orbit. The frontal branch is the largest branch of the ophthalmic nerve. This branch enters the orbit from outside the muscle cone through the superior orbital fissure and travels anteriorly outside the muscle cone superior to the levator muscle. The frontal nerve itself splits into two branches. The larger, supraorbital branch continues forward into the orbit and exits the orbit through the supraorbital notch; this branch innervates the forehead. The smaller branch is the supratrochlear nerve, which moves in a medial direction, supplying nerve roots to the forehead and the medial portion of the upper eyelid. The nasociliary nerve branch enters the orbit from inside the muscle cone and crosses over the optic nerve, sending nerve fibers medially and to the ciliary ganglion. The fibers to the ciliary ganglion form the short ciliary nerves, which continue anteriorly, penetrating the posterior portion of the globe near the optic nerve. The nasociliary nerve also gives rise to the long ciliary nerves, which continue

anteriorly and enter the posterior portion of the globe supplying the ciliary muscle, iris, and cornea. The long ciliary nerves also carry sympathetic fibers to the dilator muscle of the iris from the superior cervical ganglion. The nasociliary nerve continues along the medial aspect of the orbit just superior to the medial rectus muscle until it passes through the orbital septum to become the infratrochlear nerve. The infratrochlear nerve provides sensory input to the side of the nose, the medial aspect of the eyelids, the medial conjunctiva, the caruncle, and the lacrimal sac.²⁻⁵

The abducens nerve (cranial nerve VI) (see Fig. 44.7) provides motor function to the lateral rectus muscle. The nerve enters through the superior orbital fissure within the muscle cone and continues along the conal surface of the lateral rectus muscle, eventually inserting in the posterior one-third of that muscle.

The facial nerve (cranial nerve VII) (Fig. 44.9) is predominantly a motor nerve for the muscles of the face. This nerve exits from the stylomastoid foramen. The facial nerve travels underneath the external auditory canal to the parotid gland, where it divides into an upper and a lower branch. Ocular anesthesia is more concerned with the upper branch of the facial nerve than with the lower. The upper branch further divides into the temporal and zygomatic branches, which innervate the orbicular muscle of the eye, the superficial facial muscles, and the scalp muscles.

FIGURE 44.9 The origin and branches of the facial nerve.

Upper inset: Needle placement for the Nadbath cranial nerve VII block. *m.*, Muscle.

The vagus nerve (cranial nerve X) provides motor function to the intrinsic muscles of the larynx and the heart; it provides major parasympathetic visceral innervation elsewhere. It is also the efferent pathway for the oculocardiac reflex, which can result in bradycardia and dysrhythmias.

Orbital Fossa

The orbital fossa has been described as pear shaped. The medial walls of the orbit extend almost straight back, whereas the lateral walls diverge at approximately a 90-degree angle to each other (Fig. 44.10). The superior and inferior orbital fissures are in the orbital apex, which is located in the posterior orbit. These fissures are the entry portals for the orbital nerves and vessels (Fig. 44.11). The optic foramen lies just medial to the superior orbital fissure and is the entry portal for the optic nerve and the ophthalmic artery from the intracranial to the intraorbital area. In the medial nasal aspect of the fossa, just behind the orbital rim, is the lacrimal bone, which is used as a landmark for the medial peribulbar block (Fig. 44.12). The ethmoid bone is just posterior to the lacrimal bone.⁵

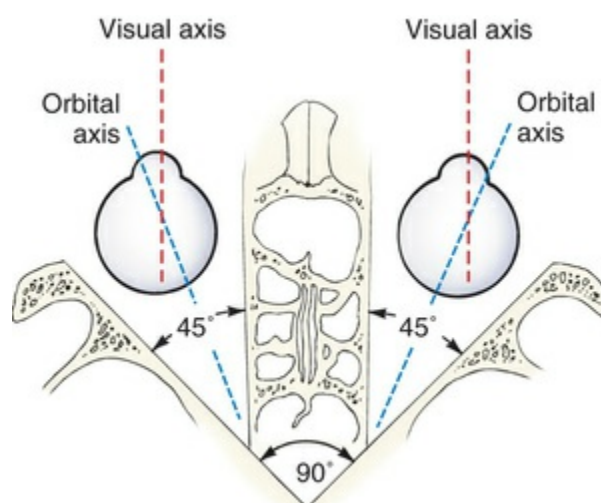

FIGURE 44.10 Superior view of the bony orbit, demonstrating the orbital and visual axes.

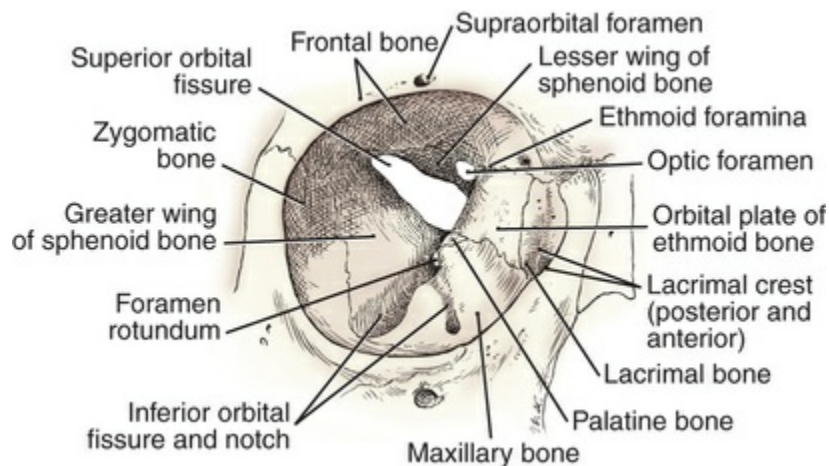

FIGURE 44.11 Frontal view of the orbital bones.

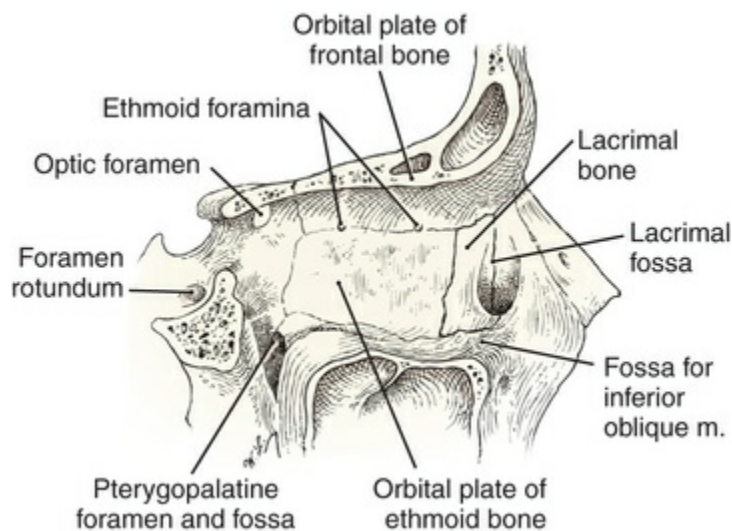

FIGURE 44.12 Lateral view of the orbital bones. *m.*, Muscle.

The supraorbital nerve exits the orbit in the supraorbital notch, which is in the superior nasal aspect of the orbital rim. The infraorbital foramen, where the infraorbital nerve and artery exit, is just below the infraorbital rim at approximately the 6-o'clock position. The infraorbital nerve is the sensory branch of the maxillary nerve. The lacrimal, frontal, and trochlear nerves all enter through the superior orbital fissure outside the muscle cone. The oculomotor, abducens, and nasociliary nerves all enter the orbit from inside the muscle cone.⁵

The ophthalmic artery (Fig. 44.13), which is the first branch of the internal carotid artery, passes into the orbit through the optic canal.

The ophthalmic artery usually lies just inferolateral to the optic nerve. The artery extends along the optic nerve for a short distance, crossing over it in most cases, and continuing medially.⁶ The first branch of the ophthalmic artery is usually the central retinal artery. The central retinal artery moves in an anterior direction underneath the optic nerve, usually entering the optic nerve on its inferomedial side 8 to 15 mm posterior to the globe.⁴ The artery continues forward into the optic nerve head and branches into the retinal arteries. The ophthalmic artery gives rise to the long and short posterior ciliary arteries. The short posterior arteries move anteriorly and divide into many small branches that penetrate the globe close to the optic nerve and supply the choroid and the optic nerve head. The ophthalmic artery also provides branches to the optic nerve. The orbital branches of the ophthalmic artery include branches to the supraorbital arteries, the rectus muscles, and the lacrimal gland.⁵

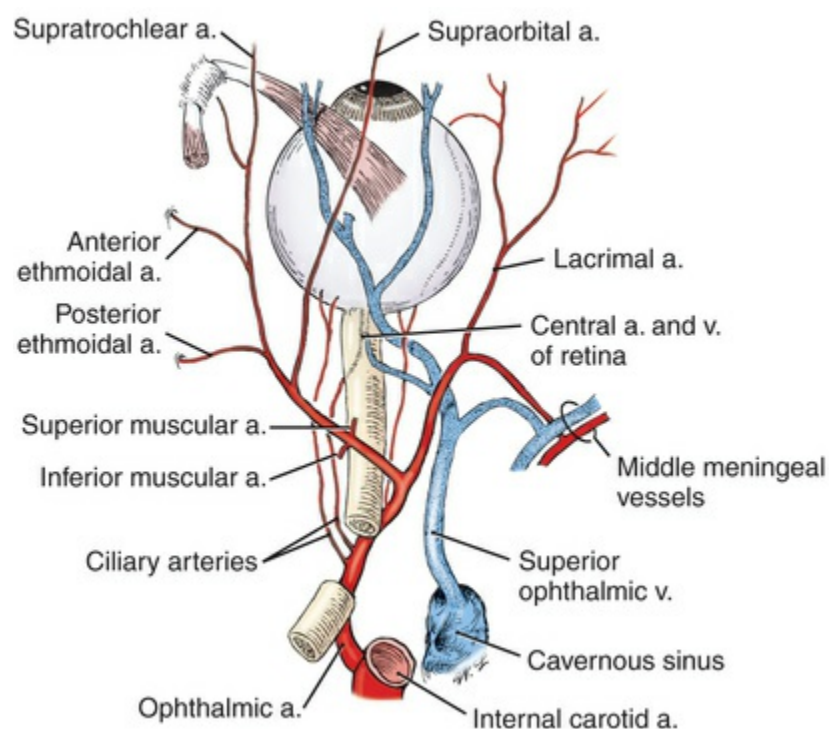

FIGURE 44.13 Superior view of the orbital arteries and veins. a., Artery; v., vein.

The lacrimal artery moves anteriorly along the superior aspect of the lateral rectus muscle to the lacrimal gland. The supraorbital

artery branches from the ophthalmic artery as it crosses over the optic nerve and extends just medial to the superior rectus and levator muscles. It continues forward on a superior nasal route and exits through the supraorbital notch or foramen.

The dorsal nasal artery is one of the terminal branches of the ophthalmic artery. It exits the orbital septum above the medial canthal tendon and joins with the angular artery, thus establishing communication between the internal and external carotid arteries.² The external carotid artery gives branches to the facial artery (the external maxillary artery). The facial artery originates near the angle of the mandible, extends toward the stylohyoid muscles, and then proceeds forward to the lower border of the mandible. The artery then turns upward and moves toward the nose, where it joins with the dorsal nasal artery in the medial canthal area. The inferior orbital fissure is the entrance site for the infraorbital artery. This artery moves anteriorly through the infraorbital canal and exits to the face through the infraorbital foramen.

The venous drainage system (see [Fig. 44.13](#)) for the orbit includes the superior and inferior ophthalmic veins, which drain into the cavernous sinus that is located intracranially. Radiographic studies have demonstrated a unique characteristic of the orbital vascular system: the orbital veins are independent of the orbital arteries. The venous system of the orbit is valveless, and blood flow in this area is determined by pressure gradients. The primary vein of the orbit is the superior ophthalmic vein. This vein travels posteriorly to the medial side of the superior rectus muscle, then beneath the superior rectus muscle inside a support hammock. The vein then emerges on the muscle's lateral aspect. The vein continues its posterior direction along the lateral aspect of the superior rectus, exiting the orbit through the superior orbital fissure, and terminating in the cavernous sinus.⁶

Several veins enter the superior ophthalmic vein: the ciliary veins, the lacrimal veins, and the superior vortex veins, which are located on the posterior quadrants of the globe and drain the choroid, or second layer, of the globe. The inferior ophthalmic vein originates from a diffuse plexus on the floor of the orbit. This vein receives several branches, including the extraocular muscles and the inferior vortex veins located on the inferoposterior quadrants of

the globe. The primary branch of the inferior ophthalmic vein also drains into the superior ophthalmic vein before its entrance into the cavernous sinus. The central retinal vein exits the globe inside the optic nerve. The central retinal vein then exits the optic nerve and enters the orbit between 8 and 15 mm posterior to the globe⁴ and usually passes directly to the cavernous sinus.²

Orbit

An evaluation of the patient's orbit and globe size is important before ocular anesthesia is conducted. The usual volume of the orbit is 30 mL (Box 44.1). The volume of a typical globe (which has a diameter of approximately 25 mm) is 6.5 to 7 mL.⁶ The balance of the orbital volume is approximately 23 mL and is composed of muscles, vessels, nerves, and fat. Katsev et al.⁷ measured 120 orbits from 60 adult skulls and found an average orbital depth of 48 mm. The distance from the middle third and lateral third of the infraorbital rim to the superior aspect of the optic foramen was also measured and ranged from 42 to 52 mm. This distance should not be confused with the depth of the orbital floor. Because of the pear shape of the orbit, the orbital floor does not extend directly to the orbital apex. The orbital floor extends only to the posterior wall of the maxillary sinus, approximately two-thirds of the depth of the orbital apex.

Box 44.1 Orbital Measurements

- Height of the orbit: 40 mm
- Width of the orbit: 35 mm
- Depth of the orbit: 42–52 mm
- Approximate orbital volume: 30 mL
- Approximate globe volume: 6.5–7.0 mL
- Balance of orbital volume: 23 mL

Orbital fat is contained in both the extraconal and the intraconal

areas. The orbital fat encircles and encapsulates all these areas of the orbit.

The orbital septum is a fibrinous tissue that defines the anatomic anterior boundary of the orbit and keeps the adipose tissue from protruding forward. The visual axis (also known as the optic axis or the geometric axis) is an imaginary line from the midpoint of the cornea (anterior pole) to the midpoint of the retina or macula (posterior pole) (Fig. 44.14). The horizontal (anteroposterior) diameter of the globe is an important consideration for ocular blocks. This measurement of the visual axis is referred to as the *axial length*. The axial length is measured preoperatively to determine the appropriate intraocular lens that should be placed in the eye after cataract removal. The axial length of the globe is only available when the ophthalmologist performs the measurement for an intraocular lens implant. Normal axial lengths range from 23 to 23.5 mm. In the hyperopic (farsighted) eye, the globe is less than 22 mm long. This shorter eye length may allow a little more working area behind the eye during an ophthalmic block; however, this advantage may be offset by a smaller overall orbit.^{5,7}

FIGURE 44.14 Cross-sectional view of the globe. *n.*, Nerve.

The longer, myopic (nearsighted) eye, whose axial length is

greater than 24 mm, presents a potential risk. The stretching of the globe is related to the extracellular matrix and biochemical properties of the sclera.⁸ As the globe stretches, it is believed that the fibrinous scleral layer thins, making the globe easier to penetrate with a needle. This increased posterior length of the globe also increases the chance of puncturing the globe. Therefore, because of a greater chance of contact in the posterior aspect of the orbit, the axial length of the eye, if this measurement is available, should be considered in the planning for the ocular block. If the axial length is unknown, which may be the case in glaucoma surgery, corneal transplants, retinal procedures, or muscle surgery, the practitioner's preoperative questions should include a history of nearsightedness or previous retinal procedures.

The separate coats, or tunics, of the eyeball (see [Fig. 44.14](#)) start with the sclera, which is the outer, fibrinous protective layer. The sclera is white and opaque and lies just posterior to the cornea. The cornea is the outer, fibrinous protective layer located anteriorly, and it is transparent and colorless. The middle, or vascular, layer is called the *choroid*. The retina is the inner layer of the posterior half of the eye. The *limbal area* is defined as the area at the junction between the cornea and the sclera.² The conjunctiva is a thin, transparent mucous membrane that covers the posterior surface of the eyelids and the anterior surface of the sclera.

A staphyloma is a bulging of the uvea, which comprises the iris, the ciliary body, and the choroid into a thin and stretched sclera. Staphylomas may occur in the anterior, equatorial, and posterior areas.³

Tissue Systems of the Orbit

Three connective tissue systems within the orbit have been defined by Koornneef.⁹ They are the Tenon capsule, the orbital connective tissue, and the fascial sheaths of the extraocular muscles ([Fig. 44.15](#)).

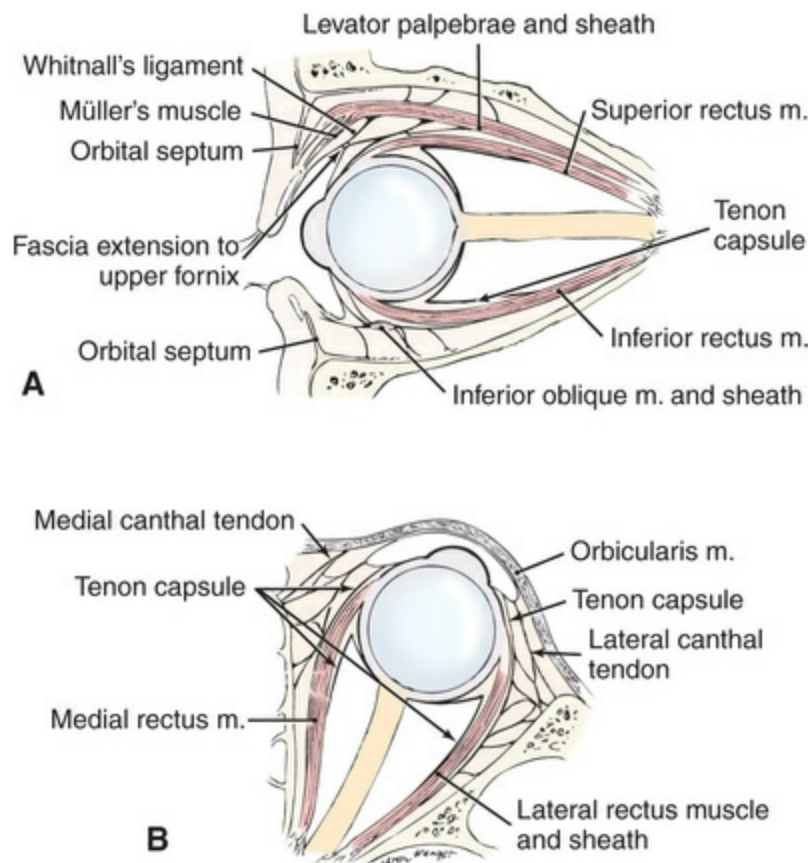

FIGURE 44.15 **A**, Lateral view of the orbital connective tissue. **B**, Superior view of the orbital connective tissue. *m.*, Muscle.

Tenon Capsule.

The Tenon capsule (bulbar fascia) consists of fibrous connective tissue that covers the eyeball from near the corneal limbus, where it is fused to the conjunctiva, and extends behind the eye, with openings for the extraocular muscles and the optic nerve. The Tenon capsule serves primarily as a cavity in which the eye moves.

Orbital Connective Tissue.

Koornneef demonstrated the presence of connective tissue attachments between both the globe and the periorbital area. The connective tissue begins at the orbital apex and continues anteriorly, becoming more complex and more clearly defined at the level of the globe. Koornneef⁹ also noted that the tissue septa are in a 360-degree encapsulation of the globe (see Fig. 44.15). These connective tissue septa encircle and support the globe within the

bony orbit. Connective tissue septa were also noted between the superior and inferior oblique muscles, the Tenon capsule, the rectus muscles, and the ligaments stabilizing the globe within the orbit. This connective tissue septa meshwork limits displacement of the globe.

Fascial Sheaths.

The intermuscular membrane is a fibrous membrane that connects the four rectus muscle sheaths. Numerous extensions from these muscle sheaths form an intricate system of fibrinous attachments that interconnect the muscles into the orbit, support the globe, and check the ocular movements.

In the posterior orbit, the fascial sheaths of the extraocular muscles are not as well defined as they are immediately behind the globe.¹⁰ Koornneef was not able to identify a common muscle cone throughout the orbit (Fig. 44.16). The muscle sheaths themselves contribute fibrinous septa to the periorbit; these septa serve as ligaments for the extraocular muscles. These fascial extensions promote the efficiency of the extraocular muscle functions.⁹⁻¹²

Pharmacology: Ocular Medications and Anesthetic Agents

A number of drugs are used in ophthalmology practice including antibiotics, mydriatics, miotics, cycloplegics, antiinflammatory drugs, viscoelastics, and glaucoma therapies. Ocular medications are listed in [Table 44.2](#). The local anesthetics and hyaluronidase are covered in detail in [Chapter 10](#).

TABLE 44.2
Ocular Medications

Class	Generic Name (Trade Name)	Comments
α_2 -Agonist	brimonidine tartrate (Alphagan) apraclonidine (Lopidine)	Glaucoma: Reduces aqueous humor production Contraindicated with MAO inhibitors
Cholinesterase inhibitors	ecothiophate iodide (Phospholine Iodide)	Glaucoma: Produces miosis by allowing acetylcholine to continually stimulate iris and ciliary muscles, improving uveoscleral outflow of aqueous humor; May prolong effects of succinylcholine; however, rarely used
β -Blockers	timolol (Timoptic) levobunolol (Betagan) betaxolol (Betoptic) metipranolol (OptiPranolol) carteolol (generic)	Glaucoma: Reduces aqueous humor production; Caution in patients with asthma, COPD, heart block, heart failure, and hypotension
Carbonic anhydrase inhibitors	acetazolamide (Diamox) dorzolamide (Trusopt) brinzolamide (Azopt)	Glaucoma: Reduces aqueous humor production
Cholinergic agonists	pilocarpine, topical carbachol (Miostat)	Miotics; used to constrict pupil for surgical procedures
Cycloplegics	atropine homatropine cyclopentolate	Pupillary dilators; cause temporary paralysis of ciliary muscle and muscles of accommodation
Intraocular gases	sulfur hexafluoride perfluoropropane	Retinal detachment: Intravitreal insufflation to tamponade retina in place. <i>Avoid nitrous oxide for up to 3 months</i>
Mydriatics	phenylephrine	Pupillary dilators; cause either a direct or indirect effect on

	tropicamide epinephrine	dilator muscle of iris
Nonsteroidal antiinflammatory agents	flurbiprofen sodium (Ocufen)	Preserves pupillary dilation during surgical procedure by inhibiting prostaglandins, which cause miosis
Osmotic diuretics	glycerin (oral agent) mannitol	Reduce intraocular pressure
Prostaglandins	latanoprost (Xalatan) bimatoprost (Lumigan) travoprost (Travatan) tafluprost (Zioptan)	Glaucoma: Promotes uveoscleral outflow of aqueous humor
Viscoelastics	hyaluronate sodium (Healon, Amvisc)	Protect endothelial cells of cornea during surgical procedures

COPD, Chronic obstructive pulmonary disease; *MAO*, monoamine oxidase.

Systemic Absorption of Eye Drops

The lacrimal apparatus includes the lacrimal gland, the puncta, the inferior and superior canaliculus, the common canaliculus, the lacrimal sac, and the nasolacrimal duct (Fig. 44.17). The lacrimal gland is located in a depression of the frontal bone in the superior temporal orbit.²⁻³ The gland has several ducts that lead to the conjunctival surface of the upper eyelid. Tears pass from the lacrimal gland through the ducts, over the cornea and conjunctiva, keeping the eye moist. Near the medial canthus, tears enter the puncta, travel through the canaliculus to the lacrimal sac, and drain into the nasolacrimal duct before entering the nasal mucosa.

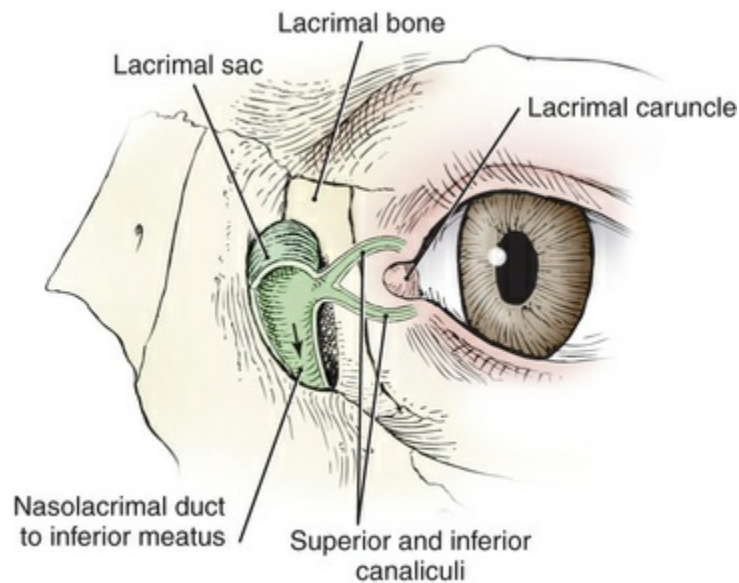

FIGURE 44.17 Frontal view of the lacrimal drainage system.

Topical eye medications enter the bloodstream through the outer eye membrane and the lacrimal apparatus. The following measures reduce the amount of topical medications that enter the bloodstream:

- Have the patient close the eyes for 60 seconds after drops are instilled to encourage absorption by the eye and minimize drainage to the nasal mucosa.
- Have the patient avoid blinking, which rapidly moves the medication into the tear outflow canal and the systemic circulation.
- Block the tear outflow canal by placing the index finger over the medial canthus after the eye is closed.³

Patients may complain of a metallic taste after the administration of ocular anesthetics. This precursor to local anesthetic toxicity needs further evaluation. However, it is usually the result of the local anesthesia passing into the nasal mucosa.

Select Ocular Anesthesia Techniques

Ophthalmic Block Techniques

Topical/Intraocular Anesthesia

Cataract and vitreoretinal surgeries are the most frequently performed intraocular surgical procedures.^{13,14} Topical anesthesia for cataract surgery (e.g., 2% lidocaine) has proven to be effective in providing adequate analgesia for the surgical procedure and is commonly used with phacoemulsification. Topical anesthesia is applied as drops or gels and may be supplemented by intracameral injection by the surgeon for better intraoperative pain control. Vitreoretinal surgery usually requires at least a sub-Tenon block and more frequently injection anesthetic techniques.¹⁴ Today's smaller-incision surgical techniques with foldable intraocular lenses provide a safer surgical experience for the patient and a more rapid recovery. Intraocular anesthesia can further enhance the analgesia for the surgical procedure; 1% lidocaine (preservative free) has been studied and recognized as safe for intraocular administration.¹⁵ However, topical anesthesia may not be appropriate in all cases for the surgeon or the patient, because it provides a lesser degree of analgesia and no akinesia of the ocular muscles or eyelids. There is wide variability in operative conditions, sensations, and pain relief, depending on the type of local anesthesia administered for intraocular surgery. Using data that present the strength of evidence as "strong evidence," "weak evidence," or "no evidence," the differences between local/regional anesthetic techniques for variables such as pain (during placement of the block and during the surgery), eye akinesia, eyelid sensation, and visual sensations were quantified on a + or - scale, and the conflicts of evidence are presented as a range in [Table 44.3](#).¹⁴

TABLE 44.3

Comparisons of Local/Regional Anesthesia Techniques

	Topical	Sub-Tenon Block	Peribulbar Block	Retrobulbar Block
Pain on administration	0 or -	+ or ++	++ or +++	+++

Surgical pain prevented	--	+++	++	++
Eye akinesia	---	0 or +	++	++
Eyelid sensation blocked	---	+	+	+
Visual sensations experienced	+++	++ or +	+	+

+ Represents strength of affirmative evidence; 0 represents insufficient evidence; – represents strength of contrary evidence.

From Vann MA, et al. Sedation and anesthesia care for ophthalmologic surgery during local/regional anesthesia. *Anesthesiology*. 2007;107(3):502–508.

Sub-Tenon Block

The sub-Tenon block will produce a more profound analgesia; however, motor movement of the globe may still be present. The Tenon tissue, as described earlier, encapsulates the globe posteriorly and fuses with the conjunctiva anteriorly. Anteriorly it is inferior to the conjunctiva. The sub-Tenon block is a procedure performed between the rectus muscles of the globe. The conjunctiva is incised, the Tenon tissue is elevated and incised, and a short cannula is inserted into the sub-Tenon space. Local anesthetic is injected with the objective of a posterior spread of the agent. The dose is usually 3 to 4 mL to achieve analgesia; however, larger doses of up to 10 mL have been reported to achieve some degree of akinesia.¹⁶

Ocular Regional Anesthesia

The ocular regional needle block still remains the most common and effective way to consistently produce a profound analgesia and akinesia of the eye and eyelids.

The term *ocular local anesthesia* has been used to refer to retrobulbar or peribulbar blocks. More correctly, local anesthesia should be defined as *superficial, topical, or cutaneous anesthesia*, used, for example, when skin-laceration suturing is performed that poses minimal risks to both the body as a whole and to proximate vital organs.

Retrobulbar and peribulbar injections are categorized under regional anesthesia methods. These blocks are designed to anesthetize multiple cranial nerves (III, IV, V, VI, and VII). As described earlier, the optic nerve is a continuation of the brain. The dura mater divides at the entrance of the optic nerve into the orbit. The visceral layer of the dura covers the intraorbital part of the optic nerve, and the parietal layer blends into the periosteum of the orbit.² Therefore, by anatomic definition, this procedure is performed in the orbital epidural space. As has been demonstrated in the anatomic reviews by Koornneef, no true muscle cone exists, especially in the posterior portion of the orbit.⁹⁻¹² Therefore, old anatomic concepts such as the image of an intact muscle cone must be set aside in favor of concepts that illustrate a communication throughout the orbit.

Techniques and Modifications

The term *retrobulbar block* refers to an ophthalmic block technique originally described by Atkinson in 1936. The patient is instructed to look up and nasally (supranasal position). A 23-gauge retrobulbar (dull) needle is inserted through the skin in the infratemporal area, just above the inferior orbital rim and advanced toward the orbital apex 35 mm (1.38 inches) deep into the muscle cone (retrobulbar space). After negative aspiration, 2 to 4 mL of anesthetic solution is injected into the muscle cone. After the injection is completed, the eyelids are closed, and digital pressure is

applied over the globe to the orbit. A few minutes later, the eyelids are opened, and the globe is inspected for akinesia.¹⁷ The popularity of the retrobulbar block for ophthalmic procedures grew, with more than 1 million blocks performed annually in the 1940s.¹⁸ Unfortunately, so also did the complication rates.

The reported complications from retrobulbar anesthesia include trauma to the optic nerve, the blood vessels, and the globe, all of which can lead to loss of vision. Respiratory arrest may result when anesthetic agents enter the cerebrospinal fluid of the optic nerve. Seizures may occur when even small amounts of local anesthetic are injected intravascularly.

As a result of the increasing number of complications being reported, practitioners began to alter the Atkinson retrobulbar technique in an effort to increase the margin of safety for ocular anesthesia.¹⁹ Three major problem areas in the Atkinson technique are identified in this chapter, and technique modifications are discussed (Fig. 44.18).

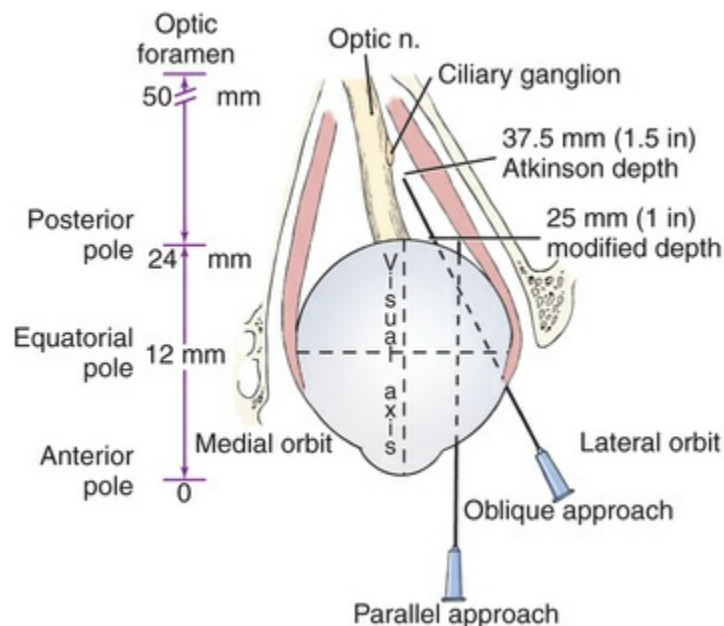

FIGURE 44.18 Superior view of the parallel and oblique approach to retrobulbar anesthetic blocks. *n.*, Nerve.

Eye Position

The position of the eye during retrobulbar block anesthesia is an

important consideration. When the patient looks upward and nasally, the optic nerve and blood vessels are placed in the path of the needle. Tension is created on the optic nerve and the surrounding vasculature, making the orbital structures more susceptible to trauma. In this position, the posterior pole of the globe also moves into the needle path. As a means of avoiding this problem, the following modification in technique has been recommended.

The primary gaze position, in which the patient is looking directly forward, allows the optic nerve to maintain its S-shaped curvature and also releases the tension on the blood vessels. The down-and-out gaze position allows the optic nerve and vessels to rotate toward the optic foramen and farther away from the needle path. Both of these eye positions have the potential disadvantage of needle visualization by the patient. The upward-gaze position should only be used as described by Gills and Lloyd.¹⁸ Their technique allows the use of the upward-gaze position because the needle is placed lateral and parallel to both the optic nerve and the vessels.

Needle Depth

A second problem is the depth of the needle insertion. The vital structures in the ocular anatomy are more crowded in the posterior orbit. Deep needle penetration in the orbit increases the likelihood of trauma to the optic nerve and vessels. If the depth of the needle insertion is decreased to approximately 25 mm (1 inch),¹⁹ the needle would lie just posterior to the globe, thereby reducing the risk of puncture of the vital structures. Studies have demonstrated that because of the wide variation in orbital and globe sizes, a needle depth of 19 to 31 mm (0.75 to 1.25 inches) is safest.⁷

Needle Tip Shape

A pertinent issue debated in the literature is the use of sharp versus dull needles for ocular blocks. Dull or flat-grind needles made specifically for retrobulbar anesthesia are touted by some clinicians as the only safe needles for use in ocular blocks. It is not so much the type of needle but where the needle is placed that increases the

risk.²⁰ Dull retrobulbar needles may not be tolerated as well by awake patients because of the sensation of pressure they create on insertion. Other needles proposed for ocular blocks include a curved retrobulbar needle²¹ and a dull pinhead needle, in which the injection port is proximal to the head of the needle.²²

Needle Angle

The angle of the needle is a third very important area that should be considered for modification. The original Atkinson technique uses an oblique approach; that is, the needle is inserted in the infratemporal area just above the inferior orbital rim and is directed toward the orbital apex, a pathway that tracts the needle tip toward the posterior pole of the globe, arteries, and the optic nerve.

Gills and Lloy¹⁸ developed a technique that takes into consideration not only the aforementioned changes, but also the length and spherical shape of the globe. This technique changes the oblique approach to a parallel approach. The lateral limbic margin, corneoscleral junction, is identified, and the needle is inserted in the inferotemporal area transconjunctivally, just lateral and parallel to the lateral limbic margin. The needle is inserted to a depth of approximately 25 mm (1 inch), entering the muscle cone just behind the globe. The advantages of this technique result from the needle position, which lies lateral and parallel to the optic nerve, the vasculature, and the posterior pole of the globe. However, the technique does not address the question “When does the needle tip pass the equator of the globe?” The needle tip must pass the equator of the globe before it may be safely redirected cephalad and inserted into the intraconal space.

The original retrobulbar block technique described by Atkinson can be made safer by modification of the technique. Modifications that decrease the risk of adverse effects are as follows:

- Position the globe to decrease tension on the vital orbital structures and position them farther away from the needle (e.g., the primary gaze position).
- Use a depth of needle insertion of approximately 25 mm (1 inch), which places the needle just behind the globe itself and avoids the structures deep in the orbit.

- Consider using a more lateral to parallel approach to the orbit than was originally demonstrated by Atkinson.

Some practitioners, in an effort to further improve the safety of ocular blocks, have advocated the use of extraconal peribulbar blocks.²³⁻²⁷ The literature describes these techniques as directing the needle outside the muscle cone, or extraconal. The anesthetic is injected, creating a positive extraconal pressure that spreads the agent inside the muscle cone to anesthetize the cranial nerves. To accomplish this, the needle is inserted parallel to, or is angled away from, the visual axis of the globe in an effort to remain outside the muscle cone. Peribulbar injections may be performed in the superior temporal, medial, and inferior temporal orbital areas. Peribulbar anesthesia requires larger volumes of anesthetic agents (8 to 12 mL). Owing to the many septal divisions of the orbit, the anesthetic flow may not adequately diffuse into the intramuscular cone. Therefore, extraconal peribulbar anesthetic injections, as described in the literature, may not consistently produce adequate akinesia and may necessitate multiple repeat injections.²⁴

Patients who may benefit from the extraconal peribulbar approach are those at increased risk for globe puncture, such as those with high myopia resulting in long axial lengths, significant enophthalmos, previous scleral buckling procedures, and staphylomas. However, peribulbar blocks have also resulted in globe punctures.²⁸

The primary goal of extraconal peribulbar blocks is the avoidance of the muscle cone and its vital structures. With modified retrobulbar blocks, the goal is not only to avoid the vital structures but also to enter the muscle cone just posterior to the globe.

Koornneef and Kramer¹¹ have described the least vascular areas to perform ocular blocks. (Fig. 44.19). The inferotemporal area can be used for both the intraconal modified retrobulbar and the extraconal peribulbar technique. The superior orbital area just lateral to the 12-o'clock position through the skin and the medial orbital area through the caruncle conjunctiva may be accessed for the extraconal peribulbar technique.

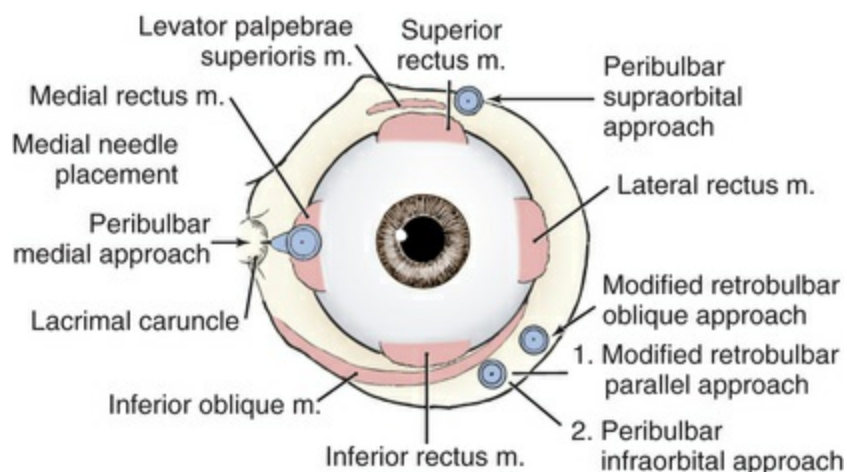

FIGURE 44.19 Frontal view of needle placement for retrobulbar and peribulbar anesthetic blocks. *m.*, Muscle.

The most important considerations for ocular blocks are the position of the eye and the depth and angle of the needle. Needle placement should attempt to avoid the optic nerve, arteries, veins, extraocular muscles, and the globe itself. At what insertion depth does the needle tip reach the equator of the globe, a spherical tangential point, beyond which it can be safely redirected into the retrobulbar space, is addressed in an abstract that was accepted and presented at the 23rd annual meeting of The Ophthalmic Anesthesia Society, "A Geometrical Method Applied to an Orbital Block." The author introduces the measurement of the dynamic orbital-globe relationship and uses the measured axial length to calculate the distance to the equator of the globe, beyond which the needle may be safely redirected cephalad and inserted into the retrobulbar space. The calculation mathematically demonstrated that a 0.5-inch (12.5-mm) needle insertion was usually beyond the equator of the globe, but recommended calculating the distance to the equator on each patient for safety.²⁹

The geometrical method was further developed into a teaching video for practitioners. The American Academy of Ophthalmology accepted the video "Orbital Block Technique" in 2013 for their Network One website.³⁰

Anesthesia Techniques

Gills-Lloyd Modified Retrobulbar Technique¹⁸

Equipment List

- One 3-mL syringe
- One 6-mL or 10-mL syringe
- One 25-gauge 1-inch needle
- 1-inch paper tape
- One 4 × 4 gauze pad

Description.

Figs. 44.20 and 44.21 and Box 44.2 present valuable reference aids for the Gills-Lloyd modified retrobulbar technique.

FIGURE 44.20 Lateral view of needle angles for a modified retrobulbar block.

FIGURE 44.21 **A**, In the Gills-Lloyd modified retrobulbar technique, the needle should be inserted transconjunctivally or transcutaneously, angled away from the visual axis of the globe toward the orbital floor until the orbital septum is penetrated. **B**, After penetrating the orbital septum, the needle should be redirected parallel to the visual axis to a depth of approximately 12 mm (0.5 inch) passing the equatorial plane of the globe. **C**, After passing the equatorial plane of the globe, the needle should be redirected cephalad to a depth of approximately 25 mm (1 inch). At this point, the needle enters the muscle cone, and the medication is injected. **D**, Needle placement, which is lateral and parallel to the lateral limbic margin. **E**, Completion of the modified retrobulbar block. Some degree of globe proptosis and drooping of the upper eyelid should be expected.

Box 44.2

The Gills-Lloyd Modified Retrobulbar Technique: Parallel Approach

- Insert the needle transconjunctivally or transcutaneously, with the bevel toward the globe, lateral to the lateral limbic margin and angled away from the visual axis of the globe toward the orbital floor, until the orbital septum is penetrated (see [Fig. 44.21A](#)).
- After penetrating the orbital septum, redirect the needle parallel to the visual axis to a depth of approximately 12 mm (0.5 inch) past the equatorial plane of the globe (see [Fig. 44.21B](#)).
- Past the equatorial plane of the globe, redirect the needle cephalad to a depth of approximately 25 mm (1 inch), entering the muscle cone while remaining lateral to the lateral limbic margin, and inject the medications (see [Fig. 44.21C](#)).

The patient should be in a comfortable, reclining position. Anesthetic drops are placed in the conjunctiva, the eyelids are closed, and the outer eyelids are cleansed. The patient is asked to look directly overhead and to stare at a finger or other object. The eye should not look inward but may look somewhat outward. Needle insertion through the skin is preferably avoided in this technique so that patient discomfort is minimized. The lateral limbic margin, corneoscleral junction, is identified. The lower eyelid is everted and controlled with a finger. The needle is placed with the bevel toward the globe, just above the inferior orbital rim, just lateral and parallel to the lateral limbic margin. The needle is then inserted through the conjunctiva and directed toward the orbital floor until the orbital septum is penetrated. The needle is then redirected parallel to the visual axis of the globe to a depth of 25 mm (1 inch). At this time, 1 to 1.5 mL of lidocaine, 1% to 2%, is injected after negative aspiration is performed. This initial extraconal peribulbar technique is effective in reducing the potential discomfort from the needle and the anesthetic injection of the modified retrobulbar block in the awake patient.

The eye is closed briefly in preparation for the modified

retrobulbar injection. The lower eyelid is again everted and controlled with a finger. The needle is placed with the bevel toward the globe, just above the inferior orbital rim, just lateral and parallel to the lateral limbic margin. The needle is then inserted through the conjunctiva and directed toward the orbital floor until the orbital septum is penetrated. The needle is then redirected parallel to the visual axis of the globe past its equatorial plane, approximately 0.5-inch (12.5 mm)²⁹ deep. At this point, the needle is redirected cephalad between the lateral and inferior rectus muscles. Resistance may or may not be felt as the needle enters the muscle cone. The needle should be inserted approximately 25 mm (1 inch), depending on the size of the orbit and the globe (range, 19 to 31 mm). After negative aspiration, the anesthetic agent is injected slowly, 1 mL/10 sec, until the orbit is filled. Orbital size governs the total amount of anesthetic injected; however, approximately 6 mL usually suffices. Once the orbit is full of anesthesia, as indicated by orbital tension, the needle is withdrawn. The eyelids are closed, a 4 × 4 gauze is placed over the eye, and positive digital pressure is applied. The pressure helps spread the anesthetic and detect any increasing orbital pressure, which might indicate a retrobulbar hemorrhage.

The initial needle insertion is directed away from the globe so that the risk of globe puncture is decreased. Resistance may or may not be felt as the needle enters the muscle cone, depending on the presence or absence of the fibrinous connective tissue in the area behind the globe, as described by Koornneef and Kramer.¹¹ The sharper the needle, the less resistance felt by the practitioner and the less discomfort felt by the patient. By comparison, use of dull needles results in more resistance, potentially resulting in greater patient discomfort. Patients have described this resistance to the needle as *pressure pain*. Because a pop may or may not be felt as the needle enters the muscle cone, attention to needle depth is important for the avoidance of deep penetration into the orbit.

During injection, the patient is told to inform the practitioner if any discomfort, such as stinging or pressure is experienced. If this occurs, the injection should be stopped to allow the agent to take effect. The pressure sensation appears to result from the spread of the local agent throughout the orbital area. The stinging is noticed

more when the agent moves into the peripheral area along the upper and lower eyelids. This slow injection process is continued until the orbit is filled with the anesthetic agent. When the anesthetic is placed into the muscle cone, the effects are seen rapidly, and the block can be evaluated for akinesia after approximately 2 minutes.¹ Generous traction must be applied to the lower eyelid, because this technique is performed before the orbicular muscles of the eyelids are anesthetized (i.e., seventh nerve block). Seventh nerve blocks can be very painful and are not well tolerated by patients. These blocks generally precede retrobulbar or peribulbar blocks but may not be necessary, because the anesthetic agent from the modified retrobulbar or peribulbar block spreads randomly throughout the orbit and eyelids, providing adequate akinesia of the eyelids.^{18,28}

Peribulbar Extraconal Techniques

Description.

Figs. 44.22 and 44.23 and Box 44.3 serve as valuable reference aids for the peribulbar technique.

FIGURE 44.22 Lateral view of needle angles for peribulbar block.

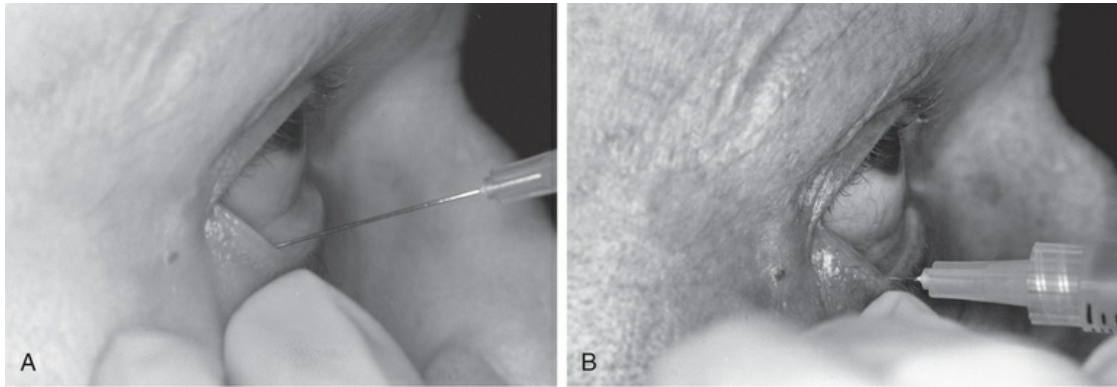

FIGURE 44.23 **A**, In the infraorbital approach, the needle is inserted transconjunctivally or transcutaneously and angled away from the visual axis of the globe toward the orbital floor to a depth of approximately 25 mm (1 inch), and the medications are injected. **B**, After penetration of the orbital septum, as shown in **A**, the needle is redirected parallel to the visual axis to a depth of approximately 25 mm (1 inch), and the medications are injected.

Box 44.3

Peribulbar Techniques

Infraorbital Approach

- Insert the needle transconjunctivally or transcutaneously, with the bevel toward the globe, lateral to the lateral limbic margin and angled away from the visual axis of the globe toward the orbital floor, to a depth of approximately 25 mm (1 inch), and inject the medications (see [Fig. 44.23A](#)).

or

- After penetrating the orbital septum, as described previously, redirect the needle parallel to the visual axis to a depth of approximately 25 mm (1 inch), and inject the medications (see [Fig. 44.23B](#)).

Supraorbital Approach

- Insert the needle only transcutaneously, with the bevel toward the globe, just inferior to the supraorbital rim, just lateral to the 12-o'clock position and superior to the globe. Angle away from

the visual axis of the globe toward the orbital ceiling, to a depth of approximately 25 mm (1 inch), and inject the medications.

or

- After penetrating the orbital septum, as described previously, redirect the needle parallel to the visual axis to a depth of approximately 25 mm (1 inch), and inject the medications.

Extraconal peribulbar blocks may be performed using different techniques. One is a supraorbital-only technique of injecting a large volume (10 to 12 mL) of anesthetic agent, which should distribute throughout the orbit for completion of the block. An inferotemporal-only technique also involves injection of a large volume (10 to 12 mL) of anesthesia, which should distribute throughout the orbit and anesthetize the eye. A more reproducible approach to extraconal peribulbar anesthesia is the use of both the inferior and superior approaches. Each of these injections may be performed with a 6-mL syringe for a total volume of 10 to 12 mL. The combination technique generally provides a more consistent result.

Infraorbital and Supraorbital Extraconal Peribulbar Anesthesia

Equipment List

- One 10-mL syringe or two 6-mL syringes
- One or two 25-gauge needles
- One 4 × 4 gauze pad
- 1-inch paper tape
- One alcohol or providone-iodine (Betadine) wipe

Description.

For the infraorbital peribulbar technique, the lateral limbic margin is identified, and the patient is asked to look directly overhead. The lower eyelid is everted and controlled with a finger. The needle is

placed, with the bevel toward the globe, just above the inferior orbital rim, lateral and parallel to the lateral limbic margin. The needle is then inserted through the anesthetized conjunctiva and directed toward the orbital floor until the orbital septum is penetrated. The needle is then redirected parallel to, or angled away from, the visual axis of the globe to a depth of approximately 25 mm (1 inch). After the syringe is secured and negative aspiration is performed, 6 mL of the anesthetic agent is slowly (1 mL/10 sec) injected. The rate of injection is determined by patient comfort. After the injection, the eyelids are closed, and positive pressure is applied for dispersal of the medication.

The supraorbital peribulbar injection is performed just inferior to the supraorbital rim, just lateral to the 12-o'clock position and superior to the globe. The needle is inserted with the bevel toward the globe through the skin. This area is generally anesthetized from the original inferotemporal injection. The needle is inserted parallel to, or angled away from, the visual axis of the globe to a depth of approximately 25 mm (1 inch). After negative aspiration is performed, the anesthetist may begin a slow injection of 4 to 6 mL of anesthetic solution until a tense orbital area is observed. A tense orbit should be expected to result from the peribulbar technique because of the increased extraconal pressure necessary to move the anesthetic intraconally.

Once this technique is completed, the eyelids are closed and taped shut. A 4 × 4 gauze pad is placed over the closed eye. A positive-pressure device is now placed over the eye to help distribute the agent throughout the orbit and achieve the desired analgesia and akinesia. The positive-pressure device also decreases intraocular pressure to an acceptable surgical level. To avoid corneal abrasion, the eyelids must completely cover the eye. It may take up to 10 minutes for satisfactory surgical anesthesia to be established from an extraconal peribulbar block. If the peribulbar block fails to attain adequate akinesia within 10 minutes, the appropriate muscles must be reblocked by use of the inferior technique for the inferior rectus, inferior oblique, and lateral rectus muscles. The superior technique is used for the superior rectus, superior oblique, and medial rectus muscles. The supraorbital approach should not be attempted through the conjunctiva because

of the potential for damage to the levator muscle of the upper eyelid; such damage may result in upper eyelid ptosis.

Medial Extraconal Peribulbar Block

Equipment List

- One 3-mL syringe
- One 30-gauge, $\frac{1}{2}$ -inch needle

Description.

Figs. 44.24 and 44.25 and Box 44.4 serve as valuable reference aids for medial peribulbar anesthesia.

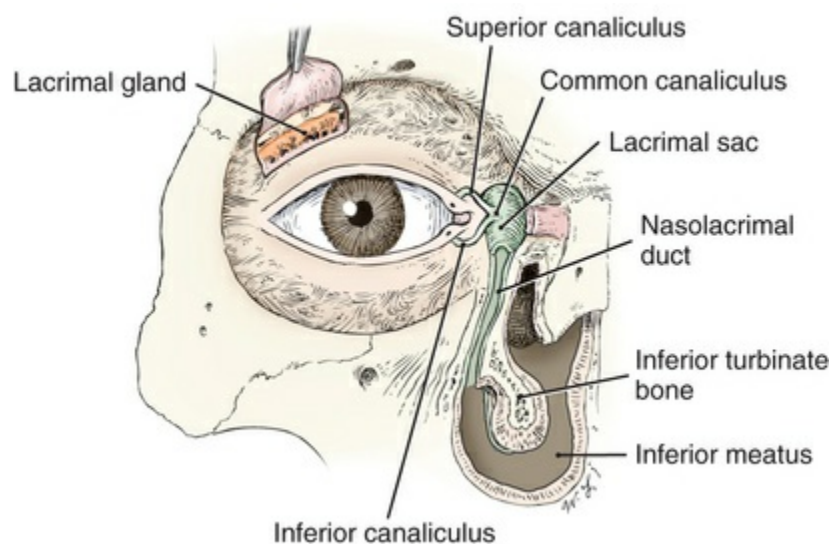

FIGURE 44.24 Frontal view of the lacrimal drainage system.

FIGURE 44.25 Superior view of the needle angle for a medial peribulbar block. *n.*, Nerve.

Box 44.4

Medial Peribulbar Block

Penetrate the caruncle conjunctiva with the bevel of the needle toward the globe and the needle angled toward the lacrimal bone, to a depth of approximately 12 mm (0.5 inch), and inject the medications.

The medial peribulbar area is a rather avascular, fatty compartment that lies just medial to the medial rectus muscle. This area narrows significantly as it approaches the posterior surface of the globe, with the medial rectus muscle lying next to the bony orbit. Superior to the medial peribulbar area is the supranasal area. This area contains a portion of the superior ophthalmic vein and branches of the ophthalmic artery and should be avoided when ophthalmic blocks are performed.

The medial area also has herniated orifices within the connective tissue that communicate anteriorly to the posterior surface of the orbicular muscle of the eye. Therefore, the anterior spread of the anesthetic agent blocks cranial nerve VII, resulting in satisfactory akinesia of the eyelids for surgery. The medial peribulbar technique

can also be used with minimal discomfort to provide eyelid akinesia before a modified retrobulbar block is performed; in this case, proparacaine drops are applied to the caruncle before the block is administered. The anesthetic agent is injected into the periorbital space that exists between the medial wall of the bony orbit and the medial rectus muscle. The technique is very effective as a secondary block both for incomplete akinesia of the medial rectus muscle and the superior oblique muscle and as a primary block for the orbicular muscles of the eyelid.

To avoid needle injuries to the medial rectus muscle, a modified insertion site, needle length, and angle may enhance the ease of needle placement and safety. The landmark for the modified technique is the caruncle, a small mound at the inner canthus of the eye formed by a conjunctival fold at its junction with the skin. The needle is inserted through the caruncle conjunctiva, tangential to the globe, and is directed medially and posteriorly toward the lacrimal bone, which is just posterior to the lacrimal sulcus. Care must be taken to avoid trauma to the puncta, the lacrimal canaliculi, and the lacrimal sac. To avoid contact with the medial rectus muscle, it is important to keep the needle angled toward the lacrimal bone and away from the visual axis. Insert the needle, bevel toward the globe, to a depth of approximately 12 mm (0.5 inch). After negative aspiration is performed, 3 mL or more of anesthetic agent may be injected for facilitation of the desired effect. After the block is completed, the eyelid should be closed and light pressure applied to reduce the incidence of bleeding.

Ocular Block Evaluation

After an ophthalmic block is performed, partial movement of one or more of the ocular muscles may occur. Residual movement should be assessed to determine which muscles are involved and whether additional anesthesia is required. Analgesia of the globe generally precedes akinesia of the eye muscles. Therefore, analgesia of the globe may be assumed, but not guaranteed, in the presence of an akinetic muscle. The effectiveness of a modified retrobulbar block may be evaluated 2 minutes after it is administered, and an extraconal peribulbar block 10 minutes after it is administered, by observing for eye movement in all four quadrants.

Eyelid Block

Once satisfactory akinesia of the globe is established, evaluation for movement of the eyelids is necessary. Partial to complete akinesia of the orbicular muscle is generally found after the ocular block. If incomplete akinesia of the orbicular muscle persists, perform a medial peribulbar to complete the block of nerve VII. Several blocks of nerve VII are described in the literature, including those by Van Lint, O'Brien, Nadbath, and Husted.^{26,31}

The O'Brien and Nadbath techniques block cranial nerve VII proximally, resulting in unilateral facial paralysis. The O'Brien and Nadbath techniques are still used; however, their popularity is decreasing because of their systemic side effects and patient discomfort. The Van Lint technique more appropriately addresses the need for eyelid akinesia, with less potential for adverse effects, by blocking the temporal and zygomatic branches of the facial nerve to the orbicular muscles. However, it is very painful. A variation of these techniques may be used for orbicularis oculi block. This technique has the advantage of being safer, less painful, and better accepted by the awake patient than the Van Lint block, but it requires injections through the skin and has the potential for causing patient discomfort and eyelid ecchymosis. The preferred technique for eyelid akinesia remains the medial peribulbar block.

Orbicularis Oculi Block

Equipment List

- One 6-mL syringe
- One 30-gauge, $\frac{1}{2}$ -inch needle
- One alcohol wipe

Description.

Fig. 44.26 and Box 44.5 serve as valuable reference aids for the orbicularis oculi block.

FIGURE 44.26 Frontal view of the needle placement for an orbicularis oculi block.

Box 44.5

Orbicularis Oculi Block

- *Lower lid:* Insert the needle subcutaneously, bevel down and tangential to the lid in the infratemporal area, and inject the medications.
- *Upper lid:* While slightly depressing the globe, insert the needle subcutaneously, bevel down and tangential to the lid in the supranasal area, and inject the medications.

This technique is performed after a modified retrobulbar or peribulbar block in which residual eyelid movement remains. The first injection is made inferotemporally in the lower eyelid. The needle is inserted bevel down, subcutaneously and tangentially to the lower eyelid, and 1 to 2 mL of the anesthetic agent is injected just under the skin of the eyelid. After the needle is removed, the local anesthesia should be digitally spread to the medial and the lateral canthi; this measure avoids running the needle across the lower eyelid. The second injection is made supranasally in the upper eyelid. A finger should be placed over the closed eyelid, slightly depressing the globe. The needle is again inserted, bevel down, subcutaneously and tangentially to the eyelid, and 1 to 2 mL of the agent is injected just under the skin of the eyelid. After the

needle is removed, the local anesthetic is digitally spread to the medial and lateral canthi. Once the anesthetic is spread throughout the eyelids, light to moderate pressure is applied over the eyelids for prevention or reduction of superficial bleeding.

Van Lint Technique

Equipment List

- One 6-mL syringe
- One 25- or 27-gauge, 1.5-inch needle
- One alcohol or providone-iodine wipe
- One 4 × 4 gauze pad

Description.

A 37.5-mm (1.5-inch) needle is inserted inferotemporally into the subcutaneous tissue of the lateral canthus. The first injection of 1 to 2 mL of anesthetic agent is directed nasally along the lower margin of the orbit and then withdrawn to its origination point. The second injection of 1 to 2 mL of anesthetic agent is directed upward along the supratemporal margin of the orbit. After the block is completed, light pressure is applied over the closed eyelids to disperse the medication and decrease ecchymosis.

Positive Orbital Pressure

The increased volume of local anesthetic required for both modified retrobulbar and peribulbar anesthetics causes an increase in orbital and intraocular pressures. The anesthetic agent not only tracks along and penetrates the fascial sheaths behind the globe, it also moves anteriorly underneath the conjunctiva, producing chemosis (i.e., subconjunctival edema) of the eye. These events may make the surgical procedure more difficult to perform. However, the random diffusion of the orbital anesthetic cannot be controlled. The agent merely tracks along the path of least resistance. Clinically, chemosis can begin with the injection of as little as 1 to 2 mL of anesthetic. In other instances, chemosis has not been seen even after the injection of as much as 12 mL of anesthetic agent.

Positive-pressure devices are used to reduce increased intraocular/intraorbital pressures and chemosis. Such devices are placed directly over the globe and orbit to enhance the orbital spread of anesthetic agent and return the orbital anatomy to a softer, more normal state for surgery. Positive-pressure devices deepen the anterior chamber by further reducing the intraocular pressure, thus allowing greater room for surgical intervention.

Positive-Pressure Device

Honan Intraocular Pressure Reducer

The Honan intraocular pressure reducer, or Honan balloon, is an inflatable pneumatic device used to apply ocular compression after retrobulbar or peribulbar anesthetic injection. A rubber head strap is placed behind the head. The eye is taped closed, and a folded 4 × 4 gauze pad is placed over the eye. The Honan cuff is placed over the gauze pad and secured with the Velcro head strap. The pressure gauge is inflated to 30 mm Hg, a value marked in yellow on the gauge.

Anesthesia Management

Preoperative Preparation

Ophthalmic procedures are most commonly performed on young children and elderly persons. Each age group has a unique set of physical problems. For the young child, the questions regarding the patient's history should include any congenital, metabolic, and musculoskeletal abnormalities, such as malignant hyperthermia, that may affect anesthesia care. In the elderly patient, multisystem medical problems may be present, and drug interactions from multiple medication regimens may exist. Therefore a thorough patient history is paramount.

Admissions on the Day of Surgery

Anesthesia practitioners must remember how stressful a surgical procedure on the eye can be for patients. A kind and professional attitude on the part of all those providing care will help patients cope more effectively with personal stress. The proper use of progressive relaxation and hypnotic techniques further helps alleviate their anxiety. Establishing a good patient-provider relationship works synergistically with pharmacologic agents in promoting the best possible surgical environment. On admission, the patient's mental and physical status, vital signs, and electrocardiogram (ECG) should be reviewed for any changes that may require postponement.

Regional Versus General Anesthesia

Patients undergoing regional block, in which they are awake for the procedure, must be evaluated for claustrophobia, severe arthritis, tremors, restless leg syndrome and any other physical derangements that may make it difficult for them to lie supine. Patients' mental status also must be evaluated so that their degree of cooperation and ability to follow commands can be determined.

Elderly patients often take multiple medications and may not remember all of them. Patients should be instructed to bring their

medications on the day of surgery. A preoperative visit to the primary care physician is advised to confirm that the patient's overall medical condition is optimized for the planned surgical procedure.

The attending surgeon, in collaboration with the anesthesia practitioner, will make the final evaluation as to the patient's fitness on the day of surgery. An ECG performed within the past year is desirable with the medical evaluation. The preoperative ECG assessment furnishes a baseline of what is optimal for the individual patient. Comparing the baseline ECG against the patient's ECG on the day of surgery helps determine whether any further preoperative testing is warranted.³² However, studies have questioned the value of a preop ECG in low risk surgery.³³ For patients receiving regional anesthesia, routine laboratory tests are not ordered unless they are medically necessary. Appropriate laboratory data may be necessary when general anesthesia is planned.^{34,35}

After the patient history and physical examination are completed, the appropriate anesthesia plan can be formulated. General anesthesia should be used for infants and young children. General anesthesia is also indicated for patients with severe claustrophobia, a history of uncontrolled acute anxiety attacks, or inability to cooperate, communicate, or lie flat (Box 44.6). It is also a consideration for procedures of greater than a duration of 2 hours.³⁶ Most adults tolerate ophthalmic procedures well when regional anesthesia is used. Given the potential risks associated with general anesthesia (Box 44.7), regional anesthesia should be considered the anesthetic of choice in adults, especially the elderly, for ophthalmic procedures.

Indications for General Anesthesia

- Pediatric patient
- Patient's lack of cooperation
- Severe claustrophobia
- Inability to communicate

- Inability to lie flat
- Open-eye injuries
- Procedures with durations greater than 2 hours

Box 44.7

Disadvantages of General Anesthesia

- Nausea/vomiting
- Retching/bucking
- Increased intraocular pressure
- Aspiration
- Complications secondary to other medical problems (e.g., cardiovascular disease)
- Time and expense

Regional Anesthesia

Regional Block With Minimal Sedation

Nothing-per-Mouth Status.

The views of anesthesia practitioners vary on the advisability of nothing-per-mouth (*nil per os*; NPO) status prior to ocular procedures, especially cataracts. Some practices allow patients undergoing surgery in the morning to eat a light breakfast the day of surgery. Those undergoing surgery in the afternoon may be told to eat a light lunch.³⁷ Patients may also be encouraged to consume clear fluids until they are admitted to the facility.³⁸ However, practitioners also may mandate a strict NPO protocol.

Patients are requested to take their medications as prescribed on the day of surgery. An exception may be patients who complain of a frequent need to urinate after taking diuretic medications. Antiglycemic agents may be reduced or withheld when patients are

NPO according to usual practice.³⁹ Evaluation and management of any anticoagulant medications are required for certain eye procedures to decrease the likelihood of bleeding. A medical consult with discontinuation several days prior to surgery may be necessary for certain anticoagulants. An increase in bleeding has been reported following vitreoretinal surgery in patients taking antiplatelet drugs.^{40,41} Others note discontinuation is not necessary.³⁸ It is generally not required that antiplatelet drugs (e.g., aspirin, Clopidogrel) and anticoagulants (e.g., warfarin [Coumadin]) be discontinued. The risk of systemic complications, such as cardiovascular accidents and myocardial infarctions, is potentially greater if administration of these products is discontinued. Continuing anticoagulant administration, however, requires consultation and agreement between the anesthesia practitioner and the surgeon.^{19,42} If bleeding occurs, it may be more severe; therefore, patients also need to be made aware of the risk and benefits of continuing their anticoagulants. Patients who are receiving or have previously been treated with chemotherapy also may have prolonged bleeding times.

Regional Block Environment

Ocular blocks are commonly performed outside the operating room. This method facilitates a more efficient case flow and a more comfortable environment for the patient. The potentially life-threatening effects of orbital epidural blocks require that appropriate resuscitative equipment and trained personnel are available to monitor the patient. The area used for performing ocular blocks should have the following:

- Oxygen
- Bag-valve mask
- Suction
- Airways
- ECG equipment
- Blood pressure cuff
- Oxygen saturation monitor
- Capnography for deep sedation

- Canthotomy set
- Ammonia capsules
- Nitroglycerin tablets
- Atropine
- Glycopyrrolate

Additional resuscitative equipment and medications as recommended by advanced cardiac life support guidelines should be available.

Sedation for Regional Blocks and Ophthalmic Procedures

The goal of conscious sedation is to help patients gain and maintain control by reducing their heightened state of anxiety. This enhances their cooperation and ability to tolerate the awake surgical procedure.

Many techniques have been advocated to relax the patient prior to the ocular block and during the surgical procedure.^{43,44} Conscious sedation techniques have included the use of benzodiazepines, narcotics, and nonbarbiturates.⁴⁵ When these medications are properly tailored they are tolerated well by the elderly patient. Sedation techniques should be designed to decrease anxiety ([Box 44.8](#)) and reduce the discomfort of the block ([Box 44.9](#)). When the block is less painful, patients require less sedation for comfort. The surgeon's preference for an awake, relaxed, or sleeping patient during the procedure also should be considered. Sleeping patients [Box 44.8](#) are more and may have sudden head movements on awakening.

Sedation Techniques

- Good rapport between patient and clinician—minimizes medications necessary
- Intravenous benzodiazepine administration
- Intravenous narcotic administration
- Intravenous propofol administration

Box 44.9

Causes of Discomfort Resulting From Regional Blocks

- Needle injection through the skin
- Needle penetration of the conjunctiva
- Needle penetration of the orbital connective tissue
- Rapid injection of anesthetic
- Stinging from peripheral spread of anesthetic

If the patient is to be asleep during the block, fasting before the procedure consistent with the facility's criteria for general anesthesia should be followed ([Box 44.10](#)). Propofol is an excellent choice for this technique because of its short duration of action.⁴⁶

Procedure for Patient Who Is Asleep During Regional Block

- Tilt head to maintain patent airway
- Open patient's eye in primary gaze position
- Administer regional block
- Administer incremental sedation as required

Sedation is typically effective and safe for ocular blocks and intraoperative use but necessitates provider vigilance and monitoring to recognize and treat any of the adverse medical events that may occur.⁴⁷

Monitoring for Regional Anesthesia

Communication is the cornerstone of interacting with the patient who is awake. Informing the patient regarding what to expect and

what to do if he or she experiences any problems is mandatory. Questions and instructions must be clear and specific, especially if the patient is hearing impaired or if a language barrier exists.

The positioning of the patient is very important. Pillows may be used under the knees to decrease back strain. The patient with severe arthritis must be carefully padded and positioned. The patient's head and neck should be placed in a satisfactory surgical position. The practitioner should ensure that the patient is warm and as comfortable as possible. Nasally administered oxygen may be considered. Monitoring equipment should consist of the standard monitors used for all procedures. Observing the surgical procedure on a television monitor is preferable. This allows the anesthetist to follow the surgical progress and visualize critical points in the procedure at which patient movement would be most detrimental.

The surgical draping placed over the patient's face should be tented, and high-flow air may be used to dissipate expired carbon dioxide more quickly. Claustrophobia can be a problem for patients who are awake. Techniques for dealing with claustrophobia include taping the nonsurgical eye or adjusting the drape so that the patient can see the room with the nonsurgical eye. If a patient experiences a claustrophobic attack, the surgical drapes should be tented away from the face immediately, while the sterile field is maintained, and verbal control of the patient is gained. At this point, the anesthetist must determine whether the patient can proceed with surgery under regional block. Rarely, the patient may experience incomplete ocular analgesia, even in the presence of muscle akinesia. This problem responds well to 2% lidocaine MPF (methylparaben-free) drops or a subconjunctival anesthetic injection.

Acute increased intraocular pressure during the surgical procedure can be catastrophic and cause loss of ocular contents. Coughing or a choroidal hemorrhage can create this problem. The increased intrathoracic pressure created during coughing is reflected through the valveless orbital veins, resulting in an acutely increased intraocular pressure of 40 mm Hg or greater.⁴⁸ A choroidal hemorrhage occurs when a vessel in the vascular choroidal layer of the eye ruptures, bleeding into the closed cavity

and creating an acute rise in intraocular pressure with potential expulsion of eye contents unless the eye is closed quickly. In the acute phase, medications that lower intraocular pressure may be of minimum benefit.

If the patient has a history of postnasal drip, vasoconstrictive nose drops may be given preoperatively. If the patient complains of a dry throat, small amounts of water may be given. These two remedies are helpful in reducing the incidence of coughing intraoperatively. The patient must also be instructed to give notice before he or she coughs. Instructing the patient to clear his or her throat effectively reduces the forcefulness of the cough. Quick, shallow breaths have been reported to help suppress the cough reflex.⁴⁸ Sedating the patient or using intravenous lidocaine to prevent further coughing can help but has minimal effect during an active coughing episode.⁴⁹

After the surgery is completed, the patient is transported from the operating room to postanesthesia recovery (PAR). Postoperative recovery time should be in accordance with the individual patient's physical and mental status and the amount of medication administered.

In a meta-analysis of regional versus general anesthesia for ambulatory anesthesia, patients who received peripheral nerve blocks, such as orbital regional eye blocks, experienced less postoperative pain, nausea, and a decreased postanesthesia care time.⁵⁰ If postoperative nausea is noted immediately after surgery, it may result from the sedative medications, increased intraocular pressure, or ocular pain.⁵¹ On the afternoon or evening after their surgery, patients are generally called at home to evaluate their status. A sudden onset of nausea at home after the procedure is more likely associated with increased intraocular pressure than anesthetic medications. Patients are usually examined the following day by the surgeon and are requested to fill out questionnaires regarding their experience on the day of surgery.

General Anesthesia

For general anesthesia, preoperative patient preparation should include the appropriate fasting guidelines for the patient's age and physical condition (e.g., diabetes). The patient should be reminded

that the surgical eye will be patched when he or she awakens. Sedation should be administered as needed to help the patient relax. Benzodiazepines such as midazolam are effective in low doses. For reduction in the incidence of postoperative nausea, the use of a standard multimodal approach should be considered. Induction of general anesthesia with propofol or etomidate is recommended because they both decrease intraocular pressure. For infants and children, inhalation induction also decreases intraocular pressure. Due to the emetic effects, narcotics should be used in low doses. Other than during examinations under anesthesia or other shorter procedures, endotracheal intubation is indicated for maintenance of the airway.

Succinylcholine causes a transient increase in intraocular pressure; however, it can be used safely for ocular procedures. Some caveats include

- The sustained contracture of the extraocular muscles after succinylcholine could cause an expulsion of the intraocular contents. This assumption is theoretical, and it is now felt that succinylcholine may be safely used in eye surgery. See full discussion later.
- In eye muscle surgery, the sustained contraction may interfere with the forced duction test used by the surgeon for the treatment plan.

Nondepolarizing muscle relaxants are satisfactory for induction and have the advantage of decreasing intraocular pressure.⁵²

Laryngoscopy, especially with light anesthesia, increases intraocular pressure, but intravenous lidocaine (1.5 to 2 mg/kg), given 1 to 1.5 minutes before laryngoscopy, helps attenuate this response. Inhalation anesthetics, which also decrease intraocular pressure, are commonly used for the maintenance of general anesthesia.

For intraocular procedures, the continued use of nondepolarizing muscle relaxants is recommended for the maintenance of an akinetic eye and a satisfactory intraocular pressure. The anesthetist must be aware of the adverse ECG changes that may result from the oculocardiac reflex, which may be elicited when traction is exerted on the extraocular muscles and orbital structures. Patients undergoing eye-muscle surgery have an increased incidence of

malignant hyperthermia and postoperative nausea. In retinal procedures in which sulfur hexafluoride or perfluoropropane is used as an intraocular gas, the use of nitrous oxide should be discontinued 15 minutes before injection.

When spontaneous ventilation returns after neuromuscular blockade is reversed, the patient may be extubated while receiving deep anesthesia with 100% oxygen and placed in the lateral position until he or she awakens. In the patient with a difficult airway, full stomach, or incompetent esophageal sphincter, gastric suction and intravenous lidocaine (1.5 to 2 mg/kg) may be given before the patient is extubated awake. This method helps reduce the incidence of coughing and vomiting, along with their deleterious effects.

The laryngeal mask airways (LMAs) also have their respective place in ophthalmic procedures. They may be inserted without muscle relaxants and removed with less risk of coughing in the awake patient. Along with the usual risk assessment for gastric aspiration, the practitioner should also consider that the lack of access to the airway during the procedure, intraoperative malposition of the LMA, and light anesthesia in the absence of muscle relaxants may result in laryngospasm or coughing. The LMA is gaining popularity in extraocular procedures such as strabismus and scleral buckle surgeries.⁵³

Postoperative care, with attention paid to the alleviation of pain and control of nausea, will help maintain a satisfactory intraocular pressure. The ophthalmologist should be made aware of continued postoperative nausea, because it may be the result of acute increased intraocular pressure.⁵¹

Open-Eye Injury and the Use of Succinylcholine

Traumatic eye injuries can be categorized as either open- or closed-globe injuries. Open-eye injury in a patient with a full stomach is at best a difficult situation for the anesthesia provider. These injuries are commonly considered emergencies requiring general anesthesia. The clinician must protect the patient from aspiration and yet avoid increased intraocular pressure that could result in expulsion of intraocular contents. Authors have traditionally debated the risks and advantages of using succinylcholine for this

procedure.^{53,54} Normal intraocular pressure (IOP) is 10 to 22 mm Hg, with slight diurnal and positional changes of 1 to 6 mm Hg. It is physiologically determined by aqueous humor dynamics, changes in choroidal blood volume, central venous pressure, and extraocular muscle tone. The most important determinant of IOP is the balance between production and elimination of aqueous humor, maintaining an average volume of 0.25 mL. Aqueous humor is formed in the ciliary process from capillaries by diffusion, filtration, and active secretion. It flows through the posterior chamber, around the iris, and into the anterior chamber. It is eliminated through the spaces of Fontana and canal of Schlemm at the iridocorneal angle, where it flows into the episcleral venous system. Any increase in venous pressure (e.g., cough, strain, head-down position) will increase IOP. Additionally, any decrease in cross-sectional area of the spaces of Fontana (e.g. mydriatic drugs) will increase IOP.⁵⁵⁻⁵⁹ Administration of succinylcholine increases IOP within 1 minute and peaks at an increase of 9 mm Hg within 6 minutes after succinylcholine administration. The exact mechanism of this increase is unknown. Some feel that tonic contractions of the extraocular muscles may explain this IOP increase. It is now thought, however, that succinylcholine-induced IOP increase is a vascular event, with choroidal vascular dilation or a decrease in drainage secondary to elevated central venous pressure, temporarily inhibiting the flow of aqueous humor through the canal of Schlemm.⁵⁶

It is clear that succinylcholine raises IOP. However, at induction of general anesthesia, there are many activities that raise IOP to a much greater degree than succinylcholine, including crying, Valsalva maneuver, forceful blinking, rubbing of the eyes, and coughing or bucking during poor intubating technique. Therefore, the increase in IOP due to succinylcholine may be inconsequential if optimal intubating conditions are not provided.

Moreno wrote: "This observation, coupled with the lack of any documented cases of extrusion of intraocular contents in open globes of humans when succinylcholine is used, causes us to question the traditional teaching that succinylcholine should be avoided in all cases when open globe is suspected or known."⁵⁵

Chidiac and Raiskin⁵⁶ have stated that two questions need to be

asked before the decision about the use or avoidance of succinylcholine in open-globe surgeries is made: Is this an easy airway; and is the eye viable? If the airway assessment shows that intubation should be easy, then regardless of the patient's aspiration risk, and regardless of the viability of the eye, succinylcholine can be avoided and replaced with rocuronium. If the airway assessment shows that this could be a difficult intubation, regardless of the patient's aspiration risk, then the second question becomes important: is the eye viable? If the ophthalmologist feels that the eye is viable, use of succinylcholine is recommended. Pretreatment with drugs that attenuate the intraocular pressure effect of succinylcholine, such as a small dose of nondepolarizing agent and lidocaine, should be used.

Choosing or avoiding succinylcholine is a matter of balance of risk. To control IOP at induction, there must be adequate dosing of drugs timed appropriately to coincide with the three potent stimuli: the administration of succinylcholine, the laryngoscopy, and the endotracheal intubation. It is clear that succinylcholine increases IOP, but this increase can be attenuated with various pretreatments, is less than increases seen with inadequate paralysis at the time of laryngoscopy and intubation, and is unimportant when weighed against the risk of loss of the airway. Therefore, in the situation of "difficult airway, eye viable," one should use succinylcholine.

Closed-globe injuries require significant planning and preparation to prevent further damage to the eye by an increase in IOP. They also require smooth induction and emergence because patient coughing or bucking will cause a detrimental increase in IOP.⁵⁷

Ophthalmic Anesthesia

Complications

Anxiety coupled with underlying cardiovascular disease may promote marked hypertension, cardiac dysrhythmias, or angina in the patient before surgery. Vasovagal responses (e.g., fainting) secondary to anxiety are not unusual. Ammonia capsules are effective in preventing and treating fainting episodes.

Chronic coughing secondary to chronic obstructive pulmonary disease, asthma, or postnasal drip must be evaluated.

Vasoconstrictive nose drops effectively decrease postnasal drip. Coughing and deep breathing before surgery help clear the lungs of excess mucus in patients with chronic pulmonary disease. Proper evaluation and treatment help reduce undesired perioperative systemic and ocular sequelae.

Most complications of regional ocular anesthetics can be attributed to direct traumatization of the orbital vessels, the globe, and the optic nerve. Trauma to these structures can result whenever a needle is placed near the eye. Frequently, the cause of complications during regional blocks and general anesthesia is patient movement.

Retrobulbar Hemorrhage

Retrobulbar hemorrhage results from trauma to an orbital vessel. The retrobulbar bleeding moves the eyeball forward (proptosis), and a subconjunctival hemorrhage is usually present. Venous hemorrhages are typically slow in onset, but arterial hemorrhage has a rapid onset and more pronounced proptosis and subconjunctival hemorrhage. Ecchymosis of the eyelids and orbit is usually present. The pressure caused by the bleeding in the bony orbital cavity produces increased orbital pressure on the optic nerve, vessels, and globe. This pressure usually resolves without problems but may result in an occlusion or spasm of the central retinal artery or vein, resulting in partial to complete loss of vision.⁶⁰ One may detect a progressively increasing orbital pressure when digital pressure is applied over the eye after an ocular block.

Continuous digital pressure may be all that is required for stopping a venous hemorrhage.¹⁹ If the orbital pressure continues to increase in the presence of digital pressure, a lateral canthotomy is indicated and may be performed by the ophthalmologist or the anesthesia practitioner, who should then notify the ophthalmologist.

Canthotomy is a procedure performed to increase the orbital space by cutting the lateral canthus and reducing the orbital pressure that results from a retrobulbar hemorrhage.

A canthotomy set should be readily available when orbital blocks are being performed (Box 44.11). The ophthalmologist should examine the central retinal artery and vein for patency. Occlusion of these vessels may warrant further surgical intervention for reduction of elevated orbital pressure.

Canthotomy Procedure

Equipment

- 1 Straight hemostat
- 1 Plastic scissors

Procedure

1. If possible, inject lidocaine along the lateral canthus.
2. Place the hemostat in a temporal direction along the lateral canthus 4–6 mm, and clamp the hemostat.
3. Remove the hemostat.
4. Use the plastic scissors to incise only in the crush marks left by the hemostat.
5. Control local bleeding with the hemostat or with digital pressure.

A localized episcleral hemorrhage also causes subconjunctival bleeding. In this situation, however, no proptosis of the globe or increase in orbital pressure is noted. These episcleral vessels are the same ones the ophthalmologist cauterizes after a conjunctival

incision. The vessels break as a result of the spread of local anesthesia through the subconjunctival area and are of no consequence. However, the ophthalmologist should be notified of their presence before the procedure begins.

Retrobulbar hemorrhage remains the most common sequelae for ocular blocks (Box 44.12). Peribulbar injections also can cause orbital hemorrhages.²⁸ Retrobulbar hemorrhages have been reported to occur in 1% to 3% of cases.⁶¹

Measures for Preventing Retrobulbar Hemorrhage

- Choose least vascular areas for needle placement.
- Avoid deep orbital injections.
- Avoid supranasal position of gaze.
- Use primary gaze position.
- Use upward-gaze position (Gills-Lloyd technique only).
- Insert needle slowly.

Intravascular Injection

Grand mal seizures have been reported to occur after retrobulbar injections with lidocaine and lidocaine-bupivacaine combinations.^{62,63} Seizures may result from a less-than-toxic dose of local anesthesia by direct intraarterial injection, resulting in retrograde flow to the cerebral circulation (Box 44.13). Mathers⁶⁴ surveyed 200 ophthalmologists. Sixty-six responded and reported three seizures occurring after retrobulbar injections. From these data, it appears that seizures after retrobulbar anesthesia may occur more frequently than reported in the literature. A reaction after an orbital vein injection has also been reported: the patient experienced uncontrolled shivering and rigor approximately 15 seconds after the retrobulbar injection. These symptoms resolved within 2 minutes of onset.⁶⁵

Measures for Preventing Seizures Resulting From Intravascular Injection

- Choose least vascular areas for needle placement.
- Avoid deep orbital injections.
- Avoid supranasal position of gaze.
- Insert needle slowly.
- Aspirate gently before injection; negative aspiration is no guarantee that you are not in a blood vessel.
- Avoid injection against resistance.
- Avoid forceful rapid injections.

Globe Puncture

Multiple reports have been published regarding globe perforations. Both sharp and dull needles have either penetrated or perforated the eye during retrobulbar and peribulbar injections. Although rare, globe punctures have occurred in the hands of experienced practitioners who have performed many thousands of ophthalmic blocks. The literature also notes that patients may or may not exhibit signs and symptoms of a puncture immediately, and the diagnosis has been made anywhere from 1 to 14 days after the event.^{20,66-69} The most rare but devastating globe injury reported is an ocular explosion. The globe can literally burst apart from the intraocular pressure exerted by the local anesthesia injection.^{70,71}

The myopic eye has an increased axial length of greater than 24 mm. Scleral thinning may result from this increased anteroposterior diameter. A previous scleral buckling procedure also increases the anteroposterior diameter of the eye. Staphyloma, a bulging of the sclera, may also predispose the patient to globe puncture. The risk of puncture increases when this abnormality is located inferoposteriorly on the globe. Enophthalmos is a recession of the eyeball into the orbit. This condition decreases the distance between

the posterior pole of the globe and the posterior orbital wall. The supranasal gaze position rotates the posterior pole of the globe in line and closer to the retrobulbar needle path. Multiple orbital injections have also been cited as a factor in globe punctures, along with unexpected patient movement (Box 44.14).

Measures for Preventing Globe Puncture

- Use caution in patients with increased axial length.
- Avoid supranasal position of gaze.
- Direct needle away from axis of globe during insertion through the orbital septum.
- Observe globe movement with needle insertion.
- Insert needle slowly, with the bevel toward the globe.
- Never forcefully inject anesthetic.
- Use modified retrobulbar and peribulbar techniques (although globe punctures have also been reported with these).

The choice of sharp versus dull retrobulbar needles is highly debated. The literature reviewed appears to draw conclusions based more on opinion than on fact. A review of the literature confirmed a lack of safety with the use of blunt needles. Optic nerve penetration, ocular perforation, and CNS complications have resulted from the use of blunt needles.²⁰ The surgeon should be notified if a globe puncture is suspected (Box 44.15).

Signs and Symptoms of Globe Puncture*

- Increased resistance to injection
- Immediate dilation and paralysis of the pupil
- Rapid increase in intraocular pressure with edematous cornea
- Hypotony of the globe

- Intraocular hemorrhage

*Patient may or may not exhibit signs and symptoms of a puncture immediately.

Optic Nerve Sheath Trauma

To review, the optic nerve sheaths surround the optic nerve and are composed of the meninges of the brain. The outer sheath contains the dura mater and the inner sheath consists of the arachnoid mater and pia mater. The subarachnoid space contains cerebrospinal fluid and is continuous with the optic chiasm. The dura splits into two layers at the optic foramen. The outer dural layer becomes continuous with the orbital periosteum. The inner layer forms the dural covering of the optic nerve; creating the orbital epidural space.² Anesthetic agents injected into the subdural or subarachnoid space may track back to the optic chiasm. Here, the anesthetic can affect the contralateral eye by blocking cranial nerves II and III as they proceed through the subdural or subarachnoid space; this block can result in contralateral amaurosis.⁷²⁻⁷⁴ The condition can be a precursor to the continued migration of the anesthetic to the respiratory centers of the midbrain, resulting in respiratory arrest.^{60,75,76}

The anesthetist should observe the contralateral pupil before an ocular block is performed. The pupil may be dilated from accidental administration of preoperative eye drops, a preoperative examination, or existing pathology. If the contralateral pupil is constricted before the ocular block and dilates after the ocular block (contralateral amaurosis), one must assume that subarachnoid or subdural injection has occurred and be prepared to treat a respiratory arrest.

The onset of respiratory arrest is usually within 2 to 5 minutes after injection; however, it may occur as late as 10 to 17 minutes after injection. Spontaneous ventilation usually returns in 15 to 20 minutes but may take up to 55 minutes for complete recovery. Treatment includes appropriate ventilatory and cardiovascular support, supplemental oxygen with oxygen saturation monitoring,

ECG monitoring for cardiac dysrhythmias, and blood pressure monitoring. The surgeon should be notified immediately so the eye can be examined for any optic nerve trauma that may require surgical intervention.

A retrobulbar hemorrhage resulting in increased extravascular pressure may result in occlusion of the central retinal artery or vein, or both. In addition, direct trauma to the ophthalmic artery or the optic nerve by the retrobulbar needle may cause artery or vein occlusion without causing retrobulbar hemorrhage⁷⁷ (Box 44.16).

Measures for Preventing Optic Nerve Sheath Trauma

- Avoid supranasal eye position.
- Avoid deep orbital injection.
- Insert needle slowly.
- Avoid forceful injection of anesthetics.
- Use modified retrobulbar or peribulbar techniques.

Ocular Ischemia

Retinal vascular occlusion or thrombosis has been reported after ocular blocks.^{78,79} Studies have also reported a decrease in the pulsatile ocular blood flow after ocular blocks, secondary to the pressure exerted by the volume of local anesthesia injected into the orbit. However, the same orbital injection volume did not cause a significant rise in the intraocular pressure. Even though not contraindicated, caution should be exercised in patients with preexisting compromised ocular circulation.⁸⁰⁻⁸³ Some authors have advocated not using epinephrine in the local anesthetic solution.^{84,85}

Optic nerve atrophy has been reported after intraocular surgery with either regional block or general anesthesia.⁶⁰ Direct trauma to the optic nerve may result in transient symptoms, such as contralateral amaurosis or respiratory arrest, or it may result in vascular occlusion or thrombosis, or both, with partial to complete

loss of vision.

Extraocular Muscle Palsy and Ptosis

Inferior muscle palsy has been reported after retrobulbar anesthesia. Segmental inferior rectus muscle enlargement was noted posterior to the globe deep in the orbit.⁸⁶ The complication has not been reported to occur after general anesthesia.⁸⁷ The initial signs and symptoms of this problem manifest after surgery as persistent vertical diplopia. Surgical intervention may be indicated for correction of this condition. Trauma to the superior oblique tendon–trochlea complex also has been reported to occur with retrobulbar anesthesia⁸⁸ (Box 44.17).

Measures for Preventing Extraocular Muscle Trauma

- Avoid needle contact with extraocular muscles.
- Avoid deep orbital penetration.
- Avoid angling needle toward visual axis of the globe when parallel to an extraocular muscle.

Carlson et al.⁸⁹ performed experiments on the rectus muscle of monkeys and humans and demonstrated minimal myotoxic damage to ocular muscles after retrobulbar administration of local anesthetics. Typically, after the injection of local anesthesia, the surface muscle fibers degenerate, then regenerate. However, direct injections of local anesthesia into the rectus muscle resulted in massive internal muscle lesions that were large enough to produce noticeable functional deficit. The myotoxicity of local anesthetics also may play a role in postoperative diplopia and/or ptosis,⁹⁰ especially in the elderly, because regeneration of their muscle fibers may not be as complete as that in younger patients. However, ptosis is also associated with the superior rectus stay suture and the eyelid speculum. Postoperative ptosis may take as long as 6 months to resolve.

Facial Nerve Blocks

Patients commonly experience discomfort as a result of blocks of cranial nerve VII. Prolonged Bell's palsy has been seen after Nadbath and O'Brien blocks, probably secondary to direct nerve trauma.⁹¹ Several authors have reported cases of dysphagia, hoarseness, coughing, and respiratory distress after Nadbath blocks (Box 44.18). They noted that these symptoms were consistent with paresis of the vagus, glossopharyngeal, and spinal accessory nerves. These nerves exit the skull approximately 10 mm medial to cranial nerve VII. Therefore, anesthesia injected for a cranial nerve VII block could also reach these nerves and result in unilateral vocal

Box 44.18 Paralysis.^{92,93}

Prevention and Treatment of Complications From the Nadbath Block

- Avoid using the Nadbath technique in patients weighing less than 45 kg.
- Avoid using large volumes of anesthesia and hyaluronidase.
- Avoid using the Nadbath technique when patients have a preexisting unilateral vocal cord dysfunction.
- Place the patient in seated or lateral position to maintain a patent airway and patient comfort.
- The patient with an unsatisfactory airway should be intubated.

Patients have also complained of jaw ache with movement for several weeks after a cranial nerve VII block. Grand mal seizure has rarely occurred (1 report) when 3 mL of 2% lidocaine with epinephrine (1 : 200,000) was injected using the Nadbath technique.

Zaturansky and Hyams⁹⁴ reported an ocular perforation that occurred when a modified Van Lint procedure was performed after a retrobulbar block. The needle penetrated the proposed eye just under the insertion of the lateral rectus muscle.

Oculocardiac Reflex

The oculocardiac reflex is a trigeminal-vagal reflex that was first described in 1908 by Aschner. The stimulus for this reflex is generated by pressure on the globe, the orbital structures (e.g., the optic nerve), or the conjunctiva, or by traction on the extraocular muscles (particularly the medial rectus muscle). The afferent pathway for the stimulus is via the long and short ciliary nerves to the ciliary ganglion and then through the gasserian ganglion along the ophthalmic division of the trigeminal nerve, terminating in the main trigeminal sensory nucleus in the floor of the fourth ventricle. The efferent pathway consists of the vagus nerve to the cardio-inhibitory center.

The reflex may be elicited during local infiltration anesthesia, retrobulbar or peribulbar blockade, and general anesthesia. The occurrence of the reflex in ocular procedures is variable, but it is commonly seen in muscle procedures performed in children. The oculocardiac reflex most often results in acute sinus bradycardia. However, it may also cause a wide variety of other cardiac dysrhythmias, such as nodal rhythms, atrioventricular block, ventricular ectopy, idioventricular rhythm, and asystole. Continuous ECG monitoring is essential for the diagnosis of dysrhythmias that result from the oculocardiac reflex. If cardiac dysrhythmias are observed, the surgeon must be instructed to immediately cease all pressure or traction on the orbit. Simultaneously, the patient should be assessed for adequate oxygenation and ventilation and for adequate anesthetic depth because one or more of these may be an underlying cause for the dysrhythmia. The aberrant rhythm usually resolves without intervention within a few seconds.

However, if the aforementioned measures are taken and the dysrhythmia continues, thus threatening to cause hemodynamic instability, intravenous atropine should be administered. Atropine, 2 to 3 mg, may be required for complete vagal blockade. Caution should be exercised with the administration of atropine, because atropine itself may induce cardiac dysrhythmias. Glycopyrrolate may be given for less severe bradycardic episodes. The surgeon may proceed only after the dysrhythmia is resolved. If the reflex recurs, the aforementioned process should be repeated. The

oculocardiac reflex, however, appears to fatigue with continued manipulations. The use of intravenous atropine or intravenous glycopyrrolate just before surgery may help reduce the incidence of the reflex, especially in children.^{95,96}

Other Complications

Corneal abrasion is the most common injury occurring after general anesthesia. It is believed to result from the drying of the exposed cornea or from direct trauma, such as an anesthesia-mask injury. Ensuring that the eyelids are closed and secured with tape should provide satisfactory protection of the cornea. Movement during ocular surgery was identified as the single most common mechanism of injury. Movement was described as coughing and bucking, which resulted in poor visual outcome. In these reported cases, muscle relaxants were used less than 50% of the time, and nerve stimulators were omitted. Chemical injury can result from spillage of cleaning materials or preparatory solutions into the eye. In these cases, the eye should be flushed immediately with saline.⁹⁷

Central retinal artery occlusion may result from prolonged pressure on the eye.⁹⁸ This type of injury may result with the patient in the prone position. Careful attention to padding and periodic checks of the eyes is necessary, especially for long procedures. Eye protectors, along with foam headrests or gel donuts for the face, may help prevent eye trauma. It is prudent to request an ophthalmic examination immediately after surgery if the patient complains of any eye problems or if the anesthesia provider suspects a problem. Ocular positioning injuries are discussed in detail in [Chapter 23](#).

Summary

Anesthesia management for ophthalmic procedures has changed rapidly in the last few years. As an anesthesia practitioner, you will be challenged with the increasingly complex comorbidities and multiple pharmacologic agents used in the care of the elderly patient. The pediatric patient also presents anesthetic challenges, many associated with the preterm infants and chronic upper respiratory infections. Newer surgical techniques for cataract surgery have increased the popularity of topical anesthesia for such procedures; however, the advances in retinal surgical techniques, corneal transplants, and adult eye muscle and glaucoma procedures are fueling an increased demand by surgeons for anesthesia practitioners to perform ophthalmic eye blocks versus general anesthesia. Orbital regional blocks have the further advantage of minimizing postoperative pain, requiring minimal to no opioid administration, with significant reductions in postoperative nausea and vomiting. General anesthesia will continue to be the technique of choice for the pediatric patient, patients with ocular trauma, and patients who are not candidates for topical or orbital regional blocks.

Anesthesia for Orthopedics and Podiatry

Maria T. Hirsch

The Merriam-Webster dictionary defines orthopedics as “a branch of medicine concerned with the correction or prevention of deformities, disorders, or injuries of the skeleton and associated structures (as tendons and ligaments)”.¹ Evidence of such “corrections” dates back many centuries. Egyptian artifacts have been found that demonstrate the use of splints for patients, and some of the earliest documented orthopedic interventions came from the battlefields of the gladiators. Jean-Andre Venel established the first orthopedic institute in 1780. Much progress in orthopedics has been made in recent decades, including the development of better arthroscopic techniques, total hip and knee replacements, ligament repairs using minimally invasive techniques, spine surgeries, and more. As the baby boomers born after World War II reach retirement age, the demand for orthopedic repair and the incidence of degenerative joint disease are expected to increase.² Over 1 million total knee and hip joint replacement procedures are performed in the United States each year.³

Anesthesia and orthopedics are described time and again in historical accounts, with the earliest events usually occurring on battlefields throughout history. Although the initial encounters involved anesthetic techniques that were rather primitive, anesthesia for orthopedics has evolved into a highly specific set of choices that are deemed to be safe for patients. Modern techniques must account for complicated, sometimes lengthy procedures requiring significant postoperative pain control.

The anesthetic plan can vary greatly; the administered anesthetic can be regional, general, a combined technique, or involve intravenous (IV) sedation. The anesthetic choice is based upon many factors: What type of surgery is the patient having? How long

will the procedure take? Does the patient have preferences? Does the patient's airway present any challenges? In what position will the patient be placed for surgery? What comorbidities are present? Answers to these questions and others carry weight in the decision-making process when determining the care of orthopedic patients.

Preoperative assessment for orthopedic patients follows much the same guidelines as those used for any other surgical candidate. A thorough review of systems, review of current medications and the last date taken, current anticoagulant status, and baseline laboratory values are only some of the components of a preoperative assessment for these patients. Often for patients scheduled for total joint replacement, a baseline complete blood count (CBC), a type and crossmatch, and a urinalysis may be completed. In addition, most orthopedic surgeons prefer to evaluate their patients for the presence of infection before committing to joint replacement surgery.⁴ Surgical site infection (SSI) is a serious and potentially catastrophic complication after joint arthroplasty.⁵ Pathogens are common in the urinary tract, and their presence can create a potential reservoir of resistant pathogens and increase patient morbidity. Screening for the presence of methicillin-resistant *Staphylococcus aureus* (MRSA) colonization allows for preoperative nasal decolonization, as the presence of MRSA increases the risk of SSI.⁶

One of the ways all surgeons attempt to decrease the chance for SSI includes the administration of appropriate preoperative antibiotics in a timely fashion. For cefazolin (a first-generation cephalosporin), the preoperative time allotment is within 1 hour of incision time; for vancomycin, within 2 hours of incision time. In 2006, the Centers for Medicaid and Medicare Services introduced a program called the *Surgical Care Improvement Project*, often abbreviated as SCIP. The goal of the project was to improve surgical care by defining common measures that can be taken and providing appropriate guidelines for applying them that would decrease risks to patients when instituted. These risks may include SSI, postoperative thromboembolism, perioperative glucose management, and maintenance of normothermia. The items included on the list are constantly updated based upon research findings and performance related to the measures.

Advances in technology have lead to a much higher rate of arthroscopic procedures. Outpatient surgery is the norm for everything from shoulder repair to orthopedic repair of the hip, knee, ankle, wrist, and elbow. The advantages of today's surgical techniques are readily apparent. Smaller incisions result in less postoperative pain. Patients who have arthroscopic procedures experience faster recovery from anesthesia, have shorter lengths of stay, use fewer narcotics for pain relief, and return to work more quickly than those undergoing open procedures.⁷

Pneumatic Tourniquet

One of the methods in which blood loss can be decreased during extremity surgery is through the application of the pneumatic tourniquet. A bloodless field provides important advantages for the surgeon. Pneumatic tourniquets maintain a relatively bloodless field during extremity surgery, minimize intraoperative blood loss, aid identification of vital structures, and expedite the procedure.^{8,9}

The components of the pneumatic tourniquet consist of an inflatable cuff, connective tubing, a pressure device, and (usually) a timer. Specialized training and understanding of the application and management of the pneumatic tourniquet is required for proper intraoperative management of the device. Safety considerations for the use of a pneumatic tourniquet are noted in

Box 4511

Safety Measures for Preventing Tourniquet Complications

- The tourniquet should be applied where the nerves are best protected in the underlying musculature.
- Proper functioning of the equipment should be tested before it is operated.
- The tourniquet should be used for no longer than 2 hours.
- The widest cuff possible should be chosen (wide bladders can occlude the blood flow with the use of a lower cuff pressure).
- A minimum of two layers of padding should be placed around the extremity. Check for the presence of loose fibers/lint that can become embedded in the contact closures. The best protection of the skin occurs with the use of an elastic stockinette.
- The tourniquet size should be half of the limb diameter. The cuff should overlap for 3 to 6 inches. Large areas of overlap result in rolling and wrinkling of the underlying skin and increased

pressure in that area.

- The tourniquet size chosen should allow placement of two fingers between the cast padding and the cuff.
- When possible, the extremity should be exsanguinated prior to inflation of the cuff. An Esmarch bandage is most commonly used.
- Only the minimally effective pressure should be used for occluding blood flow to the extremity. For the upper extremity, 70–90 mm Hg more than the patient's systolic blood pressure should be used. For the lower extremity, twice the patient's systolic pressure should be used. For Bier block anesthesia, a minimum standard tourniquet pressure of 250 mm Hg should be used unless the tourniquet is on the upper leg. In this instance, twice the patient's systolic pressure should be used unless that amount is less than 300 mm Hg.
- The pressure display must accurately reflect the pressure in the tourniquet bladder.

Tourniquets are most often applied after the initiation of anesthesia. The time of inflation should be documented in the anesthesia record and should match the time documented in the operating room (OR) record. The interruption of blood supply leads to tissue hypoxia and acidosis.¹⁰ The degree of hypoxia and acidosis is partially influenced by the duration of insufflation. For this reason, the inflation device also comes with a built-in timer, generally set for 60-minute increments, with an alarm that will sound as a warning when the allotted time has been exhausted. A maximum of 2 hours is generally considered safe.^{8,11} The pressure to which the tourniquet should be inflated depends on the patient's blood pressure and the shape and size of the extremity.

Deflation of the tourniquet results in the release of metabolic waste into the systemic circulation. The release of these substances can cause metabolic acidosis, hyperkalemia, myoglobinemia, myoglobinuria, and renal failure.^{12,13} Deflation of the tourniquet may be marked by transient changes in the hemodynamics or pulse

oximetry readings for the patient. Most of these changes resolve quickly, except in patients with extreme conditions related to their cardiac or vascular status. [Box 45.2](#) lists common physiologic changes that occur with the release of a pneumatic tourniquet.

Physiologic Changes Caused by Limb Tourniquets

Neurologic Effects

- Abolition of somatosensory evoked potentials and nerve conduction occurs within 30 minutes.
- Application for more than 60 minutes causes tourniquet pain and hypertension.
- Application for more than 2 hours may result in postoperative neurapraxia.
- Evidence of nerve injury may occur at the skin level underlying the edge of the tourniquet.

Muscle Changes

- Cellular hypoxia develops within 2 minutes.
- Cellular creatinine value declines.
- Progressive cellular acidosis occurs.
- Endothelial capillary leak develops after 2 hours.

Systemic Effects of Tourniquet Inflation

- Elevations in the arterial and pulmonary artery pressures develop. This is usually slight to moderate if only one limb is occluded. The response is more severe in patients undergoing balanced anesthesia that does not include a potent anesthetic vapor.

Systemic Effects of Tourniquet Release

- Transient decrease in core temperature occurs.
- Transient metabolic acidosis occurs.
- Transient decrease in central venous oxygen tension occurs, but systemic hypoxemia is unusual.
- Acid metabolites (e.g., thromboxane) are released into the central circulation.
- Transient fall in pulmonary and systemic arterial pressures occurs.
- Transient increase in end-tidal carbon dioxide occurs.

Non-Pneumatic Tourniquets

A silicon ring tourniquet (SRT) may be used instead of a pneumatic tourniquet, particularly for brief procedures. An SRT consists of a silicone ring wrapped in a sleeve, with two pull handles connected by straps. The SRT is sterile and is rolled onto the extremity, resulting in exsanguination and occlusion of blood flow to the limb. SRTs come in various sizes and tensions based on systolic blood pressure. An appropriate model is selected based on patient size and the measured systolic blood pressure. At the conclusion of surgery, the SRT is removed by cutting the silicone ring.¹⁴ The exsanguination and tourniquet discomfort are similar to those induced by a pneumatic tourniquet, but the application time is more rapid.¹⁵ Because these tourniquets are not electronic, they do not sound an alarm when a designated time is exceeded, so tourniquet time must be carefully monitored.

Tourniquet Pain

One of the greatest concerns when a tourniquet is in use is the patient perception of tourniquet pain. In 1944, Denny-Brown and Brenner¹⁶ reported the first investigation into the cause of tourniquet discomfort. They listed characteristic anatomic changes associated with tourniquet ischemia that were due to acute compression of the nerves under the inflated cuff. Compression of the intraneural blood vessels caused a secondary ischemia of the nerve fibers. Similar reports of “tourniquet discomfort” or “aching” despite adequate spinal anesthesia prompted the direction of considerable attention toward discovering ways to minimize subjective discomfort. Based on their discoveries and subsequent measurements of “occlusive pressure,” in 1979, Klenerman and Hulands¹⁷ suggested using tourniquet pressures of twice the patient's systolic blood pressure to minimize the subjective discomfort and destruction of tissues. Klenerman¹⁸ modified this recommendation a year later to a value of 50 to 75 mm Hg greater than the patient's systolic blood pressure.

The ischemic pain associated with tourniquet application is

similar to that of thrombotic vascular occlusion and peripheral vascular disease.¹⁹ Approximately 45 to 60 minutes after tourniquet pressurization, patients report various symptoms that typically include dull aching, which progresses to burning and excruciating pain that may require general anesthesia. Once the pain begins, it is often resistant to analgesics and anesthetic agents, regardless of the anesthetic technique. Even with the use of a well-controlled general anesthetic at the time of tourniquet inflation, ischemic pain may begin during this same time interval and may increase the heart rate and blood pressure to the point that pharmacologic intervention is required.²⁰

Although the specific neural and metabolic factors responsible for tourniquet pain are still unknown, several researchers have identified the nerve fibers that are responsible for transmitting the impulses. The burning and aching pain corresponds to the activation of the small, slow-conducting, unmyelinated C fibers. The pinprick, tingling, and buzzing sensations that frequently accompany tourniquet application, often even after deflation, correspond to activation of the larger and faster myelinated A-delta fibers.

Myelinated A-delta and unmyelinated C fibers differ in their sensitivity to local anesthetics. As the concentration of local anesthetic decreases, the activation of C fibers increases, but A-delta fiber activation is still suppressed. Thus C fibers may be more difficult to anesthetize than A-delta fibers; tourniquet pain therefore seems more consistent with pain sensation carried by C fibers.¹⁹ Other research has shown that certain local anesthetics enhance the effect of the blockade in the presence of increased stimulation of the isolated nerve fiber. For example, the potency of bupivacaine is enhanced by an increase in the rate of nerve stimulation, and may offer an advantage by lowering the incidence of tourniquet pain.²¹

Regardless of the level of sensory blockade achieved in these patients, they still experience tourniquet pain. For leg surgeries, high-quality blockade of the sacral roots is more important than blockade at the thoracic sensory level for reducing the incidence of tourniquet pain, because the intensity of pain may be due to ischemia of the entire leg, as well as under the cuff.²² The addition of opioids, ketorolac, melatonin, clonidine, or dexmedetomidine to

local anesthesia solutions has shown some efficacy in reducing the incidence of tourniquet pain.²³⁻²⁶

Postoperative Tourniquet Paresthesias

Properly placed tourniquets inflated to appropriate pressures rarely cause injury. The use of excessive tourniquet pressure for a prolonged time may cause postoperative paresthesias that are frustrating to treat and very painful for the patient. Excessive tourniquet pressure causes deformation of the underlying nerves—the myelin may be stretched on one side of the node and invaginated on the other. Nerve damage due to rupture of the Schwann cell membranes may also be present.²⁷ Use of proper padding, appropriate choice of tourniquet size, and adherence to recommendations for appropriate pressure and usage time minimize the incidence of this complication.

Patient Positioning

[Chapter 23](#) provides an excellent overview of proper positioning during surgery. It is important to have a thorough understanding of the physiologic changes that occur in various positions.

Appropriate patient positioning must allow optimal exposure of the surgical site, enable appropriate monitoring throughout the procedure, provide good access to the patient's airway, allow for comfort and warmth, minimize or prevent physiologic functioning compromise, protect all body systems, and maintain patient dignity.²⁸ Positions chosen may include supine, lateral decubitus, prone, or beach chair/sitting. Neutral alignment and proper padding of exposed neural pathways can help diminish the incidence of positioning-related injuries sustained intraoperatively. Communication between the entire team (i.e., anesthesia, OR nurse, and surgeon) will yield the best outcomes for the patient.

Over the millennia, human physiology has adapted to being in an upright or erect position for the majority of the waking hours. For example, in the upright position, there are three zones of ventilation-perfusion within the lungs: (1) areas where alveolar pressure is greater than arterial pressure, (2) areas of complex, variable pressure gradients between alveolar and arterial components, and (3) areas where arterial pressure is greater than alveolar pressure. [Fig. 45.1](#) illustrates lung zones 1, 2, and 3. Other examples of physiologic adaptation are the valves found in dependent areas of the venous system, such as the extremities, and the absence of valves in nondependent areas, such as the cranium. Changes from the upright position produce corresponding physiologic changes ([Fig. 45.2](#))^{28,29}

FIGURE 45.1 Lung zones: the effect of gravity on ventilation-perfusion.

FIGURE 45.2 Gravity dependence of ventilation and perfusion, as noted by lungs depicted in the (A) standing,

(B) supine, and **(C)** lateral positions.

Arthroscopy

Arthroscopy is a minimally invasive surgical procedure performed to examine and sometimes repair damage of the interior of a joint using an arthroscope.³⁰ The concept was introduced in the United States in 1926.³¹ However, without the availability of practical sources of illumination, arthroscopy languished. The development of fiber-optic light sources in the 1970s led to a resurgence of interest in the use of arthroscopy. Initially, arthroscopy was used to obtain a diagnosis of a patient's orthopedic malady so that a definitive, corrective surgical procedure could be performed. As interest in the procedure and technique increased and the necessary smaller surgical instrumentation was developed, previously open surgical procedures on the knee, such as partial or complete meniscectomy, loose-body removal, or ligament repair or reconstruction, were attempted and refined solely via the arthroscope.

Successful performance of arthroscopic procedures on the knee has several benefits for the patient, including reduced blood loss, less postoperative discomfort, and reduced length of rehabilitation. The success achieved with arthroscopic procedures on the knee led to application of the principles and techniques to other joints (e.g., the shoulder, elbow, wrist, hip, ankle, and phalangeal joints of the foot).³²⁻³⁴ Many of these surgeries have become routine outpatient procedures. Through the mid-1990s, application of arthroscopic procedures focused on the shoulder. Accordingly, shoulder arthroscopy procedures range from simple debridements to more complex rotator cuff repairs.³⁵ The development and refinement of shoulder arthroscopic procedures mirrored that of knee arthroscopic procedures; that is, as more skill and comfort were obtained with initial procedures, more traditionally open surgical treatments were attempted solely via the arthroscope.

Anesthetic Management

Patients undergoing arthroscopic procedures may be managed by almost any of the available anesthesia techniques (e.g., general

anesthesia, regional anesthesia, combined regional and general anesthesia, or local blockade with sedation). Patient selection for a given anesthetic technique is crucial with arthroscopic procedures, as with all operative procedures. As previously mentioned, for some patients there is absolutely no substitute for receiving general anesthesia. Critical factors in the selection and presentation of the available anesthesia techniques appropriate for arthroscopic procedures are the patient positioning necessary to facilitate the proposed arthroscopic procedure and the overall state of health of the patient. For example, shoulder arthroscopy uses one of two positions to accomplish the surgery: either the lateral decubitus or the modified Fowler (“beach chair”) position.³⁶ The choice of position is determined in part by the nature and extent of the malady being surgically addressed. For some shoulder arthroscopy procedures, supplemental traction with weights and abduction may be necessary to provide optimum operative visualization (Fig. 45.3); for others, the modified Fowler position may be used, as the force of gravity or manual traction will provide sufficient operative visibility. Reviewing the patient's chart and more importantly, personally interviewing the patient, along with having an adequate understanding of the physiologic changes associated with various positions, assist in choosing the best care for each patient.

FIGURE 45.3 Shoulder arthroscopy positioning.

Patient positioning for arthroscopic procedures can encompass the entire gamut of possible operative positions. Most often, arthroscopic procedures for lower extremity joints use the supine position, as do most arthroscopic procedures on the upper extremities. Arthroscopy on the knee requires the supine position, with the foot of the OR bed lowered (Fig. 45.4). The nonoperative leg should either be wrapped with an elastic bandage or have some form of compression stocking in place to reduce pooling of blood and the potential for thrombus formation. At times, patients undergoing elbow arthroscopy may be placed in the supine, lateral decubitus, or prone position; the position is dictated by operative necessity and surgeon preference (Figs. 45.5 and 45.6). The prone position is advantageous, primarily because of better limb stability during the procedure.³⁷ Shoulder arthroscopy is frequently accomplished via either the modified Fowler position or the lateral decubitus position, based on optimal access to the injury and surgeon preference (see Fig. 45.3).³⁶ Hip arthroscopy is also typically accomplished via the lateral decubitus or the supine position, with the patient on a fracture table (Fig. 45.7). The fracture table is used to provide greater stability while traction is applied, using either weights and counterweights (lateral decubitus

position) or mechanical traction attached to the leg-holding device of the fracture table (supine position).³³

FIGURE 45.6 Prone position for elbow surgery.

FIGURE 45.7 Fracture table. Allows easy access for X-ray equipment.

Complications associated with arthroscopic procedures occur in a small percentage of the total number of procedures performed.³⁸⁻⁴¹ Complications that may occur include subcutaneous emphysema, pneumomediastinum, and potentially life-threatening tension

pneumothorax. The full range of potential anesthetic complications associated with patient positioning apply (e.g., inadvertent extubation, eye or corneal injury, visual loss from the prone position, and nerve injury from improper patient positioning). Blood loss is not generally a concern, but significant and sustained hypotension warrants immediate and thorough investigation. A pneumatic tourniquet may be used to provide a clear, bloodless surgical field. Trocar insertion sometimes results in inadvertent damage to vascular structures that may go undetected because of the tourniquet. In procedures that are performed proximally (i.e., hip or shoulder) and therefore without a tourniquet, vascular damage is discovered much earlier.

To provide optimal visualization of joint structures during arthroscopic procedures, the irrigating fluid used to distend the operative joint is instilled under pressure. This is achieved through gravity or mechanical pressurization. The typical irrigation setup uses large (3–5 L) bags of irrigating solution. The nurse anesthetist should be aware of the amount of fluid being infused in comparison with the outflow. Even small differences can add up to a large volume for the patient, especially in the case of an extended procedure. This absorption could potentially lead to fluid volume overload, congestive heart failure, pulmonary edema, or even hyponatremia (if sterile water is used).^{38–41}

Subcutaneous emphysema, tension pneumothorax, and pneumomediastinum have been reported during shoulder arthroscopy when subacromial decompression is used.⁴¹ These complications appear to be associated at least in part with the use of mechanical irrigation pumps and power-saver suction. Careful assessment during this irrigation period is important. [Box 45.3](#) lists the signs and symptoms of tension pneumothorax. Because tension pneumothorax is a potentially life-threatening event, early recognition and treatment are paramount. Ideally, placement of a chest tube is the most desirable way to relieve the increased intrathoracic pressure. An immediate and very effective treatment is needle decompression with a 14- to 18-gauge IV angiocatheter placed into either the second or third intercostal space anteriorly or the fourth or fifth intercostal space laterally. Successful decompression is accompanied by a sudden rush of air, as well as

readjustment of physical symptoms and vital signs back toward the patient's normal parameters. After successful decompression, the IV catheter stylet should remain in place and be covered or capped to prevent air from being sucked back into the chest cavity until a chest tube can be properly inserted.^{42,43}

Signs and Symptoms of Tension Pneumothorax

- Sudden, inexplicable hypoxemia
- Elevated central venous pressure
- Tachycardia
- Absent breath sounds on the affected side
- Cyanosis
- Diaphoresis
- Decreasing oxygenation
- Tracheal shift
- Agitation (may be observed in patients receiving regional anesthesia)
- Hypotension
- Jugular vein distention
- Increased airway pressure
- Asymmetric chest wall movement
- Percussive hyperresonance over the affected side
- Extreme anxiety (may be observed in patients receiving regional anesthesia)

Arthroplasty

Arthroplasty is the surgical replacement of all (total arthroplasty) or part (hemiarthroplasty) of a joint to restore the natural motion and function of the joint, as well as restoring the controlling function of the surrounding soft tissues (i.e., muscles, ligaments, and tendons). The goals of arthroplasty are pain relief, stability of joint motion, and deformity correction. The original hip prosthesis was fabricated from stainless steel. Prostheses currently in use are stronger metal alloys based on nonferrous metals (generally cobalt or titanium). These alloys demonstrate greater tensile strength and are more resistant to fatigue than the original stainless steel. The search for stronger metals that can withstand greater amounts of abuse continues due to the increasing demand for these components to last longer. In fact, increasingly younger patients are lining up for joint replacements as people have become more active and athletic. The rigors of activities such as running and skiing are leading to the need for increased numbers of joint replacements in patients that are younger than ever before.⁴⁴

Joint Arthroplasty

Hip Surgery

Several hundred thousand patients in the United States undergo some form of total hip arthroplasty (THA) each year. The mean age of patients undergoing THA is nearly 65 years, and most patients present with multiple comorbidities. Nearly 50% of these patients are obese.^{45,46} THA is most often indicated for patients experiencing degenerative joint disease or arthritic damage. A report on outcomes noted that, in patients having total joint arthroplasty (TJA), younger age and male sex are associated with an increased risk of revision. Older age and male sex are associated with increased risk of postsurgical mortality, and older age is related to worse function, particularly among women. Age and sex do not influence the level of postsurgical pain. Despite these differences, all subgroups derived benefit from TJA.⁴⁷

Several surgical approaches may be used for THA. The most

common is the posterior approach, which requires a large incision extending from near the iliac crest across the joint to the midhigh level. More recently, the direct anterior approach (DAA) has gained in popularity, as it offers a minimally invasive alternative to THA. The DAA is a muscle-sparing procedure that involves a shorter incision, as well as less muscle and soft-tissue dissection, resulting in shorter hospitalization and faster postoperative recovery. The DAA is technically more challenging than traditional approaches.^{48,49} Regardless of the surgical approach, several large muscle groups must be incised and dissected through or separated to gain access to the joint, after which the joint is disarticulated. The muscle relaxation provided by a subarachnoid block makes this anesthetic technique ideal for facilitating the surgical process. The anesthetic plan for patients undergoing THA frequently involves the use of regional anesthesia. In the event of patient refusal or contraindication for spinal anesthetic, general anesthesia may be selected. Nitrous oxide should be avoided, due to the risk of air entrapment. The duration of the surgery, the level of narcotic required to maintain patient comfort, and the required positioning make it less desirable to perform these surgeries utilizing a laryngeal mask airway, unless the patient is undergoing a DAA.

Once anesthesia induction is complete, the patient is positioned, prepped, and draped for incision. After a final timeout, skin incision is accomplished. The femoral head and neck are excised, leaving the femoral canal open. The femur is highly vascular, as is the acetabulum, and the reaming required to prepare them for receipt of orthopedic components often opens venous sinuses, which can result in significant blood loss. For these patients, intraoperative blood loss may exceed 1 L.⁵⁰

A growing body of evidence supports the administration of tranexamic acid (TXA), a synthetic plasminogen-activator that helps to decrease blood loss through inhibition of fibrinolysis and clot degradation, to patients undergoing total joint replacement. One to two grams of TXA is administered perioperatively, either intravenously or topically. The use of TXA has been shown to decrease perioperative blood loss and transfusion requirements in these patients, with minimal risk of complications.^{50,51}

The hemoglobin threshold at which red cell transfusion is

warranted is controversial. A study conducted in 2011 compared a liberal strategy of transfusion at hemoglobin levels below 10 g/dL after hip fracture with a more restrictive strategy of transfusion at hemoglobin levels below 8 g/dL. The liberal and restrictive strategy groups were similar with regard to rates of death, inability to walk independently at 60-day follow-up, and in-hospital morbidity in elderly patients at high cardiovascular risk.⁵²

After reaming of the femoral canal is complete, the canal is further cleaned with a sponge to prepare the surface for receipt of adhesive. Methyl methacrylate (MMA) cement may then be instilled into the femoral canal. For some procedures, usually in younger or very physically active patients, MMA is not used to secure the femoral prosthesis, and the prosthesis is referred to as being *press-fit*. In these cases, the femoral prosthesis is inserted into the canal and forcibly “seated” with a mallet. Physiologic changes are common with the instillation of the MMA. These changes are termed *bone cement implantation syndrome* (BCIS).

There is no expert consensus as to the definition of BCIS, although it is characterized by a number of clinical features including hypoxia, hypotension, cardiac arrhythmias, increased pulmonary vascular resistance, unexpected loss of consciousness when regional anesthesia is administered, and cardiac arrest. The etiology of these effects is poorly understood. Some theories involve the role of emboli formed during cementing and prosthesis insertion. Several mechanisms such as histamine release, complement activation, and endogenous cannabinoid-mediated vasodilation have been proposed. BCIS is most commonly associated with hip arthroplasty but may also occur during other cemented procedures including knee arthroplasty and vertebroplasty. Although definitive studies are lacking, BCIS is estimated to occur in 2% to 17% of surgeries. It usually occurs at the following stages in the surgical procedure: femoral canal reaming, acetabular or femoral cement implantation, insertion of the prosthesis or joint reduction, and occasionally after limb tourniquet deflation.⁵³ Numerous patient-related risk factors have been

Box 45.4 implicated; these are shown in [Box 45.4](#).

Significant Risk Factors for Developing

Bone Cement Implantation Syndrome

- Preexisting cardiovascular disease
- Preexisting pulmonary hypertension
- American Society of Anesthesiologists class III or higher
- New York Heart Association class 3 or 4
- Canadian Heart Association class 3 or 4
- Surgical technique
- Pathologic fracture
- Intertrochanteric fracture
- Long-stem arthroplasty

Adapted from Donaldson A, et al. Bone cement implantation syndrome. *Br J Anaesth.* 2009;102(1):12–22.

An abrupt decrease in end-tidal carbon dioxide concentration may be the first indication of clinically significant BCIS under general anesthesia. Early signs of BCIS in the awake patient undergoing regional anesthesia include dyspnea and altered sensorium. If BCIS is suspected, the inspired oxygen concentration should be increased to 100%, and supplementary oxygen should be continued into the postoperative period. It has been suggested that cardiovascular collapse in the context of BCIS be treated as right-sided heart failure. Aggressive fluid resuscitation is recommended, and hypotension should be treated with α -agonists.⁵³

Communication between the surgical team and the anesthesia team is imperative at the time of cementing. Prior to cementing, the patient's blood pressure should be optimized, the patient should be placed on 100% fraction of inspired oxygen (FiO_2), pressure bags should be available for rapid IV fluid administration, and IV fluid bags should be full or nearly full. It is also important to document the cement time on the anesthesia record.

After cementing is complete, the acetabular component is secured in place with screws and bone grafting.

Positioning.

Patients undergoing THA utilizing an anterior approach are positioned supine on a specialized traction table. Patients being prepared for posterior THA are generally positioned in the lateral decubitus fashion. Placing the patient in a lateral decubitus position produces physiologic changes similar to those found in the supine patient. Although the majority of organ systems are unaffected, the physiologic alterations of greatest concern revolve around pulmonary and cardiovascular functioning.⁵⁴ In an upright position, the lungs contain three zones of ventilation-perfusion distribution. Placing the patient in the lateral decubitus position results in a significantly greater proportion of the uppermost lung being classified as *zone 1*, where ventilation is more abundant than pulmonary blood flow, and a large portion of the dependent lung is classified as *zone 3*, where pulmonary blood flow exceeds alveolar ventilation (see [Fig. 45.2](#)). In addition, the percentage of the *zone 2* areas of the lung fields is reduced and split between the lungs, with the larger amount being in the dependent lung.

The alteration in ventilation-perfusion distribution is accompanied by reductions in vital capacity and tidal volume. On assuming the lateral decubitus position, healthy, conscious individuals experience an approximate 10% reduction in vital capacity as a result of reduced anterior, as well as lateral, movement of the dependent rib cage, along with restriction of the dependent hemidiaphragm. Ventilation-perfusion distribution may be further altered by the shift in the mediastinum toward the dependent side, which rotates the heart on its axis. This cardiac rotation can impede venous return, reducing cardiac output. The reduced cardiac output can produce hypotension, which must be judiciously treated with either fluid challenges or small doses of vasoactive medication. Judicious attention to padding and warming and continuous assessment are required.^{54,55}

Thromboprophylaxis.

Patients undergoing total hip and total knee arthroplasty, as well as

other orthopedic patients, are at risk for venous thromboembolism (VTE), which includes deep vein thrombosis (DVT) and pulmonary embolism (PE). Most deep vein thromboses are asymptomatic, but they can lead to the same degree of long-term morbidity as symptomatic deep vein thromboses. Orthopedic surgery patients may exhibit unique coagulation factors that differ from those seen in patients undergoing other types of surgery.⁵⁶ The American College of Chest Physicians has developed evidence-based guidelines for preventing thromboembolism in orthopedic surgery. They recommend that patients undergoing major orthopedic surgery receive low-molecular-weight heparin; fondaparinux; dabigatran, apixaban, and rivaroxaban (for total hip or total knee arthroplasty, but not for hip fracture surgery); low-dose unfractionated heparin; adjusted-dose vitamin K antagonist; aspirin; or an intermittent pneumatic compression device (IPCD) for a minimum of 10–14 days. Thromboprophylaxis for up to 35 days is preferred. The guidelines recommend the use of low-molecular-weight heparin in preference to the other agents, and suggest adding an IPCD during the hospital stay. In patients with an increased bleeding risk, the use of an IPCD alone with no pharmacologic prophylaxis is recommended.⁵⁷

Knee Arthroplasty

Total knee arthroplasty (TKA) is the other frequently performed joint replacement procedure. The pneumatic tourniquet is placed circumferentially over the thigh to decrease blood loss and maintain full view of the joint for the surgeon. Nevertheless, blood loss as a result of TKA can be greater than 1 L.⁵⁰ During the procedure, the articulating surfaces of the femur and tibia are excised via precise angular cuts, and the patellar articulating surface is shaved, all to conform the bones to surfaces of the prostheses. Both the femoral and tibial surfaces are covered with MMA cement, and the individual prosthesis components are forcibly seated with a mallet. The high-density polyethylene patellar component is cemented and seated with a viselike clamp. The medial and lateral menisci are replaced with a conforming wedge of high-density polyethylene. The same considerations related to MMA as discussed in hip arthroplasty apply for this procedure.⁵⁸

Ankle Arthroplasty

Ankle arthroplasty is performed for a number of orthopedic problems. The most common intraarticular procedures are osteochondral lesion, ankle or subtalar debridement, subtalar fusion and partial talectomy. The most common extraarticular procedures are os trigonum excision, tenolysis of the flexor hallucis longus tendon, and endoscopic partial calcaneotomy. End-stage osteoarthritis of the ankle is a major cause of pain and disability.⁵⁹ Arthroscopy is used not only to evaluate and treat intraarticular abnormalities, but also to perform endoscopic and tendoscopic procedures.⁶⁰ A tourniquet may be used to facilitate a bloodless field. DVT, PE, and fat embolism are all associated with ankle arthroplasty. Thromboprophylaxis was discussed previously.

Anesthetic Management

These procedures can be performed with either a regional or a general anesthetic technique. Ankle procedures that require a tourniquet are commonly performed under spinal or epidural anesthesia. A combination of regional techniques may be used, such as spinal anesthesia for the surgical procedure followed by a popliteal, femoral, or a combination of leg blocks for postoperative analgesia.^{61,62} Regional anesthesia that combines sciatic and femoral nerve blocks is sufficient for all surgical procedures below the knee that do not require a thigh tourniquet. The femoral nerve innervates the medial leg to the medial malleolus, and the remainder of the leg below the knee (including the foot) is innervated by the common peroneal nerve and tibial nerve, both of which are branches of the sciatic nerve. The sciatic nerve is usually blocked high in the popliteal fossa to ensure anesthesia of the tibial and peroneal nerves.⁶³

Upper Extremity Arthroplasty

The number of shoulder arthroplasties, particularly total shoulder arthroplasties (TSA), performed is rapidly increasing. The use of reverse total shoulder arthroplasty (RTSA), which was approved by the Food and Drug Administration in 2003, may be part of the

reason for this increase, as it provides a better treatment option for more complex pathologies, rotator cuff tears, and revision of failed TSAs.^{64,65}

The goals of TSA include pain reduction and improved range of motion. Indications for shoulder arthroplasty include posttraumatic brachial plexus injuries, paralysis of the deltoid muscle and rotator cuff, chronic infection, failed revision arthroplasty, severe refractory instability, proximal humerus fracture, and bone deficiency after resection of a tumor in the proximal aspect of the humerus.⁶⁴ TSA is performed with the patient in either the lateral decubitus or modified Fowler (beach chair) position (see Fig. 45.3). Arthroscopy often represents an efficacious and less invasive option compared to arthroplasty, and it may be used for diagnostic purposes or to treat osteoarthritis, impingement syndromes, and rotator cuff tears.³⁴ Because a pneumatic tourniquet cannot be used, shoulder arthroplasty is associated with higher amounts of blood loss.

Elbow arthroplasty is performed less frequently than shoulder arthroplasty. The goals for elbow arthroplasty are much the same as for shoulder arthroplasty: pain relief and improvement in joint function. The indications for elbow arthroplasty include rheumatoid arthritis, traumatic arthritis, and ankylosis of the joint.³⁴

Anesthetic Management

Patients undergoing TSA can be managed by general anesthesia, interscalene blockade, or supraclavicular blockade. Combined regional and general anesthesia is commonly used. It is important to be mindful of the ongoing potential for inadvertent extubation, which may occur as a result of patient positioning, as well as surgical manipulations in close proximity to the patient's head and neck. The patient's neck may be subjected to excessive stretch during the surgical manipulations, and, if the patient's head becomes dislodged from the supportive device used, there is the potential for cervical spine injury. It is essential to carefully monitor the patient's eyes for pressure throughout the surgery.

For patients undergoing shoulder surgery in the beach chair position, pulmonary function will more closely resemble “normal” function than in the lateral position. The potential for venous air embolism is increased in this position. The risk of fat or bone

marrow embolism and thromboembolism is incumbent with the required reaming of the shaft of the humerus. The potential cardiovascular effects of MMA cement also must be considered if the humeral component is cemented in place. The sitting position may result in cerebral ischemia in patients who develop hypotension.⁶⁶ Blood pressure measurements obtained on the arm are higher and not reflective of pressure within the circle of willis. Complications during shoulder arthroscopy in the beach chair and lateral decubitus positions are compared in [Table 45.1](#). Approaches for preventing position-related complications during shoulder arthroscopy are described in [Table 45.2](#).

TABLE 45.1
Position-Related Complications During Shoulder Arthroscopy

Beach Chair	Lateral Decubitus
Hypotensive bradycardic events with interscalene block (4% to 29%) Cervical plexus and hypoglossal nerve neurapraxias Air embolism/pneumothorax	Temporary paresthesia (10%) Neurapraxias of the dorsal digital nerve of the thumb and the musculocutaneous, ulnar, and axillary nerves
Deep vein thrombosis	Permanent neurapraxia (2.5%)
Unilateral vision loss and ophthalmoplegia Cerebral hypoperfusion event	Risk of musculotendinous nerve injury (5-o'clock portal) (rare)
	Postoperative stroke
	Deep vein thrombosis
	Fluid-related obstructive airway compromise

Adapted from Rains DD, et al. Pathomechanisms and complications related to patient positioning and anesthesia during shoulder arthroscopy. *Arthroscopy*. 2011;27(4):543–541; Li X, et al. A comparison of the lateral decubitus and beach-chair positions for shoulder surgery: advantages and complications. *J Am Acad Orthop Surg*. 2015; 23(1):18–28.

TABLE 45.2
Prevention of Position-Related Complications During Shoulder Arthroscopy

Beach Chair	Lateral Decubitus
Reference systolic pressures at level of brain	Use of safe shoulder positions when arm is placed in traction
	45 degrees of forward flexion with 90 degrees of abduction
	45 degrees of forward flexion with 0 degrees

	of abduction
Attentive care to intraoperative head positioning	Placement of anterior inferior portal out of traction
Consider use of HBE prophylactic measures when using interscalene block	Consider use of general anesthesia for longer cases

HBE, Hypotensive bradycardic episodes.

From Rains DD, et al. Pathomechanisms and complications related to patient positioning and anesthesia during shoulder arthroscopy. *Arthroscopy*. 2011;27(4):543–541.

Postoperative visual loss may be especially problematic in patients having arthroscopic procedures that make deliberate use of hypotensive techniques. When intraoperative hypotensive techniques are used, cerebral perfusion and blood supply to the cranial nerves, including the optic nerve, are diminished. Intraoperative cerebral ischemia resulting from hypoperfusion has been reported. The decreased cerebral perfusion is likely due to several factors, including the decrease in blood pressure associated with anesthesia and an upright position. Other factors include failure to correct for the cerebral pressure being lower than the point of blood pressure measurement, and vascular compromise related to malpositioning of the head and neck, probably through changes in cerebral blood flow from a combination of postural hypotension and excessive head and neck manipulation. Pressure measurements must be assessed at the level of the brain, because autoregulation occurs in the intracranial arterioles and capillaries. When the patient is seated upright, there is a significant hydrostatic gradient between the brain and the site of blood pressure measurement. The magnitude of the gradient is approximately 2 mm Hg per inch of height differential. When the cuff is on the upper arm, this difference can easily be 25 mm Hg. Failure to properly measure the blood pressure may lead to inaccurate assessment of the patient's true cerebral perfusion.⁶⁷

Hypotensive bradycardic episodes (HBEs) are a relatively common adverse effect of shoulder arthroscopy and may lead to potentially devastating complications. HBEs have been defined as a decrease in heart rate of at least 30 beats/min within a 5-min interval, any heart rate less than 50 beats/min, and/or a decrease in systolic blood pressure of more than 30 mm Hg within a 5-min interval or any systolic pressure below 90 mm Hg. These transient

but profound hypotensive and/or bradycardic events have been reported in almost 30% of patients undergoing shoulder surgery in a semiupright position under an isolated interscalene block anesthetic. The etiology of these HBEs is unknown, but the most common proposed mechanism is activation of the Bezold-Jarisch reflex.⁶⁸

The Bezold-Jarisch reflex is an inhibitory reflex mediated through cardiac sensory receptors with a vagal efferent limb. In the case of surgical positioning with the patient in the beach chair position, enhanced venous pooling occurs due to dependent extremities, leading to a subsequent increase in sympathetic tone and ultimately a low-volume, hypercontractile ventricle. Cardiac hypercontractions lead to activation of the Bezold-Jarisch reflex with an abrupt autonomic withdrawal of sympathetic response and activation of increased vagal tone. The combination of venous pooling and paradoxical increased vagal tone results in sudden, profound bradycardia and hypotension that can be difficult to reverse rapidly.

The first descriptions of HBE, historically, were in patients receiving spinal anesthesia for a variety of surgeries. The mechanism clearly involves sympathetic blockade; however, decreased sympathetic tone to the heart with decreased cardiac filling is an important contributor. It has been proposed that epinephrine used with the local anesthetics for interscalene block may actually contribute to HBE by increasing cardiac hypercontractility, as well as exacerbating the position-related hypovolemic state.

It is possible that, when administered in a regional block, epinephrine is absorbed slowly, thereby physiologically mimicking low-dose IV administration. At such concentrations, epinephrine could predispose to HBE by increasing cardiac contractility, resulting in ventricular emptying, increasing heart rate (which reduces cardiac filling) and increasing peripheral vasodilation and pooling (decreased afterload); these factors ultimately create ventricular hypovolemia with hypercontractions.

Prophylaxis to prevent HBE includes aggressive treatment of fluid deficits and blood loss. Minimize venous pooling in the upright position with support stockings. Avoid the use of local

anesthetics containing epinephrine, and consider the use of intraoperative β -blockade in select patients.⁶⁷

Elbow arthroplasty can be performed in any of three positions: supine, lateral decubitus, or prone. The deciding factors on which position to use for this procedure are surgeon preference and the health of the patient. Elbow arthroplasty can be managed by general anesthesia or supraclavicular, infraclavicular, interscalene, or brachial plexus blockade. During elbow arthroplasty, a pneumatic tourniquet is generally used to minimize blood loss and provide a clear surgical field. It is necessary to be prepared to treat the patient's tourniquet pain whenever regional anesthesia is used. Any time a pneumatic tourniquet is used, the risk of thromboembolism exists. This risk is increased in those patients with a history of VTE.⁶⁹

Spinal Surgery

Minimally invasive techniques are also being used for noncomplex spinal procedures. Percutaneous endoscopic lumbar discectomy is the technique of choice for minimally invasive spine surgery.⁷⁰ Other procedures that may be treated with minimally invasive techniques include vertebroplasty and kyphoplasty, cervical discectomy and foraminectomy, and intradiscal electrothermal therapy. The procedures are performed in an interventional radiology suite and usually require local anesthesia with IV sedation. General anesthesia is occasionally used for difficult procedures, and low-dose propofol, remifentanyl, or dexmedetomidine infusions have all been used successfully.⁷¹ The greatest anesthetic challenge may be positioning because these patients often have severe osteoporosis and other spinal deformities. They are often elderly and have significant comorbidities, so thorough preoperative workup and preparation is essential.⁷² Adequate postoperative analgesia improves recovery⁷³

Back injuries account for a large percentage of work-related injuries, and are a leading cause of work absences. Occupational factors suspected of accelerating spinal degeneration include accident-related trauma; heavy physical loading, lifting, bending, and twisting; prolonged sitting; and sustained nonneutral work postures and long periods of sitting while driving.

Complex spinal surgery presents several anesthetic challenges including airway control, positioning, fluid and blood transfusion management, hemodynamic control, and postoperative analgesia. Most spine patients will be placed in the prone position for surgery.

Patients in this position for prolonged periods present significant challenges. It is important to maintain adequate venous return to maintain the hemodynamics of the patient. If the increased intraabdominal or intrathoracic pressures resulting from being prone reduce venous return, the cardiac output will be reduced. In addition, placing a patient in the prone position increases both systemic and pulmonary vascular resistance. These increases lead to decreases in stroke volume and cardiac index. Adequate volume resuscitation can help maintain normal hemodynamics. Use of a

support system that allows a pressure-free abdomen, such as the Jackson spine table or longitudinal bolsters for prone positioning, will minimize the effect on cardiac output.^{74,75}

Respiratory dynamics are greatly affected by placing the patient in the prone position, as this position rearranges the three-zone model discussed earlier. The proportion of zone 2 reduces, whereas that of zone 3 increases.⁷⁶ Care is taken to prevent barotrauma through appropriate changes in ventilatory settings to maintain oxygenation and positive pressures within acceptable limits.

The use of pressure- versus volume-controlled ventilation may allow for lower peak airway pressure in the prone position.⁷⁷

Finally, the prone position can alter central nervous system dynamics more than the supine position, which is of particular concern if head injury or closed head pathology is present or suspected.⁷⁸ The anterior neck is particularly supple and lacks considerable bony structural and protective support. Turning an unconscious patient or a patient under general anesthesia from the supine position to the prone position, and any head rotation undertaken during positioning, must be done with great care. If the patient's head is rotated 60 degrees, compression of the contralateral vertebral artery begins to constrain blood flow; if rotated 80 degrees, the contralateral vertebral artery becomes completely occluded.⁷⁹ The carotid artery and jugular vein on the upper side of the neck can become compressed by extreme degrees of head rotation, and those on the lower side of the neck may become compressed by inappropriate head support.⁷⁴ Optimal cerebral blood flow and cerebrovenous drainage only occur when the head is in a centered position.⁸⁰

Under general anesthesia or with a patient whose level of consciousness is already altered, the alteration in arterial blood supply to the brain may not be easily recognized. Therefore, it is prudent to maintain the patient's head in a neutral anatomic alignment while in the prone position. In addition, even if no arterial or venous compression occurs, if the patient's head rests below the level of the heart, he or she is at an increased risk for postoperative visual loss, which is discussed later. Whether the head is rotated to the side or placed in a neutral sagittal position, careful attention must be paid to avoiding pressure on the orbit.

This can be accomplished with soft surgical pillows or one of several commercially available foam supports. The use of a Mayfield (pinned) head holder or Gardner-Wells tongs for cervical spine traction provides an additional level of stability and eliminates pressure on the face or the eyes.^{81,82}

In the past, laminectomies required large incisions to afford the surgeon optimal visualization of the affected area of the spinal column. Currently, less invasive techniques that make use of the microscope afford the surgeon better visualization while eliminating the need for the large incisions that were commonplace in the recent past, even for straightforward, “simple” lumbar laminectomies. In addition, the smaller incision results in reduced blood loss, faster wound healing, less trauma to surrounding soft tissues, shorter recovery, shorter length of hospitalization, and quicker return to a preinjury level of activity.⁸³

The most common reasons for spinal surgery are intervertebral disc herniation and spinal stenosis. These maladies can occur anywhere along the spinal column from C2 to C3 through the L5 to S1 vertebrae. Bony decompression by laminectomy is considered the gold standard surgical approach for spinal stenosis. Surgical intervention via the posterior approach consists of a midline incision and tissue dissection to expose the disc herniation or stenotic areas. Surgery is undertaken to relieve the pressure on the nerve root that is causing the pain. Bony decompression may lead to spinal instability, and surgical lumbar interbody fusion (LIF) may be performed in addition to laminectomy.⁸⁴

In addition to providing spinal stability, LIF may be used to treat spinal deformity and radiculopathy secondary to degenerative disc disease (DDD). Several techniques can be used to accomplish this fusion, including bone grafting via allograft or iliac autograft, the use of pedicle screws, or the use of cage devices. Approaches for LIF include anterior, lateral, posterior, and transforaminal. The posterior and transforaminal approaches are the most common. The fusion of two or more adjacent vertebrae through the disc space immobilizes the intervertebral joint and prevents painful movement. The goal of LIF is to prevent further degeneration and loss of the surgical correction achieved.⁸⁴⁻⁸⁶ Cervical radiculopathy caused by nerve root compression may also be surgically managed.

Surgical options include anterior cervical decompression and fusion, cervical disc arthroplasty, and posterior foraminotomy.⁸⁷

Although surgical treatment of DDD is most often achieved by fusion, some patients, particularly younger individuals, undergo total disc replacement.⁸⁸ Total disc replacement procedures are most commonly accomplished via an anterior approach. Anterior approaches to spinal surgery often require the assistance of a general surgeon to aid in the displacement of organs and vasculature.⁸⁶⁻⁸⁹ A double-lumen tube may be used for lung isolation to facilitate surgical exposure. Fusion within the cervical spine is most often accomplished by initial discectomy followed by the insertion of a wedge-shaped bone graft (often cadaveric), or by fusion of the joint with a plate and screws.

Scoliosis is lateral curvature of the spinal column by more than 10 degrees. Eighty percent of scoliosis cases are idiopathic. Other causes of scoliosis include congenital skeletal abnormalities, neuromuscular disease, neurofibromatosis, or irritative phenomena resulting from spinal cord compression from a tumor. If left untreated, scoliosis can lead to 3-dimensional structural deformities including curvature in the anterior-posterior plane, angulation in the sagittal plane, and rotation in the transverse plane. Scoliosis may result in chronic pain, neurologic and cardiopulmonary compromise, and cosmetic concerns.⁹⁰ Treatment pathways are determined by the severity and cause of the deformity, and may be nonsurgical or surgical.

Surgical intervention consists primarily of fusion of multiple joint spaces, with or without anterior release, and may include extensive instrumentation (e.g., Harrington rods or other instrumentation). Scoliosis repair may require anterior or posterior approaches, or a combination of both. Any approach is a major surgical intervention, but the anterior approach is more technically involved. The anterior approach to the thoracic spine requires performing a thoracotomy.

In conjunction with the development of "cage" technology, the principles of laparoscopy/endoscopy are being adapted and applied to spinal surgery. The first use of laparoscopy for lumbar discectomy was documented by Obenchain⁹¹ in 1991. Laparoscopic techniques were first used for thoracic spinal surgery by Mack et al.⁹² in 1993. Application of laparoscopic principles and techniques

offers numerous advantages to anterior vertebral joint fusion ([Box 45.5](#)), the most important being better respiratory functioning, diminished blood loss, and shorter length of stay, resulting in decreased medical costs. The major disadvantage of using laparoscopic techniques in spinal surgery is the time it takes for the surgeon to become proficient at the technique to avoid prolonged [Box 45.5](#) the OR.

Advantages of Laparoscopy for Anterior Spinal Surgery

- Enhanced visualization
- Decreased potential for infection
- Reduced trauma to surrounding soft tissues
- Shorter hospitalization
- Shorter rehabilitation period
- Decreased blood loss
- Improved intraoperative and postoperative ventilation
- Reduced intensive care unit time
- Better cosmetic appearance
- Reduced overall costs

Not all patients are good candidates for the laparoscopic approach. It is contraindicated for lumbar repair in patients with abdominal adhesions from inflammatory processes or previous laparotomies, and in abdominal trauma patients. In addition, patients with marked cardiac or pulmonary disease processes may not be able to tolerate the hypercarbia that can result from abdominal insufflation with carbon dioxide. Laparoscopy is currently contraindicated for thoracic spinal surgery candidates who are unable to tolerate one-lung ventilation, and for those with

severe or acute respiratory insufficiency, high positive airway pressures, and pleural symphysis. Patients who have required previous thoracotomy or chest tube placement must be more extensively evaluated preoperatively to determine whether thoroscopic spinal surgery should be used. Additionally, at present, patients in need of internal fixation with extensive instrumentation of the anterior spine are not considered to be candidates for thoroscopic spinal surgery.⁹³

Anesthetic Management

General anesthesia provides the safest approach for spinal surgery. Not only is the airway secure, but muscle relaxants can be used, preventing movement at critical times during surgery. Aspirin, antiplatelet drugs, and anticoagulants should be appropriately managed and discontinued as soon as possible. Preoperative testing should include a CBC, platelet count, and coagulation studies. A preoperative chest X-ray, pulmonary function tests, electrocardiogram, and echocardiogram should be obtained, as appropriate. Evoked potentials will likely be monitored, and other neurologic testing may be performed, as indicated (see [Chapters 19](#) and [31](#)).

A major anesthesia concern during spinal surgery revolves around patient positioning. For spinal surgery involving the posterior approach, the patient will almost always be placed prone to facilitate the surgery. While turning the patient, special attention must be given to the head and the endotracheal tube. Foam, gel pads, or head supports should be put in place prior to turning. Once the patient is turned, the first goal is to reconnect the breathing circuit and recheck the breath sounds to ascertain whether the tube is still in the correct place and has not migrated into the bronchus. The potential for eye or corneal injury is high in the prone position. Care must be taken to pad the extremities and prevent neural injury.

When in the prone position, the patient's abdomen should not be compressed, because compression of the abdominal cavity will displace the organs, and therefore the diaphragm, in the cephalad direction, producing reduced functional residual capacity, reduced tidal volume, and increased airway pressures. Abdominal

compression also contributes to engorgement of the epidural venous network, and can be a contributing factor to greater blood loss during the surgical procedure. To avoid abdominal compression, the abdomen must be elevated from the surface of the OR bed.

Numerous methods and devices can be used to greatly reduce or eliminate abdominal compression. The simplest method is the use of bilateral “prone rolls” or “chest rolls,” which are firm but compressible pads that extend from the shoulder to the iliac crest (Fig. 45.8). Other devices include the Wilson frame (Fig. 45.9), the Relton adjustable pedestal frame (Fig. 45.10), and the Andrews frame (also known as a *spinal surgery table*) (Fig. 45.11). Each of these positioning devices is designed to allow the abdomen to “hang” freely and reduce the possibility of compressing major vascular structures.

FIGURE 45.8 Prone position using chest rolls.

FIGURE 45.9 Convex saddle frame (Wilson frame) used

for spinal operations.

FIGURE 45.10 The Relton adjustable pedestal frame.

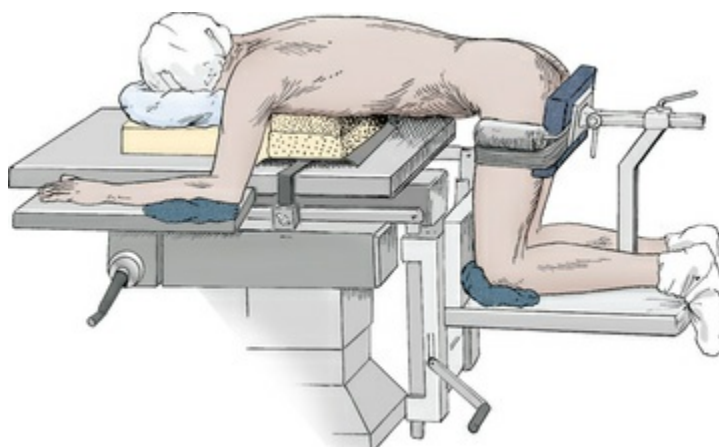

FIGURE 45.11 The Andrews frame.

The Andrews spinal surgery table is the most complex of the positioning devices. With the Andrews table, as with the other positioning devices, the patient is induced and intubated on the transport stretcher, after which he or she is lifted onto the table. On initial positioning on the Andrews table, the patient lies prone with the legs resting perpendicular to the plane of the table. A buttock support is securely attached to the framework of the table, and the bony prominences of the hips and especially the knees are adequately padded. The leg portion of the table is then lowered until the weight of the lower body rests on the knees, resulting in the patient's hips and knees being flexed at 90 degrees. This table produces a modified knee-chest position, allows the abdomen to hang freely, and greatly reduces the potential for compression of

the major vascular structures of the lower abdomen and pelvic region (femoral arteries and veins). This position also maximizes the surgeon's visualization of the surgical site. Blood loss is decreased by using the Andrews spinal surgery table.^{94,95} However, hypotension frequently occurs when this table is used, as a result of blood pooling in the dependent lower extremities. Antiembolic stockings may help counteract the tendency for blood to pool in the lower extremities, and any hypotensive event must be treated.

Scoliosis correction with large-scale instrumentation (e.g., Harrington instrumentation) is a major surgical intervention. The surgeon may choose a posterior, anterior, or thoracoabdominal approach to accomplish the procedure, depending on the location and severity of the defect. The posterior approach requires the patient to be in the prone position. Scoliosis of the lower thoracic to upper lumbar spine may necessitate a thoracoabdominal incision and require the patient to be placed in a semilateral position. Scoliosis exclusively of the thoracic spine requires the patient to be placed in the lateral decubitus position.

Entry into the thoracic cavity necessitates placement of a double-lumen endobronchial tube so the ipsilateral lung can be deflated to facilitate visualization of the thoracic spine. Intubation may be difficult at best if the patient has a severe deformity. For surgical correction of scoliosis by spinal fusion with anterior release, the patient is placed in the lateral decubitus position for the thoracotomy incision and will require endobronchial intubation. Depending on the direction of curvature of the thoracic spine, the heart may need to be manipulated, which may produce cardiac dysrhythmias. In patients who are myelopathic or have cervical spine instability, a fiberoptic or other assisted device intubation, either awake or after the induction of general anesthesia, may be indicated. This also may be necessary in patients who have undergone previous spinal fusion with limitation of neck extension. In the anesthetized patient, evoked potentials can be measured before and after intubation, as well as before, during, and after positioning.⁹⁶

With the large incision and complex dissection required for the multilevel spinal fusions and instrumentation needed to surgically correct the scoliosis, significant blood loss may occur. The need for

blood transfusion during the course of the procedure is virtually ensured. Procedures more likely to be associated with major blood loss are those involving the thoracic spine, particularly for malignancy or trauma. Autologous blood donation, the use of cell salvage devices, and serial monitoring of hemoglobin, hematocrit, and urine output are all used to manage fluid and transfusion therapy. The choice of anesthetic drugs is standard, with consideration for evoked potential monitoring and postoperative analgesia included as part of the plan.

As described, laparoscopic principles and techniques are beginning to be applied more frequently to spinal fusion surgery. Spinal fusion via laparoscopy provides the surgeon with enhanced visualization of the surgical site, reduces operative time once the surgeon and staff have acquired and are comfortable with the necessary skills, results in greatly reduced trauma to the surrounding soft tissues, produces dramatically less blood loss, reduces recovery and rehabilitation time, greatly reduces medical costs, contributes to an earlier return to preinjury level of activity, and is aesthetically more pleasing to the patient. It is important to compensate for any hypercarbia that may accompany insufflation of carbon dioxide, particularly during long procedures.

Sudden, dramatic, unanticipated, sustained hypotension requires rapid intervention and assessment of cause. The surgeon should be informed, and a plan to rapidly determine the cause and initiate appropriate effective treatment measures may be instituted together. Because of the close proximity to the spinal column, injury to the aorta can occur during surgery on the thoracic or lumbar spine. In addition to aortic injury, the inferior vena cava, iliac vessels, and common femoral vessels may be damaged as a result of traction during laparoscopic spinal procedures.⁹³ Injury to these vascular structures can be a truly emergent situation. If the patient is in the prone position, rapid closure of the surgical wound is imperative so the patient can be repositioned, to facilitate repair of the damaged vessel. Volume resuscitation may be required in the event of an injury to a blood vessel. For this reason, it is advisable to have two large-bore IV access sites established, in addition to verifying the availability of blood. Venous air embolism can occur in certain procedures, and appropriate monitoring and vigilance is

required (see [Chapter 23](#), positioning for anesthesia and surgery).

Postoperative Visual Loss

Postoperative vision loss (POVL) associated with general anesthesia and prone positioning in spinal surgery has increased over the past several decades. The American Society of Anesthesiologists (ASA) has developed a Postoperative Visual Loss Registry in an effort to better understand and evaluate this devastating operative complication. Over 93 incidents have been reported between 1999 and 2005.⁹⁶ The main causes of visual loss after nonocular surgery are retinal vascular occlusion and ischemic optic neuropathy. Direct pressure to the periorbital region of the eye can cause increased intraocular pressure and blindness as a result of central retinal artery occlusion. The cause of ischemic optic neuropathy (ION) is still unclear. Although it can strike patients of any age, there is an increased incidence in patients with less than 18 and more than 65 years of age. The Postoperative Visual Loss Study Group has reported that obese and male patients have an increased risk of developing ION after major spinal surgery in the prone position. Increased intraabdominal, intrathoracic, and intraocular pressure in the prone position may lead to venous congestion and therefore contribute to the problem. Obesity, male sex, Wilson frame use, longer anesthetic duration, greater estimated blood loss, and lower percentages of colloid administration were significantly and independently associated with ION after spinal fusion surgery.^{97,98} It has been speculated that estrogen has a protective effect on the optic nerve, which could explain why females are less likely to experience postoperative ION. The other five risk factors for ION are potentially related to increased venous pressure in the head with development of interstitial edema ([Box 45.6](#)). Other researchers have also noted that significant risk factors include male sex, anemia from blood loss greater than 1 L, surgery lasting over 5 hours, and intraoperative hypotension. Volume replacement with colloid causes a smaller decrease in oncotic pressure and theoretically diminishes edema formation. This may explain why anemia alone was not identified as an independent risk factor in the multivariate analysis, as anemia may only be a surrogate marker for low oncotic pressure. Unlike corneal abrasion (the most common

surgical eye injury), which is usually self-limiting, the prognosis for **Box 45-6** recovery from POVL is poor.^{99,100}

Risk Factors for Ischemic Optic Neuropathy Associated With Spine Surgery

- Male sex
- Obesity
- Use of Wilson frame
- Anesthesia duration > 6 hours
- Large blood loss
- Colloid as percent of nonblood fluids

From Lee LA et al. Postoperative Visual Loss Study Group. Risk factors associated with ischemic optic neuropathy after spinal fusion surgery. *Anesthesiology*. 2012;116:15–24

Most cases of POVL occurring after spinal surgery are bilateral. Visual loss typically occurs within the first 24 to 48 hours postoperatively. There is usually painless visual loss, an afferent pupil defect or nonreactive pupil, and no light perception (or other visual field deficit). Color vision is decreased or absent. Elevated intraocular pressures greater than 40 mm Hg from prolonged prone positioning and fluids may be a factor. It is advisable to position a patient's head level with or above the heart, where possible, and in a neutral position.

A foam headrest should be used. Placing the head in pins is also used, but is more invasive. For most procedures in which the patient is prone, it is reasonable to use any of the commercially available square foam headrests. It is not advisable to cover the eyes with goggles when the head is positioned prone in a square foam headrest. With a transparent surgical table headpiece, a mirror can enable indirect viewing of the eyes. A foam headrest with a mirror attachment allows eyes to be viewed easily during surgery. Ensure that the eyes are properly positioned and checked intermittently by

palpation and visualization. Document eye checks at least every 20 minutes. A horseshoe headrest should not be used because of the greater risk of head movement caused by the surgeon, along with the resulting compression of the eye.^{99,101-103} The ASA Task Force recommendations for the prevention of visual loss are given in [Box 45.7](#).^{96,98,102} A complete discussion of postoperative visual loss can be found in [Chapter 23](#).

Recommendations of the American Society of Anesthesiologists Task Force on Perioperative Blindness

1. Consider informing patients who will undergo spine operations in the prone position anticipated to involve prolonged duration and/or substantial blood loss that they have a small but unpredictable risk of perioperative visual loss.
2. Continually monitor systemic blood pressure.
3. Colloids should be used along with crystalloids for maintaining euvolemia.
4. Hemoglobin or hematocrit values should be monitored periodically during surgery, but no optimal transfusion threshold to prevent perioperative visual loss has been identified.
5. The decision to use α -adrenergic agents should be made on a case-by-case basis.
6. Direct pressure on the eye should be avoided to prevent central retinal artery occlusion.
7. Position the head in a neutral position with the face down and the head level with or higher than the heart to minimize venous outflow obstruction.
8. Consider staging very prolonged procedures in high risk patients with careful consideration of the risk:benefit ratio.

9. Assess vision when the patient becomes alert.

. An urgent ophthalmologic consultation should be obtained if there is concern for postoperative visual loss.

. Consider optimizing hemoglobin, hematocrit, hemodynamic status, and arterial oxygenation.

. Consider magnetic resonance imaging to rule out intracranial causes of visual loss.

. Antiplatelet agents, steroids, or intraocular pressure–lowering agents have not been shown to be effective for treatment of perioperative ION.

Perioperative visual loss. *Best Pract Res Clin Anaesthesiol*. 2016;30(1):69–77.

Foot and Ankle Surgery

Each of us is acutely aware of any problems with our ankles or feet. They carry the weight of our bodies around, and we can feel any compromise in their integrity almost immediately. Patients may seek the care of an orthopedic surgeon for problems with their feet, or they may see a doctor of podiatric medicine. Both these specialists are highly skilled in the surgical correction of the multitude of problems that occur with the feet and ankles.¹⁰⁴

The most commonly performed procedures on the ankle involve surgical repair of ankle fractures and fusion of the ankle joint. The Achilles tendon is also a frequent focus of surgery, particularly in more physically active individuals. The most widely known surgical procedures on the feet are bunionectomy (with or without fusion), correction of hammertoe deformities (with or without fusion), and plantar fasciotomy (either open or endoscopic).

Open repair of ankle fractures is usually accomplished using plates and screws to hold the bone fragment in proper alignment until the fragments grow back together. Ankle fusion (arthrodesis) is performed for a multitude of medical reasons, and may involve two or three bones being fused together to provide pain relief and greater joint stability. Incisions are usually made on both the medial and lateral aspects of the ankle joint to allow for optimal surgical access to the involved bones. The fracture is reduced, after which a plate is placed across the fracture site or sites. Holes are drilled with the plate acting as the template, and screws are placed into these holes. For ankle fusions, incisions are typically made across the medial and lateral aspects of the joint, and wires or screws are used to fuse the appropriate bones in place. The incisions are closed, and some type of inflexible stabilizing device is applied (e.g., cast, plaster splints, or ambulatory boot) while the patient is under anesthesia. Pneumatic tourniquets are almost always used to keep blood loss at a minimum and provide a clear surgical field.

Bunion deformity usually involves the first, or great, toe. Incision is made along the anterior surface from about midtoe across the metatarsophalangeal joint. The bony deformity is excised. Depending on the variation of the bunionectomy procedure chosen,

excision of the bony deformity may be the totality of the procedure, or the angular deformity may be corrected with a screw or wire fusion.

Hammertoe deformity correction involves incision of the anterior surface of the malformed toe or toes. The incision crosses the joint containing the bony deformity. The surgeon dissects down to the joint and excises the bony deformity. Depending on the severity of the deformity, the interphalangeal joint may be fused by inserting a wire.

Plantar fasciotomy is indicated for severe foot pain during or after ambulating or on arising after sleep. Pain results from chronic plantar fasciitis that has not responded to conservative therapy. Open fasciotomy is accomplished via a small incision along the posterior surface of the calcaneus. The plantar fascia is incised to relieve the tension across the plantar arch. Endoscopic plantar fasciotomy is accomplished via two “miniature” incisions, one medial and one lateral, at the beginning of the plantar arch. A small trocar is inserted through these incisions. The sheath of the trocar is slotted to allow visualization of the plantar fascia with the endoscope. The full thickness of the plantar fascia is incised, and the skin incisions are closed.

Anesthetic Management

Patients scheduled for foot or ankle surgery are excellent candidates for regional anesthesia. Most surgical procedures on the foot or ankle can be accomplished within a 2-hour time frame often on an outpatient basis. Spinal anesthesia provides sufficient surgical anesthesia to allow completion of most procedures. However, the postanesthesia recovery phase may be long and require an overnight stay in the hospital or outpatient facility, which may be unacceptable to the patient.

Nerve blocks are especially effective for surgical procedures on the foot or ankle. IV sedation by either continuous infusion or intermittent bolus can provide amnesia and minimize or eliminate any anxiety the patient may have. The surgeon can inject the surgical site with long-acting local anesthetic (e.g., bupivacaine) to maintain the patient's comfort immediately and for several hours postoperatively.

Forearm and Hand Surgery

Surgical procedures on the hand or forearm may be precipitated by trauma resulting in complex or dislocated fractures to the bones of the forearm, hand, or fingers, or may be performed to alleviate numbness of the hand resulting from compression of the nerves of the forearm or wrist, as in carpal tunnel syndrome. Procedures on the fingers and hand are often relatively quick, requiring 1 hour or less to complete, whereas surgical correction of complex or dislocated fractures of the forearm may require considerable instrumentation and time to complete. For virtually all surgical procedures of the hand and forearm, a pneumatic tourniquet is used.

Anesthetic Management

Patients scheduled for surgical procedures on the forearm or hand are good candidates for regional anesthesia. Ultrasound-guided brachial plexus blockade or an IV regional block provide excellent surgical anesthesia for most surgical procedures of the forearm and hand anticipated to last less than 1 hour.

For procedures that may require considerable amounts of time to accomplish, for example, those precipitated by traumatic injury, such as complex, comminuted fractures, or reconstruction of the vascular and nerve structures of the hand or forearm, the better anesthetic choice may be general anesthesia. Tourniquet pain becomes an issue with longer procedures if regional anesthesia is chosen. Also, for the patient requiring surgery as the result of traumatic injury, the patient's nothing-by-mouth (NPO) status becomes important. Frequently, trauma patients have eaten or ingested liquids close to the time of the injury. For these reasons, rapid-sequence induction of general anesthesia may be a more appropriate anesthetic course.

Arthritic Syndromes

Of the many arthritic syndromes, two are especially disconcerting: rheumatoid arthritis (RA) and ankylosing spondylitis (AS). Both these arthritic conditions extend beyond the primary affliction to the skeletal system, and often require interventions from orthopedic medicine. They are both also associated with specific concerns related to the airway, and should be indicators for a thorough airway assessment in the preoperative period. RA is the most prevalent chronic systemic inflammatory rheumatic disease.

An autoimmune disease, RA may lead to severe disability and premature mortality. RA is characterized by joint swelling, joint tenderness, and the destruction of synovial joints. In 2010, the American College of Rheumatology and the European League Against Rheumatism revised the classification criteria for RA. Criteria include presence of synovitis in at least one joint (not otherwise explained), as well as confirmatory serological testing. The updated scoring system allows for earlier detection and treatment of RA.¹⁰⁵

Of particular concern are the effects of RA on the cervical spine, temporomandibular joint, larynx, and pulmonary system. Deposition of rheumatoid nodules causes inflammation of the intervertebral discs and dura, which is expressed as atlantoaxial joint subluxation. The synovium of the temporomandibular joint is also affected by RA, and can result in severe limitation of joint range of motion. The cricoarytenoid joints are common sites for rheumatoid nodule deposition. The resultant chronic synovitis may cause fixation of the vocal cords in adduction and airway obstruction. Finally, RA is associated with several forms of pulmonary disease, including pleural effusion, interstitial lung disease, obliterative bronchiolitis, and vasculitis.^{105,106}

Ankylosing spondylitis is also a chronic inflammatory process. The primary target is the spinal column and surrounding soft tissues. The progressive nature of AS means that the spine can be injured by seemingly inconsequential trauma. Patients with AS also may experience cardiac valvular dysfunction, conduction delays, bundle branch blocks, and restrictive lung disease.¹⁰⁷

Anesthetic Management

The primary concern when caring for a patient with either RA or AS is the patient's airway. The mobility of the patient's cervical spine must be meticulously evaluated during the preoperative interview. Any neurologic symptoms that occur during movement of the cervical spine must be thoroughly documented at that time. As a result of RA or AS, cervical mobility may be severely restricted; therefore, the patient may prove to be extremely difficult to intubate. Because of the high risk to these patients from cervical spine manipulation during direct laryngoscopy for tracheal intubation, awake fiberoptic or other intubation techniques may be the safer course of action. The prudent anesthetic course also may include positioning the patient such that neurologic symptoms remain absent before induction of general anesthesia. The cervical spine must be neutrally positioned throughout any surgical procedure, during emergence, and during transfer to the postanesthesia care unit. Regional anesthesia is a safe approach to extremity surgery for these patients.^{108,109}

Summary

Orthopedic surgical procedures are varied, and require a wide variety of anesthetic plans. The patient's health history, the acceptability of various anesthetic techniques to the patient, the proposed surgery and its duration, the patient's intraoperative position, and the need for postoperative pain management are important considerations in planning and preparing for a safe and comfortable outcome. In addition, many of these procedures carry high risk for blood loss, so preoperative typing and cross-matching are indicated in nearly all these cases. The anesthetic plan must be adapted to the needs of the patient and the proposed surgery, rather than expecting the patient to adapt to one anesthetic technique.

Developments in orthopedics over the last few decades have resulted not only in an increase in options and techniques, but also in an improvement in patient outcomes. The invention of the arthroscope has diminished some of the severe consequences of certain repairs and has provided a diagnostic tool for surgeons. Coupled with this is a decreased length of stay and fewer side effects from anesthesia. Trauma surgeries and high-profile surgeries corresponding to the increasing geriatric population are challenging, and require techniques that reduce complications and provide postoperative pain management.

The Immune System and Anesthesia

Bernadette T. Higgins Roche

The immune system has evolved to protect the body from a wide variety of pathogenic microbes such as viruses, bacteria, prions, fungi, and protozoa, as well as self-cells with abnormal proteins. A key characteristic of the immune system is the ability to distinguish between self and nonself. To effectively eliminate pathogens without destroying its own tissues, the immune system must be able to detect structural differences of a pathogen that distinguishes it from self or host cells.

The immune system is comprised of two subcategories, the innate (natural) immune system and the adaptive (acquired) immune system.¹⁻³ The response of both the innate and adaptive systems to pathogens includes a humoral response and a cell mediated response. The term *humor* is a medieval term for body fluid and refers to the liquid, noncellular component of blood and lymphatic fluid. The humoral immune response is mediated by B lymphocyte antibodies circulating in the lymph or blood. The cell mediated response is produced by phagocytes, T lymphocytes, and cytokines. Cell-mediated immunity is directed primarily at microbes that survive in host cells. It also plays a major role in rejection of transplanted organs. Although the innate and the adaptive immune systems work differently and are historically presented as two different parts of the immune system, an effective immune response toward a pathogen requires a cooperative synergy between the two systems. The innate system generates the first line of defense; the adaptive system becomes prominent as it develops antigen specific antibodies in response to activation by the innate system (Fig. 46.1).

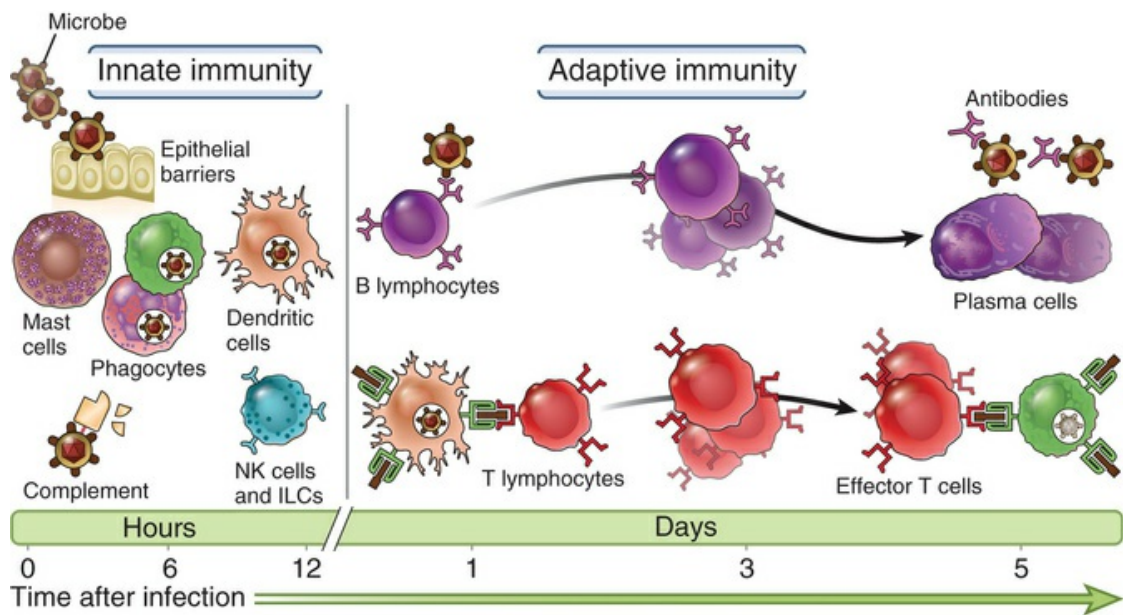

FIGURE 46.1 Response of innate and adaptive immune systems to pathogens. *NK*, Natural killer cells; *ILCs*, Innate lymphoid cells. (From Abbas AK, et al. *Basic Immunology*. 5th ed. St. Louis: Elsevier; 2016;2.)

The Immune System

Innate Immune System

The innate immune system is inherited and constitutes the first-line of defense to an invading pathogen.¹⁻² It has a rapid response but lacks immunological memory. The innate immune system does not require prior antigen exposure for activation and its response is always the same, regardless of prior encounters with the same pathogen. It is not specific in its mechanism of defense; consequently, it must activate the adaptive immune system to mount a pathogen specific response. Immune system cells are derived from hematopoietic stem cells that differentiate into a common myeloid stem cell and a common lymphoid progenitor, the precursor of the innate immune system cells (Fig. 46.2). The major cellular components of the innate system include granulocytes (neutrophils, eosinophils, basophils), agranulocytes (monocytes and macrophages), dendritic cells (DCs), cytokines, and the complement system (Table 46.1).¹⁻⁴

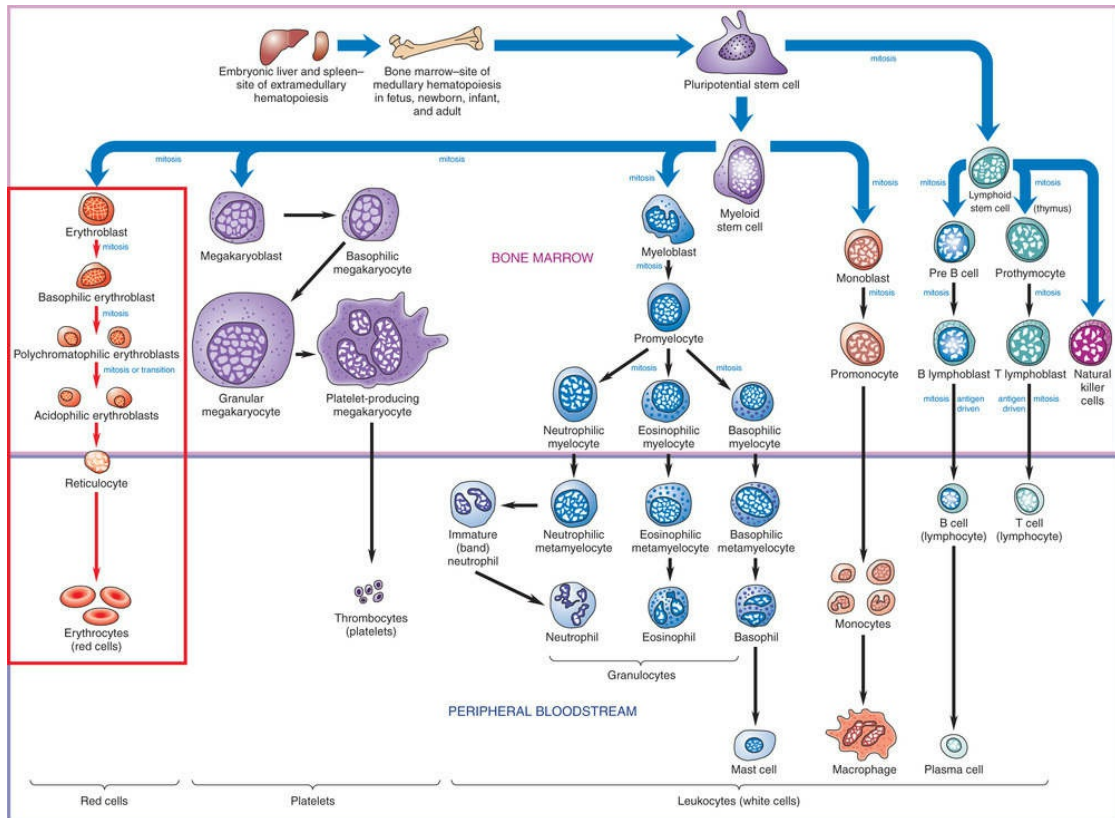

FIGURE 46.2 Maturation of human blood cells showing pathways of cell differentiation from the pluripotent stem cell to mature granulocytes, monocytes, lymphocytes, thrombocytes, and erythrocytes. Production begins in embryo blood islands in the yolk sac. As the embryo matures, production shifts to the liver, spleen, and bone marrow. In an adult, nearly all hematopoiesis occurs in the bone marrow. The two major differentiation pathways are the myeloid pathway and the lymphoid pathway. The lymphoid pathway produces lymphocytes, whereas the myeloid pathway produces granulocytes, monocytes, platelets, and red blood cells. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:160.)

TABLE 46.1
Components of the Innate Immune System

Component	Type	Function
Granulocytes	Neutrophils	Prominent phagocyte of early inflammatory response; release of cytotoxic cytokines, phagocytosis, presentation of antigen to cells of adaptive immune system.
	Eosinophils	Phagocytosis, release of cytotoxic cytokines, degradation of mast-cell inflammatory mediators, destruction of parasites.
	Basophils and Mast Cells	IgE receptors, release of histamine, leukotrienes, cytokines, prostaglandins and other mediators of inflammation.

Agranulocytes	Monocytes and Macrophages	Prominent phagocyte of late inflammatory response; phagocytosis, release of cytotoxic cytokines.
Dendritic Cells (DCs)		Phagocytosis, presentation of antigen to cells of adaptive immune system, release of cytotoxic cytokines.
Cytokines	Interleukins (IL)	Regulation (activation and inhibition) of inflammatory response.
	Interferons (INF)	Destruction of viral antigens.
	Tumor Necrosis Factor (TNF)	Mediation of inflammatory response
	Chemokines	Leukocyte chemotaxis, migration of phagocytes to site of infection, release of phagocytes from bone marrow.
Complement		Opsonization of pathogens for destruction, cell lysis, leukocyte chemotaxis.

Phagocytosis, the process of ingesting pathogens including bacteria, viruses, fungi, parasites, tumor cells, and apoptotic cells, exposes the pathogen to intracellular chemical pathways that destroy it. Neutrophils, eosinophils, monocytes, macrophages, and DCs are phagocytes. Neutrophils have the fastest response to a pathogen; macrophages and DCs have a longer but sustained response time. In addition to direct activation by pathogens, phagocytes are also activated by opsonization, a process where antibodies and complements (opsonins) bind to the pathogen and mark it for destruction by the phagocytes. The mononuclear phagocyte system (MPS), formerly known as the *reticuloendothelial system*, includes phagocytes located in reticular connective tissues, including the lymph nodes, lungs, liver, and spleen. The MPS is activated when it encounters a pathogen; in addition to phagocytosis of the pathogen, the MPS phagocytes secrete cytokines that promote the migration of neutrophils, monocytes, eosinophils, and basophils to the site of infection. They also secrete colony-stimulating factors that stimulate the production and release of additional phagocytes from the bone marrow. Erythrocytes and platelets possess complement receptors and appear to play a role in the innate immune response.⁵ The innate system also includes surface barriers such as epithelial cell layers with tight junctions, which are present on the skin and mucous membranes of the gastrointestinal (GI), genitourinary, and respiratory tracts. The innate system is activated when a pathogen is first encountered. Initial responses include sneezing, tearing, coughing, sweating, and maintenance of normal body temperature and gram-positive normal flora of the skin.

Immune cells of the innate system use intracellular or membrane

pattern recognition receptors (PRRs) to recognize the molecular patterns of microbes.^{2,4} Evolving through natural selection, PRRs are specific for broad classes of infectious organisms, including bacterial lipopolysaccharides, peptidoglycans, bacterial DNA, and viral RNA. The PRRs can recognize specific pathogen-associated molecular patterns (PAMPs) found exclusively on bacteria, fungi, parasites, and viruses. They also recognize danger-associated molecular patterns (DAMPs), also known as *alarmins*, on stressed host cells in response to infection, trauma, ischemia, and tissue damage.^{6,7} The Toll-like receptor (TLR) was the first identified PRR, and there are approximately 10 different types of TLRs. The TLR-2 receptor can identify gram-positive bacteria and the TLR-4 receptor is responsible for recognition of gram-negative bacteria.^{2,8} When a ligand binds to a TLR, the cell responds with increased production and secretion of cytokines and phagocytosis of the pathogen. Other PRRs include the Nod-like receptor (NLR), the RIG-I-like receptor (RLR), the cytosolic DNA sensor, and the C-type lectin receptor (CLR).⁸

In addition to their role in phagocytosis and direct destruction of microbes, phagocytes are also antigen-presenting cells (APC) responsible for identifying and preparing a pathogen for presentation to cells of the adaptive immune system. Once the PRR receptor on the phagocyte binds an antigen, it processes it into short peptides and binds it with a “self” protein receptor called a *major histocompatibility complex* (MHC) molecule, found on the surface of the phagocyte.¹ Class I MHC proteins are essential for presenting viral antigens; they are found on nearly every cell type, with the exception of red blood cells (RBCs). Class II proteins are only found on B cells, DCs, monocytes, and macrophages (Fig. 46.3).¹ The T cells of the adaptive immune system can only recognize a “non-self” target, such as a pathogen, after it has been processed and presented in combination with an MHC molecule by an APC of the innate immune system; this allows the T cell to ignore free extracellular antigens and focus on antigen infected cells (Fig. 46.4). Cytotoxic or killer T (Tc) cells only recognize antigens coupled to class I MHC molecules, whereas helper T (Th) cells and regulatory T (Treg) cells only recognize antigens coupled to class II MHC molecules. In humans, MHC molecules are classified as human

leukocyte antigens (HLA). Class I MHC contains three genes, HLA-A, B, and C, and their proteins are expressed on most cells.^{1,4} The proteins of class II MHC genes, HLA-DR, DQ, and DP are expressed on APC macrophages, DCs and B cells. Over 40 different diseases are associated with certain class I or II HLA alleles, including ankylosing spondylitis and type I diabetes mellitus. Similarities in MHC proteins between family members allow donor and recipient matching that lowers the risk of transplant rejection, which occurs when the recipient's immune system attacks the donor tissue or organ.

FIGURE 46.3 Nearly all nucleated cells of the body are able to process and display antigen in association with major histocompatibility complex (MHC) class I protein. The antigens come from the intracellular compartment, and a common source of foreign antigen is viral infection. The viral proteins made within the cell's cytoplasm are processed into peptide fragments in the proteasome and then enter the endoplasmic reticulum (ER) through TAP transporters. There they combine with MHC class I proteins. The MHC class I–antigen complex then shuttles to the cell surface within a vesicle. When the vesicle combines with the plasma membrane, the MHC class I–antigen complex is displayed on the cell surface. CTL, Cytotoxic T lymphocyte; TAP, transporter associated with antigen processing. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:178; Redrawn from Abbas AK et al. *Cellular and Molecular Immunology*. 7th ed. Philadelphia: Elsevier; 2012:131.)

FIGURE 46.4 Only specialized cells are able to obtain extracellular antigen for processing and presentation in association with major histocompatibility complex (MHC) class II protein. These cells are primarily dendritic cells, macrophages, and B cells. The antigen is first engulfed into a vesicle called a *phagosome*, which fuses with a lysosome. Enzymes within the phagosome break the protein into pieces. MHC II molecules are synthesized on the endoplasmic reticulum (ER) and then transported to the phagosome in a vesicle. The binding cleft of the MHC II protein is completed with a blocking protein to prevent it from retrieving peptide before it reaches the phagosome. The phagosome and vesicle fuse, and the MHC II loses its blocking protein and picks up an antigen peptide. The complex then migrates to the cell surface and combines with the cell membrane. The MHC II–antigen complex is then displayed on the cell surface. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:180; Redrawn from Abbas AK et al. *Cellular and Molecular Immunology*. 7th ed. Philadelphia: Elsevier; 2012:130.)

Neutrophils

Neutrophils are the most numerous of the white blood cells (WBCs) and largely responsible for the elevated white cell count that occurs with infection (Table 46.2). They migrate rapidly to the site of bacterial infections, where they release cytotoxic cytokines and phagocytize and internally destroy microbes and particulate antigens through the production of reactive oxygen molecules that are cytotoxic to bacterial pathogens. Neutrophils have a half-life of only 6 hours and are sensitive to the acidic environment of infected tissues; dying neutrophils become part of the purulent exudate at

the site of infection.

TABLE 46.2

Normal Adult White Blood Cell Count (WBC)

Cell	Plasma Count	% of WBC
WBC	$4.00\text{--}11.0 \times 10^9/\text{L}$	
Neutrophils	$2.5\text{--}7.5 \times 10^9/\text{L}$	40%–60%
Lymphocytes	$2.5\text{--}7.5 \times 10^9/\text{L}$	20%–40%
Monocytes	$0.2\text{--}0.8 \times 10^9/\text{L}$	2%–8%
Eosinophils	$0.04\text{--}0.4 \times 10^9/\text{L}$	1%–4%
Basophils	$0.01\text{--}0.1 \times 10^9/\text{L}$	0.5%–1%

Monocytes and Macrophages

Monocytes are the largest blood cells (see [Table 46.2](#)). They circulate in the blood before entering tissues to become tissue-specific macrophages, including Langerhans cells in the epidermis, Kupffer cells in the liver, alveolar cells in the lungs, and microglia cells in the central nervous system (CNS).⁴ Macrophages are larger than monocytes and are more effective phagocytes. Monocytes and macrophages are mobilized shortly after the neutrophils and are responsible for phagocytic destruction of microbes and particulate antigens that have been marked by immunoglobulins (Ig) or complement proteins. They produce nitric oxide (NO) that destroys the microbe, and cytokines that activate the adaptive immune system. Their presence is persistent at sites of chronic infection and they also play a major role in systemic granulomatous disorders.

Basophils and Mast Cells

Basophils are the least common blood granulocyte (see [Table 46.2](#)). Their counterparts, the mast cells, reside in peripheral tissues, especially connective tissue close to blood vessels. Both cell types express cell surface high affinity receptors for immunoglobulin E (IgE) and are key initiators of immediate hypersensitivity reactions through the release of histamine, leukotrienes, cytokines, and prostaglandins; they also stimulate smooth muscle contraction. They play a major role in atopic allergies such as hay fever, asthma, and eczema. They also respond directly to bacterial pathogens.

Eosinophils

Eosinophils are heavily concentrated in the GI mucosa, where they are the primary defense against parasites, and also the mucosa of the respiratory and urinary tracts (see [Table 46.2](#)).^{2,4} Similar to neutrophils, they release cytokines capable of killing microbes. They also play a role in allergic reactions and asthma. Eosinophil lysosomes are responsible for degrading mast-cell inflammatory mediators and limiting the vascular effects of inflammation.²

Dendritic Cells

DCs are found throughout the body but are concentrated in secondary lymphoid tissue such as the spleen, lymph nodes, mucosa-associated lymphoid tissues, and tissues that have direct contact with the external environment, namely the skin and mucous membranes. DCs are the most potent APCs; they express class I and class II MHC molecules that bind peptide fragments of antigens and display them on the cell surface for recognition by the appropriate T cell.⁹ A second type of DC, the plasmacytoid DC (pDC), produces high levels of type I interferon (IFN) and is believed to play a role in antiviral host defense, as well as autoimmune disorders. Both myeloid stem cells and common lymphoid progenitor cells give rise to DCs and pDCs. After encountering a pathogen, the immature DC rapidly matures and migrates to the lymph tissue, where its MHC molecules present the pathogen peptide to the T-cell receptor (TCR) on the surface of Th and Tc cells. DCs are important for stimulating naive T cells that lack immunologic memory. The release of DC cytokines promotes B cell activation and differentiation, and contributes to B cell memory. The DCs are also capable of direct destruction of an antigen by phagocytosis (see [Table 46.1](#)).

Cytokines

Cytokines are small proteins with diverse functions that are secreted by immune cells, endothelial cell, neurons, glial cells, and other types of cells.⁴ They act as messengers in the immune system and modulate the response to pathogenic microbes, tumor cells,

and apoptotic cells.^{1,2} They include interleukins, IFNs, tumor necrosis factor (TNF), and chemokines. Interleukins are produced by lymphocytes and macrophages in response to microbes or products of inflammation. Over 30 different interleukins are involved in the activation or inhibition of the inflammatory response (see [Table 46.1](#)). The major proinflammatory interleukins are IL-1 and IL-6; antiinflammatory interleukins include IL-10 and transforming growth factor-beta (TGF- β).⁴ IFNs are low-molecular weight proteins necessary for destruction of viruses. They respond to viral RNA and viral PAMPs that are displayed by virally infected cells and “interfere” with or prevent viral replication. Macrophages produce type I IFNs which induce production of antiviral proteins in virally infected cells that cause viral resistance in the surrounding cells; this is the mechanism of action of therapeutic agents, such as IFN-alpha, in the treatment of melanoma. TNF- α is a proinflammatory cytokine, primarily secreted by macrophages in response to PAMP recognition by TLRs. Its primary role is regulation of proinflammatory effects, including induction of fever; it has also been implicated in tumor regression and septic shock. Chemokines are low-molecular weight peptides produced by multiple cell types in response to proinflammatory cytokines. Their primary role is stimulation of leukocyte chemotaxis.

Complement

The complement system is so named because it “complements” the role of immune cells in both the innate and adaptive immune system. Activated complement augments pathogen opsonization, a process where pathogens are targeted for destruction by phagocytes and antibodies. Its main function is to mark pathogens for permanent destruction and to recruit other immune cells to destroy the pathogens. It includes over 30 plasma and cell surface proteins, most of which are produced in the liver. Many of the proteins are proteinases and activation occurs in a cascade. The classic pathway for complement activation is initiated by an antigen-antibody complex that activates complement component 1 (C1). The alternative pathway is activated by microbial cell wall components, mannans, which neutralize inhibitors of spontaneous complement activation and directly activate component C3.¹ A

number of immunologically active components are generated upon activation. Components C3 and C3b are deposited on the surface of the microbe (opsonization) and enhance phagocytosis of the microbe by phagocytes with C3 surface receptors (Fig. 46.5). Components C3a, C4a, and C5a cause degranulation of mast cells and C5a attracts neutrophils to the area. Complement components C5b and C6–C9 perforate and destroy the cell membrane of the microbe.^{1,4,10}

FIGURE 46.5 Complement cascade. The cascade is activated by the first complement molecule, C1, which binds an antigen-antibody complex. This event begins a domino effect, with each of the remaining complement proteins performing its part in the attack sequence. The end result is a hole in the membrane of the offending cell and destruction of the cell. Activation of the complement cascade results in the formation of membrane attack complexes that insert in the cell membrane. These porelike structures allow sodium and water influx, which causes the cell to swell and rupture. (From Copstead LE, Banasik J.

Pathophysiology. 5th ed. St. Louis: Elsevier; 2013:169; Redrawn from Schindler LW. *Understanding the Immune System*. NIH Pub. No. 92-529, Bethesda; U.S. Department of Health and Human Services: 1991;11.)

Other Components of the Innate Immune System

Nucleotide-binding domain leucine-rich repeat proteins are found in the cytoplasm of immune cells; they recognize bacterial particles and signs of intracellular damage such as uric acid crystals. They initiate the inflammatory process through the activation of IL and recruit immune cells to the site to destroy the microbe and facilitate tissue repair. Dectin-1, collectins, pentraxins, and ficolins are also pattern-recognition proteins.¹ They are responsible for opsonization of the microbe for phagocytosis, activation of proinflammatory cytokines, and production of antimicrobial reactive oxygen free radicals. The pentraxins include C-reactive protein (CRP) and serum amyloid P-component (SAP). Binding of CRP to bacterial low-density lipoproteins and polysaccharides, and apoptotic host cells, activates the complement system and phagocytosis. Binding of SAP to microbial carbohydrates and amyloid fibrils activates complement; SAP is involved in autoimmunity and amyloidosis. The ficolins also bind microbial carbohydrates and activate the complement system.

Adaptive Immune System

The adaptive system is responsible for the proliferation of antibodies with specificity for different pathogens. Initially, it has a slower response than the innate system but develops immunological memory that allows it to respond more aggressively upon repeated exposure to the same pathogen ([Table 46.3](#)).

Adaptive immune system cells are derived from hematopoietic stem cells that differentiate into a common lymphoid progenitor. The common lymphoid progenitor further differentiates into four types of mature lymphocytes; B lymphocytes (B cells), T lymphocytes (T cells), natural killer cells (NK), and natural killer T (NKT) cells (see [Fig. 46.2](#)). Of the two major types of lymphocytes, B cells and T cells, 20% to 50% are circulating lymphocytes; the remainder reside in secondary lymph tissues, which includes lymph nodes, tonsils, spleen, Peyer's patches of the intestines,

appendix, and mucosa associated lymphoid tissue (Fig. 46.6). Lymphocytes constitute 20% to 40% of the body's WBCs; approximately 80% are T cells, 15% are B cells, and the remainder consist of undifferentiated cells (see Table 46.3). First time exposure to a pathogen requires a coordinated effort of both NKT and Th cells, as well as antibody secreting B cells. Both memory T and B cells are responsible for stimulating a stronger and more rapid immune response to subsequent encounters with the same antigen.

TABLE 46.3
Components of the Adaptive Immune System

Component	Receptor	Function
B Cells Surface markers: CD21, CD40	BCR	Antibody production (IgG, IgM, IgA, IgD, IgE). BCR is composed of a membrane-bound antibody that "tags" antigen for recognition by Th cells and destruction by complement and phagocytes.
T Cells		
Th1 Surface marker: CD4	TCR, binds Class II MHC proteins	Secrete cytokines, INF- γ and TNF- β that activates phagocytes and Tc, and induces B cells to make produce antibodies. Effective against intracellular pathogens. Associated with many autoimmune diseases, including multiple sclerosis and arthritis.
Th2 Surface marker: CD4	TCR, binds Class II MHC proteins	Secrete IL-4, IL-5, and IL-23 that stimulate isotype switching and production of IgE and IgG subsets antibodies by B cells. Effective against extracellular bacteria. Involved with allergic responses.
Th17 Surface marker: CD4	TCR, binds Class II MHC proteins	Secrete cytokines, IL-17 and IL-23 that recruit phagocytes and stimulate inflammatory response in tissues with direct contact with external environment. Involved in pathogenesis of inflammatory disorders, such as Crohn's disease.
Treg Surface markers: CD4, CD25	Distinct set of TCRs	Secrete cytokines, IL-10 and TGF- β . Modulate immune response by suppressing effector T cell proliferation in thymus and down-regulating Th cells to prevent excessive immune responses to self-antigens.
Tc Surface markers: CD8	TCR, binds Class I MHC proteins	Secrete INF- γ , TNF- α and cytotoxic substances that destroy infected cells: perforins damage cell membrane and granzymes cause intracellular destruction of the pathogen. Stimulate production of B-cell antibodies.
NK Surface markers: CD16, CD56	Lack TCR.	Secretion of cytokines INF- γ , TNF- α for destruction of virus-infected "self" cells, tumor cells and other abnormal cells that are missing MHC markers required for identification by other T cells and B cells.
NK T cells Surface markers: CD1d	Unique TCR- $\alpha\beta$ binds MHC I-like molecules	Recognizes lipid and glycolipid antigens presented by MHC I-like molecules; produce multiple cytokines, INF- γ , TNF- α , IL-4, IL-13, and MSF destroy bacterial and viral pathogens.

BCR, B-cell receptors; *CD*, cluster of differentiation; *IL*, interleukin; *INF*, interferon; *MHC*, major histocompatibility complex; *MSF*, macrophage-

stimulating-factor; *NK*, natural killer cells; *TCR*, T-cell receptor; *TNF*, tumor necrosis factor.

FIGURE 46.6 Cells of the mononuclear phagocyte system. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:159; redrawn from Schindler LW. *Understanding the Immune System*. NIH Pub. No. 92-529, Bethesda, MD; U.S. Department of Health and Human Services: 1991;19.)

B Cells

The major function of B cells is the production of antibodies, specialized glycoproteins that recognize and bind to foreign proteins of bacteria, viruses, and tumor cells (Table 46.4). Antibodies are large, Y-shaped protein composed of two identical light chains and two identical heavy chains held together by

disulfide bonds.^{3,4} The N terminal or variable region (Fab) of each chain binds the antigen and is different for each class of immunoglobulin. The C terminal, or constant region (Fc), is composed of a relatively constant amino acid sequence that binds to Fc receptors on phagocytes (Fig. 46.7). The amino acid sequence of the Fc codes for five classes of Ig (G, M, A E and D), as well as the subclasses of G and A (see Table 46.4). The five Ig classes are distinguished by their heavy chains. The IgG molecule has gamma (γ)-chains; IgM has mu (μ)chains; IgA has alpha (α) chains; IgE has epsilon (ϵ) chains; and IgD has delta (δ) chains.³ The IgG and IgA antibodies are produced close to mucosal membranes and end up in secretions such as tears, saliva, and mucous, where they protect against GI and respiratory tract infections. The IgM antibodies are formed in response to infection; IgD is coexpressed with IgM on the surface of mature B cells and functions as a transmembrane antigen receptor. Allergic reactions are associated with IgE antibodies.

TABLE 46.4

Properties of Immunoglobulins

Class	Heavy Chain	Subclass	Structure	Percent Total IG	Molecular Weight (kDa)	Plasma levels mg/dL (Adult)	Half-Life (Days)	Placenta/Milk Transfer
IgG	gamma (γ)	IgG1, IgG2, IgG3, IgG4	Monomer	70%	150	760–1590	23	+/+
IgM	mu (μ)		Pentamer	10%	900	37–286	5	-/-
IgA	alpha (α)	IgA1, IgA2	Dimer	20%	160	61–356	6–8	-/+
IgD	delta (δ)		Monomer	0.2%	180	0.3–3	2–8	-/-
IgE	epsilon (ϵ)		Monomer	0.002%	190	0.002–0.2	1–5	-/-

FIGURE 46.7 Structure of immunoglobulin E. (From Parija SC. *Textbook of Microbiology and Immunology*. 3rd ed. Gurgaon, India: Elsevier India; 2016:91.)

The IgG and IgD antibodies are anchored in the B-cell membrane where they function as B-cell receptors (BCRs) that are able to recognize a small region of the pathogen, called the *antigenic epitope*, that is bound to a MHC molecule on an APC, such as a DC. The BCR can recognize and differentiate between the self MHC molecule and short peptide strands of the antigen. When an antibody binds with a MHC-antigen receptor complex, it activates other immune cells to destroy the pathogen. Clonal selection is initiated when a B cell has a receptor that can bind the invading antigen, resulting in a rapid increase in the number of plasma B cells with a high affinity and specificity for the antigen (plasma cells). Most immune responses are polyclonal because antigens can present with several different epitopes.³ Multiple antibodies for a single antigen make it difficult for a pathogen to escape recognition and the coating of an antigen with multiple antibodies also makes it easier for other immune cells to recognize and kill it. A number of activated B cells become memory cells. Naïve B cells express IgM and IgD as BCRs; as they mature under the influence of Th cells, they undergo isotope switching to IgA, IgE, and subsets of IgG (Fig. 46.8).¹ At the same time, they undergo somatic mutations of the antigenic-binding portions of the heavy and light chains; the B cell will die if the mutation results in a loss of affinity for the antigen. If the mutations increase affinity, the cell continues to proliferate. Memory responses are characterized by production of specific IgG, IgA, or IgE antibodies, which allow the B cell to respond more

quickly and aggressively upon repeated exposure to the same pathogen.

FIGURE 46.8 Activated B cells undergo class switching from IgM to IgG, IgE, or IgA. Class switching is influenced by the presence of specific cytokines. *IFN*, Interferon; *IL*, interleukin; *TGF*, transforming growth factor. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:187; redrawn from Abbas AK et al. *Cellular and Molecular Immunology*. 7th ed. Philadelphia: Elsevier; 2012:257.)

There are two types of B cells. The B1 cells produce IgM antibodies; although the IgM antibody can recognize several different antigens, it tends to have a low affinity for them. Most B cells are B2 cells and express both IgM and IgD antibodies. By the time the B2 cells have become memory cells, they have undergone class switching and produce IgG, IgA, or IgE antibodies (see Fig. 46.8). Plasma immunoglobulins are composed of 70% IgG, 20% IgA, 10% IgM, and small amounts of IgD and IgE (see Table 46.4). When an antigen is encountered for the first time, only B cells with a BCR that can identify the antigen are stimulated to differentiate and proliferate (clonal selection) into plasma cells. During initial exposure to the antigen, there is a lag time of 5 to 7 days between

recognition of the antigen and maturation and proliferation of B plasma cells and memory cells. In the initial response to the antigen, IgM is produced first, followed by IgG; antibody levels fall as the antigen is destroyed. A second exposure to the antigen produces a rapid response with IgG as the predominant antibody (Fig. 46.9).³

FIGURE 46.9 Time phases in the immune response. The primary response takes much longer to develop and declines rapidly. On second exposure, a much quicker and greater antibody response is achieved. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:188.)

T Cells

T cells originate in the bone marrow; they mature and differentiate in the thymus before migrating to the secondary lymphoid organs. Despite the partial degeneration of the thymus at puberty, T-cell development in the thymus continues throughout life. Most T cells die in the thymus (apoptosis) because of failure to interact effectively with MHC molecules or because they react against self-components of host cells.³ T cells that can recognize foreign antigens mature and migrate to lymphoid tissue. Two distinct types of T cells are produced in the thymus: T helper cells (Th) and T killer or cytotoxic (Tc) cells (Fig. 46.10). Naïve T helper cells (Th₀)

continuously circulate in the blood and lymphoid tissues. They expand clonally and differentiate into several subsets after exposure to an antigen. Some T cells become memory T cells that have a quicker response the second time they encounter the antigen.

FIGURE 46.10 Two major classes of T lymphocytes can be differentiated by CD markers on the cell surface. T helper cells have CD4 markers, whereas cytotoxic T cells have CD8 markers. CD4 cells can be further differentiated into TH1, TH2 and TH17, which secrete different cytokines. CD8 cells are cytotoxic T cells. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:167.)

Mature T cells have transmembrane TCRs that can bind short antigenic epitopes bound to MHC molecules on APCs. Similar to the BCR on the B cells, the TCR can recognize and differentiate between self MHC and the antigenic epitope. The majority of T subsets are defined by their selective surface expression of the CD4 or CD8 protein (CD refers to cell membrane proteins that are clustered into different groups); these coreceptors are necessary for antigen recognition and T cell activation. Immature T cells express both CD4 and CD8 proteins and can recognize antigen-derived peptides presented by either MHC class I or class II molecules (see [Fig. 46.10](#)). As they mature in the thymus, they differentiate into CD4 and CD8 T cells that can recognize only MHC class II or class I

proteins respectfully.^{1,3} The CD4 Th cells can recognize antigens presented by MHC class II molecules and are responsible for activating both humoral immune responses (B-cell antibodies) and cellular responses (delayed-type hypersensitivity reactions). The Th cells lack cytotoxic activity and do not kill pathogens or infected cells. A small number of Th become T memory cells that induce secondary cell-mediated immune responses. There are four major Th subsets, Th₁, Th₂, Th₁₇, and Treg; differences in their production of cytokines, surface receptors, and internal adhesion molecules account for the different functions of the Th subsets.³ The Th₁ cells secrete cytokines that activate the phagocytes and Tc. The Th₂ cells stimulate the secretion of antibodies by B cells (Fig. 46.11). The Th1 and Th2 cells display reciprocal inhibition and Th1/Th2 ratio is dependent upon the nature of the immune response. The Th₁₇ cytokines stimulate the inflammatory response. The Treg cells down-modulate the immune response, including suppression of effector T cell proliferation in the thymus and down-regulation of Th cells when they are no longer needed, to prevent excessive T cell activation and possible development of autoimmune disease. Destruction of helper CD4T cells is seen with infection by the human papilloma virus (HPV). A loss of functional CD4 T cells leads to the symptomatic stage of human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS).

FIGURE 46.11 Activation of a B cell requires T helper cell “help.” This help is given through a number of cell-to-cell

interactions via receptors, as well as through the secretion of cytokines that stimulate B-cell growth and differentiation.

(From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:185.)

The Tc cells display CD8 proteins and can bind to antigens on MHC class I molecules (see [Fig. 46.10](#)). All nucleated cells have MHC class I molecules and can directly establish contact with CD8 Tc. The CD8 Tc can recognize and demonstrate direct cytotoxic activity toward virally infected cells, tumor cells, and transplanted organs. The Tc can destroy the abnormal cell in one of two ways: secretion of perforins and enzymes that penetrate the membrane and cause destruction of intracellular proteins, or secretion of a surface molecule that interacts with a surface protein on the target cell to induce apoptosis.³ They can also down-regulate immune response (suppressor cells).

Natural Killer Cells

The NK cell is a large granular lymphocyte that lacks both a TCR and surface immunoglobulin and does not directly attack pathogens. The NK cells are activated when they do not see a normal self MHC on a virus-infected or tumor cell; they release perforin that damages the cell membrane and cytotoxic enzymes that enter the cell and destroy it. They can also recognize and destroy self-cells that have down-regulated MHC class I molecular expression, which is a strategy that infected cells use to avoid detection by T cells. The NK and Tc cells complement each other. The Tc cells kill abnormal cells that express MHC class I proteins; the NK cells kill abnormal cells that have suppressed expression of Class I MHC proteins. The NK cells also release cytokines that modulate the activity of other immune cells. Their cytotoxic activity is inhibited by self-MHC molecules through inhibitory surface receptors that can recognize class I MHC molecules on healthy cells.

Natural Killer T Cells

The NKT cells are a specialized population of T cells with properties of both T cells and NK cells. They express both a unique TCR alpha beta receptor (TCR $\alpha\beta$) that recognizes molecules

presented by MHC I-like proteins and surface antigens typically associated with NK cells. The TCR $\alpha\beta$ receptor recognizes lipid and glycolipid antigens presented by the MHC I-like molecule rather than protein peptides presented by MHC I or II molecules. Activated NKT cells rapidly produce multiple cytokines, including IFN, macrophage stimulating factor, IL, chemokines, and TNP, that can destroy bacterial and viral pathogens. In the case of tumors, they can either contribute to immune surveillance or immunosuppression; likewise, they can either inhibit or promote the development of autoimmune diseases such as diabetes mellitus type I.

Active and Passive Immunity

The immune response to an antigen is a result of clonal expansion of B and T cells upon initial exposure to an antigen, followed by a more rapid and vigorous response upon subsequent exposure to the antigen (see Fig. 46.9). Long-term immunity is acquired when B and T memory cells are activated in response to a pathogen. As with prior antigen exposure, vaccinations or immunizations affect the adaptive immune system by establishing long-term immunologic memory.

Active Immunity

Active immunity is achieved when a pathogen is deliberately administered to an individual for the sole purpose of stimulating the immune system to produce antibodies specific for the antigen. Upon repeat exposure to the antigen, the adaptive immune system is able to provide a quicker and more efficient response. Vaccines are composed of live attenuated or inactivated/killed viruses, inactivated bacterial toxins, bacterial toxins, or segments of the pathogen (subunit and conjugate).^{11,12} Live, attenuated vaccines typically provide long lasting immunity, but there are concerns for potential mutation or reversion of the vaccine virus to an active form capable of causing disease; consequently the live oral polio vaccine has been replaced by the inactivated vaccine.

Inactivated/killed vaccines provide a shorter length of protection than live vaccines, and require booster vaccinations for long-term immunity. Toxoid vaccines are composed of inactivated bacterial toxin and are used for bacterial diseases, such as tetanus, that are caused by a toxin produced by the bacterium and not the bacterium itself. Recombinant vaccines are subunit vaccines that contain sections of a pathogen that the immune system can recognize as a foreign antigen.¹³ The hepatitis B (HBV) and the HPV are examples of recombinant subunit vaccines, produced by the insertion of a segment of virus gene into a yeast cell; the modified yeast cell produces HBV or HPV surface antigens that stimulate an active immune response in the recipient. Conjugate vaccines use a

combination of a bacterial membrane protein that does not generate a strong immune response on its own and a carrier protein that elicits a strong immune response resulting in active immunity against future infections with the bacteria. The *Haemophilus influenzae* type B (Hib) vaccine is a conjugate vaccine. The Centers for Disease Control and Prevention (CDC) have published immunization guidelines for children and adults (Table 46.5).¹⁴

TABLE 46.5
Centers for Disease Control and Prevention (CDC)
Immunization Guidelines

Vaccine Type	Recommended Childhood (Ages 0–6) Immunization Schedule
Live, attenuated	Measles, mumps, rubella (MMR combined vaccine) Varicella (chickenpox) Influenza (nasal spray) Rotavirus
Inactivated/Killed	Polio (IPV) Hepatitis A
Toxoid (inactivated toxin)	Diphtheria, tetanus (part of DTaP combined immunization)
Subunit/conjugate	Hepatitis B Influenza (injection) <i>Haemophilus influenzae</i> type b (Hib) Pertussis (part of DTaP combined immunization) Pneumococcal Meningococcal
Other Available Vaccines	
Live, attenuated	Zoster (shingles) Yellow fever
Inactivated/Killed	Rabies
Subunit/conjugate	Human papillomavirus (HPV)

From Immunization Schedules. Centers for Disease Control and Prevention. <http://www.cdc.gov/vaccines/schedules/index.html> Updated: February 1, 2016. Accessed 2016.

Passive Immunity

Passive immunity occurs when a person receives another individual's antibodies to help prevent or fight certain infectious diseases. The protection offered by passive immunization is immediate but short-lived, usually lasting only a few weeks or months. During pregnancy, the fetus benefits from natural passive immunity provided by the mother's antibodies, specifically IgG, which has the same antigen specificity as the mother (Fig. 46.12).¹⁵ After birth, neonatal IgG antibodies decline over time and

protection fades by six months of age; the maternal IgG can suppress vaccine-induced immune responses in the infant during the first six months of life. In contrast, maternal IgA antibodies are continuously supplied through breast milk; they enter the GI tract of the newborn and do not affect the immune response of the newborn to vaccination.¹⁵ Passive immunization is also used to temporarily boost a patient's immune system through the administration of immune globulins (IG) prepared from the pooled plasma of several thousand donors. Treatment with IG can be used for patients infected with diphtheria or the cytomegalovirus. It can also be used as a preventive measure in high-risk individuals with immune system deficiencies following exposure to the respiratory syncytial virus, measles, tetanus, hepatitis A, HBV, rabies, or chickenpox. Males with X-linked agammaglobulinemia who are unable to manufacture antibodies also benefit from IG administration. In special cases, the IG preparation may be harvested from individual donors who recently had a specific disease, such as rabies or tetanus. Similarly, patients exposed to TPA anthrax, a disease caused by the bacterium *Bacillus anthracis*, may receive IG from military personnel previously actively immunized with the anthrax vaccine. Other examples of passive immunity include administration of Rh immune globulin or RhoGAM, to Rh-negative mothers to prevent their immune system from developing antibodies to a fetal Rh antigen. As with natural, passive immunity, IG conferred immunity is short-lived and does not promote development of long-lasting memory cells in the adaptive immune system. Passive and active immunity may be used together; for example, an individual bitten by a rabid animal may receive IG rabies antibodies for an immediate response and rabies vaccine to elicit a long-lasting immune response.

FIGURE 46.12 Antibody levels in umbilical cord blood and in neonatal circulation. Early in gestation maternal IgG begins crossing the placenta and enters the fetal circulation. At birth, the fetal circulation may contain nearly adult levels of IgG, which is almost exclusively from the maternal source. The fetal immune system has the capacity to produce IgM and small amounts of IgA before birth (not shown). After delivery, maternal IgG is rapidly catabolized and neonatal IgG production increases. (From McCance K, et al. *Pathophysiology: The biologic basis for disease in adults and children*. 7th ed. St. Louis: Elsevier; 2014:257.)

Monoclonal Antibodies

Monoclonal antibodies (MABs) are laboratory engineered molecules that mimic natural antibodies. They attach to abnormal cells and mark them for identification and destruction by the immune system (immunotherapy); the surrounding healthy cells are unaffected by the MAB. A number of MAB drugs are currently used to treat different types of cancer (Fig. 46.13).¹⁶ Rituximab (Rituxan) attaches to a specific protein (CD20) found only on B cells; it can mark lymphomas arising from these cells and make them visible for destruction by the immune system. Cetuximab (Erbix) attaches to the receptor for epidermal growth factor (EGF) on cancer cells and slows or prevents the progression of certain cancers. Bevacizumab (Avastin) targets a vascular endothelial

growth factor (VEGF) that cancer cells secrete to develop new blood vessels. Ado-trastuzumab emtansine (Kadcyla), an MAB combined with a chemotherapeutic drug, is used to treat human epidermal growth factor receptor 2 (HER2) positive breast cancers. Radioimmunotherapy combines an MAB with a radioactive isotope, for example Ibritumomab (Zevalin), which attaches to cancer cell receptors and destroys the cancer cell through radiation. Originally developed for the treatment of cancers and to prevent rejection of transplanted organs, MABs are also used in the treatment of autoimmune diseases; Adalimumab (Humira) and Etanercept (Enbrel) interfere with TNF and are used in the treatment of rheumatoid arthritis (RA) and Crohn's disease. Although MABs exert selective immunomodulation by targeting specific cells expressing a specific antigen, they are associated with a widespread perturbation of the immune system and a possible increased risk of infections and cancer progression.

FIGURE 46.13 Cancer cells express abnormal antigens (tumor-associated antigens) on their cell surface that can activate immune cells or be used as targets for monoclonal antibodies. Numerous medications are now available that use monoclonal antibodies to target cellular proteins relevant to several different types of cancer. *BCR*, B-cell

receptors; *EGFR*, epidermal growth factor receptor; *HER2*, human epidermal growth factor receptor 2; *VEGF*, vascular endothelial growth factor. (From Copstead LE, Banasik J. *Pathophysiology*. 5th ed. St. Louis: Elsevier; 2013:137.)

Hypersensitivity

A hypersensitivity reaction or intolerance refers to an immune system response to a foreign, environmental antigen that causes an altered T cell and antibody response upon reexposure to the antigen. It requires prior sensitization to the antigen; it can be immediate or delayed and is dependent upon the time between the antigen exposure and the onset of symptoms. Common antigens include environmental allergens such as grass, pollen, and animal dander; topical allergens such as latex; food allergens such as gluten; and medications. The reaction may be physically uncomfortable, damaging to organ function, or fatal to the individual. The traditional I-IV classification system of Gell and Coombs divides hypersensitivity reactions into four types based on the mechanisms involved and time required for the reaction. However, a fifth class, stimulatory hypersensitivity, involving autoantibodies is now recognized. In addition, some conditions or diseases may involve more than one type of hypersensitivity reaction. The immune mechanism may be the primary cause of the tissue damage or may be secondary to the disease process.

Type I Hypersensitivity

A type I hypersensitivity reaction, also known as an *immediate hypersensitivity*, occurs within 15 to 30 minutes of exposure to the antigen. Following initial exposure, T cells stimulate the B cells to produce antigen specific IgE antibodies that bind to IgE receptors on mast cells and basophils. Upon a second exposure to the antigen, cross linking of two IgE receptors on the mast cells and basophils by the antigen increases calcium (Ca^{++}) influx. The increased intracellular Ca^{++} is responsible for degranulation of the cells and release of preformed mediators, including histamine, heparin, proteolytic enzymes, and chemotactic factors.¹⁷ Degranulation also increases the production of other mediators responsible for modulating the inflammatory response, including bradykinins, leukotrienes, interleukins, slow-reacting substance of anaphylaxis, serotonin, prostaglandins, and thromboxanes. Histamine is the

most important mediator of type I reactions. Binding of histamine to H₁ receptors triggers bronchoconstriction, increased vascular permeability, vasodilation, urticaria, pruritus, increased gut permeability, and increased mucous production. Binding of the H₂ receptors increases gastric acid secretion and decreases histamine release from mast cells and basophils. Histamine also activates other cells of the immune system, including complement via the alternate pathway. Immediate hypersensitivity reactions that are IgE mediated require prior exposure to the offending agent. In the United States, the most common causes of adult anaphylaxis are drugs, food, and insect stings.¹⁸ Non-IgE mediated Type I reactions, previously called *anaphylactoid reactions*, can occur upon first exposure to an antigen and are a result of direct degranulation of mast cells and basophils and complement activation. Manifestations of a type I reaction vary in onset, severity, and intensity; they are graded I–V depending upon their presenting signs and symptoms, which can range from mild cutaneous or GI manifestations to cardiovascular collapse and death (Table 46.6).^{19,20} A severe allergic reaction can result in anaphylaxis characterized by angioedema, systemic vasodilation, hypotension, extravasation of protein and fluid, bronchospasm, and dysrhythmias. Clinical manifestations of anaphylaxis occur within minutes of exposure to the precipitating antigen, especially in sensitive individuals.

TABLE 46.6

Hypersensitivity Reactions

Type	Mediator	Antigen	Mechanism	Conditions
I Immediate, (Anaphylactic)	IgE, mast cells, basophils	Exogenous	IgE binding to mast cells and basophils releases reactive substances	Drug allergy, hay fever, asthma
II Cytotoxic)	IgG, IgM, compliment	Cell surface or tissue antigen	Antigen-antibody complex activates complement and destroys target cell	Erythroblastosis fetalis, blood transfusion, acute transplant rejection, myasthenia gravis
III Immune Complex	IgG, IgM, neutrophils, Compliment	Soluble	Antigen-antibody complex deposited in tissue stimulates inflammation	Systemic lupus erythematosus (SLE), Rheumatoid arthritis (RA).
IV Delayed	T cells, monocytes macrophages, cytokines	Tissues	Antigen activates Tc that kills target tissue.	Poison ivy, transplant rejections
V Stimulatory	Humoral	Cell	Antibody binding mimics	Graves' disease

	antibodies	surface receptor	receptor-ligand interaction	
--	------------	------------------	-----------------------------	--

Treatment of type I reactions includes antihistamines to prevent systemic effects of histamine; cromolyn sodium to inhibit mast cell degranulation, and bronchodilators for treatment of bronchospasm including β 2-adrenergic receptor agonists (Albuterol), leukotriene receptor blockers (Singulair, Accolate) and inhibitors of the cyclooxygenase pathway (Zileuton). In addition, IgG antibodies against the Fc portions of IgE that binds to mast cells can block mast cell sensitization and is used in treatment of certain allergies. Hypersensitization (immunotherapy or desensitization), requiring injections of small amounts of the allergen over a period of months to years, may be used to treat allergies to insect venoms and pollens.²¹ Diagnostic tests for type I reactions include skin (prick and intradermal) tests with suspected allergens and immunoassays that measure plasma total IgE and specific IgE antibodies. Increased IgE response to skin tests or elevated IgE levels is indicative of an atopic condition; however, IgE can be elevated in nonatopic diseases such as myelomas and helminthic (parasitic) infections. Tryptase is released from mast cells, and is significantly elevated during an allergic response in approximately 70% of individuals.²⁰

Intraoperative Anaphylaxis

The anesthetized patient is exposed to multiple agents with the potential for producing a potentially fatal anaphylactic or anaphylactoid reaction, including anesthetics, antibiotics, antiseptics, and blood products. The estimated incidence of a hypersensitivity reaction in anesthetized patients is one in 3500 to 20,000 depending upon the reporting country, with a mortality rate of 3% to 10%.^{17,22,23} Approximately 60% to 70% of anesthesia related reactions are IgE mediated type I reactions.^{24,25} Neuromuscular blocking agents (NMBA) are the most frequently incriminated drugs, accounting for 50% to 70% of the reactions. In decreasing order of occurrence, the incidence of type I reactions is highest with succinylcholine, vecuronium, atracurium, pancuronium, mivacurium, and cisatracurium.²⁶ However, when one considers the current use of muscle relaxants, succinylcholine and rocuronium account for the highest incidence of type I reactions,

followed by vecuronium and pancuronium; atracurium, mivacurium and cisatracurium have the lowest incidence of type I reactions.^{26–28} The quaternary ammonium structure of NMBA is believed to be the cause of the reaction.¹⁷ The majority of NMBA reactions occur upon first exposure, a result from a cross reaction with common chemicals that include the same quaternary ammonium group, including shampoos, detergents and toothpaste, and food preservatives such as metabisulfites. Cross reactions are also noted between iodinated contrast agents, NMBAs, penicillin and first-generation cephalosporins.²⁹ Females are three times more likely to be affected by a type I reaction; however there is no sex difference in adolescence, suggesting a role for sex hormones in the increased incidence observed in adult females.²⁵ The use of sugammadex has been proposed as a possible treatment of rocuronium-induced anaphylaxis. However, systemic review of the literature revealed 15 cases of hypersensitivity that were identified within 4 minutes of sugammadex administration; 73% of the cases met World Anaphylaxis Organization (WAO) criteria for anaphylaxis. In addition, sugammadex-induced anaphylaxis has been confirmed by skin testing.^{30–32} The second and third leading causes of anaphylaxis in the operating room (OR) are antibiotics and latex, respectively.^{22,23,26} Less commonly implicated agents in type I reactions include opioids, hypnotics, and colloids.³³ Paralleling their increased use in the general population, the occurrence of type I reactions to nonsteroidal antiinflammatory drugs (NSAIDs) is increasing.²⁶ Allergic reactions to local anesthetics are uncommon and in general, reactions appear to be due to high plasma concentrations secondary to inadvertent intravascular injection of the drug rather a hypersensitivity reaction.^{33–36}

In the anesthetized patient covered by surgical drapes, the cutaneous signs of a type I reaction frequently go unrecognized. Type I drug reactions occur within minutes of intravenous (IV) drug administration, frequently occurring at time of induction; skin or mucosal reactions to chlorhexidine occur in 15 to 30 minutes, and reactions to latex can take 30 to 60 minutes.³³ The primary presenting symptoms of anaphylaxis in anesthetized patients include hypotension, tachycardia, and bronchospasm followed quickly by hypovolemia, shock, and hypoxemia; left untreated it

rapidly progresses to pulseless electrical activity (PEA) and cardiac arrest. Epinephrine is the definitive treatment (Box 46.1).³⁷ Its vasoconstrictor alpha 1 (α_1) stimulatory effects support the blood pressure; beta 1 (β_1) stimulation increases the inotropic and chronotropic response of the myocardium, and β_2 stimulation causes bronchodilation. Rapid administration of IV fluids is necessary to counteract the loss of intravascular volume into extravascular space, a consequence of altered vascular permeability. Arginine vasopressin is indicated for hypotension that is unresponsive to epinephrine; it decreases NO production via the nonadrenergic vasopressin-1 receptor. Similarly, methylene blue, a selective inhibitor of guanylate cyclase, prevents NO mediated vascular smooth muscle relaxation.^{38,39} Glucagon directly activates adenylyl cyclase and is indicated for continuing hypotension and bronchospasm in patients on β -blockers. Second-line treatment includes antihistamines, H₁ antagonists (diphenhydramine and hydroxyzine), and H₂ antagonists (ranitidine). Bronchodilators, β_2 -agonists, albuterol, terbutaline, and anticholinergic ipratropium bromide are used to treat bronchospasm. Corticosteroids may be indicated for airway edema. Elevated plasma total tryptase and β -tryptase levels confirm the degranulation of mast cells and basophils; because of a short half-life of tryptase, the blood sample must be obtained within 120 minutes. Tryptase levels are not affected by the emergency drugs administered during resuscitation.⁴⁰ Postoperatively, patients should be provided with a detailed explanation of the allergic reaction and referred for skin testing for potential allergens.⁴¹ However, skin prick testing will only identify an IgE-mediated hypersensitivity and a negative skin test does not necessarily exclude a drug as a non-IgE-mediated allergen trigger.²⁰

Treatment of Intraoperative Anaphylaxis in the Adult Patient

Assessment

Grade 1: Cutaneous signs: generalized erythema, urticaria, angioedema.

Grade II: Cutaneous signs, hypotension, tachycardia, cough, difficult ventilation.

Grade III: Hypotension, tachycardia or bradycardia, arrhythmias, bronchospasm.

Grade IV: Cardiac and/or respiratory arrest, pulseless electrical activity (PEA).

Initial Treatment

Discontinue triggering agent

Trendelenburg position

Ventilation with 100%

Epinephrine

Grade II: 10–20 mcg SC/IM

Grade III: 100–200 mcg SC/IM/IV q 1–2 mins; 1–4 mcg/min

Grade IV: 1 mg IV repeat as needed: 0.05–0.1 mcg/min

Fluids

Normal Saline/Lactated Ringers: 10–30 mL/kg or Colloid: 10 mL/kg

Secondary Treatment

Epinephrine unresponsiveness: Vasopressin: 2–10 units IV;

Norepinephrine: 0.05–0.1 mg/kg per min *Bronchospasm:* Albuterol or Ipratropium inhalants, Terbutaline 0.25 mg sc. (may be repeated in 15–30 minutes),

Preoperative Beta blockade: Glucagon 1–5 mg IV every 5 minutes; 5–15- mcg/min

Antihistamines: Diphenhydramine or Hydroxyzine: 0.5–1.0 mg/kg

IV and Ranitidine: 50 mg IV

Airway edema: Hydrocortisone: 250 mg IV

Post Resuscitation

Serum Tryptase < 120 minutes

24-hour monitoring for recurrence

Patient/family notification of reaction

Referral to allergist

Type II Hypersensitivity

Type II hypersensitivity, also known as *cytotoxic hypersensitivity*, is primarily mediated by IgM or IgG antibodies and the complement system, with secondary activation of macrophages, in response to endogenous antigens on host cells. In addition, exogenous antigens, including drugs, may bind to the membranes of specific cells and cause a type II reaction. The antibody–cell complex is recognized by APCs of the innate immune system, which activate the B cells to produce antibodies against the cells containing the antigen, such as circulating RBCs and basement membrane of certain tissues (see [Table 46.6](#)). The reaction time can take minutes to hours. Examples of type II reactions include type I diabetes mellitus, myasthenia gravis, drug-induced hemolytic anemia, granulocytopenia, thrombocytopenia, transfusion reactions, and Goodpasture's nephritis. Diagnostic tests include positive antibody titers against the involved tissues and presence of antibody and complement in the lesion (biopsy). Treatment includes antiinflammatory and immunosuppressive agents.

Type III Hypersensitivity

Type III hypersensitivity, also known as *immune complex hypersensitivity*, is a result of failure of the immune system to effectively rid the body of antibody-antigen complexes. It is also mediated by IgG and IgM antibodies but the antigen is soluble and

not tissue fixed; it may be exogenous (bacteria, virus, or parasite) or endogenous (see [Table 46.6](#)). The antibody-antigen complexes are deposited in joints and various tissues, including the kidneys, skin, and eyes, where they activate complement (C3a, 4a, and 5a) and stimulate the release of inflammatory mediators; the inflammatory response is directed toward the antibody-antigen complex and is not tissue specific. Type III reactions can take hours to weeks to develop. Examples include serum sickness, systemic lupus erythematosus (SLE), and RA. Confirmatory diagnosis includes tissue biopsies of immunoglobulin complexes, macrophages, and complement; depletion in complement level is also diagnostic. Treatment includes antiinflammatory and possible immunosuppressant agents.

Type IV Hypersensitivity

Type IV hypersensitivity, also known as *cell mediated* or *delayed type hypersensitivity*, is characterized by a delayed cellular response to an antigen taking anywhere from 24 hours to 14 days. Unlike the other types, it does not involve antibodies; the primary mediators are T lymphocytes and monocytes and macrophages (see [Table 46.6](#)). The Th cells secrete cytokines which activate Tc and recruit and activate monocytes and macrophages. Localized mast cell degranulation occurs prior to the local invasion of the monocytes and macrophages. Examples of type IV reactions include contact hypersensitivity (poison ivy) and granulomatous sensitivity (tuberculosis and leprosy). Treatment of type IV reactions is symptomatic. The Mantoux or purified protein derivative (PPD) reaction is a classic example of a type IV reaction that is used as a diagnostic test for exposure to the tuberculin bacilli (TB). Greater than a 10-mm induration in 48 to 72 hours following an intradermal injection of 0.1 mL PPD is confirmatory of TB exposure. However, there may be a false negative result (anergy) in individuals with low T cells, especially CD4, including the elderly and individuals with HIV infections. Skin patch testing is used for diagnosis of contact dermatitis.⁴¹ Antiinflammatory and immunosuppressive agents are used for treatment of type IV reactions.

Type V Hypersensitivity

Although less understood, type V hypersensitivity is a result of autoantibodies that bind and stimulate specific cell targets (see [Table 46.6](#)). Graves' disease is a type V reaction. It is caused by antibodies that stimulate the thyroid-stimulating hormone (TSH) receptor on the thyroid gland, leading to excessive secretion of the thyroid hormones.

Alloimmunity

Alloimmunity, or isoimmunity, is the response of the immune system towards the tissues of other members of the same species. It includes transient neonatal disease, transfusion reactions, and transplanted graft failure. Rejection of solid organ transplantations is due to an immune response directed at MHC antigens on the allogeneic organ.

Transient Neonatal Disease

Transient neonatal disease is a maternal response toward fetal antigens. Fetal antigens (inherited from the father) cross the placenta and stimulate antibody production in the mother; the antibodies cross the placenta and produce alloimmune disease in the fetus. Because the mother lacks the antigens, she will have no symptoms of the disorder. Secondary neonatal alloimmune disease occurs when the mother has preexisting IgG autoantibodies that produce an autoimmune disease in both the mother and fetus.⁴²

Transfusion Reactions

Transfusion reactions occur in response to surface antigens on donor RBCs. There are over 80 different RBC antigens, but the strongest humoral alloimmune response is to the A, B and Rh antigens. The A and B antibodies, isohemagglutinins, are IgG antibodies. The A and B antigens are codominant and may be expressed simultaneously; consequently, individuals can have one of four blood types: A, B, AB or O, which lacks both the A and B antigen. Considered universal recipients, type AB individuals can receive A, B, AB and O blood because they lack both anti-A and anti-B antibodies. In contrast, type O recipients can only accept type O blood; they are considered universal donors because they lack both A and B antigens. The Rhesus (Rh) blood group includes over 50 different antigens on RBCs; five antigens (D, C, c, E, and e) are the most important. The Rh factor refers to the D antigen, and the RhD antigen determines if the individual is Rh positive (Rh⁺) or negative (Rh⁻). Approximately 15% of North Americans are Rh⁻.⁴²

During pregnancy, a Rh⁻ female develops IgG anti-RhD alloantibodies in response to fetal Rh⁺ RBCs. The antibodies cross the placenta and cause hemolysis in the fetus. Administration of anti-D antibody immunoglobulin shortly after maternal exposure to fetal Rh⁺ blood prevents sensitization of the Rh⁻ mother.

Transplant Rejection

Transplant rejection is a response to antigens, primarily HLA antigens, on the donor organ. Hyperacute rejection occurs immediately following transplantation and is due to preexisting antibodies in the recipient from a prior graft or blood transfusion of platelets and leukocytes that contained HLA antigens. It can be avoided by preoperative screening for antigraft antibodies. Acute rejection is a cell mediated immune response that can occur weeks to months after transplant; it is caused by recipient DCs responding to unmatched HLA subgroups and inducing Th1 and Tc to directly attack the donor cells. Acute antibody-mediated rejection is mediated by antibody and complement and takes approximately 2 weeks to occur. Long-term maintenance with immunosuppressive agents is necessary to prevent acute rejection. Chronic rejection, a cell mediated response to minor histocompatibility antigens, is characterized by graft arterial occlusions from increased proliferation of smooth muscle cells and production of collagen and progressive failure of the donor graft; it may take months or years to occur.

Autoimmunity

The ability of the immune system to recognize and avoid destruction of host cells is called *self-tolerance*. Central self-tolerance develops during the embryonic period; autoreactive lymphocytes are destroyed in the primary lymphoid organs during differentiation and proliferation of immature T and B cells.

Peripheral tolerance continues in the secondary lymphoid tissue and is controlled by Treg cells and APC DCs that suppress maturation of lymphocytes with self-antigen receptors.⁴²

Autoimmunity is an abnormal response to self-antigens resulting in production of self-antibodies or autoantibodies and damage to self-tissues due to dysfunction of the innate and/or adaptive immune systems. Some individuals may have a genetic predisposition toward developing an autoimmune disorder; and, not infrequently, more than one autoimmune disorder can occur in the same individual. The HLA alleles and non-MHC genes that encode for cytokines and other costimulatory factors have been implicated in a large number of autoimmune diseases. It is hypothesized that microorganisms, such as bacteria or viruses, or drugs, may trigger immune system dysfunction. Chronic inflammation is the classic sign of an autoimmune disease. There is a higher incidence of autoimmune disease in females, especially African American, Native American, and Hispanic females, as well as females of childbearing years. There are over different 80 types of autoimmune disorders that can affect almost any part of the body, including the heart, brain, nerves, muscles, skin, eyes, joints, lungs, kidneys, glands, digestive tract, and blood vessels (Box 46.2). There follows a limited discussion of the six most common autoimmune diseases relative to the associated immune dysfunction.

Autoimmune Disorders

Multiple organ systems: Systemic lupus erythematosus

Eye: Acute anterior uveitis, Sjögren syndrome

Skeletal System: Ankylosing spondylitis, reactive arthritis or Reiter

syndrome, rheumatoid arthritis

Endocrine organs: Diabetes mellitus type, autoimmune pancreatitis, adrenal 21 - hydroxylase deficiency, Hashimoto disease and Graves' disease

Skin, connective tissue: Scleroderma, dermatomyositis, psoriasis, vitiligo, alopecia areata

Nervous System: Multiple sclerosis, myasthenia gravis

Blood and blood vessels: Polyarteritis nodosa, antiphospholipid antibody syndrome, hemolytic anemia, idiopathic thrombocytopenic purpura (ITP)

Gastrointestinal system: Autoimmune hepatitis, celiac disease, inflammatory bowel disease (Crohn's disease and ulcerative colitis), primary biliary cirrhosis

Graves' Disease

The most common cause of hyperthyroidism, Graves' disease, affects 3% of adult females and 0.5% of adult males between 30 and 60 years of age. Originally believed to be a type II hypersensitivity, it is now recognized as a type V hypersensitivity caused by autoantibodies, called *thyroid stimulating immunoglobulins* (TSI) or *thyroid receptor antibodies* (TRab), to the thyrotropin or TSH receptor on thyroid follicular cells.^{42,43} The TSI stimulate the TSH receptors, causing excessive production of thyroxine (T_4) and triiodothyronine (T_3). Symptoms of excessive thyroid hormone production include tachycardia, palpitations, tremor, heat intolerance, and anxiety. Physical symptoms include thyroid enlargement (goiter) and weight loss. Ophthalmopathy changes (exophthalmus) are a distinguishing characteristic of the disease and believed to be a result of TSI binding to TSH retro-orbital tissues.⁴³ Graves' disease is diagnosed by elevated plasma levels of T_3 and T_4 , low or absent TSH, TSI radioactive iodine (RAI) uptake, and thyroid ultrasound. Treatment includes antithyroid medications (methimazole and propylthiouracil) to normalize production of T_3 and T_4 .

Thyroidectomy and RAI destruction of the thyroid are also treatment options but typically require replacement therapy. Current research is focused on TSI blockers that will prevent TSI stimulation of the TSH receptor. Surgical decompression and glucocorticoids may be required for individuals with severe ophthalmopathy.

Hashimoto Thyroiditis

Hashimoto thyroiditis, also known as *chronic lymphocytic thyroiditis* and *autoimmune thyroiditis*, is the most common thyroid disorder in the United States. Females are seven times more likely to suffer from the disease than males. Thyroglobulin (Tg), a major thyroid-specific protein, is normally not secreted into the systemic circulation. Along with other antigens, such as thyroid peroxidase (TPO), Tg can enter the circulation during acute thyroid inflammation or hemorrhage, or rapid disordered growth of thyroid tissue, and stimulate the production of Tg and TPO antibodies (TgAb and TPOAb) in some individuals. Diffuse lymphocytic infiltration of the thyroid and activation of the other components of the immune system causes follicular destruction of the thyroid.⁴⁴ A unique subtype of Hashimoto thyroiditis, IgG4 thyroiditis, characterized by high plasma levels of IgG4, is associated with rapid progression of hypothyroidism and higher levels of circulating antibodies. Symptoms of Hashimoto thyroiditis include goiter and hypothyroidism. Confirmatory diagnostic tests include low plasma levels of total T₄ and elevated TSH levels. The presence of TgAb and TPOAb will confirm the diagnosis; however, 10% to 15% of patients with the disease may be antibody negative.⁴⁵ A biopsy of Hurthle cells, large follicular cells with extensive granular eosinophilic cytoplasm, is also confirmatory for the diagnosis. Hashimoto thyroiditis is treated with thyroid hormone replacement (levothyroxine sodium).

Multiple Sclerosis

Multiple sclerosis (MS) is the most prevalent demyelinating disorder of the CNS.⁴⁵ It primarily affects young adults between the ages of 20 and 40 years but can occur at any age. Females are

affected two times more than males.⁴⁶ MS is an immune-mediated inflammatory disease that attacks the myelin, oligodendrocytes (myelin producing cells), and the underlying nerve fibers, producing significant physical disability within 20 to 25 years.⁴⁵⁻⁴⁷ The CD4 Th cells have long been implicated in the pathogenesis of the disease. However, current studies indicate that both the innate and adaptive immune-mediated system components are involved. Apart from the proinflammatory CD4 Th1/Th17 cell subsets, B-cell antibodies, NK cells, CD8 Tc, microglia/macrophages, and complement also contribute to the demyelination and neurodegeneration. Environmental risk factors for the immune system dysfunction in MS include vitamin D deficiency, EBV infection, cigarette smoking, Western diet, and the commensal microbiota.⁴⁸ Symptoms include fatigue, tingling, numbness, muscle weakness, ataxia, vertigo, tremor, spasticity, bladder and bowel dysfunction, pain, and heat intolerance.⁴⁶ The disorder is initially characterized by periods of relapse due to a new influx of immune cells into the CNS, and periods of remission characterized by remyelination. Eventually the majority of patients will develop secondary-progressive MS, characterized by diffuse CNS lesions, usually at approximately the age of 45 years, regardless of the age of disease onset.⁴⁸ Diagnosis of MS includes MS lesions on magnetic resonance imaging (MRI), elevated IgG in the cerebrospinal fluid (CSF), and decreased conduction velocity on evoked response studies (visual, auditory, and somatosensory).⁴⁶ Treatment with immunomodulatory agent is directed toward reducing the formation of new lesions and decreasing the incidence of relapse. The Federal Drug Administration (FDA) has approved a number of disease-modifying agents for MS (DMAMS). The most commonly used drugs are IFN β -1b (Betason), IFN β -1a (Avonex, Rebif) and glatiramer acetate (Copaxone); however, a significant number of MS patients are resistant to these agents.^{45,49,50} Treatment of acute relapses may include corticosteroids and plasma exchange (plasmapheresis). Antineoplastic agents, including cyclophosphamide (Cytosan) and mitoxantrone (Novantrone) are used for severe progressive MS.⁴⁷

Rheumatoid Arthritis

RA is an inflammatory autoimmune disease characterized by synovial inflammation and hyperplasia, cartilage and bone destruction, and systemic features, including cardiovascular, pulmonary, psychological, and skeletal disorders. It initially affects the smaller joints of the hand and feet but spreads to the larger joints as the disease progresses. It affects approximately 1% of the population, with a peak incidence between the ages of 35 and 50 years; females are affected three times more often than males. The disorder involves both the innate and the adaptive immune systems and a complex interaction of many proinflammatory cytokines, especially TNF- α and IL-6.⁵¹ The T cells play a pivotal role in the initiation of RA, especially the CD4 Th cells which activate macrophages and synovial fibroblasts, the main producers of TNF- α , IL-6 and IL-1. The APCs (DCs, macrophages, and activated B cells) are responsible for activating the T cells, and there is an abnormal production and regulation of both proinflammatory and antiinflammatory cytokines.⁷ In addition to their APC role, B cells produce rheumatoid factor (RF) and anticyclic citrullinated peptide (anti-CCP) antibodies. Approximately 60% of RA patients have a (HLA)-antigen D Related (DR)4 cluster for certain HLA-DR molecules associated with RA. However, the concordance rate is only 12% to 15% for identical twins, which supports the theory that nongenetic factors play an important role in the disease. Environmental triggers can trigger an autoimmune response and can increase proinflammatory gene expression. Infection may also play a role, especially periodontopathic bacteria; the synovial fluid of RA patients has been found to contain high levels of oral anaerobic bacterial antibodies. Extraarticular involvement is more common in patients with RF and/or the HLA-DR4 gene. Systemic manifestations include vasculitis and accelerated atherosclerosis, pericarditis, pulmonary fibrosis, visceral nodules, anemia, leukopenia, and Sjögren syndrome. Diagnostic tests for RA include an elevated erythrocyte sedimentation rate (ESR) and CRP, and the presence of RF and (anti-CCP) antibodies. Synovitis, bone erosion, and destruction of cartilage are evident on x-rays and MRIs.⁵² The introduction of disease-modifying antirheumatic drugs (DMARD) significantly changed the course of the disease by decreasing pain and inflammation and reducing joint damage. Methotrexate (MTX)

is the most commonly used first-line DMARD; it inhibits cytokine production and blocks lymphocyte and monocyte proliferation, and prevents osteoclast formation.^{53,54} Biologics, a subset of DMARDs, target specific immune mediators of the inflammatory process and are frequently combined with MTX.⁵⁵ NSAIDs and corticosteroids are effective in early or mild cases. Surgical procedures for RA include synovectomy, tendon repair, joint fusion, and total joint replacement.^{53,56}

Systemic Lupus Erythematosus

SLE is an autoimmune inflammatory disease with wide spread effects, including cardiovascular, hepatic, pulmonary, renal, joints, and skin. It occurs in young adults; approximately 20% develop the disease before the age of 20 years, and it is ten times more common in females. Early diagnosis of SLE is difficult because of widespread and nonspecific symptoms. It is characterized by a large variety of autoantibodies including, but not limited to antibodies against coagulation proteins, erythrocytes, lymphocytes, nucleic acids, platelets, and phospholipids.¹² The American College of Rheumatology has identified 11 common findings in SLE; a minimum of four symptoms are required for a diagnosis of SLE. These include a butterfly-shaped rash on cheeks/red rash with raised round or oval patches/rash on skin on exposure to sun, mouth sores, arthritis, pleuritic or pericarditis, renal impairment, CNS involvement (seizures, strokes or psychosis), and abnormal blood tests.⁵⁷ Environmental triggers of acute symptoms (flares) include viral infections, sunlight, cigarette smoking, fatigue, and certain drugs, including hormone replacement therapy and oral contraceptives. Laboratory abnormalities includes anemia, leukopenia, or thrombocytopenia, elevated ESR and/or CRP levels and presence of antinuclear antibodies (ANA). Confirmatory diagnostic tests include: anti-double-strand DNA (anti-dsDNA), anti-Smith (anti-Sm) or antiphospholipid antibodies, lupus anticoagulant (LA), IgG and IgM anticardiolipin (aCL), IgG and IgM anti- β 2-glycoprotein, elevated C3 and C4 or CH50 complement levels, and a false-positive blood test for syphilis.⁵⁷ Treatment is dependent upon the severity of the symptoms. Avoidance of triggers and NSAIDs are effective in mild cases, whereas

corticosteroids or immunosuppressants (azathioprine, mycophenolate, mofetil, MTX) are necessary for severe cases. In combination with steroids and nonbiologic DMARDs, the MAB belimumab (Benlysta), has FDA approval for treatment of SLE. A B-lymphocyte stimulator–specific inhibitor, belimumab reduces the number of severe flares, as well as exhibiting a steroid sparing effect.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus accounts for less than 10% of diabetes cases; similar to other autoimmune diseases, the worldwide incidence is doubling every 20 years.^{56–60} Type 1A diabetes (T1AD) is a result of autoimmune destruction of the insulin-producing β cells of the pancreatic islets of Langerhans. In contrast, type 1b (T1BD), idiopathic diabetes, is characterized by almost complete insulin deficiency, a strong hereditary component, but no evidence of autoimmunity. The pathogenesis of type 2 diabetes involves both decreased insulin release and insulin resistance. Latent autoimmune diabetes of adulthood (LADA) is a form of T1AD that occurs later in adults. The majority of individuals with T1AD are diagnosed between 5 and 7 years of age or around puberty; females and males are affected equally.⁵⁸ The onset of the clinical symptom correlates with the end stage of β -cell destruction. Approximately 1 in 20 siblings of patients with T1AD will develop the disease, compared to 1 in 300 individuals in the general population; 60% of monozygotic twins have T1AD.⁶⁰ The major genetic determinants of T1AD are three classes of HLA genes, specifically class II genes HLA-DQ and HLA-DR, which are expressed on APCs responsible for presenting antigens to CD4 Th cells.³⁸ The great majority of individuals with T1AD have HLA-DR3 or DR-4 class II antigens. The increased incidence of T1AD over the last 50 years supports the influence of unidentified environmental factors. Immune markers are detectable after the onset of the autoimmune process and long before clinical presentation of the disease.⁵⁸ The pathogenesis of T1AD involves T-cell infiltration, specifically CD8 Tc cells and macrophages, of the islets that results in insulinitis and destruction of β -cells, decreased insulin production, and insulin dependent diabetes. Four autoantibodies are involved in destruction of the β -

cells: islet cell antibodies (ICAs), glutamic acid decarboxylase (GAD-65), insulin autoantibodies (IAAs), and protein tyrosine phosphatase (IA-2A). Pancreatic α cell function is also abnormal in T1AD, resulting in excessive secretion of glucagon.⁵⁹ Relatives with two or more antibodies have a 90% predictive incidence of T1AD. Insulin replacement therapy is the mainstay treatment of T1AD, but despite insulin therapy, the disease is associated with nephropathy, retinopathy, neuropathy, and cardiovascular disease. Current research includes the use of antigen based therapies, including vaccinations with GAD and insulin peptides, that may decrease autoimmunity towards the β -cells.

Immunodeficiency Disorders

Primary immunodeficiency disorders (PID) are a result of a genetic defect in cells of the immune system, including lymphocytes, antibodies, phagocytes, and complement proteins. Secondary deficiencies are a consequence of disease, such as cancer, infections, malnutrition and medications. Immune function decreases in old age as a result of reduced production and diminished function of mature lymphocytes in secondary lymphoid tissues. The hallmark of both primary and secondary immunodeficiency is an increased susceptibility to infection.

Primary Immunodeficiency Disorders

According to the National Institute of Health (NIH), there are over 200 different forms of PID, rare, genetic disorders that are caused by a defect in the immune system and are often sex-linked. They are characterized by low antibody levels, defective antibodies, or defective cells of the immune system, including T cells, B cells, neutrophils, and complement (Table 46.7). The International Union of Immunological Societies (IUIS) classification of PIDs is based on the genetic defect, laboratory findings, and associated features.⁶¹ In the United States, approximately 500,000 people have a PID; most present at birth or in early childhood, but can present at any age. Increased susceptibility to repeated infections is characteristic of PID, including recurrent, unusual, or difficult to treat infections, especially pneumonia, ear infections, and sinusitis. Other symptoms include poor growth patterns or weight loss, recurrent deep abscesses of organs or skin, enlarged lymph glands or spleen, and a coexisting autoimmune disease.

TABLE 46.7

Primary Immunodeficiency Disorders

B-Cell Deficiencies	IgA deficiency
	Common variable immunodeficiency
	X-linked immunodeficiency with hyper-IgM syndrome
	X-linked agammaglobulinemia (XLA)
T-Cell Deficiencies	Wiskott–Aldrich syndrome

	DiGeorge syndrome
Combined B- and Cell-Deficiency	Severe combined Immunodeficiencies
Macrophage Deficiency	Chronic granulomatous disease

Common Variable Immune Deficiency

Common variable immune deficiency (CVID) is one of the most common types of PIDD; it is also known as *acquired agammaglobulinemia*, *adult-onset agammaglobulinemia*, or *late-onset hypogammaglobulinemia*. It occurs in 1 in 25,000 to 50,000 individuals, and females and males are equally affected. It is characterized by low or absent antibody levels. The number of B cells may be normal but they fail to differentiate into plasma cells that produce antibodies.^{62,63} Although CVID can occur at any age, it is most commonly diagnosed between ages 20 and 40.⁶² Low levels of antibodies in the blood, including IgG, IgA, and IgM, are diagnostic of the disorder, especially in response to a challenge with vaccines such as tetanus, diphtheria, and pneumococcal polysaccharide. Recurrent infections are common, especially respiratory infections. Approximately 25% of individuals with CVID also have an autoimmune disorder, most commonly immune thrombocytopenia, autoimmune hemolytic anemia, and RA.⁶² There is also an increased incidence of malignancies, especially lymphomas of a B-cell phenotype. Treatment for CVID is immunoglobulin replacement therapy, administered intravenously (IVIG) or subcutaneously (SCIG); antibiotics are indicated for acute infections, and steroids for autoimmune disorders.

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA), also called *Bruton agammaglobulinemia* and *congenital agammaglobulinemia*, is caused by a gene mutation of Bruton tyrosine kinase (BTK) on the X chromosome, an enzyme that is crucial for normal B-cell development. The lack of B cells causes a severe antibody deficiency. Approximately 1 in 250,000 males have XLA; diagnosis is usually not made until 9 to 12 months of age because of passive maternal IgG protection.⁶³ Females can present with an immunodeficiency called *autosomal recessive agammaglobulinemia*

(ARA) with an antibody deficiency that is similar to XLA. In addition to frequent infections, patients with XLA have underdeveloped secondary lymphoid organs, including small tonsils, lymph nodes, and spleen, which is an indication of low or absent B lymphocytes. The diagnosis of XLA is confirmed by low or absent plasma B cells and IgG, and no detectable IgM or IgA; a low B-cell count is the most reliable indicator of both XLA and ARA. A confirmatory diagnosis test is absence of the BTK gene. Treatment includes prophylactic antibiotics and passive immunotherapy with IVIG or SCIG every 3 to 4 weeks. Hematopoietic stem cell transplantation (HSCT) may also be used for correction of B cell and myeloid deficiencies.⁶³ Live vaccines should be avoided in patients with XLA.

X-Linked Hyper-IgM Syndrome

The X-linked Hyper-IgM syndrome (XHIGM) is a rare form of PIDD caused by a genetic mutation of the CD40L gene that codes for the CD40 ligand.⁶⁴ An X-linked recessive trait, XHIGM is only found in males. When the CD40 ligand binds to the CD40 receptor on B cells, it triggers the B cells to undergo class-switching from IgM to IgG, IgA, and IgE. Individuals with XHIGM have normal or elevated IgM and low levels of IgG, IgA, and IgE. The CD40 ligand also plays a key role in T cell differentiation and activation of macrophages. Symptoms of XHIGM are present in the first or second year of life. In addition to recurrent infections, approximately 50% of the patients develop neutropenia, which is associated with inflammation or ulceration of mucosal membranes and skin infections. Other symptoms include enlargement of the lymph nodes and spleen; enlarged tonsils and adenoids may cause snoring and obstructive sleep apnea. A rare form of XHIGM, ectodermal dysplasia, is characterized by sparse body hair, conical teeth, and recurrent infections. Diagnosis of XHIGM is confirmed with normal or elevated levels of IgM and low or absent IgG, IgA, and IgE. DNA tests may be used to confirm the CD40L gene mutation. Treatment includes antibiotics and IVIG or SCIG. Granulocyte-colony stimulating factor (G-CSF) is indicated for patients with severe neutropenia. HSCT may be considered for patients with severe symptoms. Patients with XHIGM have an

increased susceptibility to *P jiroveci* pneumonia, and prophylactic treatment with trimethoprim-sulfamethoxazole is initiated as soon as the diagnosis of HIGM is confirmed.

Selective IgA Deficiency

Selective IgA deficiency (SIgAD) is the most common type of PIDD, affecting 1 in 700 to 2000 individuals, especially those of European descent.^{63,65,66} The exact cause of selective IgA deficiency is unknown. In affected individuals, B cells are normal but they lack a response to interleukins and fail to become plasma cells that produce IgA; production of other immunoglobulins is normal.⁶⁶ IgA antibodies are transported in secretions to mucosal surfaces that come in contact with the environment, including the mouth, ears, sinuses, nose, throat, respiratory tract, GI tract, eyes, and genitals, where they play a major role in protecting those sites from infection.⁶⁵ People with selective IgA deficiency are at risk for repeated infections of the ears, sinuses, GI, genitourinary, and respiratory tracts. Allergies are more common in individuals with selective IgA deficiency. Over 30% of patients with selective IgA deficiency have an autoimmune disorder, especially RA and SLE. An absence of IgA and normal levels of IgG and IgM are confirmatory of the disorder. Treatment includes antibiotics for infections; unlike other PIDD, IVIG or SCIF is not indicated unless the individual also has a concomitant IgG subclass deficiency. Some individuals with selective IgA deficiency have anti-IgA antibodies and are at risk of an anaphylactic reaction if they receive blood products, including IVIG, which contain IgA. In these individuals, washed RBCs or irradiated blood and IgA-depleted IVIG are indicated.

IgG Subclass Deficiency

IgG is divided into four subclasses: IgG1, IgG2, IgG3, and IgG4. Circulating IgG is 60% to 70% IgG1, 20% to 30% IgG2, 5% to 8% IgG3, and 1% to 3% IgG4. An IgG subclass deficiency is a result of no or very low levels of one or two IgG subclasses; IgG4 and IgG2 deficiency frequently occur together. The IgG subclasses have different protective roles and a lack of a specific IgG subclass is

associated with specific types of infections. The IgG1 and IgG3 subclasses are effective against serious bacterial infections such as diphtheria and tetanus, as well as viral infections. The IgG2 antibodies are effective against the polysaccharide coating of bacteria that cause ear and sinus infections, pneumonia, and meningitis. Diagnosis of IgG subclass deficiency is confirmed by low plasma levels of one or more IgG subclass antibodies and normal levels of total IgG, IgA, and IgM. An additional subset of patients have normal levels of IgG and IgG subclasses but are unable to produce antibodies in response to infections or vaccines. The IgG subclass deficiency tends to improve over time without medical intervention. Antibiotics may be needed to treat recurring infections; IVIG or SCIG may be used in limited circumstances for serious infections.

DiGeorge Syndrome

DiGeorge syndrome, also known as *22q11.2 deletion syndrome*, is due to a genetic defect on chromosome 22.⁶⁷ It is the most common microdeletion syndrome, occurring in 1 in 4000 live births, and affects females and males equally. The genetic mutation causes a wide variety of abnormal cell and tissue growth during fetal development. Defects in cardiac and major vessels, poor immune system function, cleft palate, hypoparathyroidism, hypothyroidism, esophageal atresia, urogenital anomalies, and unusual facial features, including mandibular hypoplasia, heavy eyelids, and abnormal ear lobes, are associated with DiGeorge syndrome. Patients with DiGeorge syndrome have a higher incidence of autoimmune disease. Hypoplasia of the thymus is associated with a decreased production of T cells; B cells are normal but their production of antibodies is inhibited by the absent or low number of mature T cells. Diagnosis of the syndrome is primarily based on DNA testing for the chromosome 22 deletion present in 90% of individuals with DiGeorge syndrome. Individuals lacking the genetic defect are diagnosed by clinical features and exclusion of other syndromes. Treatment of the immune presentations of the disease includes antibiotics, IVIG or SCIG, thymic tissue transplant, and steroids.⁶⁷

Wiskott–Aldrich Syndrome

The Wiskott–Aldrich syndrome (WAS) is caused by a mutation of the WAS gene that codes for WASP, an important signaling protein found on the surface of all blood cells. It is a recessive gene mutation on the X chromosome and only affects males. Both the T and B lymphocytes are affected; WAS is associated with decreased IgM, low to normal IgG, and elevated IgA and IgE.⁶³ Classic symptoms of WAS include thrombocytopenia purpura, recurring bacterial, viral, and fungal infections, and eczema. There is also a higher incidence of autoimmune disorders in individuals including hemolytic anemia and idiopathic thrombocytopenia purpura (ITP). Cancer is also more common, especially B-cell lymphomas and leukemia. Microthrombocytopenia, a decreased number and size of platelets, is unique to WAS and characteristic of the disorder. Absence of the WAS protein in blood cells, or a mutation within the WAS gene may be used for confirmatory diagnosis. Treatment of WAS includes antibiotics, and IVIG or SCIG. A HSCT offers a curative option for patients with WAS.

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID), also known as *alymphocytosis*, *Glanzmann–Riniker syndrome*, *severe mixed immunodeficiency syndrome*, and *thymic alymphoplasia*, refers to a rare group of PIDDs considered to be the most serious form of PIDD. Numerous genetic mutations are responsible for the absence of functional T and B lymphocytes and the heterogeneous clinical presentations.⁶⁸ Approximately 50% of the mutations are sex-linked to the X chromosome. The majority of SCID is characterized by a genetic mutation in the IL-2 receptor gamma (IL2RG) gene or JAK3, an important signaling molecule for IL2RG. In other forms of SCID, a genetic deficiency of enzyme adenosine deaminase causes an accumulation of adenosine that is toxic to immature lymphoid cells of the immune system. Infants with SCID have a high rate of serious and life-threatening infections, including pneumonia, specially *Pneumocystis jiroveci*, meningitis, cytomegalovirus infection, and septicemia. They are also susceptible to vulnerable fungal infections and chronic diarrhea, which can lead to growth

failure and malnutrition. Protective isolation of the infant is necessary to decrease the risk of infection. Diagnosis includes low levels of plasma lymphocytes and low T-cell function. Curative therapy includes HSCT; there is greater than a 90% success rate if it is undertaken during the first 3 months of life.⁶⁹ Other treatment includes IVIG or SCIG, enzyme replacement, and gene therapy (GT).⁶⁸

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD), also known as *Bridges-Good syndrome*, *chronic granulomatous disorder*, and *Quie syndrome*, is a diverse group of immune disorders due to inability of phagocytes to kill ingested pathogens. In the phagocyte, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is responsible for oxidizing NADPH and reducing molecular oxygen to produce reactive oxygen compounds (superoxide radical and hydrogen peroxide) that destroy ingested bacteria. The rapid release of reactive oxygen compounds is called a “respiratory burst.” In CGD, phagocytes lack or have a defective NADPH oxidase and are unable to produce the reactive oxygen compounds that are necessary to kill ingested microorganisms.⁷⁰⁻⁷² The incidence of CGD is 1 in 250,000 and the most common form of it is X-linked; however, there are other autosomal-recessive forms of the disease. The majority of children with CGD are diagnosed before the age of 5 years. Individuals with CGD suffer from recurrent infections at epithelial surfaces such as the skin, GI tract, respiratory tract, and organs with a large number of phagocytes, such as the liver. Granulomatous lesions are frequently found throughout the GI tract, causing dysphagia, dysmotility, or obstruction. Defective neutrophil uptake of dihydrorhodamine, a fluorescent dye, is diagnostic of the disorder. In addition to antibiotics for recurrent infections, treatment includes glucocorticoids, IFN, anti-TNF, and cyclosporine. Surgery may be required for GI granulomata; an allogeneic HSCT offers the only cure for CGD.⁷⁰

Acquired Immune Deficiency Disorders

Approximately 90% of immune deficiencies are acquired. One of

the most recognized form of acquired immune deficiency (AID), also known as *secondary immune deficiency*, is acquired immune deficiency syndrome (AIDS). However, the most prevalent cause of AID worldwide is severe malnutrition. Other causes of AID include human T-cell lymphotropic virus type 1 (HTLV-1) infection, lymphoid cancers such as leukemia and lymphoma, autoimmune disease such as T1AD, splenectomy, aging, malnutrition, and immunosuppressant drugs, including corticosteroids, chemotherapy, and DMARDs. Secondary immunodeficiency affects both the innate and the adaptive immune systems; treatment of the primary condition usually results in improvement of the associated AID.

Acquired Immune Deficiency Syndrome

AIDS is the final stage of infection caused by HIV, a retrovirus that was first identified in 1983. There are two forms and many subtypes of HIV. Over 90% of HIV-1 infections belong to the HIV-1 group M. According to the CDC, approximately 1.2 million people in the United States are HIV positive. An estimated 44,073 individuals were diagnosed with HIV in 2014; the number of new cases of HIV infections has declined 19% since 2005.⁷³ Although it also affects monocytes and macrophage, the T cells, specifically the CD4, are the central targets of attack by HIV. A retrovirus, HIV is a single-stranded RNA molecule; through the process of reverse transcription, the infected CD4 cell makes a DNA double-stranded helix that contains all the viral genetic information. The infected cells produce viral progeny at a slow, steady rate for an indefinite period. The CD4 protein normally helps Th cells activate other immune cells; cytokines from Th cells induce B cells to become activated and undergo clonal expansion to form mature plasma cells that secrete HIV antibody. Infected cell membranes display viral glycoproteins that contain several regions that are highly antigenic and can be recognized by APCs for presentation to NK, Tc, and B cells for destruction.^{74,75} However, HIV is capable of changing the amino acid sequences of the antigenic regions of their glycoproteins; the new version is not recognized by the existing antibodies and escapes destruction. The virally infected cells continue to multiply until the immune system is able to produce

new, virus specific antibodies. In contrast, the smallpox, polio, and measles viruses are not antigenically variable and immunity established against one form of those viruses provides lifelong protection against other forms of the same virus. Acute HIV infection is characterized by flu-like symptoms, a result of increased release of inflammatory mediators, including IL-1 and TNF- α , and transient decline in circulating CD4. During this stage, viral levels in the blood are high and the individual is very contagious. A variable asymptomatic period follows, as HIV antibodies destroy the infected T cells. However, HIV reproduction continues at very low rates, and there is a gradual, progressive fall in CD4 Th cells concomitant with a gradual increase in the plasma viral load; the individual is still contagious. Over time, the immune response is unable to control viral replication and mutation, the CD4 cell count falls below 200 cells/mm and the individual moves into the final stage of infection, AIDS. Common symptoms of AIDS include chills, fever, sweats, swollen lymph glands, weakness, weight loss, and heightened risk of severe opportunistic infections and diseases.⁷⁵

Diagnostic tests for HIV include plasma HIV antigen and HIV antibodies; a CD4 T-cell count less than 200/mL (normally 600–1500/mL) is diagnostic of AIDS. The HIV viral load (HIV RNA) measures the number of HIV virus particles, called *copies*, in a milliliter of blood. The goal of treatment is to suppress the viral load to an “undetectable” level; the lower limit of HIV detection varies from 20 to 75 copies/mL depending on the laboratory performing the test. High viral loads are associated with faster disease progression. Genotyping of HIV is necessary to determine if the particular virus is resistant to any of the anti-HIV medications. Currently there are 31 FDA-approved antiretroviral drugs (ARVs) that suppress, even to undetectable levels, but do not completely eliminate HIV from the body. The ARVs include fusion inhibitors that interfere with the HIV's ability to fuse with a cellular membrane; entry inhibitors that interfere with the ability of HIV to bind to external cell receptors; nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs); faulty DNA building blocks that interfere with HIV DNA synthesis; nonnucleoside reverse transcriptase inhibitors (NNRTIs) that bind to reverse transcriptase

(RT) and prevent the conversion of HIV RNA into HIV DNA; protease inhibitors (PIs) that interfere with HIV protease which is essential for cutting long chains of HIV proteins into smaller individual proteins; and integrase inhibitors that block the HIV enzyme integrase that is responsible for the integration of viral RNA into the DNA of the infected cell.^{75,76} Highly active antiretroviral therapy (HAART), a combination of two or more different classes of antiretroviral drugs, is recommended to prevent strains of HIV from becoming resistant to one type of antiretroviral drug.⁷⁶ The CD4 cell count increases with effective HIV treatment; however, individuals can still transmit the virus and must continuously take ARVs. Clinical trials of HIV vaccines have produced mixed results, in part due to the ability of HIV to undergo multiple mutations.

Cancers of the Immune System

According to the Leukemia and Lymphoma Society, 1,237,820 individuals in the United States have leukemia, lymphoma, or myeloma, which are cancers of the WBCs and lymphatics (Box 46.3). Their distribution is often age-related. These diseases account for approximately 10% of cancer deaths.⁷⁷

Leukemia

Leukemia is a result of uncontrolled clonal proliferation of

malignant, dysfunctional leukocytes that grow rapidly and prevent the development of normal hematopoietic cells in the bone marrow. The incidence is higher in males and increases with age.^{77,78} Down syndrome and neurofibromatosis, environmental exposure to radiation treatments and benzene, cigarette smoking, and a family history of leukemia are associated with an increased risk of leukemia. Survivors of leukemia have an increased risk of other cancers, possibly an effect of leukemic chemotherapy and radiation treatments. Childhood survivors are at increased risk for osteonecrosis of the large joints and endocrine abnormalities.⁷⁸ Signs and symptoms are dependent upon the type of leukemia. Malignant lymphoblasts replace the normal marrow elements, significantly decreasing production of normal blood cells; consequently, anemia, thrombocytopenia, and neutropenia occur to varying degrees in all leukemias.^{79,80} The abnormal lymphoblasts also proliferate in lymphoid organs, including the liver, spleen, and lymph nodes. Common symptoms include fever or chills; fatigue; weakness; frequent or severe infections; weight loss; enlarged lymph nodes, liver, and spleen; bruising; recurrent nosebleeds; petechiae; and bone pain. A bone marrow biopsy with immunophenotyping is necessary for accurate diagnosis. Classification of the leukemia is based on the abnormal cell origin, lymphoid or myeloid, and the rate of the progression, acute or chronic. Lymphoid cells are precursors of lymphocytes and lymphocytic leukemia affects lymphocytes of lymphoid or lymphatic tissue. Myeloid cells are immature blood cells that are precursors of granulocytes or monocytes; myelogenous leukemia affects the myeloid cells of the bone marrow.⁸¹ Acute leukemia involves immature blood cells that multiply aggressively and rapidly. Chronic leukemia involves mature blood cells that multiply slowly and can go undetected for years. Rare forms of leukemia include hairy cell leukemia, myelodysplastic syndromes, and myeloproliferative disorders.

Acute Lymphocytic Leukemia

Approximately 50% of acute lymphocytic leukemia (ALL) in the United States occurs in children and teenagers. It is the most common cancer and most frequent cause of cancer death before 20

years of age. Approximately 85% of ALL is classified as precursor B-cell and 15% has precursor T-cell lineage. There are distinct genetic mutations associated with ALL; the increased incidence of T-cell ALL among males suggests a Y-chromosome related mutation. Symptoms of ALL include thrombocytopenia, anemia, and neutropenia. The cancer progresses rapidly as leukemia cells spread to the brain, liver, lymph nodes, and testes, where they continue to grow and divide, causing a wide array of symptoms. Patient age and initial WBC count are strong predictors of treatment outcomes. A standard risk is seen with children ages 1 to 9 and WBCs of 50,00/mL or less; children 10 years or older and WBCs of 50,000/mL or greater are considered high risk. An age of less than 1 year is associated with poorer outcomes. The time required to reach undetectable levels of leukemic cells is the single most powerful prognosticator of successful treatment in children with ALL.⁸² Treatment includes an intensive induction and consolidation regimen that is associated with an 85% 5-year event-free survival rate and an overall 90% survival rate. Survival rate among teenagers with ALL is less than younger children. Induction of remission includes 4 to 6 weeks of prednisone, vincristine, anthracycline, cyclophosphamide and/or L-asparaginase. However, relapse is inevitable within 6 to 8 weeks and consolidation therapy is necessary to prevent development of overt CNS leukemia. This includes repeated courses of methotrexate and folinic acid, followed by 18 to 30 months of antimetabolic therapy with mercaptopurine, thioguanine, daunorubicin, cytosine arabinoside (Ara-C), and methotrexate, and possibly 5 to 7 day “pulses” of prednisone and vincristine. There is a 15% to 20% relapse rate for ALL and cure rates are lower after relapse. Treatment with an allogenic HSCT is more common after relapse. Other treatment options include immunotherapy. A cell surface antigen receptor, CD19, is present on most ALL B-cells. Blinatumomab, a monoclonal anti-CD19 antibody, binds to the CD19 receptors on T-cell receptors and activates them to recognize and destroy B-cells with the CD19 surface antigen.^{79,82} Patients with ALL frequently need blood transfusion therapy, a result of both an inability to produce normal blood cells and the effects of chemotherapy. All blood products must be irradiated.

Acute Myelogenous Leukemia

Acute myelogenous leukemia (AML), also known as *acute myeloblastic leukemia*, *acute granulocytic leukemia*, or *acute nonlymphocytic leukemia*, is the most common type of acute leukemia and accounts for 98% of acute adult leukemia; the median age at diagnosis is 64 years.^{78,83} It is associated with abnormal myeloid stem cells which have the potential to produce different cell types; consequently there are eight different AML subtypes that can present in a variety of ways. Acute granulocytic leukemia is the most common AML subtype. Similar to ALL, the onset of AML is abrupt but the survival rate is poorer; less than 50% for children, 35% to 40% for individuals less than 60 years of age, and 5% to 15% for patients older than 60 years.^{83,84} Relapse occurs within 3 years in the majority of patients.⁸⁴ Treatment of AML includes induction and consolidation therapy; as with ALL, an allogenic HSCT is reserved for patients with relapsed AML. Individuals who relapse again after transplant may receive repeat induction therapy and supplemental donor lymphocytes. Individuals ineligible for HSCT may be treated with cytarabine and hypomethylating agents, decitabine, and azacitidine.⁸⁴

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) accounts for 30% of leukemias. The average age at diagnosis is 67 years and it is rarely seen in children.^{78,81,83} A malignant B-cell precursor is responsible for 95% of CLL cases. It is a slow growing disease; approximately 70% of individuals with CLL are asymptomatic and the disease is discovered on a routine blood test (neutropenia, anemia, and thrombocytopenia).⁸¹ Lymphadenopathy and splenomegaly, a result of malignant lymphocyte invasion of lymphoid tissue, are usually the presenting symptoms. The CLL B-cells do not produce normal antibodies and patients are susceptible to infection. Diagnosis is confirmed by the clonal expansion of plasma B lymphocytes and confirmed by immunophenotyping; a bone marrow biopsy is not necessary for diagnosis of CLL.⁷⁸ The disease may be monitored without treatment in individuals with indolent disease; chemotherapy and allogenic HSCT may be used to induce

remission in individuals with rapidly progressing disease.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) accounts for approximately 15% of leukemia; the highest incidence is in adults aged 40 to 50 years. Approximately 95% of patients with CML have an abnormal shortened chromosome 22, called the *Philadelphia chromosome*, a result of reciprocal translocation between chromosomes 9 and 22. The Philadelphia chromosome is responsible for stimulating cell proliferation and decreasing apoptotic cell death.^{78,81,83} In addition to the common symptoms of leukemia, CML usually presents with an increased granulocyte count and splenomegaly. Its categorization as chronic is an indication that CML grows slowly. However, it can change from a slowly progressing form of cancer into a rapidly growing, acute form that can spread to almost any organ in the body. Tyrosine kinase inhibitors (TKIs), such as imatinib, targets the enzyme responsible for the uncontrolled cell proliferation in the bone marrow. Although not curative, TKIs can provide long-term control of the disease; HSCT is reserved for younger patients or patients who fail to respond to TKI.

Lymphoma

Lymphomas are a diverse group of neoplasms that are a result of proliferation of malignant lymphocytes in the lymphoid tissue. Lymphoma can occur at any age but is the most common cancer in young adults. Lymphomas are divided into two groups, non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL); classification is based on a range of pathologic and clinical features. Approximately 90% of lymphomas are NHL and 10% are HL. Lymph node biopsies are mandatory for the diagnosis and classification of lymphoma. Computed tomography (CT), MRI, positron emission tomography (PET), bone marrow biopsy, and CSF analysis are used to stage the lymphoma. The stages of lymphoma identify the degree of cancer spread. The tumor is localized in stage I and there is limited spread confined to one side of the diaphragm in stage II. Regional spread to either side of the diaphragm or to an area near the primary lymph node tumor is

observed in stage III, and in stage IV there is distal spread beyond the lymphatic system. Lymphoma is further divided into A or B according to the associated symptoms; B-denoted cancer is more advanced and characterized by unexplained weight loss of 10% or greater, unexplained fever, and night sweats.^{81,83}

Non-Hodgkin Lymphoma

Most of the NHLs are B-cell lymphomas; the remainder are T-cell and NK lymphomas. The two most common types of NHL are diffuse large B-cell lymphoma, which accounts for 30% to 40% of lymphoma, and follicular lymphoma.^{83,85} Although it commonly occurs in the lymph nodes, NHL can originate in any lymphoid tissue. It is more common in individuals 60 years of age and older. Overall, the risk of NHL is higher in males but some types are more common in females. The symptoms of NHL are very similar to common viral illnesses, including painless swelling of the lymph nodes, and the disease is usually in Stage III or IV when diagnosed. The tumors often arise in disparate lymph nodes and extra-nodal involvement occurs early in the disease, including infiltration of the GI tract, bone marrow, testes, liver, and skin. The prognosis varies among the different types of NHL but the overall survival rate is approximately 50%. Risk factors include environmental chemical exposure (benzene, herbicides, and insecticides), prior chemotherapy, radiation exposure, immune system deficiency or suppression (organ transplantation or autoimmune disease), infections (HIV, human T-cell leukemia/lymphoma virus [HTLV-1], human herpes virus 8 [HHV8], and EBV), autoimmune disease (RA, SLE, Sjögren disease, and celiac sprue), and chronic immune stimulation (*Helicobacter pylori*, HBV, hepatitis C [HCV], and *Chlamydomphila psittaci*).⁸⁶ Radiation can be curative for early stages of indolent NHL. Chemotherapy with cyclophosphamide, hydroxydaunorubicin, vincristine (Oncovin), and prednisone (the CHOP protocol) and/or MABs (rituximab) is used for advanced states. Aggressive NHL is treated with CHOP chemotherapy and radiation or rituximab; HSCT may be indicated for relapsed forms of NHL. Biological drugs, such as IFN, and immunomodulating agents (thalidomide and lenalidomide) may be used if all other treatments have failed.

Hodgkin Lymphoma

The average age of Hodgkin Lymphoma (HL) diagnosis is 64 years of age, with two peaks occurring in the mid-20s and mid-60s.⁸¹ Prior EBV infection appears to be a risk factor for HL. Reed-Sternberg (RS) cells, malignant B lymphocytes, are characteristic of HL. There are two main forms of HL. The majority of cases are classic HL, which presents earlier and has a longer survival rate. Nodular lymphocyte-predominant HL can transform into diffuse B-cell lymphoma.⁸¹ The RS cells secrete cytokines and TGF- β which induce infiltration and proliferation of inflammatory cells that result in large, painless lymph nodes. In contrast to NHL, the spread of HL occurs in a predictable sequential fashion to local contiguous lymph nodes.^{81,86} The cervical, axillary, inguinal, and retroperitoneal lymph nodes are most frequently affected. Confirmatory diagnosis of HL requires an RS positive lymph node biopsy. Treatment of HL includes chemotherapy, doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD), followed by radiation therapy. Brentuximab vedotin has FDA approval for the treatment of HL. An antibody-drug conjugate containing an MAB and antimetabolic drug, it binds to CD30 proteins found on HL cells. It has a high overall response rate in patients with refractory HL. One of the most curable forms of cancer, the 5-year relative survival rate for HL is 94% for individuals diagnosed before the age of 45 years.⁷⁷ The survival rate is also dependent upon the disease stage at time of diagnosis; it is 90% to 95% for stages I and II, 80% to 85% for stage III, and 75% for stage IV.^{77,81}

Multiple Myeloma

Approximately 103,500 people in the United States have myeloma. The 5-year relative survival rate is 48.5%. Multiple myeloma (MM), also known as *Kahler disease*, is the most common type of myeloma, accounting for over 90% of myelomas and 10% of hematologic malignancies.⁸⁷ It is most common in individuals over the age of 50 and is rarely seen in children and young adults. It is more common in males, and blacks are nearly twice as likely as whites to develop myeloma. A mutation of plasma B cells results in rapid proliferation of abnormal myeloma cells that crowd out the normal

stem cells in the bone marrow and interfere with the production of WBCs, RBCs, and platelets. The myeloma cells produce monoclonal proteins or M protein microglobulins. The M proteins accumulate into plasmacytomas that erode the cortex of the bone resulting in osteoporosis and bone fractures.⁸⁷ The abnormal proteins are also deposited in organs throughout the body. When present in the urine, they are called *Bence Jones proteins*.⁸¹ Anemia, bleeding, bone lesions and pain, hypercalcemia, and renal failure are common. The disease is staged as I, II, and III depending on the degree of anemia, number of M proteins, and renal damage. A bone marrow biopsy diagnosis requires at least 10% of clonal plasma cells or plasmacytoma plus evidence of associated end-organ damage.^{81,87} In addition to chemotherapy and glucocorticoids, treatment includes targeted drug therapy with proteasome inhibitors (bortezomib) that induces cell death, immunomodulating drugs (thalidomide, lenalidomide, pomalidomide) that enhance the immune system's ability to recognize and destroy the myeloma cell, and MABs (daratumumab, elotuzumab) that target receptors on myeloma cells.^{87,88} IFN can slow the growth of myeloma. Bisphosphonates (alendronate, zoledronic acid) MABs (denosumab), and recombinant parathyroid hormone (teriparatide) are used to increase bone density. Autologous or allogeneic HSCT following high dose chemotherapy may be used for advanced stages.

Surgery and the Immune System

Surgery and anesthesia are associated with a variety of metabolic and endocrine responses which cause a generalized state of immunosuppression that can result in a reduced resistance to infection, development of postoperative septic complications, and tumor metastasis.^{89–92} In addition, the effectiveness of prophylactic medications intended to prevent the development of a postoperative infection is dependent on a functioning immune system. A number of factors play a contributing role in perioperative immune system dysfunction, including, but not limited to a preexisting immune deficiency, immune suppression therapy (autoimmune disease, organ transplantation), increasing age, preexisting disease such as diabetes mellitus, preoperative sepsis, perioperative blood transfusion, and postoperative pain management (Box 46.4).^{93–96}

Perioperative Immune Suppression

- Surgery
- Blood transfusion
- Hyperglycemia
- Hypothermia
- General anesthesia
- Opioids

Surgical Site Infections

The CDC defines a surgical site infection (SSI) as one that occurs at or near the surgical incision within 30 days of the procedure or within 1 year after implantation of a prosthetic device. The CDC health care–associated infection (HAI) prevalence survey found that SSIs account for 31% of all HAIs or nosocomial infections in hospitalized patients. Despite the use of prophylactic antibiotics

and universal infection control precautions, SSIs are reported in 12% of surgical patients worldwide.⁹³ In the United States, SSIs occur in 2% to 5% of the 30 million surgical procedures performed annually. The incidence of SSI is much lower in ambulatory surgical centers.⁹⁷ Increased morbidity and mortality, prolonged hospitalization, increased health care expenses, and poorer long-term outcomes are associated with SSIs.

The innate immune system is activated during surgery and, in response to the tissue damage and blood loss, a sterile systemic inflammatory response occurs within hours of the procedure.^{93,97} The DAMPs released from injured tissue promote neutrophil and macrophage migration to the site of injury for removal of tissue debris. They also provide a link between the innate and adaptive immune system by activating APCs, including monocytes and DCs. Inflammatory cytokines, chemokines, and antimicrobial peptides are released by immune cells to enhance eradication of injured cells and microbes. Surgery is associated with an increased release of Th1 cytokines (IL-6 and TNF); postoperatively Th1 cytokines decrease and Th2 cytokines increase (IL-10 and TGF).^{92,93} Following surgery, there is also a decrease in T cells that correlates with the duration of the procedure and intraoperative blood loss. Laparoscopic surgery is associated with a decreased immune suppression and it attenuates the cytokine cascade of lymphocytes decrease and shift towards a Th2 dominance. If the acute inflammatory response to surgery is not tempered by homeostatic antiinflammatory mechanisms, it can result in excessive death of phagocytes and increased susceptibility to infection by invading pathogens. The invading microbes contain PAMPs, which further stimulate the immune effector cells. The TLRs are responsible for identifying DAMPs released from stressed cells and PAMPs from invading microbes. A vicious cycle ensues, with surgical trauma causing inflammation and immunosuppression, and subsequent infection from invading microbes increasing the inflammatory response. The end result is tissue injury and potential organ failure.

Surgery also causes profound changes in the neuroendocrine system. Stress hormones, specifically, epinephrine, norepinephrine, and cortisol, are elevated in the postoperative period. The impaired cellular immunity associated with surgery is a direct result of the

activation of the hypothalamic–pituitary–adrenal axis (HPA) and the sympathetic nervous system (SNS), as well as increased release of catecholamines and cortisol.⁹⁰ The result is an increase in the number of Th2 and Treg, an altered Th1/Th2 balance, and decreased function of NK and IL-12. Cortisol interferes with the production of cytokines and prostaglandins, impedes aggregation of macrophils and neutrophils, induces apoptosis in T cells, promotes Th2 dominance (which decreases NK function), and suppresses phagocytosis at the surgical site. Immunomodulating diets (IMD) containing supplemental arginine and omega-3 fatty acids, and β -blockade reverses the Th1/Th2 imbalance and may be beneficial in reducing the immunosuppression associated with surgical trauma.^{90,94–96} Prevention and treatment of SSIs is discussed in [Chapter 14](#).

Cancer Recurrence

Paradoxically, surgical excision of tumors may actually stimulate proliferation and metastasis of tumor cells. Surgical excision disrupts the blood vessels supplying the tumor and allows tumor cells to enter the systemic circulation.^{98–100} In addition, a number of patients may already have preoperative micrometastasis.⁹⁸ Immune control of tumor cells is carried out predominantly through cell-mediated immunity and is dependent upon the normal function of Tc cells, NK cells, NKT-cells, DCs, and macrophage inflammatory mediators, including INF, interleukins, and Th1 cytokines, which increase the cytotoxic activity of Tc and NK cells. The Th2 cytokines increase humoral immunity and suppress the Th1 response. The postoperative period is the most vulnerable period for metastasis of cancer cells. This can be attributed to the surgical suppression of cell mediated immunity which can last several days after the procedure and is proportional to the extent of the surgical trauma. Tumor cells express adrenergic β -receptors that regulate multiple cellular processes necessary for the initiation and progression of cancer; β -receptor activation suppresses NK activity and supports metastasis. The increased epinephrine and norepinephrine released in the HPA stress response bind to the β -receptors on tumor cells and increase their proliferation and survival. Current research involves the use of β -blockers to reduce the progression rate of solid

tumors.^{100,101} Immune-suppressive agents intended to prevent rejection of transplanted organs also allow cancers to grow, as well as depress the ability of the immune system to target and kill viruses associated with cancer, including HPV and HCV. Transplant recipients of solid organs have an increased risk for cancer, and are almost three times more likely to die from cancer than the general population.^{102,103} Angiogenesis is increased after surgery and is regulated by multiple angiogenetic factors, including IL-6, IL-8, 1 β , cyclooxygenase 2 (COX2), NO, TNF, VEGF, TGF, and insulin growth factor (IGF). Catecholamines also promote angiogenesis.^{104,105} Surgery-induced angiogenesis promotes tissue repair at the surgical site but also contributes to tumor growth and metastasis.¹⁰⁰ The effect of various anesthetic techniques on cancer recurrence are summarized in [Table 46.8](#).

TABLE 46.8

Effect of Anesthetic Technique on Cancer Recurrence or Metastasis

Anesthetic Technique	Effect on Cancer Recurrence and Metastasis
Volatile anesthetic agents	Conflicting evidence; some in vitro studies suggest enhanced expression of tumorigenic markers, migration of cancer cells, angiogenesis and metastasis in tumors. Insufficient evidence exists to avoid in cancer surgery
Nitrous oxide	No impact on cancer recurrence
Local anesthetics	Reduced cancer recurrence and metastasis secondary to anti-inflammatory actions and direct effects on the proliferation and migration of cancer cells
Neuraxial anesthesia	Conflicting results but generally thought to reduce cancer recurrence and metastasis by attenuating the immunosuppressive consequences of the stress response and possibly an opiate sparing effect.
Nonsteroidal anti-inflammatory drugs	Acute or chronic use associated with tumor regression presumably via cyclooxygenase-2 (COX 2) and prostaglandin inhibition in cancer cells. Beneficial choice as analgesics in cancer patients
Acetylsalicylic acid (ASA)	Reduces cancer metastasis
Opioids	Promote cancer progression and reduce long-term survival. Promote cancer cell growth, inhibit cellular immunity, enhance angiogenesis and tumor cell signalling pathways; inhibit natural killer cell function
Supplemental oxygen	Patients given 80% oxygen postoperatively have a shorter cancer free survival period. Has an angiogenic effect on micrometastasis
Dexamethasone	No effect on cancer survival

Adapted from Byrne K, et al. Can anesthetic-analgesic technique during primary cancer surgery affect recurrence or metastasis? *Can J Anaesth.* 2016;63(2):184-192.

Perioperative Blood Transfusion

Blood transfusion is associated with a depression of the immune system, an increased incidence of SSI, and earlier recurrence of cancer.^{106–109} Transfusion-related-immunomodulation (TRIM) was first recognized in the early 1970s when it was noted that kidney transplant recipients who had received allogenic blood transfusions had better allograft survival rates. The mechanism of TRIM involves donor leucocyte suppression of monocytes, altered lymphocyte function, release of immunosuppressive prostaglandins, inhibition of IL-2, and increased suppressor T-cell activity.^{100,105} In addition to higher allograft survival rates, TRIM is associated with an increased risk of postoperative infections, increased tumor recurrence after surgical resection, activation of latent viral infections, and improvement in autoimmune disease. Irradiated or leucocyte-depleted blood products are recommended for cancer patients to offset the depression of the immune system by donor leukocytes.¹⁰⁰ However, the increased risk for cancer metastasis appears to be similar for recipients of allogenic, autogenic, or leukocyte reduced transfusions.¹⁰⁴ Cancer recurrence risk does not appear to be impacted by blood storage donation.^{110,111} Use of intraoperative cell savers may also contribute to cancer recurrence because the surgical blood can contain tumor cells from the surgical site.¹⁰⁷ Transfusions are discussed in [Chapter 22](#).

Perioperative Hyperglycemia

Diabetes mellitus is associated with an increased susceptibility to bacterial, fungal, and viral infections secondary to depression of both the innate and adaptive immune systems. In a similar manner, perioperative hyperglycemia is associated with an increased incidence of SSI and poor patient outcomes. Hyperglycemia is associated with decreased neutrophil function and decreased proliferation. It decreases mobilization and adherence of monocytes at the site of infection, impedes their bactericidal activity, and limits their ability to stimulate apoptosis in pathogenic cells. Hyperglycemia decreases the complement response; it inhibits opsonization by binding to the C3 receptor and preventing the receptor from attaching to the microbe and activating phagocytosis.

Hyperglycemia is associated with increased synthesis and release of cytokines, specifically IL-6, TNF, and CRP. Hyperglycemia also suppresses vasodilation during acute tissue inflammation, effectively reducing blood flow to the infected tissue and limiting the migration of phagocytes to the site.¹¹² Even transient episodes of hyperglycemia can depress immune function, and tight blood glucose is associated with better outcomes in critically ill surgical patients. A blood glucose level of 140 to 180 mg/dL can attenuate the effects of hyperglycemia on the immune system.¹¹³

Perioperative Hypothermia

Hypothermia suppresses innate and adaptive immunity and is associated with decreased antigen presentation by APCs and cytokine secretion. Intraoperative hypothermia, a core body temperature of less than 36°C, occurs in 70% of surgical patients.¹⁰⁰ It is associated with an increased incidence of SSIs, increased blood loss, impaired wound healing, and decreased immune function.^{104,114} Hypothermia causes generalized vasoconstriction, which reduces blood flow to the surgical site and retards the movement of neutrophils and monocytes to the damaged tissue.¹¹⁵ Hypothermia is associated with a threefold increase in SSIs in colon resections, increased SSI rates after trauma laparotomy, and decreased survival rate following debulking surgery for ovarian cancer.^{116,117} It is also associated with an increased need for blood transfusions, which exposes the patient to the additional immune suppression risk of TRIM.¹¹⁸ The Surgical Care Improvement Project (SCIP), initiated by the CDC and Centers for Medicare and Medicaid (CMS), requires a temperature above 96.8°F within 15 minutes after anesthesia end time.

Anesthesia and the Immune System

Anesthesia is associated with impaired immune function, including depressed function of NK cells, neutrophils, macrophages, DCs, and T cells; however, it is difficult to separate the effects of surgery and anesthesia on the immune system. Surgery may be the trigger for a dampened immune response, but anesthetic agents may also act as immunologic modulators and influence wound infection and cancer recurrence. Most of the research on the direct effect of anesthetic agents has been performed *in vitro*; *in vivo* research is complicated because of multiple contributing factors. There is some evidence that supports an association between anesthesia and cancer recurrence or metastasis but, overall, results from primarily retrospective studies on anesthetic agents and cancer recurrence are conflicting.¹¹⁹⁻¹²⁶

Volatile Anesthetics

Volatile anesthetics suppress the cytotoxicity of NK cells and macrophages, induce apoptosis of T cells, decrease IL-2 and restrict proliferation of T cells, up-regulate tumorigenic growth factors, hypoxia-inducible factor and IGF, and enhance angiogenesis.^{99,120,121,123,127-130} Apoptosis of cancer cells is suppressed by volatile anesthetics.⁹⁰ They impair adhesion of phagocytes and inhibit the respiratory burst necessary for destruction of pathogens. Isoflurane appears to be the most frequently implicated agent in primarily retrospective studies. However, one randomized control trial found no significant difference between total intravenous anesthesia and isoflurane anesthesia for colorectal surgery.^{131,132} Nitric oxide suppresses neutrophil chemotaxis and function.¹³³

Intravenous Agents

Midazolam decreases IL-8 necessary for migration and adhesion of neutrophils.¹³⁴ Ketamine and thiopental depress NK cell activity and are associated with cancer metastasis.¹³³ The interaction with adrenergic receptors may account in part for the suppression of NK activity by ketamine. Propofol increases antiinflammatory

cytokines with antitumor activity. In addition, it is associated with minimal effects on NK cells and inhibition of COX2 and prostaglandin E2 (PGE2) in tumor cells.⁹⁹ When combined with epidural anesthesia, propofol is associated with a reduction of factors that promote angiogenesis.¹³⁵

Opioids

Uncontrolled postoperative pain, a potent stimulant of the HPA and SNS, contributes to perioperative immune suppression and amplifies the tumor promoting effects of surgery. Effective pain control attenuates the surgery-induced stress response that promotes metastatic susceptibility and opioids are commonly used throughout the perioperative period. Opioids suppress NK cells that are vital for the eradication of tumor cells and viruses, promote angiogenesis, and suppress apoptosis.^{90,98,109,121,133} Opioids are associated with a decreased antibody response and increased susceptibility to infection. A link between opioids and depression of both the innate and adaptive immune system was identified in the early 19th century when an increased incidence and severity of infections in intravenous opioid addicts could not be explained by the administration route alone.

The immune modulatory effects of opioids appear to be mediated by the mu (μ) opioid receptor (MOR) on lymphocytes.¹³⁶ Inflammatory cytokines regulate the expression of the MOR gene. The MOR is overexpressed in some types of lung cancer.¹³⁶⁻¹³⁸ Methylnaltrexone (MNTX), a selective peripheral MOR-antagonist, significantly reduces opioid-induced tumor growth and metastasis. However, in some cases, opioids appear to paradoxically suppress tumor migration and proliferation and induce apoptosis in cancer cells. Morphine inhibition of the migration and adhesion of colon cancer cells has been demonstrated, as well as induction of apoptosis in lung carcinoma and some leukemias.^{100,138}

Opioids differ in their ability to modulate the immune response. Morphine is associated with the greatest depression of the immune system. Codeine, methadone, remifentanyl, and fentanyl demonstrate strong immune modulation; weaker modulation is seen with hydromorphone, oxycodone, tramadol, and hydrocodone. Buprenorphine has minimal or no effect on the

immune system. Remifentanyl also increases antiinflammatory cytokines I:10 with antitumor activity.¹³³

Postoperative immunosuppression causes excess release of prostaglandins (PGs) which promote cancer cell adhesion, migration, and invasion; PGs also inhibit the activity of Tc and DCs, down-regulate antineoplastic cytokines (TNF- α and INF- γ), and up-regulate immunosuppressive cytokines (IL-10, IL-4, and IL-6). Cyclooxygenase converts procarcinogens to carcinogens and can initiate cancer cell growth. The COX-2 are overexpressed in some breast and colorectal cancers; their product, prostaglandin E₂ (PGE₂) is believed to contribute to the metastatic potential of these cancers. NSAIDs attenuate PG synthase by COX inhibition. Administration of COX-2 inhibitors, alone or in conjunction with morphine, prevents induced tumor growth and metastasis, as well as angiogenesis.^{139,140} Long-term use of COX inhibitors, especially COX-2 inhibitors, are associated with a reduced risk of cancer.¹⁰⁰

Regional Anesthesia

By blocking afferent neural transmission, regional anesthesia attenuates the surgical stress response and supports preservation of normal immune function. It is associated with decreased cortisol levels, normal NK cell function, and preservation of normal Th1/Th2 balance.¹⁴¹ In addition, regional anesthesia decreases the use of opioids and volatile anesthetics and is associated with a lower incidence of SSI compared to general anesthesia (GA). Local anesthetics, especially the amides, are associated with cytotoxic effects on cancer cells, which appear to be related to their lipid solubility and potency.¹⁰⁰ A combination of GA and epidural anesthesia may mitigate the surgical-induced immune suppression.¹⁴² In combination with GA or alone, regional anesthesia is associated with a longer cancer-free time interval and a lower incidence of breast, colon, prostate, and melanoma cancer recurrence.^{90,98,100,130,142,143} However, there appears to be no difference in the incidence of SSI for total joint arthroplasty between GA and regional anesthesia. A combination of propofol, COX antagonists, and regional anesthesia is associated with decreased immunosuppression.¹¹⁹ Whereas retrospective studies appear to

indicate that regional anesthesia may improve the survival rate in cancer patients, a Cochrane review of four studies with 746 participants found no evidence that regional anesthesia was associated with better long-term outcome in patients with malignant tumors.¹⁴⁴ A meta-analysis of 14 studies in surgical cancer patients also did not support a causative association between epidural anesthesia and cancer outcomes.¹⁴⁵

Anesthetic Management of the Immunocompromised Patient

Up to 1.5% of the US population may have a defective immune system and an unknown number may be immunocompromised because of underlying disease and medical interventions. Patients with immunodeficiency syndromes and iatrogenically induced immune suppression for treatment of autoimmune diseases and prevention of organ transplant rejection have an increased risk for SSIs, as well as migration and proliferation of cancer cells. Preoperative tests for immunosuppression include complete blood counts with a differential smear, serum immunoglobulins, complement assays, T-cell function (skin testing), and B-cell function (antibody titers).

Throughout the perioperative period, anesthesia providers administer medications into intravenous tubing through side ports, stopcocks, and other types of needleless connectors (NC). These sites are open to the environment and provide an immediate portal of entry for bacteria into the bloodstream; contamination and biofilm formation of the NC is responsible for approximately 50% of catheter-related infections.¹⁴⁶ Bloodstream infection from peripheral IV catheters may exceed central line-related infections. Although aseptic technique is required for all patients, deviation from the standard of care places the immunocompromised patient at a high risk for postoperative infection. It is estimated that health care providers' compliance with NC disinfection is only 10%.¹⁴⁷ According to the CDC guidelines for prevention of intravascular catheter-related infections, the NC hub should be disinfected with greater than 0.5% chlorhexidine with alcohol, 70% alcohol, or 10% povidone-iodine prior to access. Antiseptics should be allowed to dry for maximal effect.¹⁴⁸ Use of alcohol chlorhexidine disinfection caps creates a physical and chemical barrier between the lumen and the environment. Strict aseptic technique and maximum barrier precautions are mandatory for placement of central lines.

Whereas there is no evidence to support the use of regional anesthesia over GA, the addition of a neuraxial block will blunt the

surgical-induced neuroendocrine response associated with suppression of the immune system and a heightened risk of infection. Prophylactic antibiotics should be administered at least 30 minutes before skin incision. Prevention of intraoperative hypothermia through the use of active warming modalities, patient and fluid warmers, is warranted for long surgical cases. Intraoperative hyperglycemia must be avoided and may warrant an insulin infusion. Leukocyte poor and irradiated blood should be used when transfusion is unavoidable. Postoperative pain is best controlled with a combination of neuraxial anesthesia and nonopioid agents.

The American Association of Nurse Anesthetists has identified standard precautions that reduce the risk of SSIs. These include hand hygiene, safe injection practices, and targeted cleaning of the anesthetizing equipment between cases.¹⁴⁹ Although hand hygiene can significantly reduce the incidence of infection, it is often overlooked by anesthesia providers. The OR environment is not conducive to frequent physical hand washing with soap and water during case management, but use of single and double gloves that are removed after contamination, and frequent use of an alcohol based product is mandatory when caring for patients with **Box 46.5** compromised immune function (**Box 46.5**).

Anesthetic Management of the Immunocompromised Patient

- Assessment of preoperative immune status
- Risk for intraoperative type I hypersensitivity reaction
- Regional anesthesia
- Combined general and regional anesthesia
- Nonopioids for pain management
- Active patient warming for long cases
- Tight blood glucose control

- Leukocyte poor or irradiated blood transfusion if warranted
- Strict aseptic precautions

Summary

The immune system is comprised of two subcategories: the innate, or natural, immune system and the adaptive, or acquired, immune system. An effective immune response requires a cooperative synergy between the two systems to protect the body from a wide variety of pathogens. The innate system generates the first-line of defense and the adaptive system provides antigen-specific antibodies for future encounters with the same antigen. The response of both the innate and adaptive immune systems includes a cell-mediated response that is carried out by phagocytes, T lymphocytes, and cytokines in response to antigens in host cells, and a humoral response that is mediated by B lymphocyte antibodies. Passive immunity with administration of IG can temporarily increase a patient's immune system. Active immunity, achieved with prior antigen exposure or immunizations, establishes long-term immunologic memory in the adaptive immune system.

Abnormalities of the immune system include hypersensitivity reactions, alloimmunity and autoimmunity, primary and secondary immune deficiencies, and malignancies of the immune cells and lymphoid tissue and organs. Surgery causes a generalized state of immunosuppression in the immediate postoperative period that is associated with a reduced resistance to infection, development of postoperative septic complications, and tumor metastasis. Confounding factors include cancer type, allogeneic blood transfusions, and intraoperative hypothermia or hyperglycemia or administration of glucocorticoids. Anesthesia is also associated with depressed immune function, but it is difficult to separate the effects of surgery and anesthesia on the immune system. There is some evidence of an association between anesthesia and cancer recurrence but, overall, results from retrospective studies on SSI and cancer recurrence are conflicting, and there are no randomized controlled trials that support the selection or exclusion of a specific technique or agent. The decreased cortisol levels and preservation of Th1/Th2 balance that is associated with regional anesthesia may be due to a direct effect of the regional anesthesia, attenuation of the surgery-induced stress response, and/or a reduced use of opioids.

Whereas there is no evidence to support the use of regional anesthesia over GA, the combination of the two techniques will blunt the surgery induced HPA response and provide postoperative pain control in combination with nonopioid agents such as clonidine, gabapentin, NSAIDS, and acetaminophen.

Surgical patients can exhibit a wide array of immune system dysfunction as a result of primary or secondary immune deficiency syndromes, chronic immune suppression therapy, increasing age, preexisting disease, and preoperative sepsis. Consequently they have an increased risk for SSIs and postoperative migration and proliferation of cancer cells. Appropriate anesthesia care includes the issue of strict aseptic technique for invasive procedures, administration of prophylactic antibiotics 30 to 60 minutes prior to skin incision, prevention of intraoperative hypothermia and hyperglycemia, immediate removal of contaminated gloves, TNC disinfection prior to access, targeted cleaning of the anesthetizing area, and frequent hand cleansing throughout the perioperative period.

Anesthesia and Laser Surgery

Bernadette T. Higgins Roche

Introduction

The term *laser* is an acronym for *light amplification by the stimulated emission of radiation*. In 1917, Albert Einstein set the stage for development of the laser with his theory that photoelectric amplification of light could emit a single frequency, or stimulated emission. The first laser was developed by Arthur Schawlow and Charles Townes in the late 1950s; Townes later won the Nobel Prize in physics for his work on masers and lasers. The term *laser* was proposed by Gordon Gould in 1959. In 1960, Theodore Maiman built the first functioning laser using a mixture of helium and neon, and in rapid succession, a number of lasers were developed: the yttrium-aluminum-garnet laser treated with 1% to 3% neodymium (Nd:YAG) in 1961, and the argon laser in 1962. The ruby laser, the first medical laser, was introduced in 1963, followed by the carbon dioxide (CO₂) laser in 1964. Medical lasers were first used in retinal surgery. The development of smaller and more powerful lasers expanded the use of lasers to all surgical specialties; currently they are used in laparoscopic procedures, surgery of the upper and lower airways, endoscopic arthroscopic procedures, and transmyocardial and transluminal revascularization. Capable of making incisions as small as 0.5 microns, the laser scalpel offers definite advantages over traditional surgery, including improved access to operative sites, greater precision in tissue destruction and removal, increased anatomic preservation, and controlled hemostasis. Lasers have hard and soft tissue applications in dentistry. They continue to play a major role in ophthalmology, in large part because of the introduction of the excimer laser in the 1980s; laser-in-situ keratomileusis (LASIK) is one of the most common surgical procedures in the United States. Surgical lasers have revolutionized the field of dermatology and esthetic surgery. Lasers are also used in spas and beauty salons for laser hair removal (LHR) by cosmetologists and estheticians. Medical use of lasers also includes photodynamic therapy (PDT) in which laser-activated drugs are used to destroy cancer cells. Medical lasers can only be used by licensed practitioners; states regulate the practitioners authorized to use medical lasers. Lasers have

significant scientific application and are used extensively in the construction, communications, energy, and entertainment industries; military use includes target identification, energy weapons, and missile/projectile guidance.

Basic Principles of Lasers

Electromagnetic Spectrum

Electromagnetic radiation is a broad spectrum of heat energy that travels in waves. It includes radio waves, microwaves, infrared waves, visible light waves, ultraviolet waves, x-rays, and gamma rays (Fig. 47.1). A wavelength is the horizontal distance between two successive corresponding points of the wave. The wavelength decreases and the frequency increases as the electromagnetic spectrum moves from radio waves to gamma waves. The optical portion of the electromagnetic spectrum includes infrared, visible, and ultraviolet waves with a wavelength range of 200 to 1000 nm. Visible light includes a rainbow of colors—red, orange, yellow, green, blue, indigo, and violet—with a very narrow wavelength range of 400 nm (violet) to 700 nm (red).¹⁻⁴ The infrared and ultraviolet waves of the optical spectrum are invisible to humans; infrared radiation is perceived as heat and ultraviolet radiation causes a chemical reaction in human skin with little heat production.

FIGURE 47.1 The electromagnetic spectrum. (From Fonseca RJ, et al. *Oral and Maxillofacial Surgery*. 2nd ed. Philadelphia: Elsevier; 2009:237.)

Light can be described as both a wavelength and a particle of energy called a *photon*. The energy of an electromagnetic wave is proportional to its frequency and inversely proportional to its wavelength. Because of its short wavelength and high frequency, ultraviolet radiation contains a lot of energy that can damage the skin. The energy of a photon is defined as the energy emitted when an electron falls from an excited orbit to one of lower energy; the energy between the two orbits defines the wavelength of the emitted photon. The relationship between the energy and the wavelength of light is:

$$E = hc/\lambda$$

where E is energy in joules, h is Planck's constant (6.63×10^{-34} J-s), c is the speed of light (2.998×10^8 m/s), and λ is wavelength in meters.^{1,2}

Spontaneous and Stimulated Absorption and Emission of Energy

In an atom, electrons exist in specific locations called *orbits* or *orbitals*; each orbital represents a specific level of energy. The ground state or orbital closest to the nucleus has the lowest energy; the higher orbitals have the greatest energy. Energy is required for movement of an electron to a higher orbital and must equal the difference in energy between the two orbitals. Conversely, an electron will lose energy if it falls to a lower orbit. Electrons have a tendency to return to the ground state spontaneously, releasing a photon of light energy in the process. This is called *spontaneous emission of radiation*. The energy of the photon and therefore its wavelength is dependent on the energy difference between the two orbits. The light produced by fluorescent lights or incandescent bulbs is a result of electrons changing orbits and returning to ground state. Both the energy of the released photon and the wavelength of the light are proportional to the energy difference between the excited state and the ground state of the atom. Light produced by spontaneous emission is composed of different

wavelengths and frequencies; consequently, the photons oscillate randomly (noncoherence), and the light disperses as it travels.

An electron can be “pumped” up to a higher orbital of energy level by a stimulating photon with energy equal to the energy difference between the two orbitals. A stimulating photon can also cause an atom in an excited state to fall to a lower orbital and release energy. When an atom is struck by a stimulating photon, it decays back to its ground state and emits a second photon. If the energy of the stimulating photon is equal to the energy difference between the excited and ground states of the atom, the emitted photon will have the same wavelength, energy, frequency, and direction as the stimulating photon. This process is known as *stimulated emission of radiation* (Fig. 47.2). The two photons, the stimulating photon and the emitted photon, can strike other excited atoms and stimulate additional emission of photons resulting in a burst of coherent radiation as all the atoms return rapidly to ground state.

FIGURE 47.2 The interaction of light (a photon) with an

atom. Three processes are shown: **(A)** the absorption of a photon by an atom in a low-energy state, **(B)** the spontaneous emission of a photon from an atom in an excited state, and **(C)** the stimulated emission of a photon by a second photon of the same wavelength from an excited-state atom. (From Davey A, Diba A. *Ward's Anaesthetic Equipment*. 6th ed. Philadelphia: Elsevier; 2012:476.)

Coherence, directionality, and monochromaticity differentiate laser light from fluorescent or incandescent light.^{1,2} Laser beam photons have the same wavelength and oscillate synchronously in identical phase with one another (coherence). Laser light moves in a parallel, narrow beam (spatial coherence) over long distances and displays minimal dispersion. This spatial coherence, known as *collimation*, allows the laser light to be focused on a very small area. Reflection of a laser beam can reduce the collimation and increase the dispersion, especially if the reflecting surface has a matte or dull finish; however, the reduction in collimation and increased dispersion of a reflected laser beam is insignificant if the reflecting surface is smooth and shiny. The distance between the earth and the moon is calculated by the length of time it takes for a laser light to return to earth from reflectors placed on the moon. Laser light is composed of specific and discrete wavelengths; consequently, the light emitted is monochromatic and specific for each laser. Just as white light is composed of multiple colors, some lasers are tunable and can emit light at several different wavelengths. However, tunable lasers can only emit one color or wavelength at a time. A typical light bulb is more powerful than a laser, but its light is not collimated, and the dispersion of the light reduces its intensity. In contrast, the intensity of a 1-milliwatt (mW) laser is six times greater than a 100-watt (W) incandescent bulb. Although a typical laser emits only a few milliwatts of power, from a distance of 100 feet lasers can produce a highly intense beam of 1 to 2 mm that can be one million times more concentrated than light from an incandescent source.¹⁻³

Laser Physics

A laser unit requires an external energy source, optical resonating cavity, and laser medium (Fig. 47.3). The external energy source is

necessary to pump up the energy of the laser medium and allow the electrons to move to a higher energy state or orbital. External energy sources include flash lamps, continuous light, high-voltage discharge, diodes, or another laser.¹ Electric current is used to excite gas lasers, such as carbon dioxide and argon (Ar) lasers. Liquid and solid state lasers, such as the potassium-titanyl-phosphate (KTP) laser, require energy from a flash lamp or another laser.

FIGURE 47.3 A laser system consists of several components, regardless of whether the laser is a solid-based, liquid-based, or gas-based device. The central component is the laser medium itself, which may be a solid crystal of yttrium-aluminum-garnet (YAG) with a small concentration of neodymium (Nd) as dopant, or may be a tube containing carbon dioxide (CO₂). The energy pump (xenon flash lamp or an electric spark generator) provides the means of obtaining a population inversion of orbital electrons. A pair of axial mirrors permits repeated passes of collimated photons through the laser medium allowing maximum amplification by stimulated emission. The mirror on the right is not 100% reflective and allows the beam to escape. The optional Q switch increases the efficiency of pulsed lasers by allowing a small delay to increase the pumping. (From Miller RD, et al. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010:2408.)

The optical resonating cavity, a tubelike structure, provides optimal amplification of the laser beam. It contains the lasing

medium and a mirror at each end of the tube. When the lasing medium is excited by the outside energy source (e.g., flash lamp, electric current), the atoms are “pumped” to a higher energy level increasing the number of atoms in the excited state. Population inversion is necessary for stimulated emission of radiation, and it occurs when more atoms are in an unstable excited state than the resting state. When one of the atoms spontaneously decays back to its ground state, it releases a photon that “stimulates” other excited atoms to decay back to ground state, releasing additional photons. The wavelength, frequency, phase, and direction of the secondary photons are identical to those of the first photon. The mirrors reflect the excited photons back into the resonating cavity at approximately 186,000 miles per second, where they travel back and forth in a parallel fashion, stimulating the release of more photons from other excited atoms and amplifying the resultant laser light (Fig. 47.4). One of the mirrors is partially transparent and allows a very thin beam of the coherent, collimated, and monochromatic laser light to exit and focus on the target tissue.¹⁻²

FIGURE 47.4 Basic components of a laser. The optical cavity contains the lasing medium (e.g., solid, liquid, gas). The power source (e.g., flash lamp, electric current, other laser) pumps up the electrons in the lasing medium to a higher energy state. Two mirrors reflect the photons back into the cavity, where they stimulate other excited atoms to emit identical photons. One mirror is partially transparent and allows a portion of the laser beam to exit the cavity in a narrow beam.

The laser medium can be a solid, gas, liquid, or semiconductor

that is stimulated to a metastable state when pumped with an external energy source. Lasers are commonly named after the medium that determines the wavelength output of the laser. *Solid-state lasers* such as the neodymium: yttrium-aluminum-garnet (Nd:YAG) laser use a solid matrix fabricated into a rod approximately the size of a cigarette. The rod is doped with a small amount of Nd impurity (dopant) that provides the energy source for the laser. Solid-state lasers are more powerful than gas lasers and require optical pumping with white light for a flashlamp, or monochromatic light from another laser. *Gas lasers* use a variety of gases as lasing media, including argon, CO₂, helium, helium-neon, and krypton, and require an electrical source of energy for pumping. *Liquid lasers* utilize complex dyes dissolved in a liquid such as methanol; optically pumped, they are tunable over a broad range of wavelengths, mostly in the visible spectrum. *Excimer lasers* are gas lasers that use a mixture of chlorine or fluorine and an inert gas such as argon, krypton, or xenon. Electrical stimulation is used to produce a dimer of the halogen; the resultant dimer is unstable and quickly decomposes into its constituent atoms releasing energy in the form of light. *Semiconductor lasers* or diode lasers are composed of semiconductor crystals that are pumped by a high-intensity current. They are commonly used in compact disc players, laser printers, and laser pointers. The gallium-arsenide laser is an example of a semiconductor laser.

Laser Operation

Laser effect on tissue is dependent on the wavelength of the laser light, which, in turn, is determined by the laser medium. Consequently, laser selection is based on the desired effect of the laser on the targeted tissue.⁴ The majority of medical lasers deliver only one wavelength. In addition to selecting the appropriate wavelength, the surgeon must use the appropriate exposure time and energy density (power setting) to achieve the intended photomechanical, photothermolysis, or photochemical effect.

A laser beam can be delivered in a continuous wave (CW), pulsed-wave, or Q-switched mode. In the CW mode the laser continues to emit a steady beam as long as the laser medium is

excited. Output is measured in watts and can vary significantly among lasers. For example, the power of the helium-neon laser is measured in milliwatts, whereas the output of the more powerful CO₂ laser is measured in kilowatts. Power density of the beam (irradiance or flux) varies from a few watts per square centimeter to hundreds of watts per square centimeter (Box 47.1). In the pulsed mode the laser emits peak energy levels in individual pulses from femtoseconds (quadrillionths of a second) to seconds. The power of a pulsed laser is measured in joules, and energy intensity is expressed as joules per square centimeter. In the Q-switched mode the laser emits high-energy, ultrashort pulses (approximately 10 to 250 nanoseconds [nsec]). A shutter is placed in the optical path to allow the buildup of a large population inversion. After release of the shutter, the electrons fall rapidly to ground state releasing a large amount of energy that is measured in megawatts.

Laser Output

Energy: Proportional to the number of photons, measured in joules (J).

Power: Rate of delivery of the energy, measured in watts (W) (1 W = 1 J/sec.).

Fluence: Energy delivered per unit area, measured in J/cm².

Irradiance (or flux): Power per unit area, measured in W/cm².

The mode of delivery determines the effect of the laser on the tissue. For example, the Nd:YAG laser utilizes the CW mode for coagulation of tumors, the pulsed mode for hair removal, and the Q-switched mode for tattoo removal. In the CW mode the CO₂ laser can be focused very tightly and used for incision, much like a scalpel, whereas the defocused CO₂ laser can be used to vaporize a larger area of tissue. When delivered through a scanning device, the CO₂ laser beam can remove a predetermined thickness of skin. Fiberoptic cables are used for delivery of laser beams with visible and near-infrared wavelengths. Articulated arms with reflecting mirrors mounted in tubes are used to direct the beam of a far-

infrared laser (CO₂). Additional attachments include slit lamps for use on the eye, operating microscopes, and insulated fibers for use with endoscopes. Contact laser probes (sapphire) on the distal end of a fiberoptic bundle transform the light energy into heat for precise cutting and reduced penetration.

Laser Effects on Biologic Tissues

Lasers are associated with rapid and precise vaporization or coagulation of tissues and are commonly used in a variety of unrelated diagnostic and therapeutic procedures. Collateral tissue damage occurs when the laser beam is held on tissue longer than the thermal relaxation time, the time for 50% of the laser energy to be thermally conducted to surrounding tissue. Pulsing the laser beam or scanning a continuous beam concentrates the energy, limits the exposure time, and minimizes thermal damage. The duration of laser beam exposure is controlled by computerized scanning of the beam in a preset pattern prior to delivery of the laser beam to the tissue.

Laser light is monochromatic and has very selective effects on biologic tissues. The degree of laser light transmission, scattering, reflection, or absorption is dependent on the tissue and the wavelength of the light. Absorption of the light is necessary for the laser to be effective; if the tissue transmits, reflects, or scatters the light, the laser will have little or no effect on the tissue. A specific wavelength may be absorbed by one type of tissue and transmitted by another. Biologic tissues can be thought of as an aqueous solution of light-absorbing molecules. Chromophores, such as hemoglobin and melanin, and water are the main absorbing components, and they determine the reaction of the tissue to the laser light. To be effective the laser light must match the absorptive property of the tissue. If light absorption occurs, the laser light is converted to heat; vaporization or ablation of the tissue occurs when the temperature reaches 100°C. As the tissue is vaporized, the thermal energy of the laser beam cauterizes capillaries and provides immediate hemostasis. Tissue coagulation or denaturation rather than ablation occurs at lower temperatures. The reaction of tissue to light absorption is dependent on the wavelength, intensity, and exposure time of the light. Laser-tissue interactions include photomechanical, photothermal, photochemical, and photodynamic reactions ([Box 47.2](#)). Photomechanical effects are caused by powerful, short pulses of laser light that are converted into mechanical energy in the form of a shock wave causing explosive

tissue expansion and destruction. Photothermal reactions occur when low-power, long pulses of laser cause a rapid increase in temperature resulting in tissue vaporization and coagulation. When applied for longer durations, low-power lasers can cause a photochemical reaction that either breaks molecular bonds in cells or excites cellular molecules into a biochemically reactive state. In a photodynamic reaction, the laser light activates photosensitizing medications that are selectively absorbed by a specific tissue. The photosensitizing drug causes cytotoxicity by producing a biologically reactive form of oxygen (singlet oxygen) after stimulation with light of an appropriate wavelength. Biostimulation lasers, also called low level laser therapy (LLLT), cold lasers, soft lasers, and laser acupuncture devices, have Food and Drug Administration (FDA) approval for the temporary relief of pain.⁵

Laser-Tissue Interactions

Photomechanical Reaction: Mechanical energy creates a shock wave that causes explosive tissue expansion and destruction.

Photothermal Reaction: Rapid increase in temperature causes tissue vaporization and coagulation.

Photochemical Reaction: Destruction of molecular bonds or stimulation of cellular molecules into a biochemically reactive state.

Photodynamic Reaction: Laser light activates photosensitizing medications that cause cytotoxicity by producing a biologically reactive form of oxygen (singlet oxygen).

Laser Absorption

Biological tissue absorption of laser energy is a function of light wavelength. Absorption depth is defined as the tissue depth at which the intensity of the laser beam is reduced by 63%.¹ Water absorbs infrared wavelengths and allows transmission of visible wavelengths. Hemoglobin gives blood its red color because it reflects red wavelengths. Deoxygenated blood absorbs more red wavelengths and consequently appears darker than oxygenated

blood. Hemoglobin absorbs blue and green wavelengths and lasers with blue and green wavelengths, such as the argon and Nd:YAG lasers, are very effective in well perfused tissues.¹ Melanin in the skin absorbs all visible wavelengths but absorption is greatest with ultraviolet wavelengths. Zanthophyll is a pigment of the retina; its best absorption is at 460 nm. Collagen, a structural component of most tissues, readily absorbs infrared laser energy. Atherosclerotic plaques are made of fat and collagen deposits; they do not absorb visible or near infrared light and pulsed mid-infrared and ultraviolet lasers are required to ablate arterial plaques.¹

Tissue absorption is greatest with longer wavelengths such as the far-infrared wavelength of the CO₂ laser (10,600 nm). The CO₂ laser beam is completely absorbed by water in the first few cellular layers, resulting in explosive vaporization of the top layer, but little or no damage to the underlying tissues. Excimer lasers (ultraviolet) are associated with an even more superficial effect because of their strong absorption by water. Light from lasers with visible wavelengths, such as the ruby, argon, and krypton lasers, is transmitted by water and absorbed by cells that contain dark pigment. It can penetrate the skin and the cornea to coagulate pigmented or vascular lesions. Near-infrared laser light has greater tissue penetration and is transmitted rather than absorbed by water; near-infrared lasers, such as the Nd:YAG, are suitable for deeper procedures such as tumor debulking. Advantages of lasers include precision, access to remote sites in the body, reduced blood loss, reduced damage to adjacent tissue, and improved patient satisfaction. A disadvantage of laser therapy may be a delay in wound healing.

Surgical Lasers

The major types of lasers used in medicine are far-infrared (CO₂), mid-infrared (erbium [Er]:YAG, holmium [Ho]:YAG, Nd:YAG), near-infrared (diode), visible (ruby, krypton, argon, copper, and gold vapor), and ultraviolet (excimer) (Table 47.1).

TABLE 47.1

Common Surgical Lasers

Lasers	Wavelength	Applications
Far-Infrared		
CO ₂	10,600 nm	Multiple uses: general surgery, orthopedics, gynecology, urology, otolaryngology, plastic surgery
Mid-Infrared		
Nd:YAG	1064 nm	Multiple uses: gastroenterology, pulmonology, urology, ophthalmology, dermatology
Ho:YAG	2070 nm	Orthopedics, urology
Er:YAG	2940 nm	Dermatology
Near-Infrared		
Diode	800-900 nm	Multiple uses: ophthalmology, otolaryngology, periodontics, cosmetic surgery, pain management. Multiple nonmedical applications
Visible		
Argon	488 and 514 nm	Multiple uses: ophthalmology, plastic surgery, dermatology, gynecology, otolaryngology
Krypton	476, 521, 568 nm	Dermatology
Copper bromide	511 and 577 nm	Dermatology, photosynthesizer
KTP	532 nm	Dermatology
Pulsed dye	577-585 nm	Dermatology
Gold	578-628 nm	Oncology
Ruby	694 nm	Dermatology
Alexandrite	755 nm	Dermatology
Ultraviolet (Excimer)		
Argon-fluoride	193 nm	Multiple uses: ophthalmology, dermatology
Krypton-fluoride	249 nm	Dermatology
Xenon-chloride	308 nm	Multiple uses: dermatology, ophthalmology, dermatology
Xenon-fluoride	351 nm	Multiple uses: angioplasty, ophthalmology, dermatology

Er:YAG, Erbium: yttrium-aluminum-garnet; *Ho:YAG*, holmium:YAG; *KTP*, potassium-titanyl-phosphate; *Nd:YAG*, neodymium:YAG

Carbon Dioxide Laser

The CO₂ laser is the most commonly used surgical laser; it has wide application in all surgical specialties. The infrared light of the CO₂ laser (10,600 nm) is invisible to the human eye and a low-power helium-neon (He-Ne) laser (633 nm) is incorporated into the laser to provide a visible red beam for surgical aim. It is a powerful laser that emits light in the infrared region of the electromagnetic spectrum that basically melts whatever is in the path of its beam, including steel. A very precise laser, the lateral zone of damage is less than 0.5 mm from the area of incision. The laser beam is not transmitted by quartz, glass, or other transparent material, and must be delivered as a free beam or through a rigid endoscope with a mirrored, articulated arm. The CO₂ laser light is strongly absorbed by water, and vaporization of cells occurs within the first 100 to 200 μm of the irradiated surface. It can be used in both the CW and pulsed-wave mode. Focused into a tight beam, the CO₂ laser can be used for cutting tissue. Defocusing the beam decreases the power density and causes tissue vaporization or ablation. The CO₂ laser has extensive applications in general surgery, orthopedics, gynecology, urology, and otolaryngology and is associated with minimal blood loss (see [Table 47.1](#)). Thin layers of the skin are ablated for cosmetic skin resurfacing when it is used with a scanning device. The high power of the CO₂ laser has unlimited industrial applications because of its cutting, drilling, and welding capabilities.

Yttrium-Aluminum-Garnet Lasers

The lasing medium of the YAG laser is a YAG crystal rod doped with atoms of rare earth minerals, which accounts for the different properties of YAG lasers. These lasers can be used in the CW, pulsed-wave, or Q-switched mode.

Neodymium: Yttrium-Aluminum-Garnet Laser

The Nd:YAG laser emits a near-infrared invisible light at 1064 nm and requires the addition of a visible aiming beam. It has a penetration of 5 to 7 mm and can be used to cut or coagulate tissue. In the Q-switched mode, the laser removes black tattoo ink and

hair. The Nd:YAG laser has important applications in internal debulking; it is used to treat gastrointestinal and tracheobronchial tumors and genitourinary lesions. The pulsed and Q-switched Nd:YAG laser is used in ophthalmology (see [Table 47.1](#)). The energy of the Nd:YAG beam is more widely dispersed, and damage to adjacent tissues may not be evident for hours after the laser treatment.

Holmium: Yttrium-Aluminum-Garnet Laser

When doped with holmium (Ho), the YAG laser emits a mid-infrared beam at 2070 nm that is strongly absorbed by water. Output in the mid-infrared spectrum requires a coincident aiming beam. The Ho:YAG laser is used to vaporize, cut, coagulate, and sculpt avascular tissue with a minimal amount of thermal necrosis. The primary applications of the Ho:YAG laser are in endoscopic orthopedic procedures (bone and cartilage ablation), and urology (stone removal and transurethral resection of the prostate [TURP]) (see [Table 47.1](#)).

Erbium: Yttrium-Aluminum-Garnet Laser

When a YAG laser is doped with erbium (Er), it emits a mid-infrared beam at 2940 nm (peak absorption of water). Because the infrared beam is not transmitted by quartz or glass, the Er:YAG can be used only as a free beam or through a rigid endoscope. It has limited penetration and excellent precision. It is used extensively in laser resurfacing of the skin and vaporization of fibrous tissue, cartilage, and bone (see [Table 47.1](#)). The Er:YAG laser is also used in dentistry for cavity fillings, root canals, and treatment of gum disease.

Diode Lasers

Diode lasers are semiconductors that emit a near-infrared light (800 to 900 nm) when pumped with a high-intensity electric current. Medical uses include ophthalmology, dermatology (hair removal), and periodontal surgery. Diode lasers are also used to “pump” other laser media such as YAG rods. They have multiple

nonmedical applications and are used in laser printers, laser pointers, the entertainment industries, and fiberoptic communication systems (see [Table 47.1](#)).

Visible Lasers

Argon Laser

In an argon laser the argon gas has lost one or more of its electrons, and the positive ions are excited by a large electrical discharge. The argon ion laser emits visible blue-green light with wavelengths of 488 nm and 514 nm simultaneously. The light is transmitted by water, and absorbed by hemoglobin and melanin, where the main effect is photocoagulation. Penetration is approximately 1 to 2 mm, but this can vary depending on the degree of pigmentation. The beam can be passed through quartz optical fibers, allowing the laser to be used with a microscope or endoscope. The argon laser is used in ophthalmology, plastic surgery, dermatology, gynecology, and otolaryngology (see [Table 47.1](#)).

Krypton Laser

The active medium krypton is also a rare gas with one or more electrons removed, and the krypton ions are excited by an electrical discharge. The laser produces visible green and blue light at 476, 521, and 568 nm. It is absorbed by hemoglobin and used for photocoagulation of vascular or pigmented lesions. Primary application is dermatology (see [Table 47.1](#)).

Ruby Laser

The ruby laser uses a synthetic ruby crystal of aluminum oxide doped with chromium. It emits a red light with a wavelength of 694 nm and has a penetration greater than 1 mm. The light is absorbed by melanin and blue, green, and black pigment. It is very effective for tattoo removal, hair removal, and treatment of pigmented lesions such as freckles, liver spots, and nevi (Q-switched mode) (see [Table 47.1](#)). Although it was one of the first medical lasers, its use in surgery has declined in favor of newer and more powerful lasers.

Alexandrite Laser

Named after Czar Alexander II, the solid-state alexandrite laser contains a rod of synthetic chrysoberyl doped with chromium. It emits a deep red light at 755 nm but frequency doubling can produce a tunable laser output of 360 to 400 nm. Blue and black pigments absorb the beam, with a lesser degree of absorption by melanin. It is used for tattoo removal and treatment of some pigmented lesions (see [Table 47.1](#)).

Metal Vapor Lasers

The active medium of metal vapor lasers is a neutral metal heated beyond its vapor point. A pulsed electrical discharge is used for excitation of the vapor. Vaporized copper bromide emits green light at 511 nm and yellow light at 577 nm that is used to treat vascular lesions. It also has applications for facial resurfacing. The gold vapor laser (578 to 628 nm) is used in photodynamic treatment of cancer (see [Table 47.1](#)).

Photodynamic Therapy

PDT, also known as *photochemotherapy*, involves the administration of photosensitizers, chemical entities that absorb light and induce a change in another chemical. They are used in the diagnosis and treatment of cancer because of their tendency to accumulate in cancer cells. Approximately 72 hours after intravenous administration, when the photosensitizer has left normal cells but remains in cancer cells, the tumor is exposed to laser light with a red wavelength. The photosensitizer absorbs the light and reacts with oxygen to produce free oxygen radicals that destroy cancer cells (phototoxicity). Currently PDT is used to treat bladder, esophageal, pulmonary, and skin cancer. It is also used in dermatology (local application) for treatment of acne, psoriasis, and skin cancer. Its use in antimicrobial therapy is promising because of its ability to target and destroy viral, fungal, and bacterial pathogens. Patients must avoid direct exposure to sunlight during treatment because of photosensitization of the eyes and skin, a side effect of the treatment,

Potassium-Titanyl-Phosphate Laser

The wavelength of the Nd:YAG laser is halved when it is passed through a potassium-titanyl-phosphate (KTP) crystal. A solid-state laser, the KTP laser is similar to the argon gas laser. The beam is transmitted by water and absorbed within 1 to 2 mm of vascular or pigmented tissue. A bright green light (532 nm) delivered through fiberoptics, scanners, or microscopes is used to cut tissue (CW mode), and remove vascular lesions (pulsed mode), and red-orange and black tattoo ink (Q-switched mode) (see [Table 47.1](#)). Although the power density of the KTP laser is sufficient to cut vascular tissue, it does not provide effective hemostasis.

Dye Lasers

Organic fluorescent materials are dissolved in a solvent such as methanol and are typically pumped with a flashlamp or another laser. The energy levels of the dyes are very close to one another and allow the lasers to release a wide range of wavelengths. In the CW and pulsed mode dye lasers have wavelengths of 400 to 1000 nm. They can produce extremely short pulses (measured in trillionths of a second [picoseconds]). The major advantage of the dye laser is the ability to tune the wavelength to maximize the laser-tissue interaction. Dye lasers are used in dermatology for excision of vascular and pigmented lesions, in urology for treatment of urinary calculi, and in oncology for photodynamic therapy. The pulsed dye laser uses a rhodamine dye to emit a yellow laser beam at 577 to 585 nm (peak absorption of hemoglobin). It is the laser of choice for treatment of port-wine stains and thick, red scars (see [Table 47.1](#)).

Excimer Lasers

Derived from the terms *excited* and *dimer*, excimer lasers use a medium composed of a reactive noble gas (chlorine or fluorine) and an inert halogen gas (argon, krypton, or xenon). When the medium is electrically stimulated, an unstable pseudomolecule (dimer) is produced. As the dimer breaks down to its constituent atoms, it releases light in the ultraviolet range that is strongly absorbed by

water. Excimer lasers have a photochemical effect on targeted tissues (pulsed mode), with minimal thermal effect on the underlying tissue. The very short wavelength (ultraviolet) is capable of high resolution and has applications in microscopic surgery. Examples of excimer lasers include the argon-fluoride (193 nm), krypton-fluoride (249 nm), xenon-chloride (308 nm), and xenon-fluoride (351 nm) lasers (see [Table 47.1](#)). They are currently used in ophthalmology for photorefractive keratectomy (PRK) and LASIK. Other uses include removal of arterial plaques and treatment of psoriasis.

Cold Lasers

Cold lasers, also known as *low-level laser therapy* and *soft lasers*, use diodes to produce visible to infrared light. The laser beam can penetrate up to two inches without damaging tissues or producing a significant amount of heat. Through biostimulation of cellular metabolism, cold lasers speed up the healing process. They are used for treatment of carpal tunnel syndrome and other soft-tissue injuries.

Laser Safety

Lasers are divided into four classes according to their potential for causing biologic damage (Table 47.2). Class I lasers are incapable of producing damaging radiation and are exempt from radiation hazard controls. This classification includes CD players and laser printers; supermarket laser scanners are classified as IA. Class II lasers emit radiation in the visible portion of the electromagnetic spectrum, but their radiant power is less than 1 mW. The human aversion reaction to bright light will protect the eyes, but injury can occur if the beam is viewed directly for an extended period. Class II lasers include laser pointers and scanners. Class III lasers, which include spectroscopy and light shows, can cause eye injury if viewed directly. The direct and reflected beam of class IV lasers are hazardous to the eye and are potential fire and skin hazards. Reflected laser beams are specular and maintain the beam coherence; diffuse beams are scattered when they are reflected from a rough or matte surface. Most medical lasers are class IV; these lasers also create hazardous airborne contaminants and require a high-voltage power supply.

TABLE 47.2

Laser Classification

Class	Laser Description
I	Do not emit hazardous radiation and are exempt from radiation hazard controls. Typically continuous wave of 0.4 μ W at visible wavelengths. <i>Examples:</i> CD players and laser printers, CD-ROM devices, geologic survey equipment, and laboratory analytical equipment.
IA	Includes lasers that are not intended for viewing. Maximum power is 4.0 mW. <i>Example:</i> supermarket laser scanners.
II	Do not cause ocular injury unless viewed directly for an extended period. The normal aversion response to bright light protects the eye from a brief exposure. Class II lasers only operate in the visible range (400–700 nm). Maximum power is 1 mW or less. <i>Examples:</i> helium-neon lasers and some laser pointers.
IIA	Special-purpose lasers not intended for viewing. Power output is less than 1 mW. Ocular injury can occur if viewed directly for more than 1000 seconds over an 8-hour day, not continuous exposure. <i>Examples:</i> scanners and bar-code readers.
IIIA	Do not pose a serious eye hazard unless viewed through optical instruments (e.g., microscopes). Power outputs for CW lasers operating in the visible range are between 1 and 5 mW. <i>Examples:</i> solid-state laser pointers.
IIIB	Direct beam viewing or specular reflections result in ocular injury. Power output is between 5 and 500 mW for CW lasers and less than 0.125 J within 0.25 second for a pulsed laser. Do not produce a hazardous diffuse reflection and are not considered fire hazards. <i>Examples:</i> spectroscopy, stereolithography, and entertainment light shows.

IV	Significant ocular injury can result from direct beam viewing, specular reflections, and diffuse reflections. These lasers require significant controls. Power output is greater than 500 mW for a CW laser and greater than 0.125 J within 0.25 second for a pulsed laser. Skin and fire hazards are also present with class IV lasers. <i>Examples:</i> medical lasers and industrial lasers (drilling, cutting, and welding).
----	--

The US FDA regulates the manufacturing and marketing of lasers used in medicine.⁵ The American National Standards Institute's (ANSI) Z136.1–2007 standard addresses medical laser safety and defines control measures for the four laser classifications, which are applicable to medical, industrial, military, and educational laser safety programs.⁶ The ANSI requires the appointment of a laser safety officer (LSO) at institutions that utilize class IIIB or class IV lasers, who is responsible for overseeing education, operation, maintenance, safety, and servicing of medical lasers. However, institutional compliance with the ANSI guidelines is voluntary. The Occupational Safety and Health Administration (OSHA) has identified the hazards associated with the use of medical lasers and developed safety standards to protect patients and operating room (OR) personnel.⁷ The Association of Perioperative Registered Nurses (AORN) and other professional organizations have also developed standards and recommendations for laser safety ([Box 47.3](#))

Laser Safety Precautions

- Restrict laser use to qualified personnel.
- Restrict access to laser area during laser operation.
- Close all doors and cover windows.
- Post Laser Warning signs inside and outside the laser area.
- Use appropriate laser safety eyewear (LSE) for personnel and awake patients.
- Provide eye protection for anesthetized patients.
- Provide skin protection for patients and operating room personnel

- Minimize the potential for specular reflections by removal of unnecessary shiny surfaces.
- Maintain room lights as bright as possible to constrict the pupils.
- Adjust brightness of patient monitors to ensure appropriate degree of visibility with LSE.
- Require surgeon to warn of activation of laser and to keep the beam path above or below normal eye level (less than 4.5 feet or greater than 6.5 feet).
- Use an aiming beam or operational warning devices for lasers with invisible beams.
- Avoid looking into the primary beam at all times.
- Place laser in standby mode when it is not in active use.
- Do not leave an active laser unattended.
- Restrict maintenance of laser to authorized individuals who are trained in laser maintenance.

When not in use lasers should be disabled and stored in a secure location. Licensed health care providers who use lasers should have appropriate training and institutional privileges for laser use. An aiming beam should be used for lasers that do not produce a visible light. A warning sign must be posted inside and outside of all entrances; it should include the type and wavelength of the laser in use and the specific laser safety eyewear (LSE) required for everyone entering the laser area (Fig. 47.5). Entrance to a room with a laser in use should be restricted to personnel assigned to the procedure. The use of a safety interlock system, a trigger shut-off device that will disable the laser if the door is unexpectedly opened, will prevent unexpected entry. All other optical paths (windows) should be covered to prevent the transmission of a misdirected laser beam. A variety of laser-absorbing glass, plastics, laser safety curtains, and screens are available that attenuate the laser energy.

Window coverings are not necessary for CO₂ lasers because glass absorbs their laser energy (10,600 nm). Surgical cabinets and large surgical instruments should have a matte or dull surface to avoid reflection of a misdirected laser beam. Surfaces of instruments can be made laser safe by sandblasting, ebonizing, and anodization.¹¹ Lasers require a high-power source and carry the potential for electrical injury.

FIGURE 47.5 Danger sign indicating laser procedure in progress.

The majority of laser-related accidents and injuries are primarily the result of inappropriate use of the laser or intentional use of malfunctioning equipment. The most common hazards of medical lasers include thermal trauma, eye injury, perforation of organs or vessels, gas embolization, electrical shock, air contamination, and fire. Beam injuries are caused by the direct effects of the laser on the eye and skin; nonbeam injuries are secondary and caused by laser-generated air contaminants (LGACs), fire, electrical shock, and noise.^{12,13}

Thermal Trauma

The most common cause of laser-induced tissue damage is thermal in nature; exposure to high-energy beams for an extended period results in a photochemical change or thermal burn. Tissue proteins are denatured after absorption of the laser energy, and tissue

damage can range from mild reddening of the skin to blistering and charring. Skin trauma is dependent on the energy and wavelength of the laser. Longer wavelengths have a deeper skin penetration than shorter wavelengths; shorter wavelengths (400 to 700 nm) are absorbed in the first 4 mm of the skin. Burns occur with exposure times greater than 10 mcs and wavelengths ranging from the near ultraviolet to the far infrared (315 to 10,300 nm). Ultraviolet-A wave (315 to 400 nm) exposure causes hyperpigmentation and erythema, but the greatest skin damage is caused by ultraviolet-B (UV-B) radiation (280 to 315 nm). In addition to thermal trauma, carcinogenesis is a potential risk of UV-B exposure. Exposure to ultraviolet-C (UV-C) waves (200 to 280 nm) is less harmful to the skin because they are predominantly absorbed in the outer dead layers of the epidermis. The CO₂ and other infrared lasers have deeper tissue penetration and are associated with first-degree (reddening), second-degree (blistering), and third-degree (charring) burns. Lasers also may precipitate the development of or exaggerate existing skin lesions, including reactivation of viral infections.

In addition to restricted access to the lasing area and use of the laser system by qualified personnel, safety interventions to prevent thermal trauma include application of saline-soaked towels to the skin surrounding the path of the laser beam, and use of long-sleeved jackets, gloves, and face shields by OR personnel (see [Box 47.3](#)). Topical sunblock cream will protect against UV radiation for patients undergoing repeat laser treatments. In addition to the potential thermal risk of the laser beam, the liquid gases that are used to cool some lasers medium, especially liquid nitrogen, are hazardous if accidentally spilled on the skin. In addition, some of the chemicals used in dye lasers are toxic and hazardous to handle.

Ocular Trauma

Incandescent and fluorescent lights do not pose a hazard for eyes. Their light beam is not coherent and only a small portion of the energy is spread out over the retina. In contrast, the human eye is extremely vulnerable to laser radiation because the light beam is coherent and all of its energy can be focused on a very small

portion of the cornea or retina. Eye trauma from laser light is dependent on the power and wavelength of the laser beam, exposure duration, pupil size, retinal pigmentation, and location of the injury (Table 47.3). Pulsed-mode lasers present an additional hazard to the eye because they induce shock waves that rupture tissue, resulting in a larger area of permanent retinal damage.

TABLE 47.3
Effect of Lasers on Eyes and Skin

Laser	Eye Effect	Skin Effect
Ultraviolet C (200–280 nm)	Photokeratitis	Erythema (sunburn)
Ultraviolet B (280–315 nm)	Photokeratitis	Increased pigmentation
Ultraviolet A (315–400 nm)	Photochemical cataract	Darkening/burn
Visible (400–700 nm)	Photochemical and thermal retinal injury	Darkening/burn
Infrared A (700–1400 nm)	Cataract, retinal burn	Burn
Infrared B (1400–3000 nm)	Cataract, corneal burn, aqueous flare	Burn
Infrared C (3000–10,000 nm)	Corneal burn	Burn

Ultraviolet (200 to 400 nm) and mid-infrared (1400 to 3000 nm) radiation are absorbed by the cornea and can cause corneal photokeratitis (Fig. 47.6). Visible lasers and near-infrared lasers (400–1400 nm) are associated with retinal injury. Mid-infrared wavelengths greater than 1400 nm are absorbed by water; they can damage the cornea and increase the opacity of the lens resulting in traumatic cataracts. They are also associated with aqueous flare, an increased turbidity of the aqueous humor. Far-infrared radiation (3000 to 10,000 nm) is absorbed by the cornea and can result in corneal burns and potential loss of vision. Inadvertent exposure to the invisible CO₂ laser beam (10,600 nm) causes burning pain of the cornea or sclera. There are no immediate signs of exposure to ultraviolet radiation, but severe eye pain and a sensation of sand in the eye presents later. After minor injury, regeneration of the epithelium occurs without any permanent abnormality, but corneal scarring and cataract formation may result with more extensive injury.

FIGURE 47.6 Laser-associated eye injury. **A**, Mid- and far-infrared wavelengths (<400 nm and >1400 nm) are absorbed by the cornea and associated with corneal injury. **B**, Retinal injury is associated with visible and near-infrared (400-1400 nm) wavelengths.

Two types of photoreceptors, rods and cones, comprise the retina. Rods make up over 95% of the retina; they are sensitive to light but not color. Less than 5% of the total retinal area is composed of cones, which are responsible for detecting color and fine detail. They are heavily concentrated in the fovea centralis, an area associated with the sharpest and most brilliantly colored vision. Retinal damage is associated with visible and near-infrared (400 to 1400 nm) lasers. The beam is transmitted by the cornea and focused by the lens to produce an intense concentration of light energy on a small portion of the pigmented retina. Focusing of the laser by the lens amplifies the irradiance on the retina 100,000 times (see Fig. 47.6). One milliwatt of visible laser radiation entering the eye deposits 100 W/cm² at the retina. The conversion of the light energy to heat can cause retinal burns, partial visual loss, or total blindness. Wavelengths less than 400 nm and greater than 1400 nm are not associated with retinal damage.

A visible laser beam produces a bright color flash of the emitted wavelength followed by an afterimage of its complementary color (e.g., a green, 532-nm laser light would produce a green flash followed immediately by a red afterimage). If the individual's cones are damaged by a green laser light, he or she may have difficulty discriminating between blue and green colors thereafter. The Q-switched Nd:YAG laser beam (1064 nm) is especially hazardous to the eye because the beam is invisible, and the retina lacks sensory innervation. Visual disorientation resulting from retinal damage may not be apparent until considerable thermal damage has occurred. Unlike corneal injuries, laser damage to the retina is

permanent. Acute and chronic loss of color sensitivity has been reported in ophthalmologists who frequently use surgical lasers. The Rockwell Laser Industries maintain a voluntary reporting database of laser accidents; in recent years, the majority of the reports have involved temporary blindness of in-flight aircraft pilots by the accidental or intentional use of laser pointers from the ground.

All medical lasers are class IV lasers (see [Table 47.2](#)), and LSE is required to prevent injury from the direct laser beam or reflected laser beam from surgical instruments, cabinets, lights, watches, jewelry, and other smooth reflective surfaces in the OR.¹¹ Although LSE will protect against accidental exposure to a laser beam, it will not protect against direct viewing of a laser beam. The eye aversion or blink response of 0.25 second is triggered by bright, visible light only. It will not prevent the trauma of invisible laser beams and provides no protection against lasers with a wavelength of 700 to 1400 nm. In addition, the aversion response is absent or sluggish under general anesthesia and deep sedation. In ORs darkened for video and microscope use, the pupils of the eyes will dilate increasing the risk for laser exposure for both surgical personnel and awake patients. During laser procedures, OR personnel and awake patients must wear LSEs specific for the type of laser in use (see [Box 47.3](#)). Anesthetized patients should have their eyes covered with saline-moistened eye pads and laser shields. Petroleum-based eye ointments should not be used during laser procedures because they may cause severe burns if ignited by a misdirected laser beam.

The maximum permissible exposure (MPE) is the level of laser radiation exposure not associated with biologic changes in the eye. It is directly related to the wavelength and inversely related to the exposure time and expressed as radiant exposure (J/cm^2) or irradiance (W/cm^2). The ANSI standard identifies acceptable MPE levels for medical lasers.³ The nominal hazard zone (NHZ) refers to the physical space in which the direct, reflected, or scattered laser radiation exceeds the MPE. During laser procedures, the entire OR is considered to be within the NHZ; however, it may extend beyond transparent windows for certain lasers.

During laser procedures, LSE must be worn by everyone in the room (see [Box 47.3](#)). The LSE must have the appropriate optical

density (OD) and reflective properties for the laser wavelength, the beam intensity, and the expected exposure conditions; it must also have side shields (Box 47.4). OD refers to the ability of a material to attenuate or absorb energy of a specific wavelength to a safe level below the MPE while allowing transmission of sufficient ambient light for safe visibility. The definition of OD is the $\log_{10}(E_i / E_t)$ where E_i is the incident beam irradiance (W/cm^2) or worst-case scenario, and E_t is the transmitted beam irradiance (MPE limit in W/cm^2).⁶ LSE with an OD of 2 will allow transmission of 1/100 of the laser energy; in contrast, LSE with an OD of 4 will allow transmission of only 1/10,000 of the laser energy. The OD is rated for a specific wavelength or range of wavelengths; use with a different wavelength will result in a completely different OD value. Because LSE is laser specific, the wavelength and OD are imprinted on the LSE, and users must ensure they are wearing the appropriate LSE for the laser in use (see Box 47.4). For example, LSE for the Nd:YAG laser has an OD of 6 at 1064 nm, whereas LSE for the CO₂ laser has an OD of 7⁺ at 10,600 nm. In addition, LSE with an OD of 4 and a wavelength of 755 nm will not protect against a laser beam that requires LSE with an OD of 6 and a wavelength of 755 nm. Lasers may also operate at different wavelengths; for example, doubled Nd:YAG lasers, and tunable lasers, such as the titanium-doped sapphire laser, require different levels of protection at each wavelength and may require the use of two different LSE. Certain lasers require amber-, green-, or red-colored filters, but the color of the LSE lens should not be used for LSE identification. Vision correction glasses may attenuate the effect of the CO₂ laser beam but do not completely protect the eye from direct or reflected laser beams because they lack protective side shields. Medical lasers generally require LSE of 4 to 7 OD. There are no laser glasses available that protect against all types of laser beams; LSE that covers several wavelengths would require very dark filters, which would interfere with visual acuity.

Minimum Requirements of Laser Safety Eyewear (LSE)

- Permanent labels with wavelength (nm)

- Permanent label with optical density (OD)
- Side shield protection
- Visible light transmission

Vessel and Viscus Perforation

Operator error, such as a misdirected laser beam or failure to check for proper laser function before use, accounts for the majority of laser perforations of a viscus or vessel. A pneumothorax can be a life-threatening complication of a misdirected laser beam, especially during the administration of nitrous oxide (N₂O). Lasers cannot photocoagulate blood vessels larger than 5 mm, and unexpected or excessive bleeding may accompany an accidental perforation with a misdirected beam. Perforation with the laser beam of the Nd:YAG laser is associated with delayed tissue damage because of its greater tissue penetration and dissemination; perforation, bleeding, or edema may not be apparent for hours to days. Patients undergoing Nd:YAG laser surgery of the airway should be monitored for 24 to 48 hours after the procedure.

Gas Embolism

Some lasers require a coolant to prevent the tip of the quartz fibers from overheating. The coolant may be air, CO₂, or a liquid.

Although it is a rare event, venous gas embolism is a potential fatal hazard of laser procedures, especially with the gas-cooled Nd:YAG laser.¹⁴ Coronary and cerebral embolisms have occurred during endobronchial Nd:YAG therapy, and transmyocardial laser revascularization is also associated with cerebral microembolization. Fatal venous air embolism has been reported during Nd:YAG hysteroscopies. A liquid coolant will reduce the risk of air embolism. A CO₂ embolus appears to be less damaging than air or nitrogen emboli because of its faster absorption.

Air Contamination

Thermal destruction of tissue with a laser or electro-surgical unit

(ESU) creates a smoke plume called *laser-generated air contaminants* (LGAC). Ninety-five percent of the LGACs are water, the remainder is particulate matter, volatile gases, and microorganisms. Approximately 150 chemical LGACs have been identified, including fatty acid esters, hydrocarbons, phenols, nitriles, and volatile organic compounds such as acetone, ethanol, and formaldehyde (Box 47.5).^{12,15,16} Viable bacteria and viruses have been retrieved from the laser smoke plume. The smoke plume contains fine particulates (0.3 μm) that can be deposited in the lower airways. In addition to ocular and respiratory irritation, the smoke plume has the potential for causing cellular mutations. The CO_2 laser produces the greatest amount of LGAC; smoke produced from 1 g of tissue is equivalent to smoke from three to six cigarettes. Approximately 500,000 surgeons, anesthesia providers, nurses, and surgical technologists are exposed to surgical laser smoke every year.¹⁷ The LGACs have the potential to cause respiratory, ocular, dermatologic, and other diseases, including cancer, in patients and OR personnel. There has been no documented transmission of infectious disease through LGACs, however, there is potential for the LGAC to contain infectious material and viral DNA from vaporization of viral lesions, such as genital warts.

Select Laser Generated Air Contaminants (LGAC)

Acetonitrile

Acetone

Acetylene

Alkylbenzene

Butane

Carbon Monoxide

Cresol

Ethane

Formaldehyde

Methane

Nitriles

Phenol

Polycyclic aromatic hydrocarbons

Propane

Pyrrole

Styrene

There are no specific OSHA standards addressing the hazards of the surgical smoke plumes other than expecting employers to advise employees of the hazards of surgical smoke.^{17,18}

The AORN has recommended practices for laser safety that are based on the ANSI recommendations.^{8,9,19} The National Institute for Occupational Safety and Health (NIOSH) recommends the use of a local exhaust ventilation system such as a portable smoke evacuator as the most efficient method to control laser-generated smoke. It should contain a high-efficiency particulate air (HEPA) filter or equivalent for trapping particulates, and the suction nozzle should be kept within 2 inches of the surgical site to effectively capture the LGAC.²⁰ Evacuation tubing, filters, and absorbers are infectious waste, and new filters and tubing should be installed before each procedure. A triple filtration smoke evacuator is indicated for evacuation of a large smoke plume. Three-stage disposable filter systems include a HEPA filter that can filter 0.3- μm particulate matter, a layer of activated charcoal for odor absorption, and an ultra-low-penetration air (ULPA) filter that can filter particulate matter as small as 0.01 μm . Fit-tested high-filtration masks, such as the surgical N95 particulate filtering facepiece respirator, should be worn by OR personnel to prevent exposure to particulate matter

and noxious odors.^{8,9,19} Despite the support from professional organizations such as the AORN for active smoke evacuation during laser procedures, the lack of a regulatory OSHA mandate continues to place many OR personnel at risk for exposure to LGAC.^{6,8,9} In addition, noncompliance with current smoke evacuation recommendations include an institutional lack of smoke evacuation equipment or supplies, surgeons refusal to use the devices, increased noise of the smoke evacuators, and lack of OR personnel training regarding the health risks of surgical smoke.¹⁹ Compliance with smoke evacuation recommendations and personnel protective equipment during laser procedures is less common in outpatient or office practice settings.

Electrical Hazards

Lasers require high-voltage circuits and electrocution is the leading cause of laser-related injury and death in all industries; laser repair technicians appear to have the highest risk in the health care community.¹² Contributing factors for electrical shock and electrocution include damaged electrical cords, inadequate grounding, inadequate safeguards, lack of compliance with safety procedures, and use by unqualified personnel. Older laser models that use an external water cooling system present a great electrical hazard.

Surgical Fires

A surgical fire is a rare but preventable hazard of surgery that can have devastating effects on patients, including disfiguring or disabling injuries and death. Using data from the Pennsylvania Patient Safety Authority, the ECRI (formerly known as the Emergency Care Research Institute) estimates that there are 200 to 240 surgical fires annually in the United States, an incidence similar to surgical mishaps such as wrong-site surgery or retained instruments.²¹⁻²³ However, only 50% of states have mandatory reporting requirements and the actual number of surgical fires may be significantly higher than currently estimated. Historically, surgical fires were associated with the use of explosive or flammable anesthetics. Sensitivity of the OR staff to the possibility of a fire decreased when their use was discontinued in the 1970s. However, they are still a very real hazard of modern surgery. Surgical fires are primarily associated with the use of electrocautery units (ESUs) and surgical lasers; ESUs account for 90% of the fires, whereas lasers are responsible for the remaining 10%. Unlike ESUs, lasers do not require direct contact for ignition of a fuel source.

The great majority of surgical fires (85%) occur during high risk procedures, which involve the head, neck, or upper chest.²⁴ The airway is the most common site of surgical fires (34%); followed by head and face (28%).²⁵ Immediate recognition and management of a surgical fire can limit patient injury, whereas delayed recognition and response can be fatal for the patient. In addition to burns, patient injuries include inhalation of the following toxic products of combustion: carbon monoxide (CO), ammonia, hydrogen chloride, and cyanide. These can cause significant airway and pulmonary damage. In 2003 the Joint Commission issued a Sentinel Event Alert for preventing surgical fire, and in 2008 it listed reduction of surgical fires as the 11th National Patient Safety Goal, which addressed the need for education of OR personnel, control of heat sources and fuels, and minimization of oxygen concentrations under the surgical drapes.²⁶

Three components of the fire triangle must be present for a fire to occur: a fuel source, an ignition source, and an oxidizer. All three

components are frequently present in the OR, and a fire can occur any time the three components are allowed to interact. All OR personnel must understand the fire hazards presented by all three sides of the fire triangle, including those not under their direct control (see [Box 47.5](#)).^{22,27,28} Vigilance is key, and communication among all members of the surgical team is mandatory. It is imperative that surgical personnel are aware of the hazards of fire during laser procedures and know how to prevent and respond to [Box 47.6](#) (Box 47.6).²⁹⁻³¹

Prevention of Surgical Fires

- Educate surgical personnel on the fire triad and common sources of fuels, ignition, and oxidizers in the operating room (OR).
- Schedule annual mandatory fire drills for the entire OR team and include evacuation of anesthetized patients in the event of an uncontrolled surgical fire.
- Identify location of fire alarms and extinguishers and shut-off valves for pipeline gases.
- Avoid open air administration of supplemental oxygen.
- Administer supplemental oxygen through an ETT or LMA.
- Limit supplemental O₂ to < 30%.
- Alert surgical team members to potential sources of fire: oxidizers, fuels, and source of ignition.
- Avoid pooling of preparation solutions and allow adequate drying time before draping patient.
- Coat facial hair with a water-soluble surgical lubricant during head and neck surgery.
- Use flame-retardant drapes and moistened sponges and towels in the area of the laser.

- Use laser-resistant endotracheal tubes during laser surgery of the upper airway. Inflate the cuffs with saline and dye to allow early recognition of cuff rupture.
- Use moistened sponges to prevent air leaks, especially when using uncuffed tubes during airway surgery. Surgical sponges and pledgets should also be moistened to resist ignition.
- Use a properly applied incise drape to help isolate head, neck, and upper-chest incisions from an oxygen-enriched atmosphere and anesthetic gases.
- Use continuous suction to minimize the buildup of O₂ in the oropharynx during airway surgery and beneath the drapes during monitored anesthesia care for head and neck surgery.
- Have a container of water immediately available to extinguish burning materials. Two syringes of sterile saline should be available during laser surgery of the airway.
- Have fire extinguishers available in the room or immediately accessible.
- If possible, discontinue supplemental oxygen at least 1 minute before and during laser use for head and neck surgery, and especially surgery of the airway.

ETT, Endotracheal tube; *LMA*, laryngeal mask airway; O₂, oxygen.

Fuel Sources

Fuel sources are abundant in the OR and are predominantly under the control of the nursing staff. They include surgical preparation solutions, petroleum-based ointments, facial hair, surgical drapes, gloves, ointments, sponges, dressings, endotracheal tubes, laryngeal mask airways (LMAs), breathing circuits, nasogastric tubes, suction catheters, pneumatic tourniquet cuffs, silastic stents, suction catheters, and tracheostomy tubes (see [Box 47.6](#)). Bowel gas, which

contains methane and hydrogen, also provides a fuel source during intraabdominal laser procedures. Volatile organic chemicals such as alcohol, acetone, and ether are common components of skin preparations, tinctures, degreasers, suture pack solutions, and liquid wound dressings. Alcohol and alcohol-based solutions are very volatile and pose a significant fire hazard in the OR if adequate drying time is not provided.^{32,33} Care must be taken to ensure that the surgical preparation solution does not pool under the patient or saturate the drapes. Alcohol-based hand sanitizers may also release alcohol vapor, which is flammable and poses an additional fire hazard in the OR. Although they resist ignition and slow the spread of a flame in room air, fire-retardant drapes and materials are not fireproof. Materials considered nonflammable may ignite easily and burn more quickly and at a higher temperature when exposed to an oxidizer-enriched environment.³⁴

Endotracheal tubes are a fuel source during airway surgery if the laser beam or reflected laser light comes into direct contact with them. Localized thermal trauma occurs when the fire is contained to the outside of the endotracheal tube. Rupture of the endotracheal-tube cuff allows leakage of anesthetic gases into the path of the laser beam, increasing the risk of an ignition. If the fire burns through to the inner side of the tube, an intraluminal fire occurs fed by the anesthetic gases and the volatile products of combustion of the endotracheal-tube. The intraluminal flame will travel toward the source of the oxidizer; a secondary flame can shoot out of the distal end of the endotracheal tube like a blowtorch and cause extensive lower airway damage.

Careful attention to possible fuel sources is paramount; a basin of water or normal saline should be available during laser procedures to extinguish a burning endotracheal tube or other material. Two syringes filled with normal saline should be readily available to extinguish an airway fire (see [Box 47.6](#)). Use of excessive tape to secure the endotracheal tube should be avoided to allow easier removal of the tube in the event of an airway fire. Emergency supplies, including a rigid bronchoscope and forceps, should also be readily available. A carbon dioxide fire extinguisher (class BC) is appropriate for extinguishing surgical fires (see [Box 47.6](#)). The BC fire extinguisher leaves no residue and will not damage human

tissue. Dry powder extinguishers (class ABC) are inappropriate as the first response because the powder (ammonium phosphate) contaminates all surfaces, is a respiratory irritant, and may interfere with visibility.

Oxidizers

Common oxidizers in the OR include air, O₂, and N₂O, and are under the control of the anesthetist. Oxygen is the oxidizer in 95% of surgical fires.²⁴ Heavier than air, it tends to accumulate around and under surgical drapes. In an oxygen-rich environment, materials ignite faster, burn more quickly with greater intensity, release more heat, and are more difficult to extinguish.³⁴ In a closed claims analysis of surgical fires that occurred during high-risk procedures and monitored anesthesia care (MAC), an open delivery system of oxygen was involved in all of the surgical fires; whereas alcohol-containing preparation solutions and volatile compounds were involved in only 15% of the MAC cases.²⁴

Ignition Source

The surgeon controls the sources of ignition including ESUs, fiberoptic light sources or cables, high-speed drills, and lasers (see [Box 47.6](#)). However, electrical sparks from malfunctioning equipment not under the surgeon's control, including monitors and defibrillators, can also result in a fire. Desiccated anesthesia soda lime is another possible source of ignition in the breathing circuit.

Prevention of a Surgical Fire

All OR personnel must be educated on the fire triangle, be able to identify the procedures that present a risk of fire, understand their role in preventing a surgical fire, and know how to respond to a surgical fire.²⁹ They should be aware of the fire hazards present in the laser area, including anesthetic gases, skin preparation solutions, adhesive plastic tape, and surgical drapes (see [Box 47.6](#)). A number of advisory and professional organizations have developed practice guidelines and educational resources to assist health care institutions develop policies and procedures that

address fire prevention and effective response strategies to a surgical fire.^{21,31,35} In collaboration with the Anesthesia Patient Safety Foundation (APSF), the ECRI developed a clinical guide to surgical fire prevention (Fig. 47.7).²⁶ The American Society of Anesthesiologists (ASA) has an OR fire algorithm for both airway and nonairway fires (Fig. 47.8).³⁶ Fire posters are available on the ECRI website, and a free video on the prevention and management of OR fires is available on the APSF website.^{21,37}

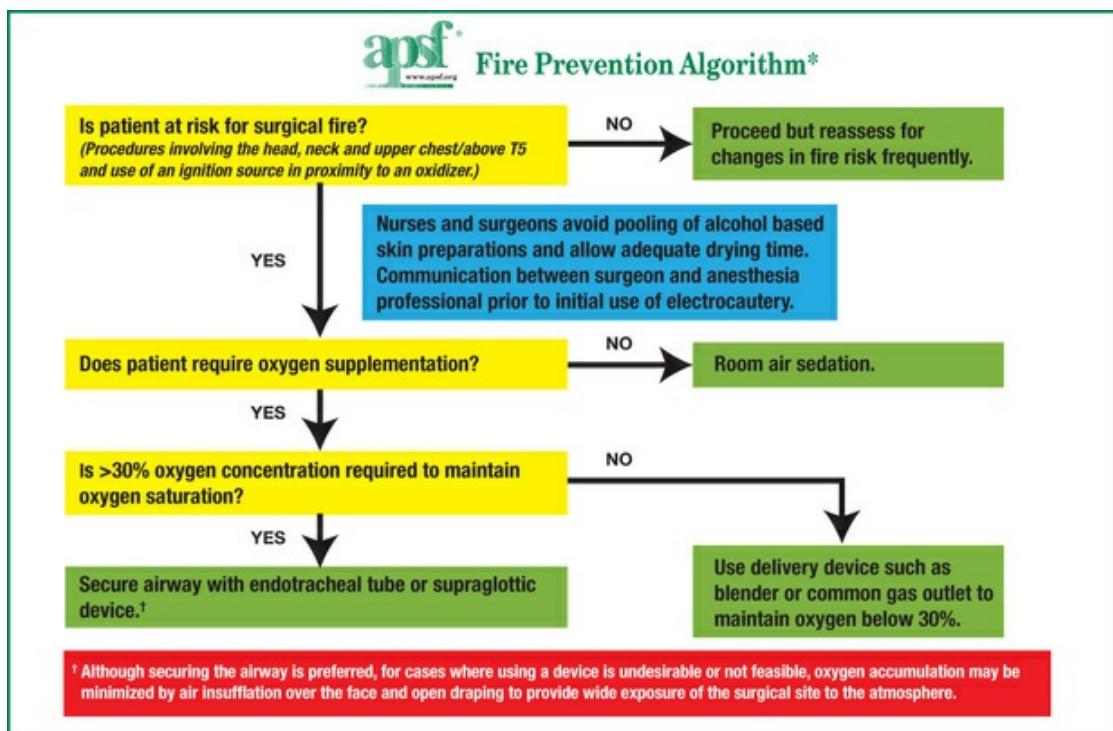

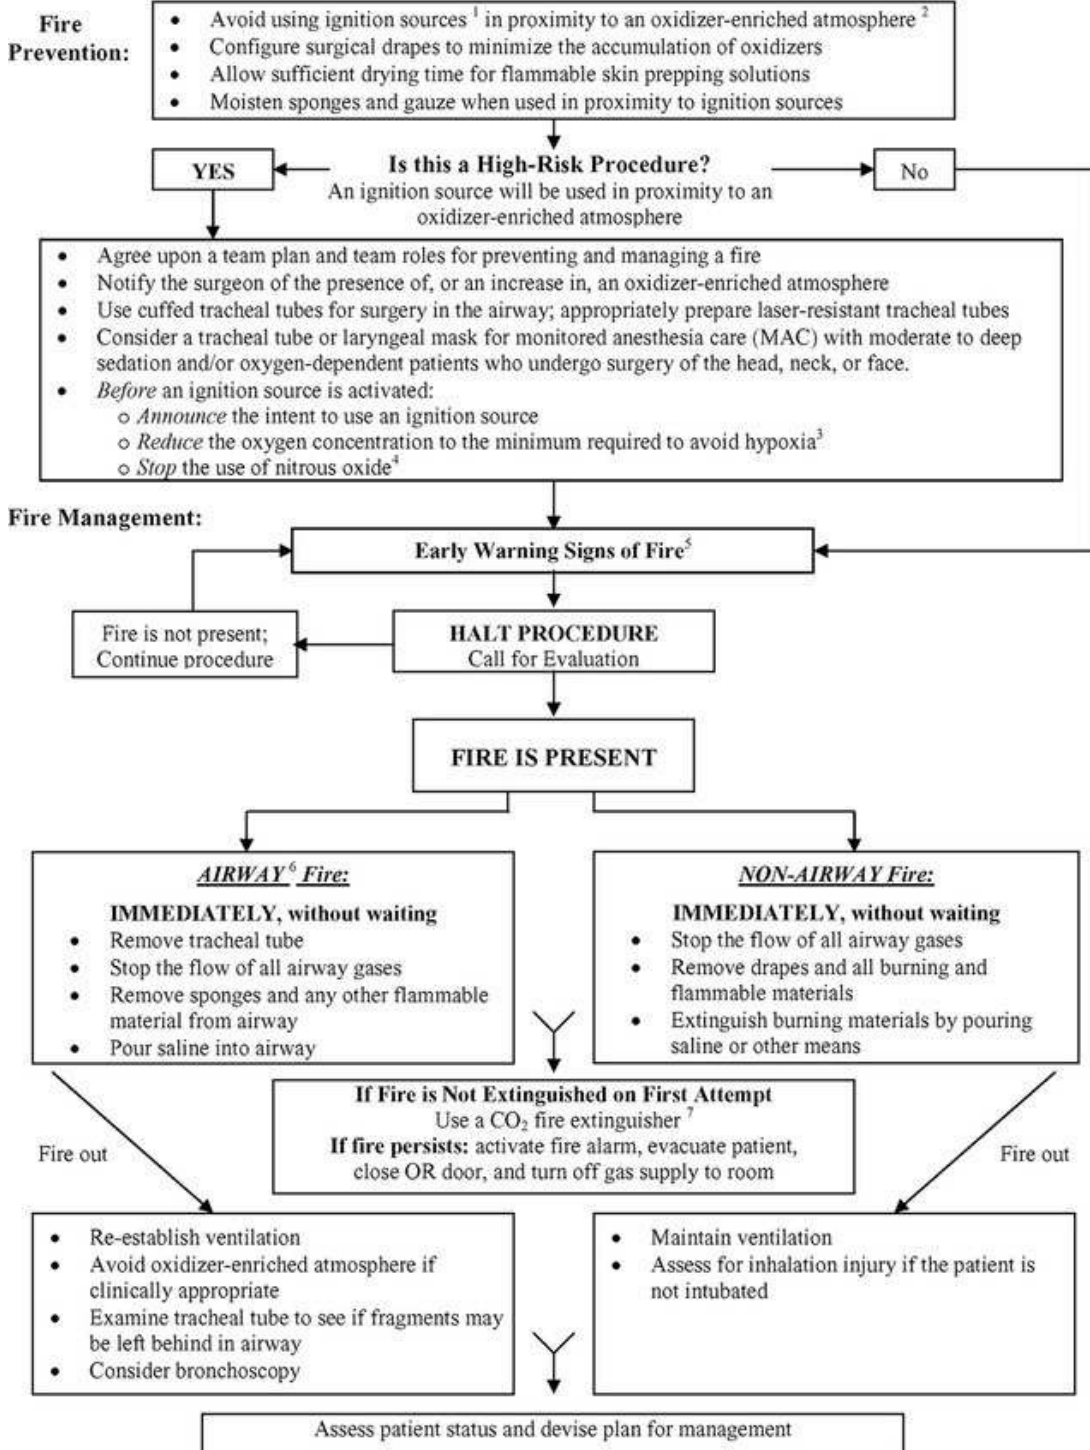

FIGURE 47.7 Fire prevention algorithm. (From Anesthesia Patient Safety Foundation. Surgical Fire Injuries Continue to Occur. *APSF Newsletter*. 2012;26(3):41–68. Accessed 2017, at http://www.apsf.org/newsletters/html/2012/winter/01_firesafety.htm.)

OPERATING ROOM FIRES ALGORITHM

¹ Ignition sources include but are not limited to electrosurgery or electrocautery units and lasers.
² An oxidizer-enriched atmosphere occurs when there is any increase in oxygen concentration above room air level, and/or the presence of any concentration of nitrous oxide.
³ After minimizing delivered oxygen, wait a period of time (e.g., 1-3 min) before using an ignition source. For oxygen dependent patients, *reduce* supplemental oxygen delivery to the minimum required to avoid hypoxia. Monitor oxygenation with pulse oximetry, and if feasible, inspired, exhaled, and/or delivered oxygen concentration.
⁴ After stopping the delivery of nitrous oxide, wait a period of time (e.g., 1-3 min) before using an ignition source.
⁵ Unexpected flash, flame, smoke or heat, unusual sounds (e.g., a “pop,” snap or “foomp”) or odors, unexpected movement of drapes, discoloration of drapes or breathing circuit, unexpected patient movement or complaint.
⁶ In this algorithm, airway fire refers to a fire in the airway or breathing circuit.
⁷ A CO₂ fire extinguisher may be used on the patient if necessary.

FIGURE 47.8 Operating room fires algorithm. (From the Committee on Standards and Practice Parameters: Practice Advisory for the Prevention of Operating Room Fires: An Updated Report by the American Society of Anesthesiologists Task Force on Operating Room Fires. *Anesthesiology*. 2013;118:271-290.)

Additionally, OR personnel must be familiar with the location and function of fire alarms, fire extinguishers, and emergency exits and should know how to shut off electrical and medical gas supplies (see [Box 47.6](#)). OR departments should have a fire safety plan in place that includes mandatory fire drills for all OR personnel including anesthesia providers and surgeons.^{31,32} Simulation of a surgical fire scenario in a high-fidelity simulation center provides an excellent opportunity for team training in the prevention and management of a surgical fire.³⁸

Anesthetic Gases

An oxygen concentration less than 30% reduces the risk of a rapid and widespread propagation of fire ([Table 47.4](#)). Clinical guidelines developed by the ASA, ECRI, and the APSF advise against the use of 100% oxygen during head, face, neck, and upper chest surgery.^{21,36,37} Oxygen should be avoided during MAC cases for patients who can maintain a safe oxygen saturation on room air. For patients with normal pulmonary function, low-dose sedatives and narcotics can be administered without supplemental oxygen. Pulse oximetry will identify the patient who may require supplemental O₂, in addition to the patient who can tolerate short periods of ventilation with room air. Mild drug-induced respiratory depression that results in a stable decrease in saturation as low as 92% does not require supplemental oxygen. Saturation of 90% or less is undesirable. If supplemental oxygen is necessary, the airway should be secured with a LMA or endotracheal tube, and oxygen concentration should be the lowest possible to support acceptable patient oxygenation, but should not exceed 30%.^{21,36,37} The anesthetist must be alert to the possibility of trapping of O₂ and anesthetic gases under the drapes.³⁹ Buildup of oxygen should be minimized by scavenging the operative site with suction; the

oropharynx should be suctioned throughout the airway procedures. Incorporation of a constant flow of carbon dioxide at the site of the laser beam can separate the oxidizer and the source of ignition.³⁴ However, this is not recommended during airway and facial procedures because of the risk of hypercarbia.

TABLE 47.4
Gas Mixtures That Deliver 30% Oxygen or Less

Air (L/min)	Oxygen (L/min)	Total Gas Flow (L/min)	O ₂ Concentration
0.90	0.10	1	28.9%
1.80	0.20	2	28.9%
2.70	0.30	3	28.9%
3.60	0.40	4	28.9%
4.50	0.50	5	28.9%

If unanticipated supplemental O₂ (< 30) via a mask or nasal cannula becomes necessary during a MAC case, it should be discontinued at least 1 minute before and during laser use; this will require close communication between the anesthetist and the surgeon, who must give adequate notice of his intent to activate the laser. N₂O readily supports combustion and should be avoided in cases with potential for fire. Suitable gas mixtures for laser procedures include O₂ and air, O₂ and nitrogen (N), and O₂ and helium (He). Helium has a high thermal conductivity and is more resistant to ignition. In addition, its lower viscosity can help overcome the increased resistance from the requisite smaller internal diameter (ID) endotracheal tubes or airway obstruction. Volatile anesthetics are nonflammable, but their use is not recommended during airway laser procedures because of their potential to deteriorate into toxic compounds in the presence of a fire.

Airway Management Devices

Polyvinyl chloride (PVC) nasal cannulas, masks, oral and nasal airways, and endotracheal tubes ignite easily and produce toxic materials that can increase the amount of damage to the airway. In addition, the plastic circuit attached to the patient airway poses an additional fire hazard. The PVC endotracheal tube is susceptible to

damage by the CO₂ laser; however presence of blood on a PVC tube also makes it susceptible to damage by the Nd:YAG laser. In addition, the radiopaque barium sulfate strip found on most PVC tubes has a faster ignition rate than the PVC. Red rubber tubes appear to be more resistant to initial ignition, have a slower rate of burn, and produce less toxic smoke. However, they tend to melt and can produce carbon monoxide. Although silicone tubes are also less combustible, inhalation of silica ash may produce pulmonary damage.

Laser Resistant Endotracheal Tubes

Laser-resistant endotracheal tubes should be used during laser surgery of the airway (see [Box 47.6](#)). Historically, application of a metallic foil wrap (aluminum or copper) or a thin metal-coated plastic tape has been used to protect PVC and red rubber endotracheal tubes during laser surgery of the airway. Recognized problems with foil wrappings include laser reflection damage, potential areas of exposed tube, unprotected cuff, need for a smaller ID tube, and airway damage from the sharp edges of the foil wrap. Only the Merocel Laser-Guard endotracheal tube wrap (Medtronic) has FDA approval for endotracheal-tube protection. The Laser-Trach (Kendall/Sheridan) is a red rubber tube with an embossed copper foil for use with CO₂ and KTP lasers. The Laser-Flex tracheal tube (Nellcor) is a flexible stainless steel tube with a matte finish that is resistant to the CO₂ and KTP lasers. In the event of a proximal-cuff rupture with a laser beam, the distal cuff will maintain a tracheal seal and prevent anesthetic gases from leaking into the path of the laser beam. The LaserTubus (Rüsch) is a soft, white rubber tube that is resistant to the argon, Nd:YAG, and CO₂ lasers. The lower 17 cm of the tube is covered with a Merocel Laser Guard wrap that dissipates the laser light and prevents backscatter. Soaking the tube in water will reduce ignition potential. The LaserTubus has two high-volume cuffs, one inside the other. Manufactured from natural rubber latex, it should be avoided in latex sensitive individuals. The Bivona Fome-Cuf (Portex), a silicone and aluminum spiral tube, is designed for use with the CO₂ laser. It has a polyurethane self-inflating foam cuff covered with

silicone that is designed to maintain a tracheal seal in the event of a cuff rupture. Inability to deflate the foam after cuff rupture is a recognized problem with this tube.

Laser-resistant endotracheal tubes are not laser-proof and carry an inherent risk of ignition. Cuff rupture is often the prelude to an airway fire and cuffs should be inflated with normal saline; addition of methylene blue will alert the surgeon to cuff rupture.³⁶ The endotracheal-tube cuff should be fully inflated and absence of an air leak should be confirmed before the laser is used. Saline-moistened cotton gauze should be placed proximal to the endotracheal-tube cuff; the gauze and the attached cotton strings should be constantly remoistened. At least 1 minute should elapse before a laser is used after reinflation of an endotracheal-tube cuff or repositioning of the endotracheal tube for correction of a leak.

Laryngeal Mask Airways

The tube of the standard silicone LMA is more resistant to laser beams than the disposable PVC LMA, but the PVC cuff is more resistant to laser beams than the silicone cuff. The intubating LMA (silicone and steel) is more sensitive to the KTP laser. The presence of blood increases the vulnerability of all LMAs, especially with the KTP laser. Similar to endotracheal tubes, precautions for use of an LMA during laser procedures include inflation of the cuff with saline and methylene blue and protection of the cuff with moistened gauze. The use of 5 to 10 cm H₂O positive end-expiratory pressure (PEEP) has been advocated during laser surgery of the airway to prevent hot, toxic gases from reaching the lower airways.

Management of a Surgical Fire

Fire must be anticipated during any laser procedure.

Communication among all members of the surgical team is vital for the prevention of and coordinated response to a surgical fire. Fire management includes early recognition, procedure termination, fire extinguishment, room evacuation if necessary, and appropriate postoperative care of the patient.^{31,36,37,40,41} For a nonairway fire, all gases should be discontinued and all drapes and burning material removed from the patient and extinguished with saline, water, or

by smothering. The patient should be immediately assessed for thermal trauma or smoke inhalation. In the event the fire spreads, the acronym *RACE* refers to the necessary steps required of OR personnel: *R*escue the patient, *A*lert other staff and *a*ctivate the fire alarm systems, *C*onfine the fire by shutting doors, closing off gas supplies and electrical power, and using fire extinguishers, and **Box 47.7** *E*vacuate the room (Box 47.7)

RACE Response to Fire

Rescue the patient.

Alert other staff and *a*ctivate the fire alarm system.

Confine the fire by shutting doors, closing off gas supplies and electrical power, and using fire extinguishers.

Evacuate the room.

In the event of an airway fire, the anesthetist has approximately 6 seconds for recognition and removal of a burning endotracheal tube or LMA. Signs of an airway fire include darkening of the endotracheal tube, LMA, or breathing circuit with soot, an orange or red glow to the endotracheal tube or LMA, and the presence of flames in or around the endotracheal tube or LMA. The endotracheal tube and LMA act like a blowtorch, with high concentrations of O₂ adding to the intensity of the fire. Within seconds the flames can reach a height of 5 to 10 inches. Intraluminal fires will spread toward the proximal end of the tube, the source of the oxygen. Severe thermal or chemical trauma is unlikely to occur if the flame is vented through the tube or oropharynx. Downstream gases contain the products of oxidation and a low concentration of oxygen; however, a free-end fire can occur if the products of oxidation ignite in the oxygen rich alveoli.

In rapid succession, the endotracheal tube should be removed, all flammable and burning material removed from the airway, all gases discontinued, and saline poured into the patient's airway to extinguish any residual smoldering material and cool the tissues (see Fig. 47.8).³⁶ Ventilation should be resumed, but an oxygen-

enriched gas mixture should be avoided until all risk of reignition is eliminated. The endotracheal tube or LMA should be examined for intactness, and direct visualization of the tracheobronchial tree with a rigid bronchoscope is recommended for assessment of thermal injury and removal of foreign material including endotracheal tube fragments. A flexible bronchoscope may be necessary for evaluation of distal airways, and tracheobronchial lavage with saline solution should be considered. If reintubation is indicated, a smaller endotracheal tube should be used; a chest x-ray (CXR) and arterial blood gases (ABGs) are indicated to guide postoperative management. Carboxyhemoglobin (CoHgb) levels are needed for assessment of smoke inhalation.

After an airway fire, 24-hour observation of the patient is indicated. A patient with minor burns should be monitored for development of laryngeal-tracheal edema. A patient with severe airway burns should remain intubated and receive 30% to 60% humidified O₂; a tracheostomy and mechanical ventilation with PEEP may be warranted. Corticosteroids have been recommended for the treatment of both smoke inhalation and bronchospasm that may be precipitated in patients with irritable airways. Additional treatment is dependent on the extent of the injury and the response of the patient. Complications may be delayed, and tracheal stenosis can occur months after an airway fire. A monthly laryngoscopy or bronchoscopy may be indicated for up to 6 months. All equipment and materials involved in a surgical fire should be retained for further inspection; all surgical fires should be reported to The Joint Commission as sentinel events. Recommendations for management of an airway fire are listed in [Box 47.8](#).

Management of Airway Fires

- Discontinue use of laser.
- In rapid succession, remove ETT or LMA, turn off all gases, remove sponges and any flammable material, and pour saline into airway.
- Extinguish burning ETT/LMA in basin of water.

- Resume ventilation with air. Ventilate with 100% O₂ only when the fire is extinguished.
- Examine airway and remove residual debris with rigid bronchoscope. Consider lavage with normal saline. Examine small and distal airways with flexible fiberoptic bronchoscope.
- Administer humidified O₂ by mask if airway damage is minimal and risk of laryngeal edema is low.
- If indicated, reintubate with a smaller ETT.
- Assess extent of thermal trauma with ABG, carboxyhemoglobin levels, and CXR.
- Keep patient intubated and administer 40% to 60% humidified O₂ if airway burn is present or suspected.
- Consider tracheostomy and mechanical ventilation for postoperative management.
- Consider administration of steroids.
- Admit patient to ICU for a minimum 24-hour observation.
- Retain all equipment and materials involved in the fire for further inspection.
- Reassemble surgical team to identify the sequence of events that led to the surgical fire.
- Report fire as a sentinel event to The Joint Commission, ECRI, and the FDA.

Anesthesia for Laser Procedures

Anesthesia is frequently required for laser procedures and most anesthetic techniques are suitable for these procedures. Although they may appear to be less invasive, laser procedures have complications similar to those of traditional surgery. Continuous use of LSE by OR personnel and awake patients is mandatory during laser surgery. The lenses of CO₂ LSE are usually clear and do not affect color perception, but tinted or colored LSE required for some lasers can affect color perception (see [Box 47.3](#)). Some Nd:YAG LSE can significantly dim the green color on monochrome monitors, tempting the anesthesia provider to remove the LSE while the laser is in use. Prior to anesthetizing a patient for a laser procedure, the anesthetist should observe the monitors through the LSE to ascertain the effect of the tinted LSE on the visibility of the displayed parameters. Display lights and alarms of patient monitors should be set to maximum brightness or otherwise adjusted to compensate for the color restriction. Audible alarms should be adjusted to the loudest setting.

Major anesthetic concerns exist when the airway is shared between the anesthetist and the surgeon during a laser procedure. The proximity of the endotracheal tube and anesthetic gases to the laser beam creates a very real hazard of airway fire.^{24,31,36,37,41} Communication between the surgeon and the anesthetist is paramount to ensure patient safety, maximize surgical access, and avoid complications. Ventilation techniques during laser procedures of the airway are dependent on surgeon preference and the site of the laser application.

Supplemental oxygen is indicated for patients with less than or equal to 90% O₂ saturation (SaO₂) on room air; the airway should be secured with an LMA or endotracheal tube, and oxygen concentration should not exceed 30%. Use of an air/O₂ blender will allow delivery of the desired O₂ concentration. The anesthetist can also deliver less than 30% O₂ directly from the flowmeters, but the exact O₂ concentration delivered to the patient can vary especially with manual flowmeters and demands the continuous use of an O₂

analyzer (see [Table 47.4](#)). A sudden, unexpected need for supplemental O₂ during a MAC case, as evidenced by a SaO₂ less than 90%, mandates continuous communication between the surgical team. Continuous scavenging of the operative site with suction is necessary to prevent buildup of O₂. The supplemental oxygen should be discontinued 1 minute before and during laser use. During airway procedures, small-sized endotracheal tubes are necessary to maximize surgical view and access for airway procedures, and the anesthetist must be prepared to deal with the associated increase in resistance to ventilation. Even when the airway is secured with an LMA or endotracheal tube, the oropharynx should be continually suctioned throughout an airway procedure. Some surgeons may prefer an apneic technique, in which case the airway is alternately shared between the surgeon and the anesthetist. The patient is hyperventilated by mask with less than 30% O₂ after brief intermittent periods of laser application. The pulse oximeter must be monitored closely and ventilation immediately resumed if oxygenation decreases 2% to 3% below the patient's initial saturation, or when 1.5 to 2 minutes have elapsed. However, this technique is to be discouraged because high O₂ concentrations can build up in the upper and lower airways during the apneic periods and are susceptible to ignition by the laser beam. Volatile anesthetics are best avoided during laser surgery of the airway because of their potential to deteriorate toxic compounds in the presence of a fire.⁶ Containers of water and syringes of normal saline should be readily available during airway procedures.

Summary

Lasers have numerous applications in all surgical specialties because of their ability to cut, coagulate, vaporize, and selectively destroy abnormal tissue. Newer and more powerful lasers are an integral part of a surgeon's armamentarium. Consequently, anesthesiologists are involved on a daily basis with patients undergoing laser procedures in hospital ORs and off-site locations, ambulatory surgeries and clinics, and private practice offices. Safe provision of anesthetic care requires an understanding of laser physics and recognition of the potential hazards associated with the use of lasers. Use of eye and skin protection for both the patient and OR personnel, high filter surgical masks, and continuous use of a smoke evacuator is mandatory. The anesthesiologist must be acutely aware of the risk of fire during laser procedures, especially during high risk procedures of the airway, head, neck, and upper chest. Fire safety education is the most effective way to both prevent and manage surgical fires. Fire drills with mandatory involvement of all members of the surgical team, including anesthesia providers and surgeons, should be held annually.

Obesity and Anesthesia Practice

Mary Ann Krogh

Overview

Obesity is a complex, multifactorial, chronic disease that develops from an interaction between an individual's genotype and the environment.¹⁻⁶ It is the second leading cause of preventable death in the United States.¹ Whereas the number of people presenting as overweight and obese has increased significantly over the last several decades, the upward trend has leveled off somewhat in recent years.⁷ Obesity is associated with an increased incidence of a wide spectrum of medical and surgical conditions and morbidity. As a result, anesthesiologists can expect to encounter overweight and obese patients frequently in their practices. These patients may present a considerable challenge due to the multiple pathophysiologic changes associated with obesity. A thorough understanding of the pathophysiology, pharmacology, and specific anesthetic considerations associated with obesity will promote optimal anesthesia care.

Statistics

The prevalence of obesity around the world continues to rise, and in the United States, millions of Americans are considered to be severely obese. Current estimates are that over 210 million, or 75%, of US adults are classified as overweight or obese. The age-adjusted prevalence of obesity in 2013–14 was 35.0% among men and 40.4% among women. The corresponding values for class 3 obesity (body mass index [BMI] ≥ 40) were 5.5% for men and 9.9% for women. For women, the prevalence of overall obesity and of class 3 obesity showed significant linear increasing trends between 2005 and 2014; there were no significant trends for men.⁷

There are an estimated 26 million people in the United States with a BMI of at least 35 kg/m², and 15 million with a BMI of 40 kg/m² or higher.^{1,4} There has been an increase in the proportion of obese persons aged 20 years and older from 23% in 1994 to approximately 35% today (Fig. 48.1).

¹Significantly different from those aged 20-39

²Significantly different from women of the same age group

FIGURE 48.1 Prevalence of obesity among adults aged 20 and over, by sex and age: United States, 2011–2014. NOTES: Totals were age-adjusted by the direct method to the 2000 U.S. census population using the age groups 20–39, 40–59, and 60 and over. Crude estimates are 36.5% for all, 34.5% for men, and 38.5% for women. (From Ogden CL, et al. Prevalence of Obesity Among Adults and Youth: United States, 2011-2014. *NCHS Data Brief*. 2015;219:1–8. Source: CDC/NCHS, National Health and Nutrition Examination Survey, 2011–2014.)

Obesity is not confined to the United States; it is a health problem that is increasing at an alarming rate throughout the world. Globally, there are approximately 2 billion individuals documented as overweight (BMI of 25 kg/m² to 29.9 kg/m²), which approximates the number of individuals who are starving worldwide.^{8,9} It is estimated that there were more than 600 million obese people worldwide in 2014,¹⁰ and three countries report that more than 50% of their population is obese. According to the World Health Organization (WHO), the global obesity incidence has more than doubled since the 1980s. Concerns about the global obesity crisis are growing, and WHO reports that obesity accounts for more than 400,000 deaths annually, making it second only to tobacco-related disease as a cause of preventable and premature death.¹¹

In the United States, individuals who are obese have a 10% to 50% greater risk of death from all causes compared with healthy-

weight individuals (BMI 18.5 to 24.9). Obesity is associated with approximately 112,000 preventable deaths per year.¹² Most of the increased risk is due to cardiovascular causes.¹³

Cost of Obesity

More than \$315 billion was spent in 2014 for health care costs related to obesity.¹⁴ This does not take into account the additional dollars spent annually on weight-reduction programs, exercise equipment, low-fat diet products, pharmacologic agents, advertising, and marketing related to obesity.⁴ Obesity is a major health concern, and obese patients admitted for surgery may exhibit one or more medical conditions in addition to the primary underlying problem.¹⁵ Clearly, identification of obesity-related conditions is vital to the safe administration of an anesthetic.

Definitions

BMI is the accepted measure of body habitus that describes adiposity normalized for height.¹ BMI can be calculated according to the following formulas:

- $\text{BMI} = \text{weight (in kilograms)} / \text{height (in meters)}^2$
- $\text{BMI} = (\text{weight [in pounds]} / \text{height [in inches]}^2) \times 703$

Overweight is defined as a BMI of 25 to 29 kg/m², and *obesity* as a BMI of 30 kg/m².¹⁻³ Historically, individuals with a BMI greater than 30 kg/m² had higher mortality rates for a number of conditions, especially those associated with cardiovascular disease. However, evidence suggests that modern screening has limited the excess mortality related to obesity, particularly in obese patients with a BMI less than 35 kg/m².¹⁶ A person's degree of obesity is commonly defined using the BMI, as shown in [Table 48.1](#). A BMI greater than or equal to 25 kg/m² is considered overweight, and a BMI greater than or equal to 30 kg/m² is considered obese. Obesity can be subcategorized into Class I (30–34.9 kg/m²), Class II (35–39.9 kg/m²), and Class III (> 40 kg/m²). The term *morbid obesity* has been abandoned due to its negative connotations, and the term *extreme obesity* is used instead.¹⁶ *Ideal body weight* (IBW) is a term that is used interchangeably with *normal weight* and *desirable weight*.¹⁻³ IBW is a

measurement of height and body mass that exhibits the lowest morbidity and mortality for a given population.² Determination of IBW is especially useful in calculating drug and intravenous infusion doses in morbidly obese patients. Certain drugs, if administered according to actual body weight, can produce toxicity, renal damage, or hemodynamic instability. Conversely, some drugs must be given according to actual body weight if therapeutic effects are to be achieved. The lean body mass increases by approximately 30% in obese individuals due to the increased muscle developed to carry extra body weight. As a result, lean body weight (LBW) is 30% higher than IBW. Simplified weight calculations for IBW and LBW are as follows:

TABLE 48.1

Classification of Overweight and Obesity by Body Mass Index

	Obesity Class	Body Mass Index (kg/m ²)
Underweight	—	Less than 18.5
Normal	—	18.5–24.9
Overweight	—	25–29.9
Obesity	I	30–34.9
	II	35–39.9
Extreme obesity	III	Greater than 40

- For men: IBW = Height (in centimeters) – 100
- For women: IBW = Height (in centimeters) – 105
- LBW = IBW × 1.3

Risk Factors

Obesity is associated with an increase in the incidence of many medical conditions (Box 48.1). The risk for cardiovascular disease, certain cancers, diabetes, and overall mortality is linearly related to weight gain. Type 2 diabetes, coronary heart disease, hypertension, and hypercholesterolemia are common conditions in overweight and obese patients.¹⁻³ With increasing weight gain and increased adiposity, glucose tolerance deteriorates, blood pressure rises, and the lipid profile becomes more atherogenic.² Using BMI, age, and gender as independent variables, a multiple logistic regression model established that males (P = 0.021), those with higher BMI (P <

0.0001), and older individuals ($P < 0.0001$) tend to have [more.comorbidities](#) These data suggest that, male gender, the extent of obesity, and age are risk factors because they are markers for sicker patients.¹⁷ Hormonal and nonhormonal mechanisms contribute to the greater risk of breast, gastrointestinal, endometrial, and renal cell cancers.⁶ Psychological health risks often stem from social ostracism, discrimination, and impaired ability to participate fully in activities of daily living. Coexistent feelings of worthlessness and low self-esteem can lead to depression that not only magnifies anesthetic morbidity, but also contributes to an [increased](#) incidence of suicide among extremely obese persons.

Conditions Associated With Obesity

Cardiovascular System

- Coronary heart disease
- Hypertension
- Dyslipidemia
- Cerebrovascular disease
- Thromboembolic disease
- Cardiomegaly
- Congestive heart failure
- Pulmonary hypertension

Endocrine System

- Type 2 diabetes
- Thyroid disorders

Respiratory System

- Restrictive lung disease
- Obesity hypoventilation syndrome
- Obstructive sleep apnea

Gastrointestinal System

- Hiatal or inguinal hernia
- Gallbladder disease
- Nonalcoholic fatty liver disease: steatosis, cirrhosis, hepatomegaly
- Gastroesophageal reflux disease (GERD)

Other Systems

- Gout
- Infertility
- Impaired immune response
- Wound infections
- Osteoarthritis
- Malignancy: esophageal, gallbladder, colon, breast, uterine, cervical, prostate, renal
- Urinary incontinence
- Pancreatitis
- Low back pain
- Obstetric complications

Adipose Tissue

Adipose tissue has major integrative physiologic functions, secretes numerous proteins, and is considered an endocrine organ.² Its major functions as an organ are to provide a reservoir of readily convertible and usable energy and to maintain heat insulation.^{2,3,18} Functions associated with liver fat metabolism include degradation of fatty acids into usable units of energy, synthesis of triglycerides from carbohydrates and proteins, and synthesis of other lipids from fatty acids, particularly cholesterol and phospholipids.¹⁸ The ability of the liver to desaturate fatty acids is tremendously important because all cells contain some unsaturated fats synthesized by the liver.

Body fat is also important in heat regulation and insulation. Fat cells, which arise from modified fibroblasts, enlarge and fill with liquid triglycerides to nearly 95% of their storage capacity.^{18,19} When the skin is exposed to cold conditions (over several weeks), the fatty acid chains of the triglycerides shorten, or become more unsaturated.³ This phenomenon lowers their melting point, which allows the fat in the fat cells to maintain a liquid state. Metabolically, this is significant, as only liquid fat can be hydrolyzed and transported from the cells to be used for energy.³

Body Fat Distribution

In early childhood, fat cell formation occurs rapidly.² Overfeeding during this time accelerates fat storage and triggers hyperproliferation of fat cells. During adolescence, the number of fat cells stabilizes and remains constant throughout adult life. Children become obese through an increase in fat cell numbers, whereas adults become obese through hypertrophy of existing fat cells.^{2,3} The distribution of body fat, however, is a clearer indicator of increased health risk.¹⁹

Central, android, or abdominal visceral obesity (“apple” shape), with a waist/hip ratio greater than 0.85 in men and greater than 0.92 in women, is correlated with a higher risk of comorbidities in obese patients^{2,20} (Fig. 48.2A). The waist/hip ratio is calculated by dividing

the narrowest waist measurement by the broadest hip measurement, taken while the patient is standing.² Waist circumference is the newly established marker for abdominal obesity. A waist circumference greater than 102 cm (40 inches) in men or a waist circumference greater than 88 cm (35 inches) in women denotes an increased risk for ischemic heart disease, diabetes mellitus, hypertension, dyslipidemia, and death.^{1-3,18}

FIGURE 48.2 Obesity. **A**, Central, android, or abdominal visceral. **B**, Peripheral, gynecoid, or gluteal.

Peripheral gynecoid, or gluteal femoral obesity (“pear” shape), with a waist/hip ratio below 0.76, is associated with varicose vein development, joint disease, and a reduced incidence of non-insulin-dependent diabetes mellitus (see Fig. 48.2B). Medical risks are decreased in individuals with gynecoid fat distribution compared to those with the android pattern.^{1,21}

Differences in morbidity between android and gynecoid fat distribution are attributable to the metabolic characteristics of the adipose tissues and adjacent tissues. Gynecoid repositories of fat, found primarily in women, are metabolically static and are proposed to function as energy depots for pregnancy and lactation.^{3,21} Android fat distribution, typically seen in males, is metabolically active with regard to free fatty acid (FFA) release.² When elevated levels of FFAs are mobilized from adipose tissue, portal venous drainage delivers high concentrations of FFAs to the

liver. Continual delivery of excessive FFAs stimulates hepatic synthesis of very low density lipoproteins (VLDLs) and circulation of low density lipoproteins (LDLs). Hepatic exposure to high concentrations of FFAs also increases gluconeogenesis and inhibits insulin uptake, which induces the development of non-insulin-dependent diabetes mellitus. Although VLDLs, LDLs, and hyperglycemia are catalysts for the formation of associated cardiovascular and cerebrovascular disease, some studies support the possibility that hyperinsulinemia alone may cause hypertension.^{2,3} Additionally, patients with gynecoid fat distribution have an increased risk of visceral and retroperitoneal fat, which increases the compression of renal veins, lymph vessels, ureters, and renal tissues. This increased pressure has been linked to a higher risk of hypertension.²²

Causes of Obesity

Body size is dependent on genetic and environmental factors. Genetic predisposition, believed to be a primary factor in the development of obesity, explains only 40% of the variance in body mass.⁶ The significant increase in the prevalence of obesity has resulted from environmental factors that result in increased calorie intake and reduced physical activity.^{6,18} Other factors such as socialization, age, sex, race, and economic status affect the progression of obesity. In the United States, food consumption has risen as a result of the “super-sizing” of portions and the availability of high-fat fast food and snacks. Physical activity has been reduced as a result of modernization (e.g., television and computers), as well as sedentary lifestyles and work activities. Cultural and lifestyle variations play an important role in the development of obesity.⁶ For example, some ethnic foods contain high levels of fats and carbohydrates, whereas others (e.g., Asian) focus on low-fat foods such as fish and vegetables.

There is increased interest in the role of inflammation in obesity. Several inflammatory mediators, such as angiotensinogen, transforming growth factor beta, tumor necrosis factor alpha, and interleukin 6, are elevated in morbidly obese patients. Weight loss results in a reduction in both the inflammatory mediators and comorbidities associated with obesity.²³ Continued investigation into genetic-environmental interactions may provide further understanding of and treatment for obesity.^{20,21}

Pathophysiology of Obesity

A number of pathophysiologic changes occur as a result of overweight and obesity.²⁴ These changes involve all of the major body organ systems, leading to an increase in morbidity and premature death. The risk of many of the medical conditions associated with obesity increases linearly with increasing BMI.²⁻⁴

Cardiovascular Considerations

Cardiovascular considerations are predominantly a reflection of the progressive compensatory processes that evolve to meet the increased metabolic demands of the fat organ.^{25,26} Cardiovascular disease is the primary cause of the morbidity and mortality associated with obesity, and manifests in the form of ischemic heart disease, hypertension, and cardiac failure.¹⁴ Development and sustenance of the fat mass necessitates the formation of extra blood vessels and increased circulatory, pulmonary, central, and peripheral blood volume.²⁻⁴ For every 13.5 kg of fat gained, an estimated 25 miles of neovascularization is generated to provide blood flow at a rate of 2 to 3 mL/100 g of tissue per minute. This represents an increased cardiac output of 0.1 L/min for each kilogram of fat acquired.³ An expanded blood volume, stimulated by hypoxia-induced chronic respiratory insufficiency, is seen in severe obesity. Accelerated renin-angiotensin activity and the perfusion requirements of the fat organ further increase the vascular fluid compartment.^{2-4,25,26}

Movement of the expanded blood volume through extensive vascular tissue, under compression by adipose tissue, places greater demand on the myocardium. The increased workload caused by elevation of the basal metabolic rate is reflected in an increased cardiac output, increased oxygen (O₂) consumption, increased carbon dioxide production, and normal or slightly abnormal arteriovenous O₂ difference.^{2,27} Chronically elevated cardiac output precedes increased left-sided heart pressures and left ventricular hypertrophy. Because the heart rate usually remains the same, cardiac output must be augmented by an increase in stroke volume.

Therefore, cardiomegaly, atrial and biventricular dilation, and biventricular hypertrophy ensue. These contribute to the development of hypertension and eventual congestive heart failure.^{2-4,28}

Hypertension is defined as a systolic pressure greater than 140 mm Hg, a diastolic pressure greater than 90 mm Hg, or both.³ The prevalence of hypertension in obese patients is more than twice as high as in lean men and women.^{28,29} Blood pressure has been shown to increase 6.5 mm Hg for every 10% increase in body weight.³⁰ In severely obese individuals who are not hypertensive, decreased systemic vascular resistance may serve to facilitate forward blood flow through the doubled body habitus.^{2,4} Hypertension is precipitated by increased blood viscosity, altered catecholamine kinetics, and possibly increased estrogen concentrations. Hyperinsulinemia, elevated mineralocorticoids, and abnormal sodium reabsorption have also been implicated as causes of hypertension.

Renal mechanisms are also associated with the development of obesity-related hypertension. Causes of renal-induced hypertension include visceral compression of the kidneys from fat deposits in and around the kidney, impaired sodium excretion, activation of the renin-angiotensin-aldosterone system, and increased sympathetic nervous system activity.²²

Hypercholesterolemia (i.e., cholesterol levels greater than 240 mg/dL) often coexists with hypertension, thereby predisposing obese patients to atherosclerosis and cerebrovascular accident.^{27,29} Arrhythmias may occur as a result of hypoxemia, hypercapnia, electrolyte disorders, sleep apnea, ventricular hypertrophy, hypertension, and coronary artery disease (CAD).^{25,26}

CAD is frequently associated with obesity, but is an independent risk factor. It appears with or without hypertension, hypercholesterolemia, diabetes mellitus, hyperlipidemia, or a sedentary lifestyle.^{2-4,31} Obesity coincident with CAD results in frequent angina, congestive heart failure, acute myocardial infarction, and sudden death.^{14,27,28} Ischemic heart disease is more common in obese individuals with a central fat distribution.²⁷

Respiratory Considerations

Compromise of respiratory function results from the compression of fat on abdominal, diaphragmatic, and thoracic structures. Over time, thoracic kyphosis and lumbar lordosis develop, resulting in impaired rib movement and fixation of the thorax in an inspiratory position.^{1,3} As a result, chest wall, lung, parenchyma, and pulmonary compliance are reduced to 35% of predicted values.^{31,32} The metabolic needs of the fat organ and the greater mechanical work of breathing stimulate increased myocardial O₂ consumption. Increases in carbon dioxide production and retention, coupled with decreased ventilation, coincide with reduced respiratory muscle efficiency.² Lung inflation is inhibited, which causes declinations in functional residual capacity (FRC) to less than closing capacity. Premature airway closure increases dead space and causes carbon dioxide retention, ventilation-perfusion mismatch, shunting, and hypoxemia.^{1,20} Extreme obesity is associated with reductions in FRC, expiratory reserve volume (ERV), and total lung capacity.³¹⁻³³ FRC declines exponentially with increasing BMI.² A 2006 study of pulmonary function in morbidly obese patients indicated that forced vital capacity varies inversely with BMI, and patients with a very high BMI, even when asymptomatic, will have major reductions in lung function.³⁴

Concomitant diminution of vital capacity, total lung capacity, ERV, and inspiratory capacity are demonstrated by rapid, shallow breathing. These ventilation patterns are characteristic of restrictive lung disease.^{2,32,33} Eventual hypoventilation, hypercarbia, and acidosis result from the depression of central nervous system responsiveness to chronic hypoxia.³ Recurrent hypoxemia leads to secondary polycythemia and is associated with an increased risk of CAD and cerebrovascular disease.¹⁸ Respiratory muscle dysfunction has also been reported with obesity,³⁵ and may result from inefficiency secondary to changes in chest wall compliance or the lower lung volumes found in obese individuals. These abnormalities predispose obese patients to respiratory failure in the setting of even mild pulmonary or systematic insults.³⁶

Obesity has been closely linked to the development of asthma-like symptoms, with weight loss resulting in an improvement in shortness of breath. However, in a 2016 study, obese patients were found to be no more likely to have airflow obstruction than the

general population. The study identified possible causes of the asthma-like symptoms in the obese population, including increased perception of dyspnea, systemic inflammation, and increased work of breathing.³⁷

Obstructive Sleep Apnea

Obesity is a well-established risk factor for sleep apnea, with the incidence of obstructive sleep apnea (OSA) increasing in direct proportion with the level of obesity. Patients with OSA tend to have a BMI greater than 30 kg/m², abdominal fat distribution, and a large neck girth (greater than 17 inches in men and greater than 16 inches in women).² For patients with clinically severe obesity (a BMI of 35 kg/m² or greater) who present for bariatric surgery, the incidence of sleep apnea ranges from 71% to 77%.³⁸⁻⁴⁰

OSA is characterized by excessive episodes of apnea (10 seconds) and hypopnea during sleep that are caused by complete or partial upper airway obstruction.⁴¹ Up to 25% of all surgical patients are at risk of OSA.⁴² Obstructive sleep apnea is characterized by intermittent closure or narrowing of the upper airway during sleep, which leads to episodes of apnea-hypopnea, arousal, and O₂ desaturation.⁴³ This disorder is pervasive and affects nearly 18 million Americans.⁴⁴ It is estimated that as many as 80% to 95% of persons with OSA are undiagnosed.⁴⁵

Apnea is the cessation of airflow at the nose and mouth for more than 10 seconds.⁴⁶ Apnea is considered obstructive if there is continued respiratory effort despite airflow cessation. Hypopnea is defined as a 50% reduction in airflow for 10 seconds that occurs 15 or more times per hour of sleep, and is associated with snoring and a 4% decrease in O₂ saturation. It connotes a transient reduction in airflow caused by increased upper airway resistance.⁴⁵ OSA syndrome is diagnosed by polysomnography (PSG) using an apnea-hypopnea index (AHI).⁴⁷ There are different definitions of OSA. The AHI is the number of abnormal respiratory events per hour of sleep. Classically, the accepted minimal clinical diagnostic criteria for OSA are an AHI of 10 plus symptoms of excessive daytime sleepiness. The American Academy of Sleep Medicine defines mild OSA as an AHI between 5 and 15, moderate OSA as an

AHI between 15 and 30, and severe OSA as an AHI greater than 30. Medicare guidelines recognize the presence of OSA with an AHI of 15, or an AHI of 5 with two comorbidities.³⁸

The pathogenesis of OSA is likely multifactorial.⁴⁸ Contributing factors include airway anatomy, the state-dependent control of the upper airway dilator muscles, and ventilatory stability. The site of upper airway obstruction typically lies in the pharynx. The pharyngeal luminal area during inspiration reflects a balance between collapsing intrapharyngeal negative suction pressure and dilating forces provided by the pharyngeal muscles.⁴⁹ In awake human subjects, the patency is maintained by continual mediation of the contraction of the tensor muscles by the central nervous system. These dilator muscles oppose the negative collapsing force developed during inspiration.⁴⁵ This activation of muscle tone is typically reduced during sleep, and in many individuals leads to compromised patency of the upper airway with turbulent airflow and snoring. In obese patients, the presence of more adipose tissue in the pharyngeal structures increases the likelihood that relaxation of the upper airway muscles will cause collapse of the soft-walled oropharynx between the uvula and the epiglottis. Extraluminal pressure is increased by superficially located masses, and the upper airway is compressed externally.^{43,45,50,51}

While sleeping, any and all of these mechanical, neural, and structural factors may contribute to upper airway collapse that either interferes with or eliminates ventilation, which results in a surge of pharyngeal dilator muscle activity that subsequently opens the airway. A period of hyperventilation then follows, which reverses hypercarbia, and the central respiratory drive is then reduced correspondingly. The process can repeat itself continually throughout the night, causing intermittent hypoxia and hypercarbia, fragmenting sleep, and triggering adrenergic output with each cycle.^{45,46,49} Five or more clinically significant apneic episodes per hour or more than 30 episodes per night result in hypoxia, hypercapnia, systemic and pulmonary hypertension, and cardiac arrhythmias.^{21,32,33,41}

Holter-monitored patients with OSA have a higher incidence of nocturnal paroxysmal asystole, episodic bradycardia, and sinus node dysfunction.⁵² A study of OSA patients with permanent atrial

pacemakers demonstrated that subjects had fewer episodes of OSA if their pacemakers were set to increase their heart rate during the night. It is hypothesized that the increased vagal tone accompanying bradycardia also affects airway patency.⁵³

Patients with OSA also have a higher incidence of comorbidities. Approximately 50% to 60% of patients with OSA are hypertensive, and an estimated 50% of hypertensive patients have sleep apnea.⁵⁴

Because up to 80% to 95% of all patients with OSA are undiagnosed and untreated, the disorder will not be identified in the medical records of many patients who present for surgery. During preanesthetic evaluation, patients should be asked about their sleeping patterns, and anesthesia providers should have a high index of suspicion for OSA in all obese patients.⁵⁵ Some advocate that all obese patients, or those who observe obese patients while they sleep, be routinely asked about nocturnal snoring or apnea, arousals, and diurnal sleepiness.⁵⁶ Overnight PSG is the gold standard test used in the diagnosis of OSA, as well as many other sleep disorders. Costly, time-consuming, and labor intensive, PSG involves the simultaneous recording of multiple physiologic variables while the patient sleeps. Several screening tools have been developed for preoperative use. The STOP-Bang screening tool (Box 48.2) is easy to use and has a sensitivity of up to

Box 48.2

STOP-Bang Scoring Model for Screening for Obstructive Sleep Apnea

1. Snoring: Do you snore loudly (loud enough to be heard through closed doors)?	Yes	No
2. Tired: Do you often feel tired, fatigued, or sleepy during daytime?	Yes	No
3. Observed: Has anyone observed you stop breathing during your sleep?	Yes	No
4. Blood Pressure: Do you have or are you being treated for high blood pressure?	Yes	No
BMI: BMI more than 35 kg/m ² ?	Yes	No
Age: Age more than 50 years old?	Yes	No
Neck circumference: Neck circumference greater than 40 cm?	Yes	No
Gender: Male?	Yes	No
High risk of OSA: Answering yes to 3 or more items.		
Low risk of OSA: Answering yes to fewer than 3 items.		

BMI, Body mass index; OSA, obstructive sleep apnea.

Adapted from Chung F, et al. STOP questionnaire: A tool to screen patients for obstructive sleep apnea. *Anesthesiology*. 2008;108(5):812–821.

Before patients at increased perioperative risk from OSA are scheduled to undergo surgery, a determination should be made regarding whether a surgical procedure is most appropriately performed on an inpatient or outpatient basis. Factors to be considered in determining whether outpatient care is appropriate include (1) sleep apnea status, (2) anatomical and physiologic abnormalities, (3) status of coexisting diseases, (4) nature of surgery, (5) type of anesthesia, (6) need for postoperative opioids, (7) patient age, (8) adequacy of postdischarge observation, and (9) capabilities of the outpatient facility. The availability of difficult airway equipment, respiratory care equipment, radiology facilities, clinical laboratory facilities, and a transfer agreement with an inpatient facility should be considered in making this determination.⁵⁵

The safety of performing surgery on an outpatient basis in patients with OSA is controversial. The American Society of Anesthesiologists (ASA) guidelines recommend against discharge of the OSA patient undergoing any ambulatory procedure, except those performed under straight local anesthesia on the day of surgery. Subsequent data from Johns Hopkins challenged this position with a study that suggested that ambulatory surgery for appropriately selected patients was not associated with unplanned admission, readmission, or serious respiratory or cardiovascular adverse events.^{55,58} In 2012, the Society for Ambulatory Anesthesia issued a consensus statement addressing the appropriate patient selection for adult patients scheduled for ambulatory surgical procedures. In this document, the authors advised that OSA patients with controlled comorbidities may be reasonable candidates for ambulatory procedures if their pain can be appropriately managed with minimal or no postoperative opioids.^{42,48}

Suggestions for the management of obstructive sleep apnea patients are listed in [Table 48.2](#).

TABLE 48.2**Perioperative Anesthetic Management of the Patient With Obstructive Sleep Apnea**

Phase	Anesthetic Concern	Principles of Management
Preoperative period	Cardiac arrhythmias and unstable hemodynamic profile	Indirect evidence advocating the usefulness of PAP to reduce cardiac arrhythmias, stabilize variable blood pressure, and decrease myocardial oxygen consumption
	Multisystem comorbidities	Preoperative risk stratification and patient optimization Individualized intraoperative anesthetic management tailored to comorbidities
	Sedative premedication	Minimal or no sedation; α_2 -adrenergic agonist (dexmedetomidine) premedication may reduce intraoperative anesthetic requirements and have an opioid-sparing effect
	OSA risk stratification, evaluation, and optimization	Preoperative anesthesia consults for symptom evaluation of obstructive sleep apnea, obesity hypoventilation syndrome and metabolic syndrome, airway assessment, polysomnography if indicated, and formulation of anesthesia management and postoperative plan
Intraoperative period	Regional anesthesia	Consider regional block when appropriate
	Difficult intubation	Ramp from scapula to head Adequate preoxygenation Use CPAP during preoxygenation ASA difficult airway algorithm
	Opioid-related respiratory depression	Opioid avoidance or minimization Use of short-acting agents such as remifentanyl Regional and multimodal analgesia (e.g., nonsteroidal antiinflammatory drugs, acetaminophen, tramadol, ketamine, gabapentin, pregabalin, dexamethasone)
	Carry-over sedation effects from longer-acting intravenous sedatives and inhaled anesthetic agents	Use of propofol for maintenance of anesthesia Use of insoluble potent anesthetic agents (sevoflurane and desflurane)
	Excessive sedation in monitored anesthetic care	Use of capnography for intraoperative monitoring
Reversal of anesthesia	Postextubation airway obstruction and desaturations	Verification of full reversal of neuromuscular blockade Ensure patient is fully conscious and cooperative before extubation Semi-upright posture for recovery
Immediate postoperative period	Respiratory	Use CPAP and supplemental oxygen Avoid opiates Use intensive respiratory monitoring
	Suitability for outpatient surgery	Prophylaxis for venous thromboembolism Lithotripsy, superficial, or minor orthopedic surgeries using local or regional techniques may be considered for outpatient surgery No requirement for high-dose postoperative opioids Transfer arrangement to inpatient facility should be available
	Postoperative respiratory event in known and suspected high-risk patients with OSA	Longer monitoring in the PACU Continuous oximetry monitoring and PAP therapy may be necessary if recurrent PACU respiratory events occur (e.g., desaturation, apnea, bradycardia)

ASA, American Society of Anesthesiologists; CPAP, continuous positive airway pressure; OSA, obstructive sleep apnea; PACU, postanesthesia care unit; PAP, positive airway pressure.

Obesity Hypoventilation (Pickwickian) Syndrome

Obesity hypoventilation syndrome (OHS), or Pickwickian syndrome, is a complication of extreme obesity characterized by OSA, hypercapnia, daytime hypersomnolence, arterial hypoxemia, cyanosis-induced polycythemia, respiratory acidosis, pulmonary hypertension, and right-sided heart failure. At its extreme, patients develop nocturnal episodes of central apnea (apnea without respiratory efforts), which reflects progressive desensitization of the respiratory centers to nocturnal hypercarbia.^{32,33,41,50}

OHS is defined as obesity (BMI greater than 30 kg/m²), daytime hypoventilation with awake partial pressure of arterial carbon dioxide (PCO₂) greater than 45 mm Hg, and sleep-disordered breathing in the absence of other causes of hypoventilation. Approximately 90% of patients with OHS also have OSA. The prevalence of OHS in patients with OSA is uncertain, but is estimated to be between 4% and 20%.⁵⁹

OHS, which occurs in 8% of the obese population, is clinically distinct from simple obesity.³³ With simple obesity, the PCO₂, pH, and pulmonary compliance are within normal ranges.³¹ Hypoxia may be present, but no evidence of cardiac failure or differences in arterioalveolar O₂ exists. In contrast, OHS is diagnosed when the morbidly obese patient exhibits inappropriate and sudden somnolence, sleep apnea, hypoxia, and hypercapnia.³ A PCO₂ greater than 45 mm Hg during wakefulness with compensatory metabolic compensation and hypoxemia (partial pressure of oxygen [PO₂] less than 70 mm Hg) is suggestive of OHS.⁵⁹ Alveolar ventilation is reduced because of shallow and inefficient ventilation related to decreased tidal volume, inadequate inspiratory strength, and inadequate elevation of the diaphragm. Cardiac enlargement, cyanosis, polycythemia, and twitching also are evident on physical examination.⁴ In the early stages of OHS development, patients will maintain normocapnia during wakefulness, but have increased bicarbonate and base excess due to chronic hypercapnia during sleep. It has been suggested that early diagnosis of OHS may be facilitated by screening obese individuals at risk for the

development of the disorder for increased bicarbonate levels and base excess.⁶⁰ Activities of daily living are altered by the somnolent episodes. Operating machinery or driving a vehicle may cause injury or death in these individuals.

Gastrointestinal Disease

The incidence of gastroesophageal reflux disease, gallstones, and pancreatitis increases with obesity. Patients with excess visceral fat are much more likely to develop dyspeptic symptoms.⁶¹ Obesity is associated with a number of liver abnormalities referred to as *nonalcoholic fatty liver disease* (NAFLD).⁶² NAFLD includes steatosis, steatohepatitis, fibrosis, cirrhosis, hepatomegaly, and abnormal liver biochemistry. Patients with NAFLD are at risk for developing cirrhosis, hepatic decompensation, and hepatocellular carcinoma. The pathogenesis of NAFLD is not fully understood, although researchers have found that a combination of environmental, genetic, and metabolic factors lead to advanced disease. There have been improvements in the use of noninvasive radiographic methods to diagnose NAFLD, especially for advanced disease; however, liver biopsy is still the standard method of diagnosis for NAFLD.⁶³

NAFLD affects up to 30% of individuals in developed countries and nearly 10% of individuals in developing nations, making NAFLD the most common liver condition in the world. The pathogenesis of NAFLD is related to insulin resistance, and it is frequently found in individuals who have central obesity or diabetes. Insulin resistance and excess adiposity are associated with increased lipid influx into the liver and increased hepatic triglyceride accumulation. Defects in mitochondrial oxidation of lipids and lipid export may also contribute to hepatic lipid build-up. Clinically, NAFLD is commonly asymptomatic and usually detected incidentally by liver function tests or imaging performed for other reasons. Subjects with NAFLD have a higher mortality rate than the general population and are at increased risk of developing cardiovascular disease and diabetes.⁶² In obese patients, the mortality rate from liver cirrhosis is 1.5 to 2.5 times higher than in nonobese persons.¹⁹

Gallstones

Gallstones are 30% more prevalent in obese than nonobese women, and this prevalence increases linearly with BMI.⁴ Higher concentrations of cholesterol in the bile and an increased ratio of bile salts to lecithin are responsible for the development of gallstones.⁶⁴ Jaundice may also accompany bile duct obstruction. Laparoscopic and open cholecystectomies are commonly performed in this group of patients because of the increased incidence of gallbladder disease in the obese. Although technically more difficult for both surgical and anesthesia teams, the benefits of laparoscopic gallbladder removal (e.g., reduced postoperative pain, shorter hospitalization, earlier return to activities of daily living) outweigh the risks.

Endocrine and Metabolic Disease

Obesity is seldom the result of primary endocrine dysfunction. Thyroid, adrenocortical, and pituitary function should be investigated in obese patients who manifest atypical symptoms.³ Menstrual problems such as oligomenorrhea, amenorrhea, menorrhagia, and the presence of hirsutism may signal hypothalamic-pituitary abnormalities. Obese men may experience decreased libido or impotence indicative of hypogonadism, and low serum follicle-stimulating hormone and testosterone levels are frequently evident.²¹

Eighty percent of individuals with type 2 diabetes mellitus are obese. The risk of type 2 diabetes increases linearly with BMI.^{21,65}

There is a 35% to 40% prevalence of metabolic syndrome in the US population. Patients with obesity and metabolic syndrome may have complicated medical histories that include diabetes, heart disease, and OSA. Gynecoid fat distribution is strongly linked to the development of this obesity-related disorder.⁶⁶ Metabolic syndrome consists of an array of conditions, including glucose intolerance and/or type 2 diabetes mellitus, hypertension, dyslipidemia, and cardiovascular diseases. Patients with metabolic syndrome have an increased risk of developing CAD, stroke, peripheral vascular disease, and type 2 diabetes mellitus, and are at greater risk of mortality from coronary disease and other causes. These patients

also exist in a proinflammatory and prothrombotic state. Whether this syndrome is a disease itself or is composed of discrete disorders is the subject of much investigation and controversy. Individuals with metabolic syndrome have a cardiovascular risk that is 50% to 60% higher than normal. The definition and characteristics of **Box 48.3** metabolic syndrome are noted in **Box 48.3**.^{66,67}

Metabolic Syndrome Definition

The American Heart Association and the National Heart, Lung, and Blood Institute define metabolic syndrome as the presence of three or more of the following criteria:

1. Elevated waist circumference
 - Men: 40 inches (102 cm) or greater
 - Women: 35 inches (88 cm) or greater
2. Elevated triglycerides
 - 150 mg/dL or greater
3. Reduced HDL cholesterol
 - Men: less than 40 mg/dL
 - Women: less than 50 mg/dL
4. Elevated blood pressure
 - 130/85 mm Hg or greater
5. Elevated fasting glucose
 - 100 mg/dL or greater

HDL, High-density lipoprotein.

Adapted from Levin PD, Weissman C. Obesity, metabolic syndrome, and the surgical patient. *Anesthesiol Clin*. 2009;27(4):705–719.

Orthopedic and Joint Disease

Obese persons often develop osteoarthritis from continued mechanical stress on weight-bearing joints. There is a linear relationship between weight and the degree of arthritis.²⁻⁴ Ankles, hips, knees, and the lumbar spine are frequently burdened. Bone resorption secondary to limited physical activity also may reduce bone density and contribute to the development of stress fractures. Weight reduction can curb orthopedic injury and lessen discomfort in the back and lower extremities.

Pediatric Obesity

Obesity is a growing problem among US children. Approximately 31.8% of young people aged between 2 and 19 years old are considered to be either overweight or obese, and 16.9% are considered to be obese. The incidence of obesity in children aged 2 to 5 years has decreased significantly in recent years, from nearly 14% in 2004 to just over 8% in 2012.^{68,69} Adolescents are more overweight than preschool children.^{69,70,71} These adverse trends in obesity have potentially profound effects on children's health now and for their long-term health outlook.

Obesity is clinically diagnosed as a weight-for-height greater than the 90th percentile or a BMI greater than or equal to the 95th percentile, age- and sex-specific. Pediatric obesity is recognized as a BMI greater than the 95th percentile on the Centers for Disease Control and Prevention growth chart. Evidence-based guidelines and expert committee recommendations have repeatedly stressed that the BMI for age should be the basis of our definitions of pediatric overweight and obesity.

Studies document links between early childhood and adolescent obesity and adult obesity:

- Obese adolescents have a 70% to 80% chance of being obese adults.⁷²
- Childhood obesity is associated with a higher chance of premature death and disability in adulthood, particularly in urban areas.⁷³
- Childhood and adolescent overweight and obesity are linked with adult cardiovascular and endocrine problems.⁷⁴
- Obese children are three to five times more likely to suffer a heart attack or stroke before they reach the age of 65.⁷⁴
- Being overweight as young as 18 could be the strongest predictor of future hip replacement due to osteoarthritis.⁷⁵

Determinants of obesity are multifactorial and include genetics, biology, and social and environmental behaviors that may begin in early childhood. The escalating national and global epidemics of obesity and sedentary lifestyles warrant increased attention by

physicians and other health care professionals. The health goals for obese children and adolescents should be to develop healthy eating habits, maintain weight or reduce the rate of gain, and to be active rather than sedentary.⁷⁶

Some specific problems obese children face related to the health care community are the following:

- Pediatric obesity is more common than diabetes, HIV, cystic fibrosis, and all childhood cancers combined.
- Primary hypertension in children has become increasingly common in association with obesity and risk factors such as a family history of hypertension and an ethnic predisposition to hypertensive disease. Obese children are at approximately a threefold higher risk for hypertension than nonobese children.⁷⁷
- Most children with type 2 diabetes are overweight or obese at diagnosis and usually have a family history of type 2 diabetes. Americans of African, Hispanic, Asian, and American Indian descent are disproportionately represented in this population.⁷⁸
- OSA was very common in a clinical sample of overweight children. OSA is not associated with abdominal obesity. On the contrary, higher levels of abdominal obesity and fat mass are associated with central sleep apnea.
- Bariatric surgery may be useful, but only in carefully selected obese children with serious comorbidities and unresponsiveness to interventions. The biggest barrier to performing child bariatric surgery seems to be the psychosocial aspect, although complications include leaks, deep vein thrombi, micronutrient deficiency, bleeding, and infection.⁷⁹
- Psychosocial disorders may result when obese children are treated differently. This may be the most devastating effect of obesity on children. They may feel isolated and lonely and have self-esteem and identity problems. It is important for the health care professional to be sensitive to this issue and understand that an individual's confidence, especially a child's, is affected by self-image and the perceptions of peers.⁸⁰

Unfortunately, children with long-standing obesity (especially Class II and Class III obesity) develop medical problems previously seen only in adulthood. The medical effects of obesity that were

previously reserved for adults, such as hypertension, insulin resistance, CAD, and metabolic syndrome, are on the rise in children and adolescents.^{81,82}

The prevalence of metabolic syndrome is high among obese children and adolescents, and increases with worsening obesity. Diagnosis of metabolic syndrome in children and adolescents is only now receiving greater attention, and there does not seem to be consensus on precise standards of treatment. As with adults, the dominant underlying risk factors for this syndrome appear to be abdominal obesity, insulin resistance, hypertriglyceridemia, hypertension, and proinflammatory and prothrombotic states.⁸²

Studies show that obesity increases the burden of disease for children and adolescents, and special attention has been given to clinical complications for that population. These include cardiovascular disease (dyslipidemia and hypertension), respiratory disease (sleep apnea, snoring, asthma), orthopedic conditions (Blount disease, slipped capital femoral epiphysis), gastrointestinal disease (gallbladder, steatohepatitis), and endocrine disease (insulin resistance, hyperinsulinism, impaired glucose tolerance, and type 2 diabetes, which is normally reserved for adults). Other conditions in adolescent females include polycystic ovarian syndrome and menstrual irregularity. Studies also include psychosocial conditions such as depression, eating disorders, and social isolation.⁸³

Maternal Obesity

Obstetric complications of maternal obesity correlate more with pregravid obesity than with excessive weight gain during gestation. Maternal obesity, not diabetes, seems to be the most important link to the nation's increase in mean birth weight. The mean increase in birth weight at 37 to 41 weeks' gestation in the past 30 years was 116%.⁸⁴ Prepregnancy obesity significantly increases the parturient risk for cesarean delivery.

Both the first and the second stages of labor are longer in obese women. Obesity is a risk factor for developing gestational hypertension, insulin-treated gestational diabetes, and hydramnios. However, the neonatal outcomes for obese women are comparable to those for women with normal prepregnancy BMI.⁸⁵

The National Institutes of Health recognizes many risk factors associated with maternal obesity. Outcomes in pregnancy complicated by obesity include gestational diabetes, preeclampsia, preterm labor, cesarean delivery, postpartum hemorrhage, infection, pregnancy-induced hypertension (PIH), and macrosomic infants. The American College of Obstetricians and Gynecologists (ACOG) reports that the risk of spontaneous abortion and miscarriage in the first 6 weeks of pregnancy is almost doubled in obese women compared to nonobese women.⁸⁴ Metabolic syndrome in pregnancy manifests as preeclampsia, gestational hypertension, insulin resistance, and diabetes. The risk of preeclampsia increases further in obese women with gestational diabetes mellitus (GDM) that is poorly controlled, a previous history of GDM, a family history of type 2 diabetes, and history of a macrosomic fetus.⁸¹

Newborns considered to be large for gestational age, or macrosomic, and are at risk for long-term obesity. Weiss et al.⁸⁶ defined *fetal macrosomia* as a birth weight greater than 4000 g and found the rate of macrosomia to be 8.3% in nonobese parturients, 13.3% in those who were obese, and 14.6% in the morbidly obese. These increased birth weights have been linked to an increased incidence of adolescent metabolic syndrome and type 2 diabetes. By age 4, 25% of children who were born with fetal macrosomia have impaired glucose tolerance. Children born to mothers with BMIs

greater than 30 kg/m² in the first trimester are more likely to show fetal overgrowth and adiposity beginning *in utero* and continuing into the first years of life. One study demonstrated that at ages 2, 3, and 4, the growth of children born to obese mothers was increased by 15.1%, 20.6%, and 24.1%, respectively.⁸⁷

Peripartum risks associated with maternal obesity include the following:

- Cesarean delivery (approaches 40% in the severely obese) and associated morbidity
- Difficult placement of epidurals and spinals, requiring multiple attempts
- Difficult intubation risk, usually in an emergent setting (twice the risk of nonobese women)
- Decreased ability of ultrasound to detect cardiac and craniospinal abnormalities
- Increased postoperative complications, longer surgery times, wound infection and breakdown, endometritis, antepartum venous thrombi/emboli (VTE), and excessive blood loss during surgery (but no increased risk of postpartum hemorrhage)

Bariatric Surgery for Obese Women: Gestational Considerations

Owing to limited success with lifestyle changes, more obese women of reproductive age are seeking bariatric surgery as an alternative. One study showed an increased risk of complications during pregnancy after these malabsorptive procedures, including an increase in premature rupture of membranes, small bowel ischemia, nutrient deficiencies, and fetal abnormalities.⁸⁴ Cesarean deliveries also increased in women who had previous bariatric surgery. Gestational diabetes and PIH disorders were significantly reduced in women having laparoscopic adjustable gastric banding procedures. There were no significant differences in placental abruption and previa, labor dystocia, or perinatal complications with bariatric surgery prior to conception.

Recommendations from ACOG⁸⁸ include annual weight screening, especially for women of childbearing age with a family

history of cardiovascular disease and diabetes mellitus. They recommend physical activity, proper diet, behavioral therapy, and bariatric surgery for women with BMIs greater than 40 kg/m² with comorbidities prior to pregnancy. After delivery, continued exercise and diet, as well as breastfeeding the infant, are beneficial. During pregnancy, weight gain should be limited following the Institute of Medicine suggestions: 25 to 35 pounds in nonobese women, 15 to 25 pounds in overweight women, and 15 pounds in obese women.

Genetic predisposition, physiology, and mechanisms related to maternal and fetal-placental interactions are important to the growth and development of children. Maternal obesity is shown to be a significant risk factor in adverse outcomes in pregnancy. Higher birth weights have a definite connection to overgrowth in children and obesity in adolescents.

Treatment of Obesity

A multimodal approach in the treatment of obesity includes dietary intervention, increased exercise, behavior modification, drug therapy, and surgery. Weight-loss programs should be individualized to each patient based on the degree of obesity and coexisting conditions. Drug therapy is initiated in patients with a BMI greater than 30 kg/m² or a BMI between 27 and 29.9 kg/m² with a coexisting medical condition.²⁻⁴ Medications that promote weight loss have limited efficacy. Despite the enormous potential market, efforts to develop effective drug therapies have been disappointing. The Food and Drug Administration (FDA) guidance for long-term weight loss drugs recommends that a 5% weight reduction be maintained for 12 months after treatment initiation. Some drugs currently approved for weight loss are listed in [Table 48.3](#).^{89,90}

TABLE 48.3

Some FDA-Approved Drugs for the Long-Term Treatment of Obesity

Drug	Usual Adult Dosage	Mean Weight Loss
Sympathomimetic Amine/Antiepileptic Combination phentermine/topiramate ER (Qsymia)	7.5/46–15/92 mg once/day	4.1–10.7 kg
Lipase Inhibitor orlistat (Xenical) (Alli)	102 mg tid 60 mg tid	2.5–3.4 kg
Serotonin Receptor Agonist lorcaserin (Belviq)	10 mg bid	2.9–3.6 kg
Opioid Antagonist/Antidepressant Combination naltrexone/bupropion (Contrave)	16/180 mg bid	3.7–5.2 kg
GLP-1 Receptor Agonist liraglutide (Saxenda)	3 mg SC once/day	5.8–5.9 kg

ER, Extended release; GLP-1, glucagon-like peptide-1; SC, subcutaneous.

Adapted from Diet, drugs, and surgery for weight loss. *Med Lett Drugs Ther.* 2015;:57(1462):21–28; Heymsfield SB, Wadden TA. Mechanisms, pathophysiology, and management of obesity. *N Engl J Med.* 2017;376:254–266.

Surgical Treatment

Besides common surgeries performed within the general

population, obese persons undergo additional procedures to ameliorate obesity-related diseases (Box 48.4). The four most common bariatric procedures at present are the Roux-en-Y gastric bypass (RYGB), laparoscopic adjustable gastric bypass (LAGB), laparoscopic sleeve gastrectomy (LSG), and biliopancreatic diversion with duodenal switch (BPD with DS). All are safe, effective, minimally invasive, and relatively cost-effective. Recent advancements in endoscopic technologies and techniques have opened a new field of minimally invasive endoscopic treatment options for combatting obesity, both as a first-line and an adjunctive therapy. Presently, two endoscopic space-occupying devices (intra-gastric balloons) have received FDA approval for 6-month implantation in patients within a BMI range of 30–40 kg/m². Furthermore, full-thickness suturing has led to the development of primary endoscopic sleeve gastropasty and RYGB revision as viable endoscopic alternatives to surgical approaches. These techniques have the potential to reduce adverse events, cost, and recovery times.^{91–95} Surgical approaches designed to treat obesity can be classified as malabsorptive or restrictive.⁸⁹ Malabsorptive procedures are not commonly used. Restrictive procedures include the largely historic vertical banded gastroplasty and the increasingly common gastric banding, including LAGB and LSG. The mechanisms of various bariatric procedures are shown in Box 48.5. Despite the technically demanding nature of the RYGB procedure, it has become the procedure of choice for clinically severe obesity. LAGB is greatly increasing in frequency in the United States.^{89,91–95}

Obesity-Related Diseases Requiring Surgery

- Cholelithiasis
- Thromboembolism
- Peripheral vascular disease
- Urolithiasis and urinary incontinence

- Osteoarthritis-related orthopedic procedures
- Varicose veins
- Hiatal and abdominal wall hernias
- Cancer (endometrial, breast, prostate, colorectal, renal)
- Uterine fibroma
- Ovarian cysts
- Increased risk of fetal distress requiring Cesarean section

Box 48.5

Mechanism of Action of Select Bariatric Operations

Restrictive

- Vertical banded gastroplasty (VBG; historic purposes only)
- Laparoscopic adjustable gastric banding (LAGB)
- Laparoscopic sleeve gastrectomy (LSG)

Largely Restrictive, Mildly Malabsorptive

- Roux-en-Y gastric bypass (RYGB)

Largely Malabsorptive, Mildly Restrictive

- Biliopancreatic diversion (BPD)
- Duodenal switch (DS)

Adapted from Richards WO. Morbid obesity. In Townsend CM, et al., eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia: Elsevier; 2017:1168.

Advances in laparoscopic surgery have significantly improved surgical procedure times, as well as the morbidity and mortality related to bariatric surgery. Pneumoperitoneum can have a negative impact on respiratory system mechanics and oxygenation during laparoscopy. LAGB is associated with a shorter length of stay, lower morbidity, lower mortality, and lower hospital costs compared with an open procedure. The laparoscopic approach to gastric bypass should be considered the gold standard approach for the treatment of morbid obesity.^{96,97} Overall, the use of laparoscopic techniques has reduced morbidity related to bariatric surgery.⁹⁸⁻¹⁰¹

Indications for bariatric surgery are noted in [Box 48.6](#). Postoperatively, patients must stay in close contact with multidisciplinary team members. Rehabilitation of previous lifestyle patterns is achieved through counseling and support provided by psychologists, dietitians, physical therapists, and [Box 48.6](#).⁹²⁻⁹⁴

Indications for Bariatric Surgery

Patients must meet the following criteria for consideration for bariatric surgery:

- BMI greater than 40 kg/m² or BMI less than 35 kg/m² with an associated medical comorbidity worsened by obesity
- Failed dietary therapy
- Psychiatrically stable without alcohol dependence or illegal drug use
- Knowledgeable about the operation and its sequelae
- Motivated individual
- Medical problems not precluding probable survival from surgery

BMI, Body mass index.

Pharmacologic Considerations

Obesity causes physiologic changes that can affect the pharmacokinetics and pharmacodynamics of anesthetic agents. An overview of these changes is shown in [Box 48.7](#). The common approach to anesthetic drug administration is to give water-soluble drugs according to IBW and lipid-soluble drugs according to total body weight (TBW). Lean body mass increases approximately 20% to 40% in obesity, so adding 30% to the IBW is a convenient dose adjustment to account for this change. Contradictory results from individual drug studies in small patient groups are common; therefore, specific recommendations are frequently conflicting. A few general observations can be made. Postoperative respiratory depression is especially problematic in obese patients; therefore, most clinicians favor short-acting drugs, which allow for fast recovery. The newer inhalation agents desflurane and sevoflurane produce excellent recovery profiles in obese patients. Although desflurane is less soluble than sevoflurane, clinical differences are minimal. Nitrous oxide can be safely used in patients where a requirement for high O₂ concentrations does not preclude its administration. Nitrous oxide is being increasingly used in extremely obese patients as a volatile-sparing adjunct. The second gas effect of nitrous oxide at induction and emergence can accelerate uptake and elimination of the volatile agent. Nitrous oxide may also have the potential of reducing chronic postoperative pain, which occurs even after laparoscopic surgery. Appropriate antiemetic prophylaxis should be administered when anesthetic gases, and especially nitrous oxide, are used. Succinylcholine doses for intubation are given according to TBW to ensure excellent intubating conditions, whereas the nondepolarizing muscle relaxants used for operative maintenance are given according to IBW. Use of a nerve stimulator to guide relaxant administration is necessary to minimize residual paralysis and reversal concerns. Remifentanyl infusion is an especially popular analgesic due to its titratability and rapid offset and is administered according to IBW. Dexmedetomidine is also a useful adjunct for sedation, amnesia, and analgesia. Sugammadex is given in the usual doses. Specific

dosing recommendations for some common anesthetic agents in **Box 48.7** are listed in [Table 48.4](#).^{89,102,103}

Pharmacokinetic Changes Associated With Obesity

- Increased fat mass
- Increased cardiac output
- Increased blood volume
- Increased lean body weight
- Changes in plasma protein binding
- Reduced total body water
- Increased renal clearance
- Increased volume of distribution of lipid-soluble drugs
- Abnormal liver function
- Decreased pulmonary function

TABLE 48.4

Guidelines for Dosages of Intravenous Anesthetics in Obese Patients

Drug	Dose Recommendation	Comments
Propofol	Induction dose based on LBW Maintenance dose based on TBW	Increased fat mass does not affect initial distribution/redistribution during induction; cardiac depression at high doses is a concern
Succinylcholine	Intubating dose based on TBW	Increased fluid compartment and pseudocholinesterase levels require higher doses to ensure adequate paralysis
Rocuronium Vecuronium Cisatracurium	All doses based on IBW	Hydrophilic drugs given according to IBW will ensure shorter duration and a more predictable recovery in this respiratory-challenged population
Fentanyl Sufentanil	Loading dose based on TBW Maintenance doses based on LBW and response	Increased distribution volume and elimination time correlate with degree of obesity

Remifentanyl	Infusion rates based on IBW	Distribution volumes and elimination rates are similar to normal-sized individuals; fast offset requires planning for postoperative analgesia
Dexmedetomidine	Infusion rates of 0.2 mcg/kg per min	Useful as an adjunct; lower than usual infusion rates are recommended to minimize adverse cardiac side effects
Sugammadex	Reversal doses based on TBW	No change from usual dosing required

IBW, Ideal body weight; *LBW*, lean body weight; *TBW*, total body weight.

Anesthetic Management: Preanesthetic Evaluation

The goals of the preanesthetic evaluation are to obtain pertinent data regarding the patient's medical or surgical history, to optimize current physiologic functioning, and to determine an appropriate anesthetic plan (see [Chapter 20](#)). Of paramount importance is the need to establish a nonjudgmental and trusting relationship with the patient. Explanations of anticipated events during preoperative preparation (e.g., multiple venipunctures, central and arterial line insertions, awake intubation, pain management) and protection of the patient's privacy will allay anxiety.

Medications

Obese persons must be questioned regarding the use of weight-reducing substances, herbal supplements, and anorexiants. Patients who take over-the-counter drugs, including herbal medications, often forget or are afraid to reveal that they are taking these preparations, which can have deleterious consequences on induction. The patient's usual medications should be continued until the time of surgery, with the exception of insulin and oral hypoglycemics.¹⁰⁴ Recommendations for preoperative management of antidiabetic drugs are given in [Chapters 20](#) and [37](#). Antibiotic prophylaxis is important because of an increased incidence of wound infections in the obese.¹⁰⁵ VTE prophylaxis should be planned with the surgeon and administered as appropriate.¹⁰³

Laboratory Tests

Only the laboratory tests appropriate in light of the patient's history, physical examination, and planned surgery should be ordered.¹⁴ Baseline studies that may be directly affected by associated medical conditions such as metabolic syndrome should be considered. Preoperative testing should focus on comorbid disease states such as renal, hepatic, cardiovascular, and endocrine states related to obesity.¹⁰⁶ Because obese patients have a high risk

of cardiovascular disease and diabetes mellitus, electrocardiogram (ECG) and glucose should be considered routine. All other tests should be guided by the patient's underlying condition, medications, or surgical procedure.^{106,107}

Arterial blood gas analysis that compares samples taken with the patient lying supine and sitting while breathing room air provides baseline values and can distinguish simple obesity from OHS. The chemistry panel may reflect abnormal glucose and potassium levels, which are indicators of insulin resistance and potentiation of myocardial irritability. Concomitant use of diuretics and certain cardiac medications can exacerbate electrolyte disturbances.¹⁵ Blood urea nitrogen and creatinine levels may be elevated in response to dehydration or renal dysfunction. Liver function tests are typically elevated in obese patients. This is generally not the result of hepatic disease, but of infiltration of the hepatocytes with triglycerides (e.g., fatty liver, liver steatosis). The severity of fatty infiltration may alter the pharmacologic effects of many anesthetic drugs, thereby requiring dose reductions.

Coagulation studies are necessary if coagulopathy exists. Patients taking anticoagulants for treatment of deep vein thrombosis or atrial fibrillation may exhibit elevated prothrombin and partial thromboplastin times. Use of nonsteroidal antiinflammatory drugs (NSAIDs) may prolong bleeding times and affect surgical hemostasis.

Cardiac Assessment

Evaluation of cardiac function is essential in overweight and obese patients undergoing surgery. Investigation of prior myocardial infarction and the presence of hypertension, angina, or peripheral vascular disease is crucial. Limitations in exercise tolerance, history of orthopnea, and paroxysmal nocturnal dyspnea may indicate left ventricular dysfunction.¹⁰² A careful elicitation of drug history is invaluable in garnering clues about the patient's coexistent diseases. When possible, cardiac medications should be continued up to and including the morning of surgery.

An ECG is essential for determination of resting rate, rhythm, and ventricular hypertrophy or strain. Because of the increased incidence of CAD and myocardial infarction in this population, the

preoperative ECG is also helpful in providing a reference for comparison in the event that myocardial ischemia develops in the perioperative period. Beyond this, there is no reason to believe that extensive preoperative testing to detect CAD is indicated based solely on a patient being obese.¹⁰⁷ The ECG may be of low voltage because of the excess overlying tissue, and therefore might result in underestimation of the severity of ventricular hypertrophy. Axis deviation and atrial tachyarrhythmias are relatively common.⁴

QT-interval prolongation, discovered retrospectively in severely obese patients who died from refractory dysrhythmias, is a marker for sudden cardiac arrest.³ In cases of fatal and nonfatal dying, prolonged QT intervals were also observed on patient ECGs.⁴ In addition, sudden cardiac death is more prevalent in morbidly obese patients with left ventricular hypertrophy and ventricular ectopy.⁵ If ventricular hypertrophy or cardiomyopathy is suspected, echocardiography is useful. Tricuspid regurgitation on echocardiography is the most confirmatory test of pulmonary hypertension when combined with clinical evaluation.¹⁰⁸

Exercise testing may elicit valuable information about myocardial function in morbidly obese patients. However, most are physically unable to achieve adequate levels of exercise stress to make the studies worthwhile.¹⁵ In addition, echocardiography is useful for determining whether akinesis or wall motion abnormalities are present in the obese myocardium.

Cardiomegaly, pulmonary congestion, an elevated diaphragm, and a tortuous aorta can be identified by use of chest radiography. Results of radiographic studies serve to guide preoperative pharmacologic and medical management (e.g., diuretics, β_1 -agonists, antibiotics). Repeated radiographs may be required to obtain adequate penetration and visualization of all lung fields. Unfortunately, standard stationary and portable x-ray machines cannot accommodate massively obese persons. As a result, diagnostic x-ray examinations or evaluation of central line placement may be impossible. Under these circumstances, clinical expertise and management of subtle symptoms are invaluable. If it is indicated, the patient should be referred to a cardiologist for further investigation and optimization of his or her condition (e.g., control of blood pressure, treatment of heart failure, or treatment of

coronary pathology).¹⁰⁹

Respiratory Evaluation

Careful preoperative evaluation of the patient's respiratory function assists in the identification of potential problems. A patient who becomes dyspneic and desaturates when recumbent will experience the same symptoms during induction in the supine position. The patient must be asked about the presence or absence of OSA, orthopnea, wheezing, sputum production, or smoking history. They must also be assessed for OHS. Recent upper respiratory infection, snoring, or sleep disturbances may signal obstructive processes. The potential for difficult mask ventilation also should be considered during the preoperative visit. Obesity has been identified as an independent risk factor for difficult facemask ventilation. The presence of a beard, lack of teeth, and snoring history compound this risk in the obese patient.¹¹⁰ Room air pulse oximetry saturations and arterial blood gases obtained in supine and upright positions may reflect disturbances in cardiac compensation.¹¹¹

Airway Evaluation

A thorough airway evaluation is warranted for determination of the optimal airway management technique in overweight and obese patients.¹¹² A variety of assessment criteria have been evaluated for prediction of difficult intubation in obese patients. Most practitioners use evaluation of multiple patient physical characteristics to identify potential airway problems indicative of the unanticipated difficult airway. These include measurement of interincisor distance, thyromental distance, head and neck extension, Mallampati classification, body weight, and, most importantly, a history of difficult airway management.^{113–115} Inspection of the oropharynx is necessary to determine the Mallampati classification for intubation difficulty.¹¹³ The value of oropharyngeal Mallampati classification alone is low. Evaluation of the length of upper incisors, visibility of the uvula, shape of the palate, compliance of the mandibular space, and length and thickness of the neck provide further criteria for assessment.

Opinions differ about the use of a patient's weight (BMI) as an independent predictor of difficulty in intubation. Some have demonstrated that difficult intubation is more common in obese patients.¹¹⁶ Others have demonstrated that increased BMI *per se* is not a predictor of difficult intubation.¹¹⁷ Variables that are likely to predict difficulty in intubation of the obese patient include increased neck circumference, Mallampati classification greater than 3, increased age, male sex, temporomandibular joint pathology, a history of OSA, and abnormal upper teeth.^{117,118} Of these, a high Mallampati score (3 or greater) with a large neck circumference and a history of sleep apnea were, in the aggregate, found to be good predictors of difficulty in intubation.¹¹³

Fat rolls around the neck (restricting neck motion) and fat in the airway (decreasing glottic opening) together increase the difficulty of successfully intubating the trachea. The larger the neck circumference, the more difficult the laryngoscopy and intubation. A neck circumference of 40 cm was associated with a 5% probability of difficult intubation, and a neck circumference of 60 cm or greater was associated with a 35% probability of difficult intubation. A normal neck circumference in a 70-kg man is approximately 35 cm. Other researchers, using ultrasound to quantify the amount of anterior neck soft tissue, produced data that support these findings.¹¹⁹

Anatomic aberrations of the upper airway induced by severe obesity include reduced temporomandibular and atlanto-occipital joint movement. Unsatisfactory mouth opening, presence of neck or arm pain, or an inability to place the head and neck into “sniffing position” may indicate the need for awake fiberoptic intubation. Extreme airway narrowing in conjunction with a shortened mandibular-hyoid distance (less than three fingerbreadths) can complicate mask ventilation and intubation. The presence of a short, thick neck, pendulous breasts, hypertrophied tonsils and adenoids, or a beard can contribute to a difficult airway. Marginal room air pulse oximeter saturations, abnormal arterial blood gases, and a history of complicated airway management also indicate a potentially difficult intubation (see [Chapter 24](#) for a full description of the assessment and management of a difficult airway).^{113–115} Airway management techniques should be explained to the patient,

with emphasis on awake intubation and the need for postoperative ventilation.^{120,121}

Vascular Access

Venipuncture can be challenging in overweight and obese patients with excessive fat that obscures blood vessels from visualization and palpation.¹⁵ Central cannulation of vessels is impeded by distortion of the underlying anatomy by adipose tissue.¹²²

Hemorrhage, hypothermia, and trauma further reduce the likelihood of accessing vessels with ease. Use of a portable ultrasound machine may improve central and peripheral venous catheter placement. As in all patients, iatrogenic pneumothorax must be avoided. Morbidly obese patients are less able than nonobese patients to tolerate the ensuing respiratory impairment.

Anesthetic Management: Preparation

Operating Room Equipment

In preparation for either emergent operating room procedures or nonemergent hospital admission, appropriate equipment must be readied. Newer-model operating room tables can accommodate up to 600 lb of weight. Older-model standard operating room tables could hydraulically elevate 300 to 350 lb of weight. The anesthesia provider should always verify the weight limit on the operating room table when caring for obese patients. In cases of extreme obesity, “big boy” hydraulic beds should be obtained and used in the operating room. Heavy-duty stirrups, extra-large retractors, elongated instruments, arm sleds, doubled armboards, gel pads for positioning, and extremity tourniquets must be obtained. Sometimes a sanitized engine crane or other hoisting device must be used to suspend the panniculus adiposus for optimal surgical exposure.

Extra-large thigh cuffs can be used on the upper arm or the lower leg (over the posterior tibial artery). A regular-size or large blood pressure cuff can be used on the forearm over the radial artery until arterial cannulation for blood pressure monitoring can be performed. Bed-warming devices, fluid warmers, and warm airflow blankets should be used to prevent hypothermia, which can occur rapidly when large areas of body surface are exposed.

Airway Equipment

An equally important part of airway assessment is the preparation of equipment and personnel necessary to ventilate and intubate the morbidly obese patient. An assortment of blades, laryngoscopy handles, endotracheal tubes, masks, oral and nasopharyngeal airways, and stylets should be assembled. Laryngeal mask airways (LMAs), intubating laryngeal mask airways (ILMA), video laryngoscopes, fiberoptic and bronchoscopic devices, Eschmann introducers, a jet ventilator (or Venturi apparatus), and emergency tracheotomy and cricothyrotomy kits must be available in the event that ventilation by mask or endotracheal tube is unsuccessful. Most

departments have a difficult-airway cart that has all of the available equipment that should be placed in the operating room. The ILMA and LMA CTrach (a modified version of the intubating LMA that allows continuous videoendoscopy of the tracheal intubation procedure) have been advocated as particularly useful tools for ventilating and intubating morbidly obese patients.^{123,124}

Monitoring

Intraoperative monitoring, both basic and advanced, should address the specific needs of the patient. Selection of electrocardiographic leads, when possible, should enhance detection of myocardial ischemia and pathology (leads II and V₅). Needle electrodes may be useful for obtaining a better tracing. Cuffs with bladders that encircle a minimum of 75% of the upper arm circumference (but preferably the entire arm) should be used. Forearm measurements with a standard cuff overestimate both systolic and diastolic blood pressures in obese patients.¹²⁵ Placement of an arterial catheter is appropriate for monitoring hemodynamic status, and is advocated for all but the most minor procedures in the morbidly obese.¹⁹ The use of central venous catheters is not standard, but should be considered in patients undergoing extensive surgery, or those with serious cardiorespiratory disease.^{102,122}

Aspiration and Postoperative Nausea and Vomiting Prophylaxis

Anesthesia providers have traditionally considered obese patients to be “full-stomach” patients and at risk for regurgitation and subsequent pulmonary aspiration.^{126–128} It is known that gastroesophageal reflux and hiatal hernia are more prevalent in the obese, and this may predispose them to esophagitis and pulmonary aspiration. However, data obtained in 1998 demonstrated that obese patients (with a BMI greater than 30 kg/m²) may have a lower volume of stomach contents compared with lean patients.¹²⁹ The actual incidence of clinically significant aspiration in these patients has not been conclusively determined, but is likely quite low. The

airway should be secured expeditiously, but use of a rapid-sequence induction should be reserved for patients with a known aspiration risk.¹⁰² Ultrasonography of the stomach has been proposed as a tool for clinicians to identify obese patients at risk for aspiration. Gastric ultrasonography has been used to assess preoperative gastric volume in obese patients with a BMI of 35 kg/m² and greater. The data showed that obese individuals have a larger antral size and gastric volume than their nonobese counterparts.¹³⁰ If the gastric volume is less than 1.5 mL/kg, then the risk of aspiration can be considered low. Patients who have recently undergone gastric banding are at increased risk for pulmonary aspiration of esophageal contents.¹⁰³

There is no consensus on whether obese patients have delayed, normal, or accelerated gastric emptying.^{131,132} Current recommendations are that obese patients should follow the same fasting guidelines as nonobese patients. All patients should be allowed to drink as much as 300 mL of clear liquids until up to 2 hours before elective surgery; that volume has been demonstrated to have no adverse effect on the pH and volume of gastric contents at induction of anesthesia.¹³³

Historically, obesity has been significantly linked to the presence of gastroesophageal reflux disease (GERD).^{134,135} Although increased body mass has been shown by some researchers to correlate directly with an increased incidence of reflux symptoms,¹³⁶ others have demonstrated the opposite, and question the routine use of rapid-sequence induction on all patients who present with a diagnosis of GERD.¹³⁷

Because of the more recent and favorable data, some advocate avoiding rapid-sequence induction in obese patients as standard protocol, citing that it is a common misperception that all obese patients should be viewed as “full-stomach” patients, and in the event of failed intubation, obese patients may have poorer outcomes.^{138,139} Although obese patients and patients with sleep apnea syndrome (SAS) are prone to GERD, and both groups may also have an increased risk of difficult intubation, in the case of elective surgery in a fasted patient with no risk factors other than obesity or SAS, the requirement for rapid-sequence induction is debatable.¹⁴⁰

However, if reflux symptoms are present in obese patients with GERD, the potential increased risk of aspiration should be discussed with the patient, and prophylactic measures (e.g., cricoid pressure, H₂ blockers, and proton-pump inhibitors) should be considered.¹⁴¹ Although rapid-sequence induction may be safe for some obese patients, its safety in extremely obese patients has been questioned. For patients with a BMI greater than 50 kg/m², or those with a lower BMI who have risk factors such as OSA or a large neck circumference, either an awake intubation (with local anesthesia) with spontaneous respiration of the patient or intubation without relaxants (after only propofol administration) is suggested.¹⁴²

Nausea following bariatric surgery is very common, and is probably largely mechanical in origin, related to staple lines and pressure on the stomach tissues. The incidence of nausea is highest after gastric sleeve surgery and lowest after gastric banding. Standard multimodal antiemetics are recommended. The use of an opioid-free technique for bariatric surgery may be helpful for reducing postoperative nausea and vomiting.¹⁰²

Patient Positioning for Induction

Obese patients are more difficult to intubate in the “sniffing” position, but placed in the “ramped” position there is no evidence that this risk is greater than in members of the general population.⁶⁶ It is essential that optimal patient positioning for laryngoscopy is ensured prior to induction of anesthesia. This includes the placement of towels under the patient's shoulders and head, and putting the patient in the reverse Trendelenburg position to increase the patient's FRC. The term *HELP* (*head elevated laryngoscopy position*) reminds clinicians of the importance of patient positioning for successful laryngoscopy.¹⁴³ This position generally improves the view during laryngoscopy and contributes to increasing the safety period until patients demonstrate signs of O₂ desaturation. This is also a better patient position for using rescue ventilation techniques, such as bag-valve mask ventilation or insertion of an LMA, should they be required.

One study described positioning morbidly obese patients with the head, upper body, and shoulders significantly elevated above

the chest, such that an imaginary horizontal line could connect the patient's sternal notch with the external auditory meatus. Positioning patients in this manner resulted in successful intubation in 99 of 100 morbidly obese patients, with all having a Cormack grade I view.¹⁴⁴

Others have also concluded that the “ramped” position (with blankets used to elevate both the upper body and head of the patient) improves laryngeal view in obese patients compared with patients who were intubated with a conventional 7-cm cushion placed under the patient's head (i.e. in the sniffing position) (Fig. 48.3).¹⁴⁵ Without proper support and alignment of the oropharynx and trachea (see Fig. 24.14), ventilation may be obstructed, and visualization of the laryngeal structures may be obscured.

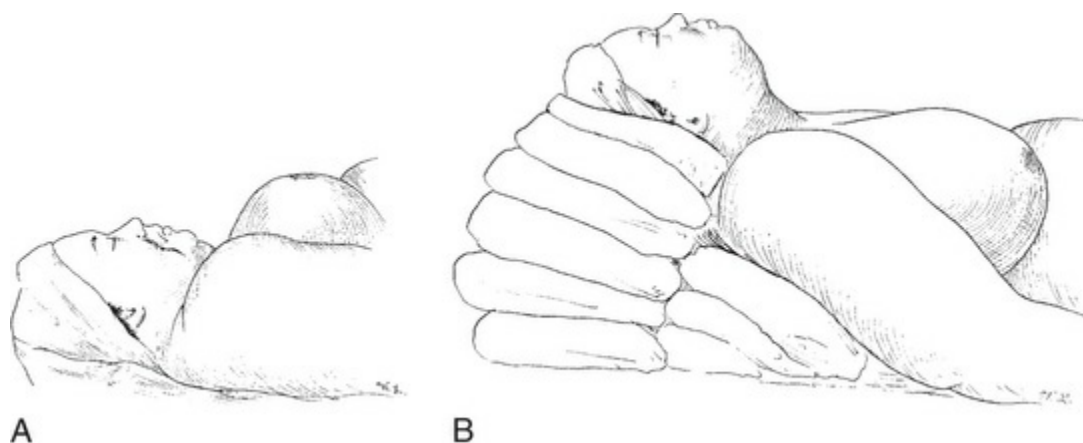

FIGURE 48.3 A, Supine position. B, Sniffing position.

The importance of proper positioning and the difficulty of repositioning morbidly obese patients during failed intubation can be underestimated by practitioners who are not experienced in airway management in obese patients. If direct laryngoscopy is unsuccessful, LMAs can be effective for establishing ventilation, and should be immediately available.^{120,133} In one study, the use of an intubating laryngeal mask resulted in better patient oxygenation compared with intubation through direct laryngoscopy in morbidly obese patients.¹²⁴

If a patient is at risk for aspiration, a rapid-sequence induction may be performed with application of cricoid pressure while the patient's trachea is intubated. There is much discussion regarding

the effectiveness of cricoid pressure and the advantages and risks associated with the technique.¹⁴⁶

In theory, when pressure is applied to the cricoid cartilage, it causes an occlusion in the esophagus between the cricoid cartilage and the vertebral body. However, it has been demonstrated that the application of cricoid pressure results in a reduction in lower esophageal sphincter pressure in anesthetized patients, but as gastric pressure is reportedly less than the esophageal pressure, the barrier to reflux remains intact.¹⁴⁷

Researchers have determined that during rapid-sequence induction, gastric pressure is approximately 14 mm Hg or less, and the gastric barrier pressure is less than 15 mm Hg. This study concluded that the amount of cricoid pressure that is adequate to protect most anesthetized patients from regurgitation is 20 Newtons (N), and that the force can be increased to 30 N as loss of consciousness occurs.¹⁴⁸

The theory, however, has been challenged. In a recent study of awake patients using magnetic resonance imaging (MRI), it was demonstrated that the application of cricoid pressure may induce lateral displacement of the esophagus. The lateral laryngeal displacement was noted in 67% of the subjects with cricoid pressure, and airway compression of at least 1 mm was demonstrated in 81% of the subjects as a result of cricoid pressure.¹⁴⁹ A newer study, however, demonstrated via MRI that the hypopharynx and cricoid ring both move synchronously when pressure is applied, and that esophageal compression occurs even when displaced laterally.¹⁵⁰

Anesthetic Management: Maintenance

Intubation

For airway management to be facilitated, the obese patient should be positioned with the head elevated (reverse Trendelenburg position) on the operating room table. This position promotes patient comfort, reduces gastric reflux, provides easier mask ventilation, improves respiratory mechanics, and helps maintain FRC. The reduced FRC in obese patients contributes to the rapid desaturation that occurs with induction of general anesthesia.¹⁵¹ To attenuate desaturation and maximize O₂ content in the lungs, patients are preoxygenated with a 100% mask O₂ for at least 3 to 5 minutes with continuous positive airway pressure (CPAP), as tolerated.^{112,152} Adequate preoxygenation is vital in obese patients because of rapid desaturation after loss of consciousness secondary to increased O₂ consumption and decreased FRC. Application of positive-pressure ventilation during preoxygenation decreases atelectasis and improves oxygenation in morbidly obese patients. A study in morbidly obese individuals (limited to 160 kg by the weight limit of the computed tomography [CT] scanner) has demonstrated that the administration of CPAP during the preoxygenation period and gentle ventilation with positive end-expiratory pressure (PEEP) during anesthetic induction significantly reduce atelectasis, as documented by chest CT scans.¹⁵³ An associated benefit to the reduced atelectasis was a significantly increased average partial pressure of arterial oxygen (PaO₂) (457 ± 130 pascals [Pa] versus 315 ± 100 Pa, $P = 0.035$) in those subjects who received CPAP-PEEP versus the control subjects. Theoretically, the increase in PaO₂ would increase the apneic time to O₂ desaturation if an airway event were to occur.¹⁵⁴

Careful administration of sedative drugs and application of topical anesthesia to the oropharyngeal structures may be instituted. Nasal O₂ is used as a supplement during awake laryngoscopy. After an awake look, if the epiglottic and laryngeal architecture is easily visualized, successful asleep intubation can be performed. If the airway structures cannot be visualized, LMA

intubation, awake fiberoptic intubation, or another type of intubation should be used.^{120,155,156} Many clinicians advocate the use of a modified rapid-sequence induction when aspiration is a concern.¹⁵⁷ This technique employs preoxygenation and cricoid pressure as usual, but the lungs are lightly ventilated prior to securing the airway. This approach avoids the rapid desaturation that frequently occurs in the obese patient, with no risk or a minimal increased risk of aspiration. The endotracheal tube must be safely secured to prevent movement during positioning and surgery.⁹⁶

The surgeon and another skilled anesthesia provider also must be in attendance during induction. Muscle hypotonus in the floor of the mouth, followed by rapid occurrence of soft-tissue obstruction and hypoxia, requires one person to support the mask and airway while another person bag ventilates the patient. In the case of inability to ventilate or intubate, the ASA's difficult airway algorithm should be followed (see [Chapter 24](#)). Intubation of the obese patient can be safely accomplished with careful assessment and planning and use of modern airway techniques.

Effects of General Anesthesia on Respiration

General anesthesia depresses respiration in normal subjects, so any preexisting pulmonary dysfunction is exaggerated by anesthesia.¹⁹ The type of surgery, positioning, and underlying disease pathology further compound the undesirable respiratory responses caused by obesity and anesthesia.^{158–163} General anesthesia causes a 50% reduction in FRC in the obese anesthetized patient, as compared with a 20% reduction in anesthetized nonobese patients.⁹⁶ Airway collapsibility is likely due to the decreased lung volume associated with deeper anesthesia, as the end-expiratory esophageal pressure is reduced with lighter planes of anesthesia.¹⁶⁴ FRC can be increased by ventilating with large tidal volumes (15 to 20 mL/kg), although this has been shown to improve arterial O₂ tension only minimally.^{91,158} In contrast, the addition of PEEP achieves an improvement in both FRC and arterial O₂ tension, but only at the expense of cardiac output and O₂ delivery.^{160,161} Current ventilation recommendations include using tidal volumes of 6–10 mL/kg of

IBW to avoid barotrauma.⁹¹ During laparoscopic surgeries, the respiratory rate should be 12 to 14 breaths per minute.⁸⁸

Prolonged (longer than 2 to 3 hours) and extensive procedures (those involving the abdomen, thorax, and spine) negatively influence respiratory function. Subdiaphragmatic packing, cephalad displacement of organs, and surgical retraction cause decreased alveolar ventilation, atelectasis, and pulmonary congestion.^{158,159} Recumbent or Trendelenburg positioning further reduces diaphragmatic excursion, which is already impaired by the weight of the panniculus (which can be very large) (Fig. 48.4). Trendelenburg positioning also causes elevated filling pressures, which then increase right ventricular preload. Subsequently, myocardial O₂ consumption, cardiac output, pulmonary artery occluding pressures, peak inspiratory pressures, and venous admixtures are increased above upright-sitting values.¹⁶⁰

FIGURE 48.4 Panniculus in a standing patient.

In a normal-weight person, cardiac output increases in response to supine posturing to maintain hemodynamic stability. By increasing left ventricular output, the centrally located circulating volume is propelled forward, thereby minimizing pulmonary congestion and hypoxia. In a severely obese patient, positive-

pressure ventilation (which impedes venous return) and an inability to increase cardiac output may result in cardiopulmonary decompensation.^{161,162} This is exhibited intraoperatively by hypoxia, rales, ventricular ectopy, congestive heart failure, and hypotension.¹⁶³ Bag ventilation by hand may be useful to attenuate hypotension resulting from positive pressure ventilation.

Use of ventilators powerful enough to inflate the morbidly obese thorax is critical to minimizing hypoxia. Pressure- or volume-controlled ventilators can be used to maintain adequate oxygenation and normocapnia. Avoidance of prolonged prone, Trendelenburg, or supine positioning also decreases ventilation-perfusion mismatch. Optimization of oxygenation by using at least 50% flow of inspired O₂ is emphatically recommended.^{19,33,91} The intermittent manual application of large volume “sighs” can also augment the FRC.

Application of PEEP can reduce venous admixture and support adequate arterial oxygenation. Large amounts of PEEP, however, can impair arterial oxygenation in some patients when it is superimposed on large tidal volumes.¹⁶² For these reasons, PEEP that exceeds 15 cm H₂O is not recommended.

Other intraoperative events, such as hemorrhage or hypotension, further impair ventilatory homeostasis and result in hypoxemia that may extend into the postoperative period.³² A vertical abdominal incision, compared with a horizontal (transverse) incision, also prolongs postoperative hypoxia.¹¹² Pain causes further reductions in diaphragmatic excursion and vital capacity, leading to atelectasis and ventilation-perfusion mismatch.^{19,91} For these reasons, 24-hour postoperative admission to a monitored bed is prudent for severely obese patients, who already exhibit higher morbidity and mortality even in the absence of anesthesia and surgery.

Some suggested ventilatory strategies are listed in [Table 48.5](#).

TABLE 48.5

Ventilatory Management of the Morbidly Obese Patient

Goal/Recommendation	Rationale/Additional Information
Prevent Hypoxemia During Induction	
HOB elevated (back-up Fowler or reverse	May increase the safe apnea period during induction

Trendelenburg) 30 degrees Use of CPAP during induction Preoxygenate with 100% O ₂ If O ₂ saturation is ≤ 95%, perform a blood gas analysis for diagnosis of OHS	
Prevent/Reverse Atelectasis	
Restrict the use of FiO ₂ to less than 0.8 during maintenance of anesthesia	Use of a high FiO ₂ concentration during anesthesia accelerates the onset and the amount of atelectasis
Recruitment (“vital capacity”) maneuver after intubation by using sustained (8–10 sec) pressure of 40 cm H ₂ O or greater	Monitor for adverse effects (bradycardia, hypotension)
Maintain Lung Recruitment	
Use PEEP (10–12 cm H ₂ O)	Monitor for hypotension or decreasing arterial oxygenation (PEEP-induced increase in pulmonary shunt fraction)
Prevent Reoccurrence of Atelectasis	
Intermittent intraoperative re-recruitment	Monitor highest oxygenation and respiratory system compliance achieved after recruitment: a decline may be a sign of redeveloping atelectasis
Avoid Lung Overdistension	
Use tidal volume 6–10 mL/kg of ideal body weight Keep end-inspiratory pressure below 30 cm H ₂ O Consider mild permissive hypercapnia if necessary	Increase the ventilation rate to control excessive hypercapnia instead of using large tidal volumes or high ventilatory pressures
Maintain Postoperative Lung Expansion	
Use CPAP or BiPAP immediately after tracheal extubation Administer supplemental O ₂ Keep the upper body elevated Maintain good pain control Use incentive spirometry Encourage early ambulation	

BiPAP, Bi-level positive airway pressure; *CPAP*, continuous positive airway pressure; *FiO₂*, fractional inspired oxygen concentration; HOB, head of bed; OHS, obesity hypoventilation syndrome; PEEP, positive end-expiratory pressure.

Adapted from Thompson J, et al. Anesthesia case management for bariatric surgery. *AANA J.* 2011;79(2):147–160; Bluth T et al. The obese patient undergoing nonbariatric surgery. *Curr Opin Anaesthesiol.* 2016;29(3):421–429.

Choice of Anesthetic Technique

Selection of the anesthetic technique is dependent on the patient history, planned surgical procedure, and anesthetist and patient preference. Diverse anesthetic techniques have been described for use with obese patients undergoing surgical and diagnostic procedures.^{66,102,165,166} Anesthetic management of obese patients can include local or monitored anesthesia, general anesthesia, regional

blocks, or a combination of techniques.

No demonstrable difference in emergence from inhalation versus narcotic anesthetic technique has been discerned in the obese patient.¹⁹ The use of short-acting anesthetic agents facilitates smooth anesthetic induction, maintenance, and emergence from anesthesia. Objectives for maintenance of anesthesia in the obese patient include strict maintenance of airway, adequate skeletal muscle relaxation, optimum oxygenation, avoidance of the residual effects of muscle relaxants, provision of appropriate intraoperative and postoperative tidal volume, and effective postoperative analgesia. Depending on the patient's condition and the type of surgery, these can be achieved by either general or regional anesthesia. An epidural anesthetic with concomitant "light" general anesthesia is frequently chosen. A light general anesthetic can facilitate management of the airway, ventilation, and the patient's level of consciousness, whereas the epidural provides surgical analgesia and anesthesia. The epidural catheter can be used for postoperative analgesic administration and will enhance earlier resumption of deep breathing and coughing maneuvers.

Volume Replacement

Despite the augmentation of circulatory fluid that accompanies extreme obesity, the estimated blood volume is actually diminished.²⁴ Fat, which contains only 8% to 10% water, contributes less fluid to total body water than equivalent amounts of muscle. The normal adult percentage of total body water is 60% to 65%.¹⁹ In the severely obese, it is reduced to 40%. Therefore, calculation of estimated blood volume should be 45 to 55 mL/kg of actual body weight rather than the 70 mL/kg apportioned in nonobese adults.¹⁸ Use of reduced parameters for volume replacement and avoidance of rapid rehydration reduce the risk of cardiopulmonary compromise. Fluid management should be guided by the usual clinical parameters such as blood pressure, heart rate, and urine output measurements. Fluid requirements for bariatric procedures may be greater than anticipated to maintain renal perfusion. Although rare, acute renal failure occurs in approximately 2% of patients undergoing bariatric procedures. Predisposing factors to renal compromise include hypovolemia, a BMI greater than 50

kg/m², prolonged surgery time, intraoperative hypotension, and preexisting renal disease.¹⁶⁷ Adequate intraoperative fluid replacement also helps reduce postoperative nausea and vomiting after bariatric procedures.¹⁶⁸ Volume expanders such as hetastarch (Hespan) should not be administered at greater than recommended volumes per kilogram of IBW (20 mL/kg). Dilutional coagulopathy, factor VIII inhibition, and decreased platelet aggregation can result from excessive administration. Albumin may be used as indicated to support circulatory volume and oncotic pressure. No difference in the criteria between the administration of blood products in normal-weight patients versus severely obese patients has been identified.

Intraoperative Positioning

Surgical positioning of morbidly obese patients necessitates extra precautions for the prevention of nerve, integumentary, and cardiorespiratory compromise. The type of surgery, combined with inordinate stretching or compression of nerve plexuses and prolonged immobility, cause local tissue ischemia and damage, which begins at the cellular level. Hypothermia, hypotension, table positioning, and the pressure the adipose tissue places on orthopedic or cardiopulmonary structures potentiate impairment.¹⁶⁹

Although many peripheral nerves are subjected to possible ischemia or necrosis, the ulnar, brachial plexus, radial, peroneal, and sphenoid nerves are the most vulnerable to injury in any anesthetized patient. In morbidly obese patients, the incidence may be increased because of excessive weight on the anatomic structures.¹⁷⁰ Care must be taken when positioning obese individuals' extremities in slings, draping them on Mayo stands, or securing them in lithotomy stirrups. Excess weight and loose skin may "strangle" or macerate tissues on the dangling ankle or wrist. Draping of heavy upper extremities atop poorly secured Mayo stands can cause cuts, bruises, or abrasions of the arm, breast, or abdomen, as well as obscure early signs of skin breakdown or circulatory compromise.

Prolonged hyperextension, external rotation, or abduction greater than 90 degrees overstretches the brachial plexus and can cause postoperative muscle pain, nerve palsies, or paralysis. Often, obese

patients do not have the range of motion that nonobese individuals possess; therefore, it may be necessary to restrict the amount of flexion, abduction, and rotation of hips, legs, and arms. Frequent palpation of pulses, generous padding, correct alignment, and repeated inspection of extremities for color and temperature can help diminish the incidence of positioning-related injuries.^{169,171}

Lower back pain can be aggravated by both spinal and general anesthesia because of ligamentous relaxation that results in loss of lumbar curvature. Surgical towels placed under the lumbar spine before induction will enhance lordosis and reduce postoperative discomfort.¹⁷⁰

Treatment of the panniculus is often a major concern for both the anesthetist and the surgeon. Extra-long straps and wide adhesive tape can secure the panniculus and reduce shifting when the operating table is changed. If Trendelenburg positioning is anticipated, some means to prevent the panniculus from sliding cephalad must be devised. The head-down position, coupled with the crushing weight of the thorax and panniculus, compresses the brachial neurovascular bundle between the clavicle and first rib. If the patient requires a fracture table, ensure that sufficient padding encircles the pole adjacent to the patient's vulva or penis.¹⁷¹ Genital and pudendal nerve injury can be profound if adipose tissue surrounding the thigh is not carefully distracted to reveal proper placement of the padding.

Integumentary Concerns

Decubitus ulcers, skin infection, and wound dehiscence are exceedingly common in the severely obese. Decubitus ulcers arise from prolonged immobility and compression of fat on bony prominences and vessels. Traction, external fixation devices, and straps may cause injury. Skin creases are subject to erosion and ulceration from sweat and constant friction with opposing skin surfaces. Inability to perform hygiene under the breasts, between neck folds, or beneath the abdominal pannus promotes organism proliferation. Concomitant diabetes further accelerates the growth of bacterial or fungal infections. As a result, wound dehiscence, particularly in the abdomen, can occur after suboptimal surgical closure of compromised skin. A poorly vascularized panniculus

and torsion on the wound by the weight of the fat apron also contribute to malunion of the tissue.¹⁷¹ Although atelectasis and hypoxia are less frequent with a horizontal laparotomy, a vertical laparotomy approach is often preferred by the surgical team. Compression of abdominal contents on superficial wound layers is lessened during ambulation, and may therefore reduce the occurrence of dehiscence.⁹³

Extubation

The risk of airway obstruction after extubation is increased in obese patients.¹⁷² A decision to extubate depends on evaluation of the ease of mask ventilation and tracheal intubation, the length and type of surgery, and the presence of preexisting medical conditions, including OSA. Criteria for extubation must include all of the standard objective and subjective criteria used by every clinician. Patients are usually placed with the head up or in a sitting position prior to extubation. If doubt exists regarding the ability of the patient to breathe adequately, the endotracheal tube is left in place, and extubation over an airway exchange catheter or via a fiberoptic bronchoscope may be performed.^{172,173}

Regional Anesthesia

Regional anesthesia can be used as the primary anesthetic in selected cases or as an accompaniment to postoperative pain and mobility management.^{19,27,171} However, difficulties are frequently encountered in severely obese patients. Anatomic landmarks used to guide conduction blockade are not easily visible, palpable, or identifiable with ultrasound. Brachial plexus anesthesia can be hampered by adipose tissue in the axillary region, an inability to position the arm, and an undetectable pulse. Full-term pregnancy, obesity, and the coincident discomfort of active labor further inhibit the discernment of spinous processes and posterior iliac crests. Redundant rolls of fat, unsatisfactory ventilation, and the inability of the patient to sustain optimal positioning make neuraxial anesthesia even more challenging.

For subarachnoid or epidural anesthesia, it is recommended that the patient sit upright so that landmarks such as C7 or L3 to L4 can

be more easily identified.⁹⁴ In addition, skin-fat folds will fall toward the operating table, and respiratory ventilation will be enhanced. A selection of longer needles (7 inches) should also be available before anesthetic administration is begun. Generous infiltration with local anesthetic will provide greater patient comfort during insertion of the “finder,” Tuohy, or spinal needle. The importance of generous administration of local anesthetic cannot be overemphasized, because repeated insertions and repositioning of the needle or introducer may be required before access to the epidural (or subarachnoid) space is achieved.

Another consideration regarding subarachnoid or epidural anesthesia in severely obese pregnant or surgical patients is the lack of predictability of the spread of the local anesthetic. Obese patients will also experience greater respiratory embarrassment from a high regional block than normal-weight patients.¹⁷⁴ Successful laparotomy procedures after epidural anesthesia have been described.¹⁷⁵

In obese parturients, a cesarean section can be performed under spinal or epidural anesthesia. A significant correlation exists with increased body mass and rostral spread of epidural subarachnoid anesthetics when a patient is in a supine position. Undesirable cephalad spread of local anesthetics can be obviated by reducing the volume and increasing the patient's upright sitting time.

Anesthetic Management: Postoperative Care

Pain Management

Optimal postoperative pain management is facilitated by the use of oral analgesics, NSAIDs, patient-controlled analgesia, local infiltration of the surgical site, and epidural anesthesia. Obese patients are more sensitive to the respiratory-depressant effects of opioid analgesics; therefore, caution and close monitoring are warranted.¹⁷⁶ Supplemental O₂ and pulse oximetry monitoring are mandated. If the patient was on CPAP (nasal or facemask) preoperatively, CPAP should be applied at all rest times in the early post-general anesthetic period. CPAP protects the patient with OSA against airway obstruction during sleep by pneumatically splinting the oropharynx.^{46,177,178} Postoperative opioids must be used judiciously.

Postoperative Complications

Morbidity and mortality rates are higher in obese patients than in normal-weight patients; however, various studies have reported that the mortality rate during the perioperative period has decreased among morbidly obese patients in recent years.¹⁷⁹ Older age, a high BMI, and male gender have been confirmed as proven surgical risk factors for morbidity in obese patients undergoing gastric bypass surgery.^{180,181} Other factors that have been shown to increase mortality risk include hypertension, diabetes, postoperative leak with bariatric procedures, and thromboembolism.¹⁸² Patients with major comorbid diseases had a higher BMI, a higher mortality, a greater leak rate, and a higher rate of surgical site infections.¹⁸³ Ventilation abnormalities are exacerbated in obese patients with OSA and OHS, and may last for several days. The maximum decrease in PaO₂ occurs 2 to 3 days postoperatively.³¹ In one study, morbidly obese subjects had a mean maximal O₂ uptake that was similar to patients with severe heart failure (mean ejection fraction 21.5 ± 8%).¹⁸⁴ The same investigators

studied cardiorespiratory fitness in 109 patients prior to LAGB. They found that severe complications and mortality were more common in patients whose maximum O₂ uptake was less than 15.8 mL/kg per min than in those whose maximum O₂ uptake was more than 15.8 mL/kg per min (P = 0.02).¹⁸⁵ This may be a promising way to identify high-risk patients and perhaps monitor their preoperative progress. Blouw et al.¹⁸⁶ investigated factors influencing the frequency of respiratory failure in patients with morbid obesity and found that a higher rate of respiratory failure is associated with having a BMI greater than 43 kg/m².

Rhabdomyolysis (RML) is a complication that occurs in approximately 1.4% of bariatric surgeries, owing to high pressures exerted on deep tissues. Measurement of serum creatinine phosphokinase (CPK) pre- and postoperatively aids in early diagnosis and treatment, and can help reduce further complications such as myoglobinuric acute renal failure, which occurs in up to 30% of patients with serum CPK greater than 5000 units/L.¹⁸⁷ RML and subsequent acute renal failure can be serious problems following bariatric operations. Risk factors of developing RML include male gender, elevated BMI and prolonged operating time. Early diagnosis and treatment are important to avoid the complications of RML. Recognition of the signs and symptoms, physical evaluation, and laboratory findings may aid diagnosis. Elevation of CPK levels is the most sensitive diagnostic evidence of RML. Treatment is geared toward preserving renal function by avoiding dehydration, hypovolemia, tubular obstruction, aciduria, and free radical release. Early recognition allows prompt treatment, including the administration of fluids, bicarbonate, and mannitol.¹⁸⁷⁻¹⁸⁹

The risk of thromboembolism, wound infections, and atelectasis is amplified in patients with increased BMI.^{31,173} Thromboembolism is facilitated by immobility (venous stasis), increased blood viscosity (polycythemia, hypovolemia), increased abdominal pressure, and abnormalities in serum procoagulants and anticoagulants.⁶ Obesity is an independent risk factor for development of VTE.¹⁹⁰ Thromboembolism is reported to be the most common cause of postoperative mortality after bariatric surgery, accounting for as many as 50% of all deaths.¹⁹¹

Four important risk factors, namely venous stasis disease, BMI of 60 kg/m² or more, truncal obesity, and OHS or SAS, are significant in the development of postoperative VTE, and if present, preoperative prophylactic placement of an inferior vena cava filter should be considered. Venous stasis disease, BMI greater than 60 kg/m², truncal obesity, OHS, OSA, a previous incidence of pulmonary embolism, and hypercoagulable states have been suggested as factors that increase the baseline risk of perioperative pulmonary embolism in obese patients after bariatric surgery.¹⁹² Administration of minidose heparin (5000 units administered subcutaneously twice per day), administration of low molecular weight heparin, antiembolic stockings, and correctly fitting pneumatic compression boots can lessen the occurrence of deep vein thrombosis in the early postoperative period. Early ambulation and maintenance of vascular volume further attenuate the likelihood that clots will develop. The incidence of wound infections and pulmonary embolism is 50% higher in obese patients than in normal-weight patients.^{193–195}

Post–Gastric Bypass Anastomotic Leaks

In a series of more than 3000 gastric bypass patients from four centers, the anastomotic leak rate was 2.1%.¹⁹⁶ The most common signs and symptoms of a leak were tachycardia (72%), fever (63%), and abdominal pain (54%). An upper gastrointestinal series was positive in 17 of 56 patients. Tachycardia is the most sensitive sign of an anastomotic leak, and a heart rate greater than 120 beats per minute should prompt an investigation, even if the patient looks and feels well. Tachypnea or decreasing O₂ saturations can also signal early sepsis from a leak, and may be clinically indistinguishable from pulmonary embolism. Signs and symptoms of an anastomotic leak are shown in [Box 48.8](#).^{89,197,198}

Signs and Symptoms of Anastomotic Leak

- Unexplained tachycardia (sustained heart rate greater than 120 bpm)
- Shoulder pain (usually left)

- Abdominal pain
- Pelvic pain
- Substernal pressure
- Shortness of breath
- Fever
- Increased thirst
- Hypotension
- Unexplained oliguria
- Hiccups
- Restlessness

Adapted from Thompson J, et al. Anesthesia case management for bariatric surgery. *AANA J*. 2011;79(2):147–160.

In general, morbidly obese patients have higher rates of postoperative and intensive care unit (ICU) complications, and may require more intensive care and increased staffing.¹⁹⁹ Investigations in surgical/trauma ICU patients universally report an adverse effect of obesity on outcomes. In a surgical ICU, investigators reported that morbid obesity conferred elevated odds of death after 4 days of ICU stay,²⁰⁰ and among blunt-trauma patients, obese patients suffered more frequent complications (e.g., multiple-system organ failure, acute respiratory distress syndrome, myocardial infarction, and renal failure), including the need for more vasopressors, additional days of ventilator support, and more frequent extubation failure. Among survivors, obese patients had a longer ICU and hospital length of stay.²⁰¹

Summary

Obesity is a complex and multifactorial disease, and its incidence is continuing to increase in the US patient population. Through an understanding of the implications of conditions associated with obesity, the anesthetist can promote more favorable anesthetic outcomes. Consideration of the physiologic and pharmacologic changes in obese patients and their implications for optimal anesthetic management guides clinical practice.

Regional Anesthesia

Spinal and Epidural Anesthesia

Joseph E. Pellegrini

Spinal and epidural blocks are known collectively as *central neuraxial blockade* (CNB) because they involve the placement of local anesthetic solution onto or adjacent to the spinal cord. Both spinal and epidural blocks share much of the same anatomy and physiology but are distinct from one another due to their unique anatomic, physiologic, and clinical features.

The persons most credited with introducing spinal anesthesia are Augustus Bier and Theodor Tuffier, who in 1898 described the injection of cocaine into the spinal column and its potential for use as a surgical anesthetic technique. When cocaine was introduced into the subarachnoid space, anesthesia lasted approximately an hour. With the development of newer and safer anesthetic drugs, needles, and techniques, regional anesthesia expanded to include many neural blocks for the enhancement of surgery and obstetrics and the management of pain.^{1,2} Modern procedures have simplified, refined, and increased the safety and success of regional anesthesia techniques.²

Applied Anatomy and Physiology of the Central Neuraxis

Knowledge of anatomic landmarks and underlying structures aids the anesthetist in forming a three-dimensional “mind's-eye” picture. This picture, coordinated with the “feel” of the structures and tissues against the needle and a steady, sensitive hand, facilitates accurate placement of the needle tip and administration of appropriate techniques and medications. Although anatomy is the oldest of medical sciences (with detailed descriptions of the spinal column dating from the 19th century), modern imaging methods such as computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic examination have permitted *in vivo* investigations that further our understanding of spinal anatomy. The following is a current review of applied anatomy of the central neuraxis.

The sequential interconnectivity of the 33 bones called *vertebrae* form the spinal, or vertebral, column, which anesthetists use as a bony reference during the placement of various anesthetics or analgesics. This column is located in the posterior midline of the trunk and allows for truncal flexibility because movable joint surfaces and cartilaginous vertebral bodies exist between 24 of the 33 vertebrae (Fig. 49.1). The vertebral column extends from the base of the skull and the foramen magnum to the tip of the coccyx. The vertebral bodies are stacked on top of one another, separated by fibrocartilaginous intervertebral disks that provide support for the cranium and trunk. The anterior, cylindrical portion of the vertebra is solid and called the *body*. This heavier portion of the vertebra forms the anterior portion of the vertebral arch. The body of each vertebra is contiguous with two pedicles that stretch in a posterior and slightly lateral direction, joining to two laminae that stretch posteriorly and medially to complete an arch, creating an oval-triangular foramen. This foramen, known as the *vertebral foramen*, allows for the passage and protection of the spinal cord. Transverse processes on both sides of the pedicles allow for muscular attachments and the control of movement. A spinous process

projects along the median plane from the union of the laminae in a posteroinferior direction. The spinous process is the long, slender, bony prominence that can often be seen and felt along the midline of the back. The spinous process also provides a place for muscular attachment and movement control. In addition, the inferior angle of the bone creates an overlap that further protects the spinal cord (Fig. 49.2).³

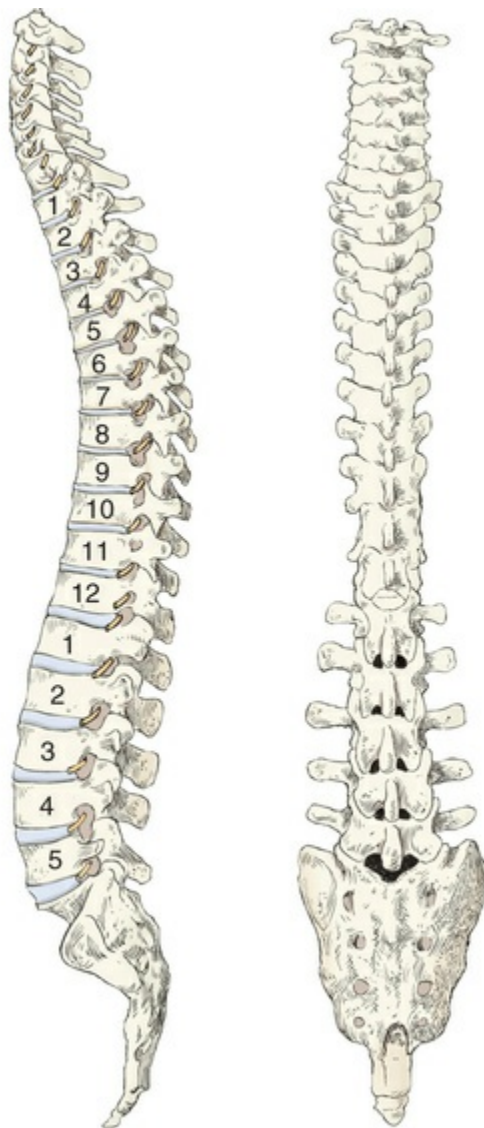

FIGURE 49.1 The spinal, or vertebral, column with its 33 vertebrae.

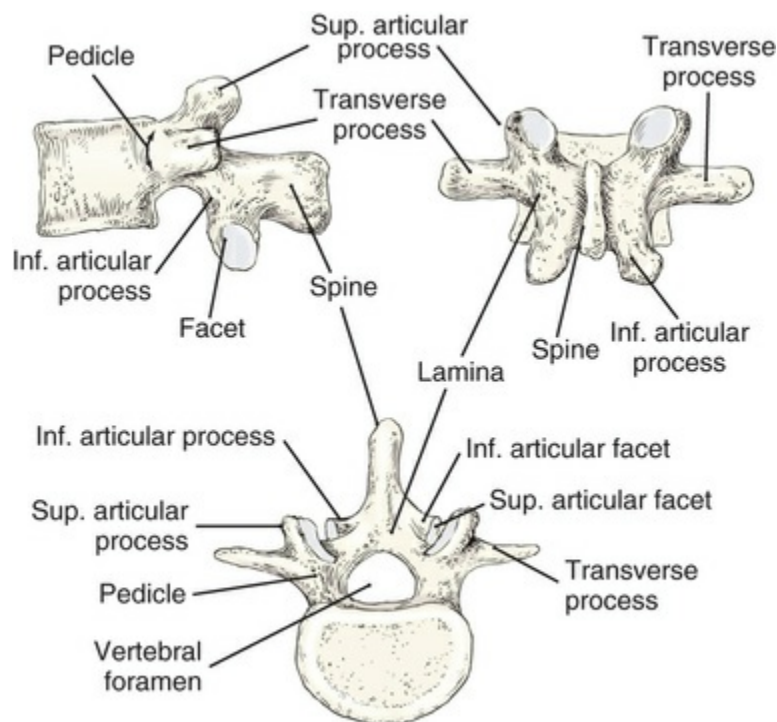

FIGURE 49.2 Articular surfaces, transverse processes, and spinous process. *Inf*, Inferior; *Sup*, superior.

The pedicles and processes of each vertebra have superior and inferior articular surfaces and lateral notches. The superior notch is shallow when compared with the deeper inferior notch. When the vertebrae are stacked, the notches and the articulating surfaces, known as *zygapophyseal* or *facet joints*, form the intervertebral foramina. The intervertebral foramina provide safe passage for spinal nerves passing from the spinal cord to the rest of the body. The articular surfaces of the facet joints are covered with hyaline cartilage, which permits a gliding motion between the vertebrae. Because the facet joints are innervated by branches from closely associated spinal nerves, these joints often become clinically important. When the joint is injured, the associated spinal nerves may also be affected, leading to pain along associated dermatomes or muscle spasm along associated myotomes.³

The size and shape of vertebral lamina and spinous processes differ among the thoracic, lumbar, and sacral regions, and variation exists within each region. Knowledge of these variations is important in the practice of regional anesthesia and in selection and administration of spinal and epidural anesthesia. For instance, cervical and thoracic vertebrae have spinous processes that angle

acutely in a caudal direction such that the process of the superior vertebra overlaps the inferior vertebra and its process. This construction adds protection to the spinal cord when an individual stands erect. When attempts are made to insert a needle into the cervical or thoracic regions, the tight construction and angles of the vertebral column must be considered.

In the lumbar region the vertebrae are larger, and the spinous processes become shorter and broader and have a posterior orientation with less overlap than in other vertebrae. Relatively large gaps, bridged by ligaments, exist between the spinous processes in the lumbar area. This provides the anesthesia practitioner easier access for needle placement, catheter passage, and the instillation of anesthetic into the epidural or subarachnoid space for surgical or obstetric procedures.

The sacrum is a triangle-shaped section of fused bodies of vertebrae. The broader portion is the base, which tapers as it approaches the coccyx. The sacrum is shaped so the weight of the body forces the base of the sacrum downward and forward. It is wedged tightly between the two iliac crests by the downward forces exerted on the spinal column. The lamina of the last sacral vertebra is incomplete and bridged only by ligaments. This area is known as the *sacral hiatus* (Fig. 49.3). The coccyx is composed of four small segments of bone that become fused into two bones as an individual ages; **between the ages of 25 and 30 years**, fusion is complete. The bodies of the vertebrae can be identified with the transverse processes and articular processes. No pedicles or spinous processes are present. The last, or fourth, bone is small and is similar to a nodule. The changing size of the bone from the first to the fourth vertebra gives the coccyx the appearance of a triangle. The projections of the rudimentary articular processes are known as the *cornua*, and the superior pair is the most pronounced. These sacral cornua are the “horns” or bony protuberances that guard the area of the sacral hiatus.³ Because they can be easily palpated in children and in most adults, they are important surface anatomic landmarks for the performance of a caudal anesthetic procedure.

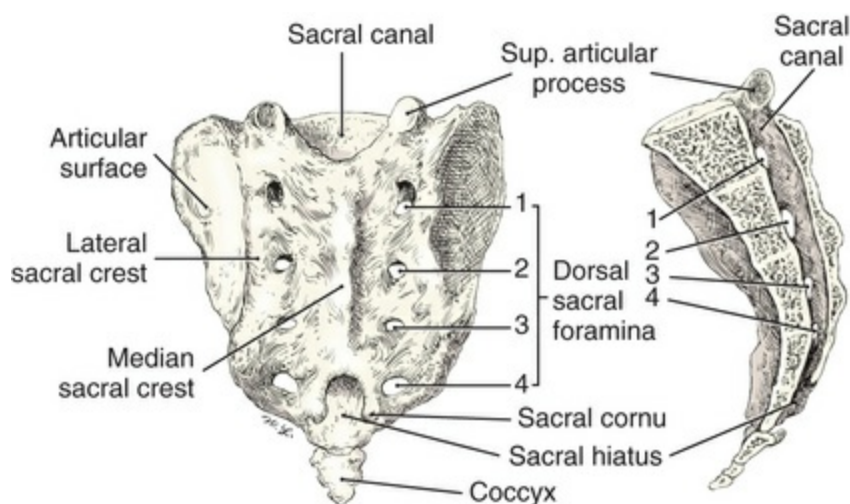

FIGURE 49.3 Sacrum and coccyx.

Of the more than 35 pairs of muscles and ligaments in the back, the supraspinous ligaments, the interspinous ligaments, and the ligamentum flavum (yellow ligaments) are of special significance to the anesthesia practitioner. These three structures act as landmarks that help in identification of and access to the epidural and subarachnoid spaces. The supraspinous ligament is a strong cordlike ligament that connects the apices of the spinous processes; it is thick and serves as the major ligament in the cervical and upper thoracic regions. The supraspinous ligament consists of three layers: the superficial layer extends over several vertebral spinous processes, the middle layer connects two or three spinous processes, and the inner layer connects only the neighboring spinous processes. The ligament blends at all levels with the thin interspinous ligaments that run between adjacent spinous processes. The interspinous ligaments are usually absent or of poor quality in the cervical region and can be exceptionally thin in the lumbar area, even in young people. The ligamenta flava are the strongest of the posterior ligaments. These broad elastic bands join the vertebral arches through vertical extensions from adjacent lamina. The ligamenta flava are paired flat ligaments that run caudad from the inferior border of one lamina to the upper border of the lower lamina on both sides of the midline. The two ligaments almost fill the space, leaving only a separation in the midline and thereby creating a V or wedge that points posteriorly to align with the interspinous and supraspinous ligaments. The V is thin on the lateral edge and thickest midline, in an adult approximately 3 to 5

mm at the L2–L3 interspace. The ligaments extend from each lamina with an overlapping of fibers that creates the appearance of a contiguous ligament from one vertebral body to the next. The ligament is thicker in the lumbar area than in the cervical area and is responsible for maintenance of upright posture. The ligaments' color comes from their high content of yellow elastic tissue.⁴

The spinal cord itself is a cylindrical structure extending from the medulla oblongata through the spinal foramen to the level of the L2 vertebra in most adults and ranges from 42 to 45 cm in length (Fig. 49.4). Because the vertebral column grows more rapidly than the spinal cord, the spinal cord in children extends initially to the level of the third lumbar vertebra. In approximately 1% of adults, the spinal cord may extend below L2 and rarely to the level of L3. The spinal cord tapers to the conus medullaris, and nerve pathways continue in a collection of rootlets called the *cauda equina* or *horse's tail*, which extends from L1 to S5. The spinal cord is enlarged in two regions. The first, called the *cervical enlargement*, extends from the spinal segments C4 to T1. The ventral rami of the spinal nerves in this enlargement form the brachial plexus of nerves that innervates the upper limbs. The second enlargement stretches from segments L2 to S3. This lumbosacral enlargement contributes corresponding nerves to create the lumbar and sacral plexuses. It is important to note that the spinal cord levels do not directly correspond with vertebral levels. For example, in adults the lumbosacral enlargement (L2 to S3) usually extends from the body of the T11 vertebra to the body of the L1 vertebra.³

FIGURE 49.4 Extension of the spinal cord to the second lumbar vertebra.

The spinal cord is enveloped by the same three membranes that line the cranium, and they are collectively called the *meninges*. The meninges are nonnervous support tissues that provide a protective covering for the cord and nerve roots from the foramen magnum to the base of the cauda equina. The linings are identified as the *dura mater*, the *arachnoid mater*, and the *pia mater*. The dura mater is the outermost layer. It is a thick, tough membrane that provides most of the protection for the central cord structures. The nerve roots are covered with dura mater while inside the spinal canal. As the roots exit the canal via the intervertebral foramen, the dura blends into the root at a junction referred to as a *dural cuff* or *root sleeve*. The arachnoid mater is a thin, spiderweb-like covering that forms the middle layer. Beneath the arachnoid mater is a space that is continuous with the central canal of the cord and the ventricles. This space, which is filled with cerebrospinal fluid (CSF), is known as the *subarachnoid space*. This mater and the fluid protect the spinal

cord from shock injuries and are the medium for the interaction with local anesthetics and opioids that occurs during the administration of regional anesthesia. The innermost layer, the pia mater, is thin and is in direct contact with the outer surface of the spinal cord (Fig. 49.5).³

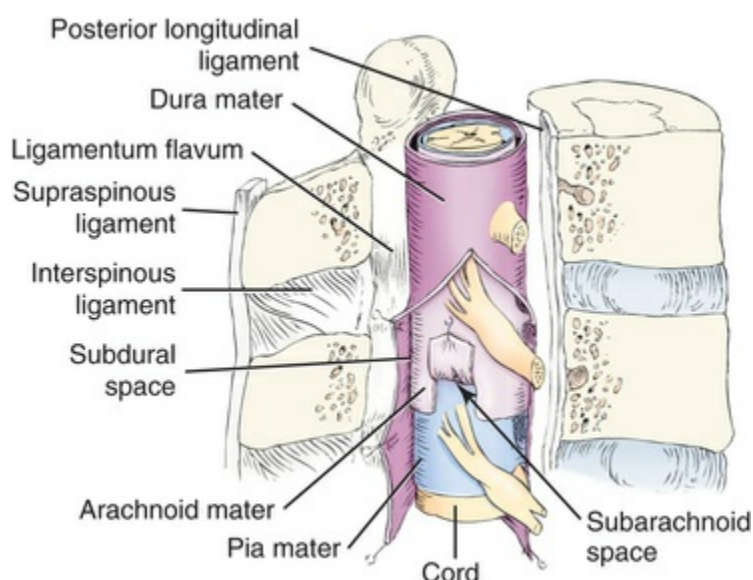

FIGURE 49.5 The linings of the spinal cord and the posterior ligaments of the spinal column.

The epidural space is a potential space outside the dural sac but inside the vertebral canal and is continuous from the base of the cranium to the base of the sacrum at the sacrococcygeal membrane. The epidural space contains epidural veins, fat, lymphatics, segmental arteries, and nerve roots. Fat in the epidural spaces is physiologically fluid, acting as a pad and lubricant for the movement of neural structures within the canal. The posterior epidural space, as it is approached by the anesthetist's advancing needle, is protected by the ligamenta flava, the lamina, and the spinous processes. It is easy, but inaccurate, to depict the epidural space as a uniform column surrounding an equally uniform and tapering spinal cord. A better mental picture is provided by a "look" along the longitudinal axes. The epidural space can be envisioned as a series of lateral, posterior, and anterior compartments existing among the vertebral body, lamina, and pedicles. The compartments, occupied mostly by fat but also by

nerves and fibrous tissue, repeat at each segment in a metameric fashion. Of greatest interest to the anesthetist, the posterior epidural space is a series of fat-filled tripodial pads, shaped like a three-sided sand dune. The pad stretches and narrows in a caudad direction as it approaches the next inferior lamina. In areas of the vertebral canal surrounded by bone, the dura actually contacts bone, leaving only a potential epidural space that physically separates the epidural fat-containing compartments. The posterior epidural space, therefore, is a discontinuous group of tapering fat pads that repeat throughout the length of the spinal canal and are separated by a potential space that allows the passage of fluids or small catheters.⁴⁻⁷

The distance from the skin to the epidural space and the depth of the epidural space, or the distance to the dura, is of interest to one wishing to avoid needle injury of neural and vascular tissues. The distance to the epidural space varies with vertebral level and is loosely correlated with patient weight. The distance from skin to the lumbar epidural space using a midline approach varies from 2.5 cm to 8 cm, with an average of 5 cm. Because the space itself is not uniform in shape, the depth of the epidural space from the ligamenta flava to the dura varies considerably. Given the tripodial, dunelike shape of the epidural space, expect the space to narrow considerably when approaching laterally to the midline and in more caudad areas in the space. The depth of the epidural space is also relative to the vertebral level of approach and angle of needle entry, but some clinical generalizations can be made. The epidural space is largest (posterior to anterior) in the midline of the midlumbar region, at 5 to 6 mm. The midline thoracic region epidural space may be 3 to 5 mm deep and is narrower there (lateral width). Caution must be exercised when one approaches the lower cervical region because the epidural space is very small (only 1.5 to 2 mm), leaving little room for error.⁵

In addition to a larger epidural space, another anatomic reason to stay midline with an approaching anesthetic needle is the presence of the epidural veins. The epidural veins are valveless veins that form a plexus draining the blood from the spinal cord and the linings of the cord. The plexus is most prominent in the lateral portion of the epidural space. In pregnant or obese patients, the

epidural veins become engorged and swollen as increased intraabdominal pressure results in venous congestion of the lumbar and sacral vessels. The potential for injury or accidental cannulation of these vessels is increased because of this physiologic compensation.^{3,4,6}

A final anatomic consideration for neuraxial anesthesia is the existence of normal and abnormal curvatures of the spinal column. A median-plane longitudinal view of the vertebral column reveals four curvatures in the normal adult. The thoracic and sacral curvatures have posterior curvatures (concave anteriorly), whereas the cervical and lumbar regions have anterior curvatures (concave posteriorly). In a supine patient, the apex of the lumbar curve is usually at L3 to L4, and the **trough of the thoracic curve is at T4.**⁸ *Scoliosis*, the most common abnormal curvature, is a lateral curvature of the spine, and *kyphosis* is an excessive posterior curvature or hump, usually of the thoracic region. Excessive *lordosis*, or hollowing of the back, may occur as a result of obesity as the body attempts to restore the center of gravity. A temporary lordosis may also occur during pregnancy. Changes in these anatomic curves will challenge the anesthesia practitioner during the performance of epidural or spinal anesthetic techniques. Clear knowledge of the curves is also important when anticipating the spread of local anesthetics in the subarachnoid space relative to the site of injection and the patient's position.⁹

Neuroanatomic Mapping and Evaluation of Neuraxial Anesthesia

The goal of neuraxial anesthesia is to block pain transmission from areas of injury, disease, or surgical intervention. Therefore, it is clinically useful to have knowledge of the innervations of body structures being operated on in relation to spinal nerve location within the vertebral column. Anatomic maps have been generated based on cutaneous sensation alone. These sensation maps are referred to as *dermatomal maps, charts, or levels*. A *dermatome* is defined as the area of cutaneous sensation supplied by a spinal nerve that is anatomically identified as it passes through an intervertebral foramen. For example, the umbilical area is directly

anterior to the L3 vertebra but receives cutaneous innervations from T7 to T11, depending on the dermatomal map consulted (Fig. 49.6).

FIGURE 49.6 Dermatomes.

For the practical clinician, use of accepted anatomic landmarks and test methods is perhaps the best method for documenting the functional level of blockade—the level of the loss of sensation achieved. The level of anesthetic can be evaluated in many ways, and tests can be used to evaluate several components of the neuraxial anesthetic. For motor function, a straight leg raise or a request to “step on the gas” works well as a clinical measure. Cutaneous sensation can be evaluated through use of a Wartenberg pinwheel, a Semmes-Weinstein monofilament aesthesiometer, or (more practically and simply) with the stylet from the spinal or epidural needle, a portion of a broken wooden tongue blade, or even a peripheral nerve stimulator. Such “pressure” or “scratch” tests are done using two surface-anatomy points for comparison.

Inform the patient that the sensation on a normal area, such as the skin surface of the shoulder, is scratchy or sharp. Next, scratch or press an area expected to be numb, such as the lateral thigh. Gradually work cephalad in 2- or 3-inch bands until the patient notices a change in sensation. Note the level of the change in sensation relative to a dermatomal map. This approximates the upper level of sensory loss. Skin refrigerant, ice cubes, and alcohol pads can be used in a similar manner to identify changes in temperature sensation that correlate to sensory block level.

Physiology and Mechanisms of Action

Despite decades of experience with spinal and epidural anesthesia, much speculation remains regarding the exact cellular locations and molecular mechanisms involved when local anesthetics, opioids, and other pharmacologically active agents bind to produce spinal analgesia and anesthesia.^{10,11} What is known and clinically important about spinal and epidural anesthesia is that the primary site of action for local anesthetics is on the nerve roots within the spinal cord. When a drug is injected directly into the CSF, the drug distributes through the subarachnoid space based on the physical and chemical properties of the injectant and the characteristics of the space in which it must spread. When the drug concentration reaches a minimal effective concentration, neuronal transmission is altered in a manner that clinically provides anesthesia. Neurons—some myelinated, others not; some relatively large, others smaller—differ in susceptibility to drugs such as local anesthetics, and these pharmacodynamic relationships are not easily explained ([Table 49.1](#)). The processes involved at the cellular level are complex, and *blockade* is perhaps a confusing term. It is more accurate to say that anesthetic drugs alter nerve transmission, predominantly by affecting sodium ion channels and inhibiting the units of information that are transferred along the spinal cord. Complete blockade or a “chemical transection” of the cord is an oversimplification. For example, somatosensory evoked potentials have been recorded in individuals made functionally insensate from lidocaine epidural anesthesia. This suggests that neural transmissions are reaching the brain without causing sensory perceptions.^{4,12}

TABLE 49.1**Classification of Nerve Fibers**

Nerve Fiber	Myelination	Conduction		
		Diameter (μm)	Velocity (m/sec)	Function
A- α	Heavy	6–22	70–120	Motor
A- β	Moderate	6–22	30–70	Touch and pressure
A- γ	Moderate	3–6	30–70	Proprioception
A- δ	Light	1–5	12–30	Pain and temperature
B	Light	1–4	3–15	Preganglionic, autonomic
C	None	0.5–1	0.5–2	Pain and temperature

When a local anesthetic interrupts nerve transmission of autonomic nerves but not sensory nerves or motor nerves (because of a variation in susceptibility), a “differential block” is said to have occurred. A differential block is seen in the more rostral spinal segments of a spinal anesthetic. As the spinal anesthetic spreads from the epicenter of injection, the distal reaches of drug distribution are presumably of lesser concentrations. A differential block is clinically important when sensory anesthesia is desired at a specific level; however, sympathetic blockade could be deleterious in a patient with coexisting disease. The level of sympathetic blockade could be as high as six or more dermatomal levels above the level of sensory blockade and therefore contribute to hypotension and bradycardia.¹¹

Drug injected into the epidural space is distributed to the same sites of action as a spinal anesthetic but in a slightly different manner. The drug must first distribute along the epidural space then diffuse through the meninges and dural cuffs to reach the nerve roots or reach the spinal cord through absorption into the radicular arteries. It has been noted that when a substance is injected into the epidural space it travels primarily by bulk flow rather than diffusion and spreads more in a noncircumferential spread, suggesting possible rationale for one sided analgesic distribution.^{11,13} Data exist to support the clinical impression that spinal anesthesia is generally more effective or complete from the patient's perspective than epidural anesthesia and therefore referred to as a more *dense* anesthetic. Epidural local anesthetics first act at sites such as the dural cuffs, at which spinal nerves pass through the peridural spaces. This is consistent with the segmental

onset often associated with epidural anesthesia. If the concentration and volume of the anesthetic agent are increased, or if time is allowed for the drug to diffuse into the CSF or pass via radicular arteries into the spinal cord, the epidural anesthetic can become denser.^{4,8}

Central Neuraxial Blockade: Indications and Preoperative Considerations

Spinal and epidural anesthesia (central neuraxial blocks) can be used successfully for a variety of inpatient or ambulatory surgical procedures involving the lower extremities, perineum, and abdomen. In addition, spinal and epidural anesthesia or analgesia is used for the treatment of acute and chronic pain syndromes, for obstetric procedures and labor analgesia, and can be applied in patients at the extremes of age.¹⁴ Spinal anesthesia techniques may also be used in combination with other techniques, such as epidural catheter techniques, general or intravenous (IV) anesthetic techniques, and with the use of a laryngeal mask airway, to provide anesthesia during surgery. Such combinations, or balanced techniques, minimize the side effects of any one anesthetic technique, maximize the benefits, and offer options in the selection of anesthesia or analgesia for surgical or obstetric procedures.¹⁵

As with any anesthetic plan, proper preparation, patient selection, education, and collaboration with surgeons and nurses are the keys to success. Often the best time to obtain a truly informed consent is during the preoperative visit. It is important to establish rapport with patients to gain their trust and cooperation. Patients eager to be involved in their own care often have the emotional maturity to understand the benefits of their anesthetic options and make rational choices. Anticipate patients' fears and anxieties; they are often easily dealt with through education and the reassurance provided by the calm voice of a confident and competent anesthetist.

Before presenting the option of a regional anesthetic to the patient, the anesthesia practitioner should answer the following three important questions about the procedure:

1. Will the patient be comfortable having this surgical procedure performed with the proposed regional anesthetic technique?
2. Will the patient be able to remain in the required position without difficulty for the length of the procedure?
3. Does this regional anesthetic technique outweigh the risks of performing this procedure using an alternate anesthetic technique?

The answers to these questions directly affect the choice of anesthetic techniques offered to the patient. When recommending any anesthetic technique to the patient, the practitioner has a responsibility to educate the patient, the patient's family, and other interested parties about the anesthesia procedure and the potential outcomes. One can then garner the trust of the patient and the family before obtaining the informed consent.

It has been shown that general anesthesia patients have a greater percentage of adverse in-hospital outcomes than those that received neuraxial anesthesia. In a 2015 study by Chu et al.¹⁶ they reported that patients receiving general anesthesia for hip surgery had a higher incidence of overall death, respiratory failure and intensive care admissions. Other potential advantages of neuraxial anesthesia include less nausea, vomiting, and urinary retention; a reduced total opioid requirement; and greater mental alertness. They also reported longer hospital stays and increased overall cost associated with general anesthesia as compared to neuraxial anesthesia. A growing body of evidence also supports improved outcomes for selected patients and situations. Spinal and epidural anesthesia blunt the body's stress response to surgery and may offer preemptive analgesia. In addition, studies have shown neuraxial anesthetics to decrease intraoperative blood loss, lower the incidence of postoperative thromboembolic events and postoperative ileus, increase patency of vascular grafts, improve respiratory function and cardiac stability, and improve outcome in high-risk surgical patients.¹⁶⁻²⁰ Small doses of local anesthetic solution injected into the subarachnoid space to selectively block only nerve roots supplying the surgical field is called *selective anesthesia*. The easiest way to achieve this is by continuous spinal anesthesia which would allow a slow titration of local anesthetic.

Lidocaine spinals are not typically used in many anesthesia practices, as single lower limb anesthesia can be produced with a low dose of hyperbaric bupivacaine. Spinal techniques produce a reliable block, with low incidence of side effects and rapid home-readiness. Reintroduction of chlorprocaine may provide a solution for bilateral, short-acting spinal anesthesia in the future.^{21,22} Although headache remains a small concern, this risk is greatly reduced because of the more frequent use of blunt tipped spinal needles.²³

Another group of patients well known to benefit from the use of CNB techniques are patients who require anesthesia for obstetric procedures. One primary example is the administration of an epidural anesthetic to the patient in labor. No other modality can provide the parturient with relative relief from the most severe discomfort and still permit the baby and mother to interact immediately after delivery, all with minimal possibility of respiratory distress or depression. In addition, epidural techniques in labor allow a safe conversion of the analgesia to a surgical anesthetic if a cesarean section becomes necessary.^{24,25}

Patient safety also may be increased with spinal or epidural anesthesia. Urologic procedures such as cystoscopic examinations and transurethral resections of the prostate (TURP) are most often performed with the use of spinal anesthesia. When awake and anesthetized to the level of the dome of the bladder (T10), the patient may verbally respond to bladder overdistention, thereby helping the urologist minimize the potential for bladder rupture. In addition, the mental status and sensorium of a responsive patient can easily be monitored and the development of conditions associated with TURP syndrome, such as hypervolemia, hyponatremia, and ammonium toxicity, are more readily detected.^{19,26}

Safety is also an issue when the patient is placed in the prone or jackknifed position as for perianal procedures. A patient in such a position under general anesthesia is at risk for inadvertent extubation and positioning injury. A hypobaric spinal anesthesia technique offers several advantages. The anesthetic procedure can be performed after the patient is positioned and has verbalized that he or she is comfortably padded. With hypobaric spinal anesthesia,

the spread of the local anesthetic is controlled, and spontaneous ventilation is maintained.

Often patients will express that pain in the postoperative period is one of their primary concerns.²⁷ Therefore, a distinct advantage of spinal anesthesia is that long-term analgesia can be provided by administration of an intrathecal adjunct, such as long acting opioids, or α_2 -agonists, such as clonidine. Long-term analgesia is better suited when an epidural catheter is used for postoperative analgesia because it is possible to administer an opioid or a low concentration of local anesthetic with or without a short acting opioid. Epidural catheter placement allows these solutions to be continuously infused or administered by patient-controlled devices, thereby keeping patients comfortable well into the postoperative period. Because the total doses of opioids and local anesthetics are small, the patient remains alert and possibly ambulatory while receiving analgesia with minimal side effects.^{4,8} The patient's right to be fully informed also necessitates a discussion of the disadvantages of CNB. Consider the patient's perspective, and keep in mind that the disadvantages and risks inherent in any anesthetic plan are relative only to those of another anesthetic option. For example, patients with a history of headaches or backaches are at increased risk of experiencing these problems after spinal and epidural analgesia, but also may have exacerbations of these problems after a general anesthetic. Such patients should be evaluated and counseled regarding this potential problem before the administration of any anesthetic. A thorough history of the patient's previous pattern of headaches or backaches is essential when faced with the challenge of evaluating similar symptoms in the postoperative period.

To many patients, the risk of paralysis is the most important concern, despite the extreme rarity of any neurologic sequela. There have been multiple studies that have reported that the incidence of any neurological injury is between 0.03–0.1%, or 1 : 240,000 cases but few of these could be directly linked to the CNB.^{4,28–31} Common patient questions may also include the following:

- “Will the injections hurt?”
- “How long will I be numb?”

- “I am afraid of hearing (or smelling or feeling) the surgery. Can I be asleep?”

Patient perceptions and fears can be diminished with thoughtful explanation and discussion of the clinician's expectations regarding the patient's case. Additional discussion should include the topic of intraoperative risks, such as the inability to obtain adequate anesthesia, paresthesia, hypotension, dyspnea, high or total spinal anesthesia, nausea and vomiting, use of additional sedation, and allergic reactions. Postoperative complications may include backache, postdural puncture headache (PDPH), hearing loss, transient neurologic symptoms, infection, and peridural abscess or hematoma formation.^{5,22,31-34}

Before administration of any anesthetic, a thorough preoperative history and physical examination must be conducted. During this part of the preoperative patient visit, any concerns regarding administration of spinal anesthesia can be identified. Often the terms *absolute* and *relative contraindications* are used; the definition of these categories varies, and their use is therefore controversial. It is more important to think of the anesthetic risks and associated complications relative to the possible benefits of the proposed anesthetic technique. **An obvious example is patient refusal or lack of cooperation. Other preoperative concerns include increased intracranial pressure, significant preexisting or therapeutic coagulopathy, skin infection at the site of injection, hypovolemia, spinal cord disease, patients with a fixed-volume cardiac state such as hypertrophic cardiomyopathy or severe atrial stenosis, and an anticipated lengthy surgical time.** Finally, if a difficult airway is anticipated, the plan of care must be discussed with both patient and surgeon.

Neurologic diseases are often listed as potential, absolute, or relative contraindications for neuraxial anesthesia, but data are often mixed. A dural puncture by a spinal needle or a larger epidural needle creates a rent in dural tissue that may or may not leak CSF. In patients with a preexisting increase in intracranial pressure, the risk of brain herniation is increased. In the case of epidural catheter placement or epidural blood patch, the addition of large volumes of fluid into the epidural or subarachnoid spaces could increase already elevated intracranial pressures.^{4,8}

Musculoskeletal deformities such as severe kyphoscoliosis, arthritis, osteoporosis, and fusion and scarring of the vertebrae are considered relative contraindications to neuraxial anesthesia. The location of the epidural or subarachnoid spaces by needle tip may be technically difficult, and spread of anesthetic agents may be limited by anatomic alterations.²⁸ Additionally, a large retrospective study surmises that osteoporosis may be an important risk factor for CNB complications.³⁵

Peripheral neuropathies can be the result of metabolic, autoimmune, infectious, or hereditary etiologies. A presumption is that patients with preexisting neural compromise are more susceptible to and less able to recover from injury when exposed to a secondary insult, compared with patients with healthy tissues. In addition, abnormal tissues may not respond to pharmacologic agents in predictable ways. Secondary insults might stem from needle or catheter trauma, ischemic injury from the use of vasoconstrictors, or direct local anesthetic neurotoxicity. For example, diabetes mellitus is the most prevalent cause of peripheral polyneuropathy, with most patients having some abnormalities in nerve conduction. In diabetic patients, it is estimated that subclinical neuropathy can be as high as 50%, thereby presenting significant challenges to the anesthesia provider because regional anesthesia can precipitate a “double-crush” phenomena. The double-crush phenomenon has been attributed to factors such as mechanical trauma by the needle, ischemia from injection of epinephrine containing solutions, or a toxic reaction from the local anesthetic solution.³⁶ Therefore, it would behoove the anesthesia practitioner to ensure that a thorough examination is performed and neurophysiological studies are considered to help identify subclinical neuropathy to minimize the risk of neurological injury. If a neuraxial block is the appropriate anesthetic choice, then precise documentation of the patient's preexisting disease state must be carried out and neurophysiological studies to help identify subclinical neuropathy to minimize the risk of neurological injury should be considered.^{4,8,28,30,31,36,37}

The existence of a significant preexisting or therapeutic coagulopathy increases the risk of spinal or epidural hematoma formation in a patient receiving a CNB. Spinal or epidural

hematoma is a rare but devastating complication, possibly resulting in permanent neurologic injury. Therefore, central neuraxial anesthesia should be avoided in any patient with a known coagulopathy. Insufficient data are available to quiet the controversy surrounding absolute laboratory values below which the practitioner should avoid CNB. To determine whether a CNB technique should be avoided, it has been suggested that the following arbitrary values be used as a guide: **platelet counts of less than 100,000 and prothrombin time (PT), activated partial thromboplastin time (aPTT), and bleeding times that are greater than two times normal values.** For a spinal anesthetic, this is perhaps an overly conservative guide.³⁸ However, severe bleeding with or without symptomatic hypovolemia or the potential for severe bleeding is a possible contraindication to the administration of a regional anesthetic because the sympathectomy caused by CNB further aggravates severely contracted volume states.

Much discussion has arisen regarding the use of spinal and epidural anesthesia when coagulopathy for thromboprophylaxis or for therapeutic treatment of coexisting disease has been initiated, planned, or is ongoing because the therapies, timing, and the effects on coagulation are highly varied. Many surgical patients take drugs that impair their coagulation and this is a concern about the risks of a CNB and risk of a compressive vertebral canal hematoma (VCH). The incidence of VCH is extremely low but increases in patients who are taking anticoagulation drugs.³⁹⁻⁴³

Even planned intraoperative anticoagulation with heparin is reasonably safe after atraumatic dural puncture if the patient presents with a normal coagulation profile. Traditionally, a patient's bleeding time was obtained prior to administration of neuraxial anesthesia, but the predictive value of bleeding time has not been established in patients taking aspirin and nonsteroidal antiinflammatory drugs (NSAIDs).^{30,39,40} In addition, with the increased use of natural and herbal medicines, anesthesiologists must be alert to the possibility of drug interactions. Alone, herbal supplements do not appear to increase the risk of spinal hematoma; however, data on combinations of herbal and other anticoagulants are not available. Herbal medications that effect hemostasis and some perioperative concerns are listed in [Table 49.2](#). If basic

precautions are followed, many thromboprophylaxis strategies have had an extensive safety record when co-administered with neuraxial anesthetics. The surgeon and anesthesia practitioner should consider the potential benefit versus risk before neuraxial intervention for patients who have been or will be anticoagulated for thromboprophylaxis. The number, variety, and indications for the use of anticoagulants and thrombolytics continue to increase.

TABLE 49.2

Herbal Medications Affecting Hemostasis*

Herb	Important Effects	Perioperative Concerns	Time to Normal Hemostasis After Discontinuation
Garlic	Inhibition of platelet aggregation (may be irreversible) Increased fibrinolysis Equivocal antihypertensive activity	Potential to increase bleeding, especially when combined with other medications that inhibit platelet aggregation	7 days
Ginkgo	Inhibition of platelet-activating factor	Potential to increase bleeding, especially when combined with other medications that inhibit platelet aggregation	36 hrs
Ginseng	Lowers blood glucose Increased prothrombin (PT) and activated partial PTs in animals Other diverse effects	Hypoglycemia Potential to increase risk of bleeding Potential to decrease anticoagulant effect of warfarin	34 hrs

* At this time, it is not deemed necessary to discontinue herbal medications and allow resolution of their effects on hemostasis before surgery or anesthesia.

Adapted from Horlocker TT. Regional anaesthesia in the patient receiving antithrombotic and antiplatelet therapy. *Br J Anaesth.* 2011;107(Suppl 1):i96–i106.

The incidence of neurologic dysfunction resulting from hemorrhagic complications resulting from neuraxial blockade is unknown. Although the incidence cited in the literature is estimated to be less than 1 in 150,000 epidural anesthetics and less than 1 in 220,000 spinal anesthetics, recent epidemiologic surveys suggest that the frequency is increasing and may be as high as 1 in 3000 in some patient populations. Overall, the risk of clinically significant bleeding increases with age, associated abnormalities of the spinal cord or vertebral column, the presence of an underlying coagulopathy, difficulty during needle placement, and an indwelling neuraxial catheter during sustained anticoagulation,

particularly with standard heparin or low-molecular-weight heparin (LMWH).^{40,41} The American Society of Regional Anesthesia and Pain Medicine (ASRA) convened its Third Consensus Conference on Regional Anesthesia and Anticoagulation in 2010, where practice guidelines on regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy were formulated. Many international anesthesia societies have also issued guidelines.⁴¹⁻⁴³ Guidelines for the use of regional blocks in patients receiving thromboprophylaxis are given in [Table 38.7](#).

By following evidence and consensus-based precautions, the low incidence of permanent neurologic complications can be decreased. A meta-analysis by Brull et al.⁴⁴ identified the risk of permanent neurologic injury after spinal anesthesia at 1 to 4.2 : 10,000 and after epidural anesthesia at 0 to 7.6 : 10,000. Because complications are very infrequent, risk factor identification is difficult, and vigilant care must be maintained for all patients. Analysis of known case reports found the median time to onset of neurologic dysfunction after initiation of LMWH therapy to be 3 days. Scrupulous postoperative nursing surveillance is also required to support patient safety. The initial complaint may be of new-onset weakness to the lower limbs and sensory deficit, although bowel and bladder dysfunction and new-onset back pain may occur. If emergent neurosurgical care is required, recovery is unlikely if surgical decompression of the hematoma is delayed more than 8 hours.^{30,35,44}

The etiology of neuraxial infection is based on the theory that needle placement disrupts the body's physiologic protective mechanisms and deposits infectious or noxious agents beyond the skin into underlying tissues and the peridural space and past the blood-brain barrier into subarachnoid spaces. Indeed, skin infection at the site of injection increases the risk of meningitis or epidural abscess formation. Infectious complications include, but are not limited to, epidural, spinal, or subdural abscess; paravertebral, paraspinous, or psoas abscess; meningitis; encephalitis; sepsis; bacteremia; viremia; fungemia; osteomyelitis; or discitis. Although colonization of the catheter may be considered a precursor to infection, colonization per se is not considered an infection. A 2010 advisory committee published guidelines noting several factors to consider to minimize infections. They included conducting a

history, physical examination, and preprocedure laboratory evaluations, use of prophylactic antibiotic therapy as indicated, and use of strict aseptic techniques including the use of proper antiseptic solution. The use of sterile occlusive dressings at the catheter insertion site, a bacterial filter during continuous epidural infusion, limiting disconnection and reconnection of neuraxial delivery systems, and limiting the duration of catheterization were also encouraged.³⁴

Although infectious complications of CNB are rare, the practitioner must maintain aseptic technique during the preparation and administration of any regional anesthetic to minimize the potential for infection. Septic meningitis or epidural abscess due to bacterial contamination, and the consequences of persistent neurologic deficits such as loss of bowel and bladder control, chronic pain, and lower extremity weakness or paraplegia, can be devastating. Other factors that increase the risk of infection include dermatologic conditions such as psoriasis that prevent aseptic skin preparation, underlying sepsis, diabetes, immunologic compromise, steroid therapy, and the preexistence of chronic infections such as human immunodeficiency virus (HIV) or herpes simplex virus (HSV). Because meningitis after spinal or epidural anesthesia is so rare, it has been difficult to directly attribute causality to the anesthetic or to identify significant risk factors. In fact, based on the limited data available, it would appear that regional anesthesia is safe in cases of secondary HSV infection and reasonable for patients in the early stages of HIV infection. Again, vigilance must be emphasized. Known predisposing factors include advanced age, diabetes, alcoholism, cancer, and AIDS. Patients are monitored for signs of meningeal irritation, fever, increasing back pain, neurologic changes, and local tenderness to injection sites. Although classic symptoms such as high fever, nuchal rigidity, and severe headache may be present, less alarming symptoms can occur, resulting in misdiagnosis. Although α -hemolytic streptococci are commonly seen in spinal block meningitis, *Staphylococcus aureus* is the most common causative organism in epidural abscesses, and iatrogenic methicillin-resistant. *S. aureus* is a growing concern. Epidural abscess, like epidural hematomas with evidence of neurologic deficit, can best be diagnosed by MRI. Early, aggressive

surgical intervention and antibiotic administration are vital.^{4,28,35,45–47}

Arachnoiditis and aseptic meningitis are rare but can occur when foreign substances irritate the meninges. As the needle is inserted, precautions must be taken to avoid introduction of glass or metal particles, highly concentrated local anesthetics or dextrose solutions, detergents or antiseptics, and a core of epidermis. Indwelling catheters, previous myelography, and hemorrhages into the subarachnoid or epidural space also have been associated with meningeal irritation and scarring. Modern technology and techniques incorporate the use of disposable equipment, needles with matched stylets, filter needles, and improved pharmacologic agents that make this complication rare.⁴⁸

Shock and severe uncorrected hypovolemia are contraindications to spinal or epidural anesthesia, because both techniques cause sympathetic blockade. The resulting vasodilation prevents physiologic compensation and may worsen hypotension. In addition, management of shock and hypovolemia often requires aggressive fluid therapy and multisystem treatments that are often physiologically and psychologically uncomfortable for the aware patient.^{4,8,28}

Patients with a fixed-volume cardiac state such as hypertrophic cardiomyopathy or severe atrial stenosis do not tolerate bradycardia, decreases in systemic vascular resistance, or decreases in venous return and left ventricular filling, all physiologic changes that can be anticipated with neuraxial block by local anesthetics. In these patients, even transient episodes of hypotension can cause serious coronary hypoperfusion and cardiac arrest. Therefore, spinal, and usually epidural, anesthesia, are avoided; however, few things in anesthesia are truly absolute. For example, epidural administration of opioids has been used to provide obstetric analgesia and may provide cardiac benefit for these patients. Precautions in such a scenario might include close hemodynamic monitoring with an arterial line and pulmonary artery catheter, careful titration of the anesthetic, intravascular volume expansion, and use of ephedrine or phenylephrine to treat hypotension.³⁰

Spinal anesthesia is typically a singular deposit of local anesthetic and therefore provides anesthesia for a fixed duration. If uncertainty exists about the anticipated length of surgery, epidural

catheter placement is more appropriate to allow for the additional administration, or continuous infusions, of anesthetic agents. If the extent of the surgery is unknown, a neuraxial anesthetic may be initiated only to be converted later to a general anesthetic when the surgeon exceeds the limits of the anesthetic block. This is rarely an ideal situation; the patient may experience discomfort, albeit brief, and the anesthesia practitioner must contend with less-than-ideal intubating conditions. Despite the advantages of neuraxial anesthesia, many patients such as the elderly and those with arthritis or musculoskeletal limitations of the neck and upper extremities poorly tolerate prolonged immobility. The judicious use of conscious sedation can quickly devolve into a “room air general,” placing the patient at risk for hypoventilation, hypoxia, and hypercarbia. To avoid such circumstances, combined neuraxial and general anesthetic techniques are advocated and offer advantages by minimizing the total dose of general anesthetic used. Such techniques lower the risk of secondary effects of general anesthesia (e.g., nausea and vomiting) while gaining the advantages associated with neuraxial anesthesia, such as attenuation of the stress hormone response and improved postoperative pain relief.⁸

The administration of spinal or any regional anesthesia to patients with a difficult airway or full stomach requires careful consideration. The use of spinal anesthesia permits the patient to retain upper airway and pharyngeal reflexes that block the sympathetic nervous system. This theoretically results in increased gastric and intestinal motility, causing the stomach to empty. However, such benefits may be negated by the perception of pain and anxiety that accompanies illness or injury. If sedation is used to counter such perceptions, the airway may again become compromised. Furthermore, if hypotension develops from the resulting sympathectomy, the patient may experience nausea and vomiting. When an injury has occurred after the ingestion of alcohol or if the patient received opioid analgesics, the pain caused by the injury may be the only stimulus for consciousness.

When spinal or other regional anesthesia is instituted, the reticular activating centers in the brain receive less input. This often results in somnolence in a normal patient but can result in

unconsciousness in the overly sedated or inebriated patient. In addition, spinal or epidural anesthesia may reach an undesirably high level that is physically and psychologically intolerable for the patient and can even become a “total spinal.” A total spinal is characterized by unresponsiveness accompanied by cardiac and respiratory compromise. In such situations, airway support is required, and the emergent management of any airway can severely compromise patient safety. Therefore, regional anesthesia is not an alternative to a secure airway. For patients identified as potentially difficult to intubate, equipment should be immediately available to secure the airway in a safe manner. Advances in airway management such as the laryngeal mask airway, improved fiberoptics, laryngoscopes, and adjunct airway equipment may tip the risk-benefit scale in favor of regional anesthesia.^{8,11,48}

Spinal Anesthesia

Spinal anesthesia became popular after the discovery of the local anesthetic properties of cocaine, the invention of the hollow needle and syringe, and the written descriptions of the first lumbar puncture. The first clinical application of the technique was reportedly performed in the late 1890s. However, spinal anesthesia's prominence was short lived. The introduction of specific, reversible, neuromuscular blocking drugs and concurrent improvements in inhalation agents for general anesthesia soon displaced its popularity. It has regained popularity, in large part because of the introduction of newer agents, equipment, and techniques to employ it safely in the ambulatory setting.

Equipment and Techniques

Preparation for spinal anesthetic procedures, like for any other regional technique, requires the immediate availability of emergency equipment and supplies should emergent resuscitation be required. Usually spinal anesthetics are administered in the operating room where the minimal requirements—functional laryngoscopes, endotracheal tubes, induction agents, cardiovascular drugs including atropine and ephedrine or phenylephrine, suction, oxygen and ventilation equipment, a noninvasive blood pressure monitor, and pulse oximetry and electrocardiographic monitoring equipment—are readily available.

The original spinal technique, performed by August Bier in 1898, has been continually examined and modified in hope of reducing the incidence of complications, primarily that of PDPH. The goal of needle design has been to create a needle that minimally rends, tears, or cuts dural tissues. As technology has improved, the use of sterile, disposable procedure trays containing needles, syringes, catheters, and drugs has virtually eliminated problems previously associated with dull needles or contaminated equipment and has allowed for the development of innovative needles. Spinal anesthesia can be administered using either a *cutting or non-cutting* needle. Examples of a *cutting needle* include the Quincke-Babcock,

Greene or Pitkin needles that have matching stylets, which minimizes tissue coring, and beveled tips with cutting edges. Example of *noncutting-tip pencil point needles* include the Sprotte, Whitacre, and Pencan needles which have a pencil point tip and rounded edges. Several of the more popular types of spinal needles are shown in Fig. 49.7. Spinal needles also have matched stylets and are marketed for spinal anesthesia use in sizes ranging from 22- to 29-gauge and in lengths of approximately 3.5 inches (88 mm) and 5 inches (120 mm). Most blocks are performed using 25- to 27-gauge, 3.5-inch (88-mm) needles.^{28,48}

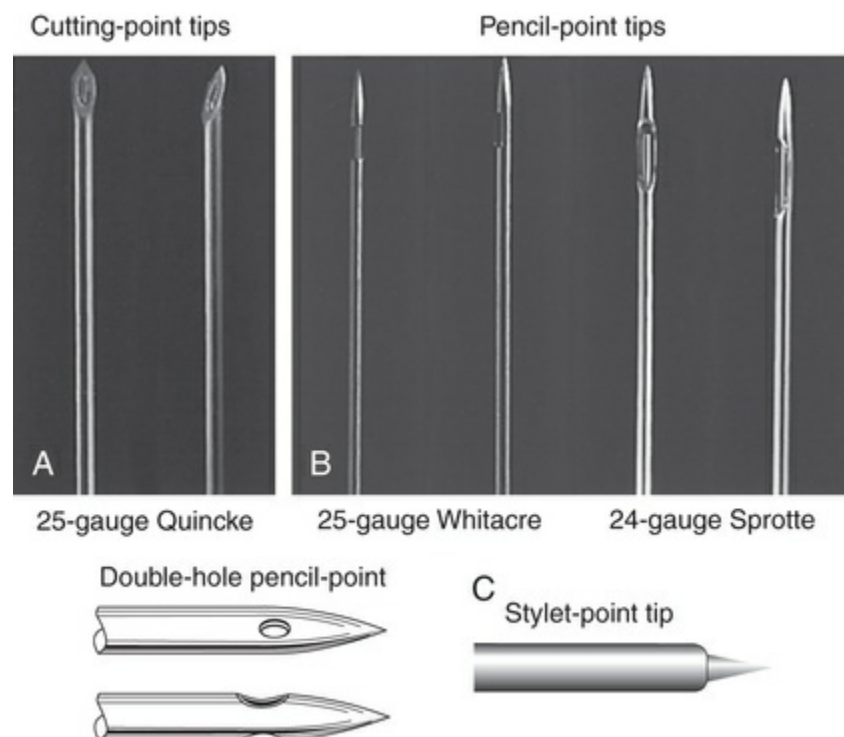

FIGURE 49.7 Graphic representations of spinal needle design features. **A**, Cutting-point tips. **B**, Pencil-point tips. **C**, Stylet-point tip. (A and B, From Chestnut DH. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier, 2009; C, From CSEN International. *Eldor Spinal Needle*. Available at: <http://www.csen.com>.)

Data support the use of noncutting-tip needles over cutting needles for several reasons.²⁸ Cadaver lumbar punctures performed with sharp cutting needles show piercing of the cauda equina roots without resistance appreciated by the practitioner. This does not occur with pencil-point needles. The bevel of cutting-tip needles

encourages tip deviation on insertion, whereas symmetric noncutting needles stay midline. The use of a beveled needle requires holding the bevel direction parallel to longitudinal dural tissue fibers to minimize the risk of PDPH. Noncutting needles may drag fewer skin contaminants into subdermal tissue than cutting needles. Pencil-point needles pierce the dura with a clearly perceptible “click” or “pop” not as easily noticed with cutting needles. Newer, thin-walled noncutting needles have improved CSF flow rates without compromise to strength. This allows for their use for CSF diagnostic procedures and helps simplify the identification of the intrathecal space by permitting quick return of CSF after stylet removal. Finally, unless prohibitively small cutting needles are used, the incidence of PDPH is clearly reduced with the use of noncutting needles. In a 2015 study that examined the impact of needle type, it was noted that when a cutting needle was used the incidence of PDPH was approximately 3 times higher compared to when a non-cutting needle was used for a diagnostic or therapeutic lumbar puncture.⁴⁹ Pencil-point needles are associated with a less than 1% risk of PDPH and a failure rate of approximately 5%.^{8,28,49,50}

After the patient arrives in the surgical or obstetric preoperative area, the consents for surgery and anesthesia should be checked, and any further patient questions or concerns should be addressed. Review of the anesthetic preoperative history and physical examination should include the addition of any last-minute changes in patient status and notation of recently obtained diagnostic results. IV access is achieved, and a continuous crystalloid infusion is begun. Preoperatively, most patients benefit from low-dose anxiolysis. With the increased emphasis on same-day admission, surgery, and discharge, long-acting agents are avoided. A rapid-acting benzodiazepine with a relatively short duration, such as midazolam, is highly titratable in 0.5- to 1-mg increments given intravenously, and minimally alters the patient's hemodynamic status when used in low doses. The drug's effects can be reversed with flumazenil.

Monitors appropriate to the patient's physical status should be applied and at minimum include blood pressure monitoring, a continuous electrocardiogram, and pulse oximetry. For the purpose

of baseline comparisons, vital signs must be assessed with the patient in both the supine position and the position in which the block will be administered.

The surgical or obstetric procedure to be performed helps determine the patient's position for the administration of the block. For example, if vaginal or urologic surgery is planned, a “saddle” block with the patient in a sitting position may be indicated. The prone position is useful for rectal surgery, because the patient can be placed in position before the block is implemented. This reduces the time required for positioning by permitting the patient to move with minimal assistance and to personally verify comfort and adequacy of padding. A lateral position favors spinal drug spread for right- or left-sided extremity or abdominal procedures. When the patient is in the lateral position, a pillow placed under the head and perhaps shoulders helps maintain neutral alignment of the spinal column. Surgical table height or patient position may need to be adjusted to compensate for variations in anatomic structure or physiologic limitations and to maximize anesthetist ergonomics. To maximize the space between spinous processes, the patient should arch the back (with assistance from the clinician) into a C shape or “like a Halloween cat.” Once the patient is positioned, anatomic surface landmarks are used to identify the lumbar region of the back to be used for dural puncture, a point below the end of the spinal cord (L2). The line formed between the tops of the iliac crests, called the *intercristal line* or *Tuffier's line*, crosses the vertebral column as high as the L3 to L4 disk or as low as the L5 to S1 disk (Fig. 49.8). The accuracy of predicting the precise level of needle insertion is at best 50%. This fact may account for variability in the spinal anesthesia level ultimately achieved, yet this landmark has been clinically useful since the advent of spinal anesthesia.⁷ The skin overlying a prominent spinous process at this level is marked for easy identification after the skin is prepared and draped. A surgical skin-marking pen is useful for this purpose, with caution exercised to avoid scratching the skin surface and predisposing the patient to infection.

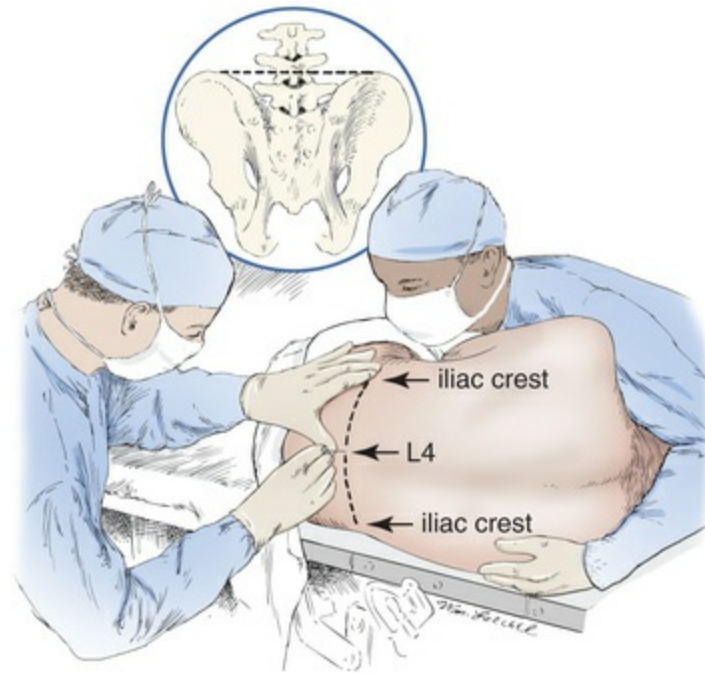

FIGURE 49.8 Patient positioning and identification of landmarks in the lumbar region of the back.

Next, the spinal anesthesia tray is opened, and sterile gloves are donned. The patient is prepared with an antiseptic solution such as Betadine, a povidone-iodine solution that releases a concentration of 1% free iodine as it dries on a surface. The solution must remain in contact with the skin for at least 1 minute to be effective, and then the dry residue can be wiped away with sterile gauze to help prevent a chemical arachnoiditis. Do not use alcohol to remove residue because alcohol neutralizes the iodine solution and minimizes its antiseptic effect. Another alternative to povidone-iodine is Dura Prep, which contains an iodophor in isopropyl alcohol that dries faster and is as effective as an antiseptic. Following antisepsis an aseptic technique needs to be maintained, and the sterile drape must be applied to the back. Many spinal and epidural drapes have a circular window that is placed over the area of anticipated injection and adhesive strips to simplify application to the patient's back. Avoid touching the adhesive, because this has been shown to create small holes in gloves, which increases the risk of infection in both the patient and anesthesia practitioner.⁵¹

A rapid-acting local anesthetic such as 1% lidocaine is used for local infiltration of the area just caudad to the identified spinous process. Approach the skin of the back with the bevel of the needle

facing away from the skin and at a 15- to 30-degree angle from the skin. Start injecting before the bevel of the needle is completely through the skin, and raise a skin wheal to place local anesthetic into the subdermal tissues most likely to contain nociceptors. Deep tissues, including the supraspinous ligament, can be anesthetized by spreading 3 to 5 mL of local anesthetic through the tissues in a fan pattern.^{8,28}

Larger 22- to 25-gauge spinal needles and epidural needles (used for continuous spinal anesthetic techniques) have tensile strength sufficient to permit introduction of the needle without additional support. However, spinal needles smaller than 25 gauge often require an “introducer” needle to help stabilize the needle during insertion and minimize infection in the surrounding dermis. The introducer is typically an 18- or 20-gauge needle with a “B” or blunt bevel. Introducer needles are approximately 3.8 cm long and matched to the spinal needles. The introducer is inserted through the skin and supraspinous ligament and into the interspinous ligament. Care must be taken, especially in thin individuals, not to enter the subarachnoid space with the introducer needle; the dura may be only 2.5 cm beneath the skin. Depth to the epidural space and the nearby dura correlates with weight but typically averages approximately 4 to 5 cm and rarely exceeds 9 cm. An introducer needle placed into the subarachnoid space would be likely to cause a PDPH.^{4,8,15,28}

Several common spinal anesthesia techniques can be used, including a straight midline approach. With this easy-to-learn technique, the anesthesia practitioner inserts the needle directly midline between the spinous processes and toward the umbilicus perpendicularly to all planes or at the lumbar level with a slight cephalad angle (Figs. 49.9 and 49.10). If bone is encountered early, the needle is withdrawn into the introducer and subcutaneous tissue. The introducer is then redirected in small angular increments in a cephalad direction. If bone is encountered when the needle is deeply inserted, the needle should be withdrawn and redirected caudad. As the tip of the spinal needle passes through the ligamenta flava, the sensation is similar to that felt when a needle is passed through a pencil eraser. As the needle tip passes through the dura, the anesthesia practitioner may sense a “pop” or

“click.” The stylet is removed, and several seconds are given for CSF to return through the small-gauge needle. Once CSF return is confirmed, some authors recommend rotating the needle 360 degrees in 90-degree increments to ensure that the needle tip is seated well within the subarachnoid space (see Fig. 49.10). Other authors suggest that such needle manipulation risks a larger dural rent or needle dislodgement. Whichever method is used, secure needle handling is important. As shown in Fig. 49.11, firmly place the dorsum of one's nondominant hand against the patient's back and below the spinal needle. Grasp the needle hub between the thumb and index finger. With this *Bromage* type of grip, the patient's body then acts as a firm support for the needle-stabilizing hand and helps prevent advancement or withdrawal of the needle tip from the subarachnoid space when the syringe is applied to inject the anesthetic agent.

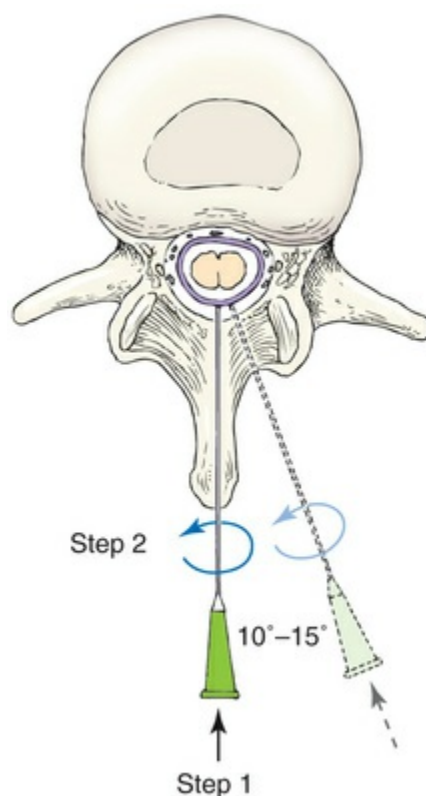

FIGURE 49.9 Insertion of the needle between the spinous processes and toward the umbilicus.

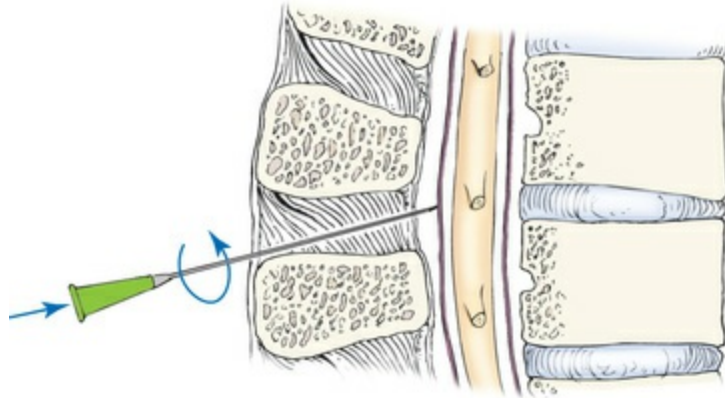

FIGURE 49.10 Spinal needle rotated 360 degrees to aid evaluation of tip location within the subarachnoid space.

FIGURE 49.11 The Bromage grip, showing needle control and syringe connection.

A second technique is called the *paramedian approach*. With this technique, the needle is inserted 1 cm or approximately one fingerbreadth lateral to the caudad aspect of the interspace. The needle is directed toward the spinal canal and angled slightly cephalad and then medially approximately 10 to 15 degrees (see [Fig. 49.10](#)). Elderly and arthritic patients may have decreased back flexibility and degenerating, calcified ligaments. For such patients, this approach may be the only possible means of entering the subarachnoid space because it aims for the largest area between processes and avoids calcified interspinous ligaments. A third

approach to the subarachnoid space, known as the *Taylor approach*, takes advantage of the L5 interspace, which is the largest interlaminar space. A point 1 cm medial and 1 cm caudad to the posterior superior iliac spine is located, and the needle is angled medially and cephalad at a 55-degree angle toward the fifth lumbar interspace. The Taylor approach is best used for pelvic and perineal surgical procedures.^{4,7,8,15,28}

Intrathecal Drugs, Spread, and Block Levels

Once the anesthetic solution is delivered into the CSF, the distribution of its active molecules through the subarachnoid space is dependent on the chemical and physical characteristics of the solution in relation to the chemical and physical characteristics of the patient's CSF and the subarachnoid space. In adults, approximately 500 mL of CSF is produced each day, predominantly by the choroid plexuses of the cerebral ventricles. Much of the CSF is reabsorbed by arachnoid granulations along the sagittal sinus to regulate CSF pressure to 10 to 20 cm H₂O. At any given time, a total of approximately 140 mL of CSF flows by bulk flow through the subarachnoid spaces, the central canal of the cord, and the ventricles of the brain. It is estimated that only 30 to 80 mL of the total CSF is present in the spinal canal. However, this quantity is difficult to measure, variable among individuals, and uncontrollable by the clinical anesthetist.^{3,4,52}

The density of a substance compared with the density of water is a ratio known as *specific gravity*. The specific gravity of CSF is 1.004 to 1.009 and can vary depending on variations in temperature and location of the fluid within the subarachnoid space. For example, the specific gravity of CSF sampled from the lumbar area is slightly greater than that of CSF from the ventricles. This difference is directly dependent on the protein in the CSF, as well as on the effects of gravity and the position of the patient. The specific gravity of CSF also tends to increase as patient age increases, correlating to increases in glucose and protein. Hyperglycemia and uremia increase the specific gravity of CSF, whereas jaundice and related liver problems may decrease its specific gravity. The change in specific gravity is related to the presence of bilirubin within the

CSF. An increase in a solution's temperature decreases its specific gravity. This decrease averages 0.001 point for each degree rise in Celsius temperature. Although all these factors have been thought to influence the distribution of an anesthetic solution injected into the CSF, they are usually beyond the control of the anesthetist.^{4,8,15,28,52}

A closely related concept, *baricity*, refers to the resting position of two fluids with differing specific gravities when the fluids are mixed in a single container, such as CSF and an anesthetic agent in the subarachnoid space. The baricity of the injected solution is compared with that of the CSF. Knowledge about the baricity of an injected solution provides the practitioner with information that helps determine the potential spread of the anesthetic mixture in the subarachnoid space. Therefore, when several medications are combined, the specific gravity of the combined solution at body temperature should be considered when the spread of the medication is anticipated. Unfortunately, these bedside mixtures are rarely controlled or measured, and use becomes reliant on practical experience. When baricity (i.e., the ratio of specific gravity of local anesthetic to patient CSF) equals 1, the solution is referred to as being *isobaric*. Because the specific gravity of CSF is variable, it is not possible to prepare a solution that is precisely isobaric. Near-isobaric solutions remain and act in approximately the same location in which they are injected. A *hyperbaric* solution has a specific gravity that is greater than that of CSF. The solution would fall, or sink to the lowest anatomic point at which CSF is contained within the subarachnoid space in relation to gravity and the patient's position (presuming that, as previously mentioned, drug preparations are corrected for body temperature). *Hypobaric* solutions that are less dense than CSF rise or float to the highest anatomic position possible when injected into the subarachnoid space.

Because the normal range for the specific gravity of CSF is variable, local anesthetics, opioids, or other solutions injected into the CSF must be predictably hypobaric or hyperbaric. By tradition, hypobaric solutions are defined as having a baricity of less than 0.999, and hyperbaric solutions have a baricity of greater than 1.0015. Clinically this is accomplished by dissolving the drug in

either sterile water to create a hypobaric solution, or 5% to 8% dextrose solutions to create a hyperbaric solution. If CSF or normal saline is added to the medications, the specific gravity of the solution is similar to that of CSF, and the drugs remain approximately where injected.^{4,8,15,28,52}

More than 23 factors, including CSF density and local anesthetic baricity, have been thought to affect the spread of local anesthetics in CSF and therefore affect the level and quality of the anesthesia achieved. Less than half of these factors have been found to have clinical significance, and an even smaller number are controllable by the anesthetist performing the anesthetic procedure.²⁸ Clinically the most important factors are those that can be manipulated by the anesthesia practitioner. These are the total dose of the local anesthetic, the site of injection, the baricity of the drug (drug choice), and (when nonisobaric solutions are used) the position or posture of the patient during and after injection.⁵²

The duration of a spinal anesthetic is based primarily on local anesthetic choice and total dose. Highly protein-bound drugs, such as tetracaine, bupivacaine, and ropivacaine, have long durations of action compared with less protein-bound drugs such as lidocaine and mepivacaine. Vasoconstrictors such as 0.1 to 0.2 mL of 1 : 1000 (1 mg/mL) epinephrine solution are sometimes added to the local anesthetic solution to prolong the duration of action. Epinephrine is thought to prolong the duration of spinal anesthesia by causing vasoconstriction, thereby delaying normal uptake of local anesthetics, by direct antinociceptor action, or by a combination of these effects. **The effect of added epinephrine on the prolongation of anesthesia is greatest with tetracaine, less with lidocaine, and minimal with bupivacaine.** In addition, local anesthetic solutions may include opioids (10 to 25 mcg fentanyl, 2.5 to 10 mcg sufentanil, or 250 mcg preservative-free morphine) or the α -agonist clonidine, 150 mcg, to prolong duration. These agents act at opioid and α_2 -adrenergic receptors, respectively. The exact nature of the synergistic effect among opioids, α_2 -agonists, and the local anesthetics is not clear, but the result is again prolonged spinal anesthesia. Volume in the tested range of 1 to 14 mL, and therefore concentration, minimally affects the duration of anesthesia or the final sensory level achieved. Increasing the total dose of a spinal

local anesthetic will increase its duration of action and affect the sensory level achieved. Duration of sensory and motor blockade for local anesthetics has been shown to be predictable. For example, increasing the dose of hyperbaric bupivacaine from 10 mg to 15 mg prolongs the duration of sensory block by 50% and increases the maximum sensory level achieved. Based on these principles, [Table 49.3](#) offers medication administration suggestions to achieve an approximate sensory level and duration of spinal anesthesia in a typical clinical setting.^{52,53}

TABLE 49.3
Choice of Medication for Spinal Anesthesia Used for Surgical Procedures

Procedure	Medication*	Dosage	Duration Without Epinephrine	Duration With Epinephrine
Vaginal delivery	Tetracaine	5 mg	1–1.5 hr	2.5–3 hr
	Bupivacaine	5–7 mg	1 hr	1.5 hr
	Lidocaine	25 mg	15–25 min	45 min–1 hr
Cesarean section	Tetracaine	8 mg	1–1.5 hr	2.5–3 hr
	Bupivacaine	10 mg	1–1.25 hr	1.5–2 hr
	Lidocaine	50–75 mg	30–45 min	1–1.25 hr
Anorectal surgery	Tetracaine (hyperbaric)	6 mg	1–1.5 hr	3 hr
	Tetracaine (hypobaric)	6 mg	1 hr	3 hr
	Bupivacaine	8 mg	1 hr	1.5–2 hr
	Lidocaine	25–50 mg	15–30 min	45 min
Genital or lower-extremity procedure	Tetracaine	6–10 mg	1.5 hr	2–3 hr
	Bupivacaine	8–12 mg	1.5 hr	2 hr
	Lidocaine	75–100 mg	45–60 min	1.25–1.5 hr
Hernia, pelvic procedure	Tetracaine	10–12 mg	1.5 hr	2–3 hr
	Bupivacaine	12–15 mg	1.5 hr	2 hr
	Lidocaine	100 mg	45–60 min	1.25–1.5 hr
Intraabdominal surgery	Tetracaine (by patient height)	5 ft to 5 ft, 5 in = 12 mg	1.5 hr	2–3 hr
		5 ft, 6 in to 6 ft = 15 mg		
		> 6 ft = 18 mg		
	Bupivacaine (by patient height)	5 ft to 5 ft, 5 in = 15 mg	1.5 hr	2 hr
		5 ft, 6 in to 6 ft = 18 mg		
		> 6 ft = 20 mg		
Back and spine surgery	Tetracaine	10–15 mg	1–1.5 hr	2–2.5 hr
	Bupivacaine	15–20 mg	1–1.5 hr	1.5–2 hr

*Local anesthetic solutions administered to intrathecal or epidural spaces must

be sterile and preservative free.

Selecting the precise site of injection, as mentioned, is technically inaccurate at the clinical level.⁷ The higher the site of injection, obviously, the higher the level of sensory block, but this is limited by the anatomy of the spinal cord and the anesthetist's desire to approach the subarachnoid space below the termination of the spinal cord. Theoretically, if a patient is administered a hyperbaric solution at the L3 level and placed supine, the local anesthetic would flow both cephalad and caudad from the relative peak of the lumbar lordosis to the troughs of the thoracic kyphosis and sacral regions. If a hyperbaric drug is placed below L3 with the patient in a sitting position, and the patient is left sitting for 5 minutes, a lumbar and sacral-root anesthetic known as a *saddle block* will occur. However, even under experimental conditions using the second to fifth lumbar interspace, the data on the ability to control the maximum sensory block level achieved are inconsistent. Therefore, the site of injection can be a poor predictor of the final level of sensory anesthesia achieved.⁵²

Several authors suggest that the level of the anesthetic can be adjusted or modified by use of position changes within the first few minutes after injection or until the medication becomes fixed on the nerve roots and the spinal cord. Some have even found that changes in position as late as 60 minutes after injection can alter the level of block achieved. For example, one of the suggested methods used to modify the level of the anesthetic is to raise a supine patient's legs 45 degrees. This position is thought to increase blood flow through the epidural venous plexus, indirectly altering CSF pressures. Such a position also flattens the lumbar lordosis, altering flow of hyperbaric local anesthetic within the subarachnoid space. The combined effects result in further cephalad spread of local anesthetic solutions. If one uses a similar line of thought, morbid obesity and third-trimester pregnancy also are associated with epidural venous engorgement when the patient is supine, and a slightly higher level of spinal anesthesia is found when compared with controls. With traditional hyperbaric solutions, the block achieved may range from T3 to T6. Therefore, the anesthetist's ability to precisely control the level of sensory anesthesia through baricity and changes in posture is associated with great variability

and low predictability from patient to patient.^{28,52,54} Once achieved, the final level of sensory blockade should be determined as discussed previously, then documented.

Continuous spinal anesthetics are administered with the same techniques used to establish a spinal or epidural anesthetic. A small epidural needle is used for the procedure, with the bevel turned parallel to dural fibers to help minimize the risk of PDPH. After the needle is inserted into the subarachnoid space, the bevel of the needle is turned either caudad or cephalad to facilitate passage of an epidural catheter into the subarachnoid space. The catheter is inserted only 2 to 3 cm into the subarachnoid space. Further insertion could result in advancement of the catheter along a nerve root or in curling of the catheter. The incidence of headache is minimal in elderly patients or when the catheter can remain in the subarachnoid space for at least 40 hours. Because of reports of cauda equina syndrome, in 1992 the Food and Drug Administration (FDA) removed small needles and microcatheters designed to further reduce the risk of PDPH from the United States market. *Cauda equina syndrome*, or persistent paralysis of the nerves of the cauda equina with resultant lower extremity weakness and bowel and bladder dysfunction, has subsequently been attributed to the deposition pooling and possibly repeat dosing of neurotoxic concentrations of hyperbaric local anesthetics, particularly 5% lidocaine.^{4,8,53,55}

This same solution of lidocaine in varying concentrations has been associated with *transient neurologic syndrome*. Symptoms are usually described as pain originating in the gluteal region that radiates to both lower extremities. Symptoms appear within a few hours up to 24 hours after recovery and spontaneously disappear in virtually all cases in 10 days. The symptoms range from mild to severe radicular back pain in up to 30% of patients, and although NSAIDs are the usual treatment, opioids may be required. Symptoms include a burning, aching, cramplike, and radiating pain in the anterior and posterior aspect of the thighs. Pain radiates to the lower extremities, and lower back pain is common. Other anesthetics have been implicated, but it is much more prevalent after spinal lidocaine.⁵⁶ Surgical positioning may be a factor as well.⁵⁷ The exact mechanism is unclear. Newer techniques and

agents other than lidocaine are being used now, and that has diminished this problem as a clinical issue. Treatment is supportive and should include NSAID agents when possible.^{58,59} A further discussion may be found in [Chapter 10](#).

Physiologic Alterations and Their Management

Spinal anesthesia causes several physiologic changes that are predictable and can usually be readily managed through anticipation and prevention or with minimal intervention.

Physiologic changes include effects on the central nervous system, cardiovascular system, respiratory system, and gastrointestinal (GI) system. In addition, physiologic alterations caused by central neural blockade affecting neuroendocrine, renal, and hepatic function are mentioned.

The obvious central nervous system effect of spinal anesthesia is the inhibition of nerve impulse conduction, resulting in spinal anesthesia. This occurs when the local anesthetic concentration exceeds the minimal blocking concentration of the particular nerve exposed to the drug. Neurons have different levels of susceptibility to local anesthetics, and this partially explains the differential block seen with spinal and epidural anesthesia. As a local anesthetic spreads from the epicenter of its injection site, the concentration of molecules decreases. As the local anesthetic spreads rostral and the concentration gradient lessens, only the most susceptible neurons will be blocked, and a differential block occurs. With spinal anesthesia, kinesthetic sense is typically inhibited at a dermatomal level higher than light touch or cold sensation, which in turn is inhibited at a more rostral dermatomal level than pinprick anesthesia. Therefore, a differential blockade among the levels of sympathetic, somatic sensory, and somatic motor fibers can be identified. Attempts to demonstrate the numbers of segments between areas of differential blockade have found that sympathetic fibers are blocked a mean of six or seven segments higher than somatic sensory fibers.^{10,11}

The reticular excitatory area in the brainstem is responsible for the brain's overall state of alertness or arousal. The primary determinant of the activity of the reticular excitatory area is the amount of sensory input from the body. Because spinal anesthesia

greatly decreases the number of sensory impulses to the reticular excitatory area, normal patients often experience somnolence. Caution must be taken during administration of spinal anesthesia to a patient in pain and already under the influence of central depressants such as alcohol or opioids. The pain caused by the injury may be the only stimulus for consciousness, and when spinal or other regional anesthesia is instituted, unconsciousness may ensue.¹¹

Spinal or epidural techniques using local anesthetics block sympathetic nerve transmission in addition to blocking sensory and motor fibers. Therefore, the sum effect of neuraxial anesthesia on the cardiovascular system depends primarily on the overall degree of sympathetic blockade in terms of the rostral spread of the anesthetic and partially on the degree of patient sedation and central sympathetic inhibition. Blockade of the sympathetic nervous system causes arterial vasodilation, decreased systemic vascular resistance, venous pooling, and a reduction in venous return. These changes cause a redistribution of blood that often results in hypotension. If the block is high enough, the sympathetic nerve fibers that innervate the heart, known as the *cardiac accelerators* (T1 to T4), become anesthetized. An imbalance occurs between vagal fibers, and the heart rate often slows, further contributing to hypotension. Baroreceptor reflexes, volume receptor reflexes, and decreased central sympathetic outflow all contribute to the complexity of the cardiovascular response to neuraxial anesthesia. The overall result is loss of normal cardiovascular homeostatic reflexes and the ability to compensate for minor cardiovascular stresses.^{60,61} Rapid changes in position, changes in skeletal muscle tone caused by relaxation, decreased venous return, low preoperative volume status, reflex surgical stimulation, preoperative medications (especially opioid- and sedative-hypnotics), and concurrent conditions such as pulmonary embolism, pregnancy, and systemic reactions to medications have all been implicated in increased severity of perioperative hypotension.^{11,60}

Hypotension is immediately relevant to the perfusion of critical organs such as the heart and brain and is important to all organs in maintaining near homeostasis. Although normotensive patients

have been shown to maintain cerebral blood flow despite a moderate decrease in blood pressure, hypertensive subjects may have altered cerebral blood flow autoregulation and are less tolerant of changes in mean arterial pressures.¹¹ A similar situation exists with elderly patients and patients with known coronary disease. With these caveats in mind, most clinicians allow a decrease in blood pressure of 20% from a patient's baseline before initiating treatment.

Clinicians continue to debate the optimal treatment of spinal anesthesia-induced hypotension (SIH) and bradycardia. There are multiple strategies proposed to prevent and treat SIH in patients but the most commonly used techniques include pelvic tilting, administration of crystalloid and colloid solutions, administration of vasopressor agents, positioning during spinal anesthesia placement, and the use of serotonin (5-HT₃) antagonists. The treatment is often dependent on coexisting disease, but some general recommendations can be made. Preventive management of hypotension includes the administration of glucose-free crystalloid or colloid solutions in volumes of approximately 15 mL/kg, 15 minutes before the start of the anesthetic procedure to maintain preload to the heart. This technique of “preloading” with a crystalloid solution has been shown to be less effective than when a colloid solution is used. Most practitioners advocate administration of a crystalloid “co-load” which is administered at the time of the injection of the spinal anesthetic to prevent SIH.⁶⁰ Another intervention that is showing promise in preventing SIH is the prophylactic administration of a 5-HT₃ antagonist such as ondansetron. Prophylactic administration of a 5-HT₃ antagonist is thought to block the reflexive decrease in heart rate caused by the sympathectomy from the spinal anesthetic thereby blocking bradycardia and subsequent hypotension. Most practitioners will administer 4–8 mg intravenously immediately before injection of the spinal anesthetic. Infusions of α -adrenergic vasoconstrictors and sympathomimetic agents have also been shown to help reduce the incidence of cardiovascular side effects requiring treatment. Should the treatment of hypotension become necessary, the ongoing administration of IV solution is often the first response; however, excessive fluid therapy can lead to fluid overload and urinary

retention, especially in the elderly.⁶⁰

Continued treatment is guided by the patient's presenting symptoms and coexisting disease. The heart rate can be used to help guide pharmacologic intervention. Ephedrine (a mixed α - and β -agonist) in 5 to 10 mg IV boluses is the agent of choice in patients with symptomatic bradycardia. Ephedrine's indirect effects cause an increase in peripheral vascular resistance and heart rate. If the heart rate is normal or elevated, incremental injections of an α -agonist, such as 50 to 100 mcg of IV phenylephrine, causes increased systemic vascular resistance without further increasing the heart rate. The use of phenylephrine may therefore be more efficacious in the elderly. Bradycardia is treated with IV atropine of 0.4 to 0.8 mg.

Severe hypotensive events should be treated vigorously with medication and fluids, because mortality from rare cardiac arrests increases when treatment is delayed.^{4,10,15,60}

Most studies demonstrate that midthoracic levels of either spinal or epidural anesthesia have minimal effects on tidal volume, respiratory rate, minute ventilation, and arterial blood gas tensions in otherwise healthy individuals. The phrenic nerve is rarely paralyzed, even when sensory levels reach the cervical dermatomes. However, the accessory abdominal and intercostal muscles for ventilation are impaired, and the ability to cough and clear secretions is inhibited. With the loss of perception of intercostal and abdominal wall muscle movement and the inability to cough, the patient may begin to feel dyspneic. Caution must be exercised if the accompanying anxiety is treated with large doses of sedatives or opioids. They may worsen ventilation and result in hypoxia. Although regional techniques have been shown to have minimal effects, adequate ventilatory ability during surgery is dependent on multiple factors, and improved pulmonary outcomes have not been clearly demonstrated. Some of the factors that affect ventilatory ability under spinal or epidural anesthesia include the presence of coexisting disease, depressant medications, patient position, type and location of the surgery and incision, and presence of hypotension and hemorrhage. The anesthetic plan must be adapted to the patient and the operation.^{10,11}

The GI tract is regulated by the parasympathetic and sympathetic

nervous systems. The parasympathetic innervation of the GI tract is primarily via the vagus nerves and is composed of both afferent and efferent fibers. Parasympathetic afferent nerves transmit sensations of satiety, distention, and nausea, whereas efferent outflow generally increases GI activities such as tonic contractions, sphincter relaxation, peristalsis, and secretion. Sympathetic innervation of the GI tract stems from the T5 to L2 spinal cord segments and via prevertebral ganglia. Sympathetic afferent nerves are responsible for transmitting pain information; efferent nerves inhibit peristalsis and gastric secretion and cause sphincter contraction and vasoconstriction. When spinal and epidural anesthesia cause a sympathetic blockade, the result is unopposed or dominant parasympathetic activity. The neuraxial sympatholysis results in a generalized constriction of the bowel, normal to increased peristalsis, increased intraluminal pressure, and increased GI blood flow.^{10,11,15} The combination of abdominal muscle relaxation and a contracted bowel offers improved operating conditions for intraabdominal procedures, but because gastric motility can be increased, some clinicians have questioned the risk of wound disruption. Several studies have reported that the intraoperative and postoperative use of neuraxial anesthesia does not increase the risk of wound breakdown. A 2014 review by Shi et al⁶² reported that the use of thoracic epidural analgesia was beneficial in bowel recovery as compared to conventional systemic analgesia.

Nausea and vomiting are associated with neuraxial block in up to 20% of patients. Nausea and vomiting are primarily related to the GI hyperperistalsis of parasympathetic dominance, although other contributing factors may include hypoxemia, hypotension, systemic medications (opioids or rapidly infused antibiotics), and psychological stimuli. A cardiac mechanism associated with spinal anesthesia, as proposed by some authors, also may lead to nausea and vomiting. Theoretically, cardiac vagal afferent nerves can be activated in response to a decrease in venous return via ventricular mechanoreceptors, especially with high block levels. Therefore, the vagolytic properties of atropine provide indirect-acting antiemetic effects in the treatment of the nausea and vomiting associated with high spinal anesthesia.^{11,15}

The neuroendocrine stress response is a combination of responses of the body to tissue trauma (such as surgery) or critical illness. The response includes components of neural, immune, endocrine, metabolic, and inflammatory systems that are closely integrated through a complex mechanism of hormones, neurotransmitters, and receptors that affect cells throughout the body. These systems are activated in proportion to the level of critical illness or tissue injury experienced by the body.¹¹ The stress response is usually associated with increases in blood concentrations of adrenocorticotropins, cortisol, insulin, growth hormone, aldosterone, and glucose. Initially a protective response, the stress response can lead to tachycardia, hypertension, catabolism, immunosuppression, and hypercoagulability.¹⁰ Regional blocks such as spinal and epidural techniques moderate the stress response to surgery. Although spinal anesthesia blocks this response only for the duration of the anesthetic administration, the use of continuous epidural analgesia well into the postoperative period has the potential to improve perioperative outcome.

Renal blood flow and function are well preserved during spinal anesthesia when blood pressure is maintained. Hepatic blood flow is directly proportional to the mean arterial pressure and therefore depends on the treatment of any hypotension associated with the spinal or epidural anesthetic.¹⁰ Spinal and epidural anesthetics block sympathetic fibers, thereby increasing the tone of the internal urethral sphincter; in addition, neuraxial opioids cause a decrease in detrusor contraction and an increase in bladder capacity. These changes in the genitourinary system can result in the rare complication of urinary retention.

Complications of Spinal Anesthesia

Postdural Puncture Headache

PDPH is perhaps the most commonly discussed and managed complication of neuraxial anesthesia, with a documented incidence that has varied over the years from 0.2% to 24%. Theoretically PDPH is caused by a decrease in the CSF available in the subarachnoid space through a leak created by the dural puncture from an intruding needle. The medulla and brainstem, having lost

their hydraulic support, drop into the foramen magnum, stretch the meninges and pull on the tentorium. This pulling, further irritated by movement and the upright position, causes a characteristic headache.^{4,22,28,63} A contributing theory suggests that cerebrovasodilation may result from low CSF pressure. This theory is supported by the beneficial effects of vasoconstrictor drugs such as caffeine and theophylline.⁶³

Several factors are known to increase the incidence of PDPH. The use of large, non-pencil-point needles or a cutting-needle bevel direction that is perpendicular to the long axis of the body will make larger holes in the dural fibers and create larger CSF leaks. In fact, the risk of PDPHA is 70% when the dura is punctured with a 16-gauge Touhy epidural needle, 5.2% when a 26-gauge Quinke (cutting needle) is used and only 1.2% when a 25-gauge Whitacre (noncutting needle) is used.^{63,64} Therefore is recommended that only a non-cutting (blunt tipped) needle should be used for spinal anesthesia, especially in those that are predisposed to PDPHA. Other factors that predispose a patient to PDPHA are multiple punctures, female gender and age. There is extensive evidence that shows that PDPH is relatively uncommon in those over the age of 60 and more prevalent in those less than 40 years of age. This is thought to occur because in the elderly the dura may be more inelastic and less likely to remain open following a dural puncture. Patients with a history of PDPHs are also predisposed to another headache after a subsequent spinal anesthetic procedure. However, one should keep in mind that not all headaches that follow spinal anesthetic procedures are PDPHs. It is common for patients to experience headaches after surgery and even after general anesthetics. Factors that contribute to headaches may include anxiety, interrupted sleep, dehydration, hypoglycemia, and even simply the lack of normal morning caffeine intake. A differential-diagnosis approach should be taken to identify serious complications such as subdural hematoma, subarachnoid hemorrhage, meningitis, sinusitis, or subarachnoid hemorrhage.^{15,22,28,50,63}

Fortunately, PDPHs have several characteristic features that aid in diagnosis. They usually occur within several hours to the first or second postoperative day. Historically, bed rest was thought to

help prevent PDPH, but subsequent studies found that avoiding early ambulation simply postponed the onset. The headache is typically described as a mild to incapacitating bilateral frontal headache that radiates from behind the eyes and across the head toward the occiput and often into the neck and shoulders. The headache is considered positional, because it is relieved when the patient is lying down. The only other form of headache that has this positional component is caused by pneumocephalus, therefore it may be beneficial to use normal saline as your medium when placing an epidural as opposed to air. Other symptoms that may be associated with PDPH include nausea and vomiting, appetite loss, blurred vision or photophobia, a sensation of a plugging of the ears and loss of hearing acuity, tinnitus, vertigo, and depression.^{8,22,28,63}

Although PDPHs are self-limiting and often resolve in less than 10 days, early identification and prompt treatment are essential if complications of immobility, depression, and patient dissatisfaction (a potential reason for litigation) are to be avoided. Conservative management includes a horizontal position, adequate hydration, oral analgesics, and the administration of 500 mg IV caffeine benzoate, 300 mg of oral caffeine, or theophylline. Caffeine has shown effectiveness for treating PDPH, decreasing the proportion of participants with PDPH persistence and those requiring supplementary interventions. Gabapentin, theophylline, and hydrocortisone also have shown a decrease in pain severity scores when compared with placebo or conventional care. There is a lack of conclusive evidence for the other drugs such as sumatriptan.⁶⁵ The horizontal position is impractical for most patients, especially mothers of newborns, and encourages further complications of immobility.⁶³ Abdominal binders, thought to increase epidural venous plexus blood flow and therefore CSF pressure, are also uncomfortable and often impractical. Increasing fluids during the evaluation and early management period was thought to increase the central volume and increase the secretion of CSF from the choroid plexus, but this is not well supported in the literature. However, adequate hydration should be maintained in all patients.²⁸ Caffeine and theophylline are both methylxanthine derivatives that cause cerebral vasoconstriction and central nervous system stimulation. Caffeine therapy, both oral and parenteral, is

the most commonly used pharmacologic treatment modality. Caffeine has been shown to eliminate headache in up to 70% of patients, but this effect may be transient.⁶³ In a 2014 review by Baysinger⁶⁶ it is reported that caffeine is frequently used and shows efficacy as does some newer treatment regimens that include administration of adrenocorticotrophic hormone (ACTH), gabapentinoids and repeated doses of hydrocortisone, with mixed results.

An epidural blood patch is considered the definitive treatment for PDPH. Thought to work via clot formation that seals the dural rent and increases CSF pressure, the epidural blood patch is associated with a greater than 90% cure rate. Clinically an epidural blood patch is performed in a manner similar to that of placing an epidural catheter. First, the availability of IV access is identified, usually in the antecubital fossa, and informed consent is obtained. Both the patient's back and IV access site are prepared and draped in an aseptic manner. An insertion site at or below the level of the lowest initial needle insertion is chosen, because blood has been shown to spread in a predominantly cephalad direction within the epidural space. The epidural space is identified by use of either loss-of-resistance or hanging-drop technique (see later in [Epidural Anesthesia](#)). Autologous venous blood (approximately 20 mL) is withdrawn from the vein and then slowly injected through the epidural needle into the epidural space. The injection proceeds until the patient senses pressure in the back, buttocks, or legs. Typically, this occurs at a volume of 12 to 15 mL, which is sufficient blood to patch most patients. A supine position should be maintained for 30 minutes to 1 hour before the patient ambulates. Relief of the headache is often instantaneous. In the rare case in which an epidural blood patch fails, a repeat blood patch may be attempted in 24 hours, with a similar success rate.^{22,28,63}

The success rate and excellent safety record of the epidural blood patch encourages the use of this therapeutic option early in the treatment of PDPH, but it has been shown that success rates for its use in treating PDPHA increases exponentially if placed greater than 24 hours after the dural puncture. However, some risks, although minor or rare, are associated with this more invasive procedure. Backache, often associated with the administration of

general, spinal, or epidural anesthetic techniques, occurs in up to 35% of patients after an epidural blood patch. Although rarely as debilitating as a PDPH, backache risk should be explained to the patient. The most common cause of backache is relaxation of the muscles of the back and flattening of the normal lordotic curve. As the muscles stretch, injury to tendons and ligaments can occur. The position of the patient might increase the severity of the problem. An exaggerated lithotomy position or a completely supine position can further increase tension on tendons, resulting in increased trauma to both the muscles and the tendons. Trauma from multiple punctures; hemorrhage; infections; use of large needles, retractors, and forceps; extremes of positions; preexisting diseases such as arthritis and osteoporosis; and prolonged labor can contribute to backaches that may persist well into the postoperative period.^{28,63}

Management of backache includes the use of antispasmodics and NSAIDs to reduce discomfort, permit ambulation, and promote a more rapid recovery. In addition, authors have reported a 5% incidence of transient (24- to 48-hour) temperature elevation, a 1% incidence of neck ache, radicular pain, nerve root irritation, cranial nerve palsy, and meningitis, although the cause of meningitis was unproven.^{23,28,63}

Several caveats regarding the treatment of PDPH are worth mentioning. Systemic infection, perhaps indicated by fever, presents a relative contraindication to epidural blood patch and warrants a trial of pharmacologic intervention. The risk of neurologic sequelae after epidural blood patch in the presence of HIV infection or sepsis is controversial, because few data are available, leading some authors to suggest alternative therapies such as epidural 0.9% sodium chloride or dextran.^{15,46,63} Prophylactic epidural blood patch placement has not been shown to be consistently successful.²² In light of the relatively low incidence of PDPH and the effectiveness of the epidural blood patch, treatment should not begin until the problem exists. Finally, an alternative diagnosis should be sought if two epidural blood patches fail to resolve the patient's symptoms.^{28,63}

Nausea

As with general anesthesia, intraoperative and postoperative

nausea and vomiting (PONV) associated with CNB is a complex issue. Although it is believed that PONV is less common with regional anesthesia techniques than general anesthesia techniques, agents such as propofol have considerably narrowed the incidence gap. Although not life threatening, PONV remains a significant concern for patients and clinicians. General strategies can be implemented to help reduce the incidence of this unpleasantness.

Nausea immediately after the initiation of CNB is often considered a sign of significant hypotension and a climbing block level. Resulting cerebral ischemia affects the vomiting centers of the medulla, possibly triggering nausea. Others posit that gut ischemia leads to the release of emetogenic substances such as serotonin. Fluid and sympathomimetic administration treats the hypotension, and the nausea resolves. Another contributing element may result from the sympathectomy caused by the onset of CNB. The resulting unopposed parasympathetic activity in the GI tract results in hyperactivity, possibly contributing to nausea. Evidence that this may be the case is that vagolytic agents such as atropine are efficacious in treating this nausea.⁶⁷

Avoiding hypotension, providing adequate hydration, and supporting perfusion with supplemental oxygen are the basis of an antiemetic plan for CNB. Premedication and intraoperative sedation can significantly affect the incidence of intraoperative nausea and PONV. **Clonidine does not influence the incidence of PONV**, and evidence supports that propofol has antiemetic effects. The addition of epinephrine to local anesthetics administered intrathecally for spinal anesthesia increases the incidence of nausea. Additionally, a dose-dependent increase in PONV occurs when intrathecal morphine is used. However, the addition of 20 mcg fentanyl or 2.5 to 5 mcg of sufentanil to spinal bupivacaine results in less intraoperative nausea compared with placebo. Similar strategies apply to epidural anesthesia, although opioid use must be matched to patient and case type to maximize analgesia while minimizing secondary effects.⁶⁷ Multimodal approaches that have been widely adapted should also be applied to PONV after regional anesthesia.⁶⁸

Urinary Retention

Urinary retention is common after anesthesia and surgery with a reported incidence of between 5% and 70%. Spinal or epidural anesthetics block sympathetic fibers and increase the tone of the internal urethral sphincter. However, other factors often contribute to the risk of urinary retention after surgery and anesthesia. These include the type of surgical procedure, bladder distention from the administration of large volumes of IV fluids, bladder trauma, prolonged hypotension, incision pain, urethral edema caused by prolonged labor, benign prostatic hypertrophy, and the use of neuraxial or intraoperative opioids, anticholinergics, sympatholytics, and other drugs. Comorbidities, type of surgery, and type of anesthesia influence the development of postoperative urinary retention (POUR). The risk of retention is especially high after anorectal surgery, hernia repair, and orthopedic surgery and increases with advancing age. Certain anesthetic and analgesic modalities, particularly spinal anesthesia with long-acting local anesthetics, adding epinephrine and epidural analgesia, promote the development of urinary retention. Reasonable fluid administration with less than 1000 mL helps avoid bladder overdistention. Portable bladder ultrasound provides rapid and accurate assessment of bladder volume and aids in the diagnosis and management of POUR. Catheterization is recommended when bladder volume exceeds 600 mL to prevent the negative sequelae of prolonged bladder overdistention. Urinary retention and subsequent catheterization can lead to complications such as urinary tract infections and urethral strictures. Low-risk patients with less than 600 mL bladder volume may be sent home with instruction to return if they cannot void.⁶⁷⁻⁷¹

Neurologic Risk

Patients greatly fear the perceived risk of paraplegia resulting from neuraxial anesthetics, and the seriousness of such complications warrants concern. However, several very large series have shown that the incidence of persistent motor paralysis is exceedingly rare (less than 1 per 10,000). Because neurologic sequelae are rare, the knowledge base of complications comes from case studies, and often the cause is not proved but rather inferred by association. Direct needle or catheter nerve injury, drug-related neurotoxicity,

anterior spinal artery syndrome, undiagnosed neurologic disease, intraneural or intramedullary injections, the presence of blood in the CSF, patient positioning, hematomas, and abscesses are associated with permanent neurologic deficits. Therefore, good clinical practice depends on (1) the use of appropriate anesthetic techniques that minimize risk and (2) the conduct of postoperative assessments in a manner that promotes early detection, diagnosis, and treatment, especially because reversibility of complications is often time dependent.^{15,28,30,72,73}

Unexpected Cardiac Arrest

Cardiac arrest associated with neuraxial anesthesia is often sudden and unexpected and can result in severe neurologic injury and death. Additionally, this undesired complication occurs in a significant number of young, previously healthy patients. Estimates of occurrence are 7 : 10,000 for spinal anesthesia and 1 : 10,000 for epidural anesthesia. This suggests that cardiac arrest is not such a rare event in neuraxial anesthesia. How then might it be differentiated from arrests under general anesthesia (3 : 10,000)?⁷⁴

Because unexpected cardiac arrest with spinal anesthesia has been reported in previously healthy patients, some authors consider this a physiologic response to neuraxial blocks.⁷⁵ Other authors suggest a pattern of presentation with a gradual downward trend in heart rate followed by an abrupt onset of severe bradycardia or asystole.^{11,76} Spinal anesthesia cardiac arrest can occur well after the onset of spinal blockade. Large recent retrospective studies note that arrests can occur 20 to 60 minutes after the onset of spinal blockade and are frequently associated with intraoperative events such as significant blood loss and orthopedic cement placement.

The etiology of cardiac arrest during spinal block anesthesia is related to cardiocirculatory factors, mainly a reduction of preload resulting from sympathetic blockade. These decreases in preload may initiate reflexes that cause severe bradycardia. Three reflex responses have been suggested. The first involves the pacemaker stretch. The rate of firing of these cells within the myocardium is proportional to the degree of stretch. Decreased venous return results in decreased stretch and a slower heart rate. The second

reflex may be attributable to the firing of low-pressure baroreceptors in the right atrium and vena cava. The third is a paradoxical Bezold-Jarisch reflex, in which mechanoreceptors in the left ventricle are stimulated and cause bradycardia.⁷⁶ Other factors that increase the risk of developing cardiac arrest include changes in patient positioning and hypovolemia.

Maintaining preload should be a priority, and prophylactic preloading with a bolus of IV fluid should not be omitted before initiating spinal anesthesia. It is important to institute treatment as soon as possible. Standard regimens for volume preloading may not be sufficient to maintain adequate preload, so a low threshold for administering additional fluid boluses, using vasopressors or repositioning the patient to augment venous return, may be appropriate. For patients with bradycardia during spinal anesthesia, the stepwise escalation of treatment of bradycardia with atropine (0.4–0.6 mg), ephedrine (25–50 mg), and, if necessary, epinephrine (0.2–0.3 mg) may be appropriate. For severe bradycardia or cardiac arrest, full resuscitation doses of epinephrine should be promptly administered.^{74–77}

Auditory, Ocular, and Facial Complications

Unexpected complications or complications that a patient may not ascribe to anesthesia may be unreported or underreported, especially if they are transient in nature and not life threatening. The complications of transient hypoacusis or hearing loss and retinal hemorrhage are thought to be caused by changes in CSF pressure, either from postdural puncture leaks or increases in pressure from the epidural administration of a large volume of solution. Epidural injection of 8 to 16 mL of fluid can increase CSF pressure by 85 cm H₂O for several minutes before compensation occurs. Horner syndrome (i.e., ptosis, miosis, anhidrosis, and enophthalmos) and trigeminal nerve palsy probably result from a high spread of local anesthetic to the sympathetic fibers of the head and neck and to cranial nerve V, respectively. These problems are usually self-limiting; however, knowledge of their previous occurrence enables the compassionate anesthetist to provide counsel and reassurance to anxious patients.^{32,78}

Epidural Anesthesia

Epidural anesthesia is a central neuraxial block that can be used for a wide variety of procedures. Unlike spinal anesthesia that results in an all-or-none block, epidural anesthesia can be titrated to deliver either analgesia or anesthesia for a wide variety of surgical and analgesic procedures. Epidural anesthesia allows the anesthesia practitioner better control of the extent of sensory and motor blockade than is offered by spinal anesthesia. The luxury of placing an epidural catheter that can be used before, during, and for an extended period after any surgical procedure is another advantage. The general indications for epidural anesthesia are the same as those outlined for spinal anesthesia, with the distinct difference that epidural anesthesia allows for continuous anesthesia secondary to placement of an epidural catheter. This makes epidural anesthesia more suitable for procedures of long duration and for extended use in the postoperative period to deliver long-term, titratable analgesia.

Local anesthetics or other analgesic solutions injected into the epidural space spread anatomically. Horizontally, medication spreads to the regions of the dural cuffs, where it is able to diffuse into the CSF and leak into the intravertebral foramen and paravertebral spaces to achieve analgesia/anesthesia. Longitudinally, medication spreads in a cephalad direction, with possible sites of anesthetic action along the paravertebral nerve trunks, intradural spinal roots, dorsal and ventral spinal roots, the dorsal root ganglia, the spinal cord, and the brain. Initial blockade is probably a result of anesthetic blockade at the spinal roots within the dural sleeves.⁴ The dural cuffs or sleeves have a proliferation of arachnoid villi and granulations that effectively reduce the thickness of the dura mater, permitting rapid diffusion of anesthetics from the epidural space through the dura and into the CSF. Differences in physicochemical properties of anesthetics (e.g., lipid solubility) may account for the differences in diffusion rates across the dura, which contributes to the variances seen in sensory, motor, and sympathetic blockade.⁵ Because epidural anesthesia is diffusion dependent, relatively large volumes (20 mL) of local

anesthetics must be used to achieve anesthesia as compared with spinal anesthesia, which routinely only requires 1 to 2 mL. In addition, because epidural anesthesia requires that the medication be delivered to the subarachnoid space by the process of diffusion and spread, anesthesia takes significantly longer to achieve than spinal anesthesia. Given these caveats, any procedure that can be done with the patient under spinal anesthesia can also be done under epidural anesthesia.⁴ However, epidural techniques allow for the placement of a continuous catheter, which is especially useful in cases of unpredictable duration, for prolonged postoperative analgesia, and for chronic pain control. In addition, labor epidural analgesia is the only method currently available that can relieve most of the discomfort of labor while minimally affecting maternal or fetal physiology. Labor epidural analgesia is highly satisfactory in these patients because it permits their participation in a comfortable delivery and allows maternal-infant bonding after delivery. Labor analgesia also satisfies obstetricians and anesthesia practitioners in that its flexibility allows quick conversion from an analgesic technique to a surgical anesthetic technique for cesarean section.

Equipment and Techniques

Patient preparation and positioning and the availability of emergency equipment and monitors are similar to the preparation for a spinal anesthetic. With a spinal anesthetic, the practitioner seeks CSF by piercing the dura, while the tip of the epidural needle seeks the fat-filled space deep to the ligamentum flavum and shallow to the dura. The standard epidural needle is typically 16 to 18 gauge and 3 inches long, with a blunted bevel and gentle curve of 15 to 30 degrees at the tip. This blunt bevel and curve allow the needle to pass through the skin and ligamentum flavum and abut against the dura, rather than penetrate through the dura. The two most common epidural needles used in clinical practice with a curvature at the blunt bevel are the Tuohy and Hustead needle designs. The Tuohy needle has the most pronounced curvature (30 degrees) at the tip and is often cited as the easiest for beginning practitioners to place because it allows directional placement of the epidural catheter into the space and the curved, blunt tip is less

likely to penetrate into the subarachnoid space. However, it has also been noted that placement of the Tuohy needle can be more difficult because the tip's exaggerated curvature is too blunt, inhibiting penetration through the skin and ligamentum flavum as compared with other needle tips. The Hustead needle is an intermediate needle with a less-pronounced 15-degree curvature that can more easily pass through skin and ligamentum flavum.

A third epidural needle is the Crawford needle. It is a thin-walled epidural needle that does not have the curvature of the Tuohy or Hustead needle. The straight tip may allow easier access through the skin into the epidural space. The Crawford needle is preferred by practitioners when catheter advancement into the epidural space is difficult or the angle of approach is steep, as encountered with thoracic epidural catheter placement. Because the Crawford needle lacks the curvature at the bevel end, it has also been implicated in a higher ratio of accidental dural punctures and is typically not used by beginning practitioners. These three common epidural needles are shown in [Fig. 49.12](#). Smaller-gauge (20- to 22-gauge) epidural needles are available in each needle design for pediatric catheter techniques, regional blocks, and specialty use. Many needle designs incorporate wings near the base or hub. The wings provide a grip for the practitioner that permits distribution of pressure equally over the needle during insertion. The wings and notches in the hub also align with the stylet and needle tip to indicate the direction of the needle tip's bevel and lumen. Needles also may have clear hubs to allow early detection of blood or CSF, plastic stylets to prevent coring, and 0.5- or 1-cm depth markings along the needle shaft.

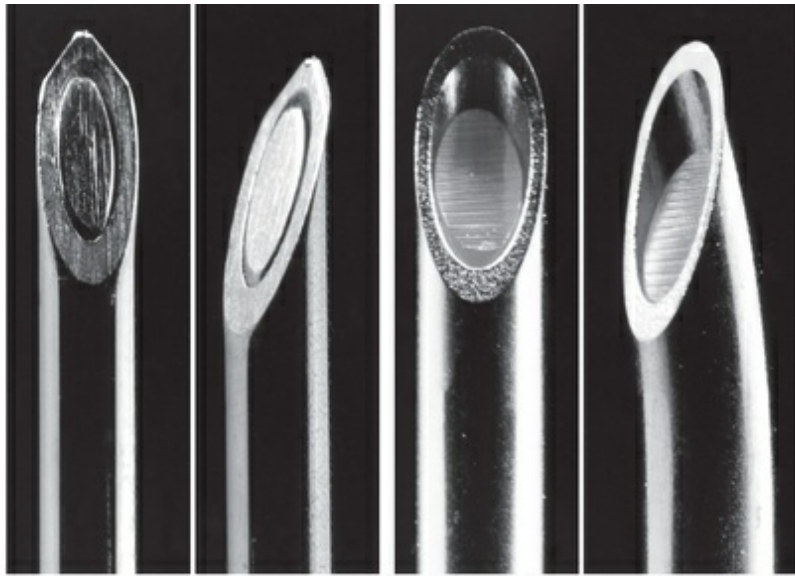

FIGURE 49.12 Epidural needles with catheter assortment. **A**, A 19-gauge, reusable Crawford epidural needle. **B**, A 19-gauge, disposable Tuohy needle. **C**, Single–end-hole epidural catheter. **D**, Closed-tip, multiple–side-hole catheter. **E**, Spring wire–reinforced, polymer-coated epidural catheter. (From Miller RD, et al. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015;1706–1707.)

Epidural catheters also come in a variety of materials and designs. Typically, catheter diameter is 2 gauges smaller than the needle. For example, a 20-gauge catheter would be used with an 18-gauge Tuohy needle. Catheters are constructed of physiologically inert materials designed to resist kinking, compression, and stretching and should be radiopaque. The two most common epidural catheters used in clinical practice are the single-holed, open-ended (uniport) and lateral-holed, closed tip (multiport) epidural catheters. Each catheter design is reported to offer several advantages and disadvantages. Studies that have compared the differences in catheter designs show a significantly lower incidence of inadequate analgesia with multiport catheters but a higher incidence of inadvertent IV cannulation.⁷⁹ Catheters have markings that identify the tip of the catheter to help verify removal of the catheter and identify when the catheter is at the tip of the needle, with 1-cm markings to measure depth of catheter placement. The depth that a catheter should be threaded beyond the needle tip and into the epidural space is often a controversial topic. Manufacturers of epidural catheters recommend that a catheter should be threaded 1 to 3 cm into the epidural space to avoid possible migration into an epidural vein or through an intravertebral foramen.^{15,80} However, in clinical practice practitioners noted that when an epidural catheter was only threaded 1 to 3 cm, a higher incidence of epidural catheter failure could result. Many practitioners reported anecdotally that when the catheter was threaded 3 to 5 cm into the epidural space, a higher success rate without a resultant increase in migration into an epidural vein or intravertebral foramen occurred. This routine clinical practice was validated by Beilin et al.⁸⁰ They reported that a catheter insertion of less than 3 cm resulted in a higher incidence of inadequate analgesia, and an insertion depth of more than 5 cm

resulted in an increase in inadvertent IV cannulation. They recommended that optimal catheter insertion should be 3 to 5 cm into the epidural space.

Proper patient positioning is important to ensure successful catheter placement. Epidural anesthesia is most often instituted with the patient in the sitting or lateral decubitus position and the landmarks, aseptic preparation, draping, and localization are similar to those for a spinal anesthetic. The spine should be in proper alignment, using pillows or pads if necessary and intervertebral spaces should be identified and marked prior to preparation of the patient's back (see [Fig. 49.8](#)). In contrast to thin, flexible spinal needles, epidural needles are larger and more rigid. Therefore, placement of the epidural needle does not require an introducer needle and offers better directional control; however, all needle-handling techniques must anticipate patient movement. Whether inserting a spinal or epidural needle into a patient, a similar controlled grip is used to accommodate for potential patient movement. This grip, described earlier as the *Bromage grip* (see [Fig. 49.11](#)), allows the patient's body to act as a firm support for the needle-stabilizing hand and helps prevent advancement or withdrawal of the needle tip from its position (1) if the patient should move, (2) when the syringe is applied, and (3) as a catheter is passed into the epidural space. The needle is placed bevel tip cephalad through the supraspinous ligament and seated in the interspinous ligament before the stylet is removed. After the stylet is removed, the needle is slowly advanced by use of either the hanging-drop technique or the loss-of-resistance technique into the epidural space.⁵

After the needle is seated in the interspinous ligament, the hanging-drop technique is accomplished by filling the hub of the needle with saline. The surface tension of the saline creates a droplet hanging on the needle hub. The needle is then advanced slowly in a slight cephalad orientation toward the epidural space. As the needle is advanced through the ligamentous structures, the drop should not move; however, as the tip of the needle enters the epidural space, the negative pressure within the space will cause the drop of fluid to be drawn into the needle. This aspiration of the hanging drop into the needle signifies that the needle has

successfully entered the epidural space. It should be noted that if the needle becomes plugged or the negative pressure in the epidural space is very low, the drop will not be drawn into the hub of the needle and passage into the epidural space will not be recognized. A dural puncture could result. Therefore, the hanging-drop technique is not recommended for the novice practitioner.⁵

The loss-of-resistance technique is the most common method used to enter the epidural space. The epidural needle is placed through the dermis into the interspinous ligament or ligamenta flava, at which time the stylet of the epidural needle is removed. Once the needle has been firmly seated into the ligament, a loss-of-resistance syringe (plastic or glass) containing 2 to 3 mL of normal saline or air and a freely movable plunger is attached. If the needle is properly seated in the ligament, it should be difficult to inject the normal saline or air, and slight pressure on the syringe plunger should result in the plunger springing back to its original position. Some practitioners use a combination of saline and air in the syringe during the loss-of-resistance technique, using approximately 3 mL of normal saline and a small air bubble (0.1 to 0.3 mL). They report that this provides them with a more compressible feel for entry into the ligamentum flavum. If the air bubble cannot be compressed without injecting the normal saline, the needle is most likely not seated into the ligamentum flavum and may still be in the interspinous ligament or off midline into the paraspinal muscles. The needle is advanced toward the epidural space by application of pressure to the needle, not the syringe or syringe plunger. If normal saline is used, constant pressure may be applied to the syringe plunger. Contact with the needle or needle wings is maintained to control needle advancement. As the needle passes through the ligamentum flavum, resistance increases, and it is very difficult to inject either saline or air. Once the bevel of the needle completes the passage through the ligamenta flava and enters the epidural space, an immediate loss of resistance occurs. The contents of the syringe can then be injected gently and without resistance. After the syringe is removed from the needle, an outward rush of a small amount of air or fluid may occur. Penetration of the dura with a large epidural needle usually results in profuse return of CSF; the needle should be removed

immediately to minimize CSF loss.

The loss of resistance experienced by a beginning practitioner, or by the experienced practitioner in a patient with difficult anatomy, may not be easily discerned. Sometimes it may be necessary to further evaluate the needle tip's location. For example, several milliliters of air can be injected through the needle while the soft tissue lateral to the spinous process is palpated. If crepitus is felt, the needle is most likely located in the tissues adjacent and shallow to the spinous process. If fluid returns from either the needle or catheter, CSF can be distinguished from normal saline or local anesthetic. CSF is warm to the forearm, compared with recently administered room-temperature fluids. Glucose test paper will detect the glucose in CSF. Local anesthetics mixed with a similar volume of thiopental will immediately form a precipitate. Multiple tests should be used to achieve the most accurate confirmation of fluid type.

Once the practitioner is reassured of the needle tip's position, an epidural catheter is threaded through the needle and into the epidural space to a depth of 3 to 5 cm. As the catheter is passed into the epidural space, it is important to warn the patient that a "funny bone" sensation may be experienced down one or both legs. This is a paresthesia that may indicate that the catheter has brushed by a nerve root as it was passing into the epidural space or perhaps even lodged into the nerve root. If the paresthesia is persistent prior to or after needle removal, the catheter must be withdrawn and replaced. Injection of medication into a patient complaining of persistent paresthesias can result in nerve-root damage or even nerve-root death and cause long-term morbidities. If the catheter is being replaced secondary to a persistent paresthesia, it is best to move to a new interspace to avoid oversensitized nerve roots. It is important that the needle remain stabilized during catheter advancement. Often if a patient does experience a paresthesia during threading of the catheter, the patient will move reflexively. Unanticipated movement and an uncontrolled needle could result in inadvertent subarachnoid puncture. Once the catheter is threaded approximately 3 to 5 cm, the needle is withdrawn slowly over the catheter. It is common practice to note the depth of the catheter at the level of the skin (by noting the cm-depth mark on the catheter)

both prior to and after removal of the epidural needle. Once the epidural needle is removed, the catheter depth should be noted and documented. If the catheter was inadvertently threaded deeper than desired into the epidural space, it should be slightly withdrawn to the desired depth as noted at the level of the skin. If the catheter migrated out of the epidural space, again the depth should be observed and recorded. Finally, if the depth into the epidural space is less than 1 cm, replacement of the catheter should be considered before any attempts are made to inject through the catheter. **Never attempt to withdraw the catheter through the needle!** This can shear the catheter and embed foreign material in the patient's back. Surgical intervention may be required for catheter remnant removal.

Once a catheter is placed and the needle removed safely, a catheter-to-syringe adapter is placed on the free catheter end. Observe the clear catheter as it enters the back. Look for backflow of CSF or blood. Owing to the greater resistance of a long and narrow catheter compared with a needle, gravity flow alone may not reveal the presence of blood or CSF. Therefore, gentle syringe aspiration is applied to the catheter via the adapter. Because tissue at the catheter tip may create a ball-valve effect, CSF or blood may not flow out; therefore, a negative aspiration test does not guarantee that the catheter tip is in the epidural space. Only if fluids do return does this test confirm that the catheter tip is placed either into an epidural vein or the subarachnoid space. The return of CSF or blood indicates that the catheter should be removed and replaced at a different interspace. To avoid this ball-valve effect or to dislodge any skin or tissue that may have lodged at the catheter tip, some practitioners advocate injection of 1 to 2 mL of normal saline solution through the catheter to confirm catheter patency before injection of medications. After needle removal, the catheter should be taped away from the midline of the back to avoid spinous processes and minimize the risks of catheter displacement from the epidural space or pressure injuries over bony prominences.

Prior to injection of a large amount of medication into an epidural space, a test dose of a small amount of medication is administered to determine whether the catheter or needle has inadvertently entered the subarachnoid space or possibly threaded into an

epidural vein. A test dose of 3 mL of a rapid-acting, low-toxicity local anesthetic agent with or without a small concentration of epinephrine is most typically used. **A lidocaine 1.5% with 1 : 200,000 epinephrine solution provides 45 mg of lidocaine with 15 mcg of epinephrine per 3 mL dose.** If the needle or catheter tip is in the subarachnoid space, this dose will result in spinal anesthesia within 3 minutes. If the same test dose is injected into a blood vessel, the 15 mcg of epinephrine will result in a 20% rise in heart rate and systolic blood pressure within 30 seconds. The patient also may experience sensations from the intravascular lidocaine, describing symptoms such as tinnitus, a metallic taste, circumoral numbness, or a rushing sound in the ears. The duration of these test-dose effects is less than 5 minutes. After the test dose is injected, vital signs are reassessed. Additionally, 100 mcg of undiluted fentanyl can be injected as a test dose to avoid potential complications caused by even low doses of epinephrine. If the needle or catheter is intravascular, the patient will experience immediate dizziness and sleepiness from the opioid. Despite all efforts to avoid them, systemic toxic reactions can still occur. Be vigilant, be cautious, and be prepared to handle emergencies.⁸¹⁻⁸³

Epidural anesthesia also can be administered by direct injection through the needle once it has been placed into the epidural space. This is called a “single-shot” epidural anesthesia technique, and the same contraindications and safety precautions apply as those already reported for catheter insertion. Once the needle is placed into the epidural space, the end of the open needle is observed for the presence of blood or CSF. Allow a few seconds for gravity flow of fluids to detect blood or CSF when the single-shot technique is used, then attach a syringe for medication administration using needle control techniques previously discussed.

Epidural anesthesia can be performed at any of the four segments of the spine but is most typically performed at the lumbar level. As with spinal anesthesia, there are two approaches, the midline and paramedian approach, that are used to facilitate placement of the epidural needle into the epidural space. The most common approach is the midline approach because it is the easiest to perform and helps place the catheter in the medial region of the epidural space. The paramedian approach is usually selected when

surgery or degenerative joint disease contraindicate the midline approach. Using the paramedian approach is more difficult for the beginner because advancement into the interspinous ligament does not occur. The needle advances primarily through paraspinous muscle mass, and resistance is only felt when entering the ligamentum flavum. The technique for paramedian placement involves identification of the desired interspace and the spinous process. The skin surface area approximately 3 cm lateral to the lowest aspect of the spinous process is prepped and anesthetized. The epidural needle is then placed through the anesthetized region and directed toward the midline using a slight cephalad orientation. Once the dermal levels are penetrated and the paraspinous muscle mass encountered, the needle stylet is removed and attached to a syringe containing either air or normal saline (or both) and advanced. The midline of the spine should be encountered approximately 3 to 5 cm from the entry point. The needle is advanced slowly using the incremental approach described earlier through ligamenta flava and then into the epidural space. When a paramedian approach is required by difficult surface anatomy or a steep approach to the thoracic levels is anticipated, the Crawford needle may be preferred. The Crawford needle's straight, blunt bevel allows the catheter to pass directly through the end of the needle, thus facilitating threading of the catheter.

Ultrasound Epidural Placement

The loss of resistance technique using air, normal saline, or a combination of air/normal saline is the gold standard method used by anesthesia practitioners to identify the entry into the epidural space. Traditionally epidural needle placement at a desired interspinous level is determined by palpation of anatomic landmarks; however, appreciating these landmarks can be extremely difficult in some patients. This difficulty could be secondary to obesity and/or scoliosis of the spine, which often require multiple passes with the epidural needle before proper placement or completely abandoning placement attempt secondary to inability to find the epidural space. Despite considerable improvement in the quality of needles and epidural catheters

within the last 30 years, the techniques for identification of the epidural space have remained the same, and as described previously, using these techniques to identify the epidural space can be impossible in some individuals.

To facilitate placement of spinal and epidural analgesia/anesthesia, ultrasound has been introduced into clinical anesthesia, and it has been found to be particularly useful in determining the spinous and transverse processes, thereby facilitating easier placement.⁸⁴ In addition, ultrasonography also allows the Certified Registered Nurse Anesthetist to adequately determine the distance from the skin to the epidural space, which may result in a lower incidence of accidental dural punctures. There are two useful acoustic windows used to assess lumbar spine anatomy. One of these windows is assessed using a transverse midline approach, whereas the other is assessed using a paramedian longitudinal approach (Fig. 49.13). The midline approach allows the anesthetist to adequately identify the midline, whereas the transverse approach allows for assessment of the interspace. In addition, the depth to the epidural space can be determined using ultrasound equipment.

FIGURE 49.13 Orientation of ultrasound probe and identification of underlying structures.

In contrast to the ultrasound machines used for peripheral nerve blocks, which operate using a high-frequency linear probe (10–15 MHz), the ultrasound probe used for spinal and epidural placement needs to be low frequency (2–5 MHz). These low-frequency probes are traditionally curved linear probes of the same type used routinely on pregnant women in labor and delivery to assess fetal function. The ultrasound can be used to identify the epidural space depth and position, or it can be used to facilitate real-time viewing of epidural needle placement into the epidural space. The technique of using one or two operators is well described in the literature.

Technique

An ultrasound machine that is capable of deep scans and equipped with a low-frequency (2–5 MHz) curvilinear probe should be used to facilitate the scan. Two different approaches (longitudinal paramedian and transverse midline) are used to help identify spinous processes, articular processes, ligamentum flavum, anterior

dura mater, posterior dura mater, and depth to epidural and subarachnoid space.⁸⁵ The patient is placed in a lateral position with flexed knees and hips or in a sitting position with the back curved out to present the spines. After proper positioning of the patient, the low-frequency ultrasound probe is placed over the sacral area, 3 cm left of midline and slightly angled toward the center of the spine. The hyperechoic (white) line of the sacrum is identified and then the probe is moved slowly cephalad until hyperechoic sawlike images are seen (see [Fig. 49.13](#)). These sawlike projections are the articular processes, and between the sawlike images are the vertebral interspaces. Next the ligamentum flavum, posterior dura mater, and vertebral body are identified, and the exact level of each interspace and the spinous process is marked. The probe is then placed horizontal along the midline of the spine at the marked levels of the interspaces and spinous processes. The hyperechoic spinous process is identified using the long triangular hypoechoic shadow. The probe is moved caudad or cephalad to capture the best view of the interspace, ligamentum flavum, and dorsal dura mater. Once a clear image is obtained, the screen is frozen and the midline is marked along the right lateral surface of the probe. The insertion point is determined by the intersection of the extensions of the two marks on the skin in the vertical and horizontal planes. One mark identifies the midline and the other identifies the interspace (see [Fig. 49.13](#)). The depth to the epidural or subarachnoid space is obtained from the “frozen screen” of the transverse view using the ultrasound machine calipers; one prong of the calipers is placed at the skin and the other at the inner side of the ligamentum flavum.⁸⁶

Epidural Drugs, Spread, and Block Levels

As with any anesthetic technique, the clinical success of epidural anesthesia is often dependent on experience because multiple factors must be managed and balanced to provide safe patient care. Two of these factors, dose and the site of injection, are the most important factors in determining the extent of dermatomal blockade. It should be remembered that the size of the segmental epidural spaces increases down the spinal cord as the spinal cord occupies less and less space. For example, when a very small volume of local anesthetic is injected into the cervical region, it will

spread across a larger number of segments as compared to when the same volume is injected into the thoracic region. This is also true when comparing the dermatomal spread between the thoracic and lumbar or caudal regions. The suggested dose of local anesthetic is dependent on the location of the catheter tip as it lies in the epidural space. Common clinical practice is to insert the epidural needle at a vertebral interspace such that the catheter tip falls near the middle of the spinal dermatomes of the proposed surgical incision. For example, an epidural catheter placed for labor or lower abdominal anesthesia would be placed at the L2 or L3 interspace. Placement would be at T8 to T10 for upper abdominal surgery; T4 to T5 for thoracic surgery; and C7 to T1 for chronic pain treatments or surgeries of the arms, shoulders, or upper chest. This has several advantages. The catheter tip, being at the relative center of the spread of the local anesthetic, creates an area of high concentration at the spinal nerves specific to the site of the operation with the least amount of local anesthetic. This high concentration at a specific location results in rapid block onset and greater block density, which often creates a differential blockade that can be controlled by dose.

Dose is described as volume multiplied by concentration. The concentration of the local anesthetic generally affects the density of the block, whereas the volume, within limits, affects the spread from the needle or catheter tip throughout the epidural space. Successful analgesia can be achieved with relatively small volumes and high concentrations of local anesthetics. Clinically useful doses are based on volumes that permit an even filling of the anterior and posterior epidural spaces at the level of insertion. For example, the suggested volumes per segment at the cervical and thoracic levels are 0.7 to 1 mL per segment, remembering that the spread will occur in both a cephalad and caudad fashion. Therefore, an initial total dose, usually less than 10 mL, will achieve a 10- to 14-dermatomal spread of local anesthetic. In contrast, when the local anesthetic is injected at the lumbar level, the volume of local anesthetic required is 1.25 to 1.5 mL per segment. A typical initial volume of 15 to 20 mL is required to ensure adequate anesthesia by blocking a total of 12 to 16 segments (6 to 8 segments above and below the catheter tip). It should also be remembered that spread of

blockade tends to occur faster in the cephalad direction from the catheter tip, possibly because thoracic nerve roots are smaller in diameter than large lumbar and sacral nerve roots.^{4,5,8}

Other factors thought to affect the level of blockade achieved with epidural anesthesia include height, weight, age, patient position during injection, pregnancy, and the speed or mode of injection. However, the clinical significance of these factors has been challenged. Correlations between patient height and weight and the spread of the epidural block are clinically insignificant, except perhaps, in the extremely tall, short, or morbidly obese patient. Studies have examined patients in the sitting and lateral positions during administration of epidural anesthetics and found small differences in spread and onset that favor the dependent portion of the patient's body. Therefore, provision of anesthesia to the sacral roots might be facilitated by having the patient sit up during the injection. In addition, leaving the patient on the operative side after the solution is injected may speed onset. However, these are clinically small differences and may not always be effective.

Drugs should be injected slowly into the epidural space to avoid rapid increases in CSF pressure, headache, and increased intracranial pressure. A rapid speed of injection has not been shown to increase the spread of anesthetic. In addition, incremental or bolus injection modes appear to have no influence on spread. The spread of epidural anesthetics may be three or four dermatomes greater in elderly patients, because age-related tissue changes create a less compliant and less leaky epidural space. Although conflicting data exist, some studies suggest that the epidural spread of anesthetics is greater in pregnant patients.^{4,5,8} Therefore, it is recommended that the volume of anesthetic solution administered to pregnant patients and elderly patients should initially be limited to 0.5 to 1 mL per segment when injected at lumbar levels.

The density of block is also more dependent on the concentration of local anesthetic used. The lower the concentration, the lower the effect the local anesthetic will have on the degree of sensory and motor blockade. Routinely a lower concentration of local anesthetic is used to facilitate analgesia (as in laboring analgesia) or to provide a sympathectomy. If the primary purpose of the epidural is to

provide complete surgical anesthesia, higher concentrations must be used. [Table 49.4](#) lists recommended volumes of local anesthetic based on the position of the catheter and the location of the intended surgical intervention. All solutions should be injected in increments of 3 to 5 mL every 3 minutes and titrated to the desired anesthetic level. With loading doses and intermittent injections, aspiration of the catheter should occur before any injection. This gradual administration of the medication slows the rate of onset of the anesthetic level and controls the development of the sympathetic blockade. After a loading dose is given, the anesthetic is maintained with either intermittent dosing or a continuous infusion technique.

TABLE 49.4
Recommended Doses for Epidural Analgesia

Procedure	Position of Catheter	Dose (mL)
Chest	T12–L2	8–12
Upper Abdomen		
Cholecystectomy	L2	12–16
Gastric resection	L2	12–16
Incisional pain	L2	7–10
Lower Abdomen		
Colon resection	L2	12–16
Repair of aortic aneurysm	L2	12–16
Retropubic prostatectomy	L3	12–16
Herniorrhaphy	L3	8–12
Incisional pain	L3	8–12
Pancreatic pain	L3	5–7
Hysterectomy	L3	10–14
Lower Extremities		
Anesthesia	L4	10–14
Sympathetic block	L2	5–7
Perineum		
Transurethral resection of prostate	L4	8–12
Vaginal hysterectomy	L4	8–12
Back and Flank		
Nephrectomy	L2	10–14
Vaginal Delivery		
First-stage labor	L3	5–7
Second-, third-stage labor	L3	10–12

Intermittent injections are most often used when high concentrations of local anesthetic (2% lidocaine or 0.5% ropivacaine) are administered. A continuous infusion is more appropriate when the goal of the epidural is to provide a consistent level of analgesia. Continuous infusions typically use a lower

concentration of local anesthetic solution (0.0625% to 0.125% bupivacaine or 0.1% to 0.2% ropivacaine), and the level of block is monitored on a regular interval basis. A continuous opioid infusion may also be used either as a sole agent or as an admixture with low concentrations of local anesthetic. Typical infusion rates range from as low as 2 mL/hr for concentrated hydrophilic opioid solutions, such as preservative-free morphine, up to 20 mL/hr for dilute solutions of local anesthesia (0.125% bupivacaine or 0.1% ropivacaine) used for postoperative or labor analgesia. Often continuous infusions will contain a dilute concentration of local anesthetic solution with an admixture of a low-dose lipophilic opioid such as fentanyl (1–5 mcg/mL), or sufentanil (1–1.5 mcg/mL). Epidural infusions of these mixtures augment the quality and duration of analgesia while limiting the side effects of any one drug.

Epidural Opioids

Opioids placed into the epidural space may undergo uptake into the epidural fat, systemic absorption, or diffusion across the dura into the CSF.⁸⁷ When administered via the epidural route, opioids produce considerable CSF concentrations of drug. Penetration of the dura from the epidural space into the subarachnoid space is influenced by lipid solubility and molecular weight. The administration of an epidural opioid by either an intermittent or continuous infusion has become common in many anesthesia practices. When an opioid is administered epidurally, it needs to cross from the epidural space through the dura to reach the opioid receptors located in the substantia gelatinosa in the spinal cord. Besides the physical barrier of the dura, epidural opioids also may be deposited in the fat and connective tissues in the epidural space, which may significantly increase the opioid dose required to achieve analgesia. In fact, to achieve adequate analgesia from epidurally administered opioids, the dose is increased by approximately 10 times the opioid dose administered intrathecally. The epidural space is also highly vascularized, and there is significant absorption of the opioids into the systemic circulation; however, the rate of absorption is dependent on individual pharmacokinetics and lipid solubility of the opioid. For example,

epidural administration of fentanyl and sufentanil (highly lipid-soluble opioids) results in a serologic level of opioid similar to that produced when the drugs are administered intravenously. When an opioid is administered by the epidural route, the onset of action and duration are dependent on the type of drug used. A faster onset and analgesic peak effect is achieved when a more lipophilic opioid is used versus an opioid that is more lipophobic. Epidural opioids can be administered by either a single bolus dose or a continuous infusion. A continuous infusion provides easier analgesic titration to patient requirements, which is especially important when a shorter-acting opioid such as fentanyl is used. Epidural opioids can also be administered using patient-controlled (assisted) epidural analgesia (PCEA), which is a hybrid of continuous infusion and patient-assisted boluses to titrate analgesic requirements based on individual patient needs. The goal is to establish a continuous or “basal rate” infusion to optimize the analgesic effect. The PCEA bolus component can then be preset by the anesthesia practitioner to meet individual patient requirements and used in the event of breakthrough pain.⁸⁷ Table 49.5 lists the opioids and dosages most commonly used to achieve epidural-based analgesia.

TABLE 49.5

Recommended Doses of Epidural Opioids

Analgesia		Continuous Infusion Rate						
Agent	Bolus Dose	Onset (min)	Peak (min)	Duration (hours)	Range (mL/hr)	Basal Rate (mL/hr)	PCEA Bolus (mL)	Interval (min)
Morphine	3–5 mg	20–30	30–60	12–24				
<i>Morphine 0.05%–0.1% solution</i>					1–6			
<i>Morphine 0.05%–0.1% + bupivacaine 0.0625%–0.125%</i>					3–6	3–4	1	20
<i>Morphine 0.05%–0.1% + ropivacaine 0.08%–0.2%</i>					2–4	3–4	10	20
Meperidine	25–100 mg	5–10	10–30	4–6				
<i>Meperidine 0.1%–0.25% bupivacaine 0.0625%–0.125%</i>					2–10	5	1	12
Hydromorphone	1 mg	10–15	20–30	8–15				
<i>Hydromorphone 0.05%</i>					0.8			
Fentanyl	50–100	5–10	20	2–6				

	mcg							
<i>Fentanyl</i> 0.001%–0.002%					4–12			
<i>Fentanyl</i> 0.001% + <i>bupivacaine</i> 0.0625%–0.1%					4–10	5	1	12
Sufentanil	10–60 mcg	5–10	20–30	4–6				
Sufentanil 0.0001%					10			

Extended-Release Epidural Morphine (DepoDur).

A sustained-release formulation of morphine sulfate (DepoDur; SkyePharma, San Diego, CA) is newly available for use in the treatment of acute postoperative pain. DepoDur consists of microscopic spherical particles with integral aqueous chambers separated by lipid membranes containing an encapsulated dose of morphine. DepoDur is unique in that it delivers standard morphine sulfate using DepoFoam technology. DepoFoam (also from SkyePharma) is a drug-delivery system composed of multivesicular lipid particles containing nonconcentric aqueous chambers that encapsulate the morphine sulfate, allowing the morphine to be released over an extended period of time (up to 48 hours) without a requirement for subsequent dosing.^{87,88} The half-life of DepoDur is dose dependent, but the DepoFoam technology allows for larger doses to be administered than could be given when conventional epidural injection is used. For example, a study done by Carvalho et al.⁸⁸ compared analgesia and side effects in groups of cesarean section patients receiving either a single epidural injection of 5 mg of preservative-free morphine or 5, 10, or 15 mg of DepoDur. After cord clamp, the authors noted that patients who received the 10- and 15-mg doses of DepoDur had significantly lower pain scores and analgesic requirements for the first 48 hours after cesarean delivery.

DepoDur is intended to be used as a sole agent and cannot be administered concomitantly with a local anesthetic solution. Because DepoDur is encapsulated by DepoFoam technology, studies have shown that administration of any local anesthetic solution may elicit a physicochemical interaction and cause a reduction in the sustainability of the DepoFoam to release the morphine over an extended period. This can result in an increase in the quantity of the encapsulated morphine released to the systemic circulation and place the patient at increased risk for respiratory

depression and hypotension. The full extent of this interaction is being investigated by the manufacturer. This recommendation for not mixing with local anesthetics does not preclude the anesthetist from testing the epidural catheter for possible subarachnoid or intravascular migration preceding injection, and it is recommended that a routine test dose be performed prior to injection of the DepoDur, with some added precautions. The manufacturer recommends that the test dose be administered using prescribed techniques, then the catheter should be flushed with at least 1 mL of 0.9% NaCl solution a minimum of 15 minutes prior to injection of the DepoDur. It has also been recognized that sustained levels of analgesia from DepoDur require a minimum dose of 10 mg. Current research shows that when a dose of 5 mg of DepoDur is administered, the terminal half-life of the morphine is comparable to a similar 5-mg dose of standard morphine.⁸⁸

Management of Epidural Anesthesia

After epidural administration of local anesthetic, the spread of the dermatomal block will continue and peak in an amount of time dependent on the factors previously mentioned and the local anesthetic solution used. Typically, the time to maximal spread is between 10 and 25 minutes, and the level of the block will regress over time; therefore, consistent monitoring of sensory dermatomal level should be performed. When the sensory level of the block has diminished by one or two dermatomes, as detected by the “scratch” or “ice” test used to denote dermatomal level, then another dose, 30% to 50% of the initial dose, is given to reestablish the initial level of anesthesia. It is important to perform consistent monitoring of the anesthetic level because tachyphylaxis, or the need for an increase in the dosage required to maintain an adequate level of blockade, may occur if the regression is allowed beyond two dermatomal segments. The phenomenon of tachyphylaxis is poorly understood but is more likely to occur with short-acting amides such as lidocaine or mepivacaine. It can be avoided by using longer-acting agents (e.g., bupivacaine, ropivacaine, and tetracaine) or using a continuous infusion device.

One of the most frustrating problems that can occur with epidural anesthesia is the phenomenon of an inadequate block, a

one-sided block or single-sensory dermatome segment that fails to achieve adequate anesthesia. A variety of techniques are used to deal with this phenomenon. Some anesthetists will attempt to increase the spread of the local anesthetic to the area of missed dermatomes by repositioning the patient with the unblocked side down (dependent) or by administering more local anesthetic solution. An inadequate block could be secondary to coiling of the epidural catheter or an anatomic abnormality. However, inadequate anesthesia during epidural anesthesia placement may be secondary to the technique used during identification of the epidural space. Studies have shown that using air during the loss-of-resistance technique may be a contributing factor in missed dermatomal spread of the local anesthetic. Studies by Beilin et al.,⁸⁹ Valentine et al.,⁹⁰ and Shenouda and Cunningham⁹¹ report that when air was used during a loss-of-resistance technique, a significant number of patients experienced “missed” dermatomal spread of the local anesthetic solution. They recommend using normal saline during catheter placement to minimize this complication.

Rarely, an epidural catheter passes through dura without penetrating the arachnoid membrane. This is sometimes thought of as intradural placement. Spread of the injected anesthetic in this situation can be very unpredictable. Anesthesia can range from a patchy, inadequate block to a rapid and high level of anesthesia requiring ventilatory support, similar to the total-spinal anesthetic complication. Fortunately, intradural catheter placement is rare, and complications can be avoided by the careful use of test doses, maintained vigilance, and a high index of suspicion. If an intradural catheter placement is suspected, the catheter needs to be removed and replaced after resolution of any side effects (e.g., hypotension, bradycardia). Additionally, it is recommended that the catheter be replaced at a dermatomal level more cephalad to the interspace previously attempted.^{5,14}

Complications of Epidural Anesthesia

As with spinal anesthesia, the hemodynamic changes seen with epidural anesthesia are attributed to sympathetic blockade and subsequent arterial and venous dilation. Use of plain local

anesthetic solutions in the epidural space to create a high level of blockade will decrease the mean arterial pressure, cardiac output, stroke volume, heart rate, and peripheral vascular resistance. The addition of epinephrine (usually a 1 : 200,000 to 1 : 400,000 solution) to the epidural local anesthetic solution diminishes and slows systemic uptake, resulting in lower plasma levels of the local anesthetic and prolongation of its duration of action. However, the epinephrine is thought to be absorbed systemically in low levels, thereby causing β_2 -adrenergic vasodilation. The result is lower arterial pressure and peripheral resistance when compared with spinal anesthesia. Treatments of these hemodynamic alterations are very similar to those used for effects of spinal anesthesia. They include ephedrine 5 to 10 mg, phenylephrine 50 to 100 mcg, or a low- to moderate-rate infusion of dopamine, keeping in mind the caveats for use of these potent vasopressors. Atropine or glycopyrrolate is also useful for the treatment of bradycardia.^{4,8}

One complication that is more prevalent with epidural anesthesia than spinal anesthesia is backache. The incidence of back pain after epidural anesthesia is between 30% and 45%, especially in the obstetric patient.¹⁵ There have been several studies that have identified various techniques to use to decrease the incidence and severity of back pain after epidural anesthesia. For example, Todd et al.⁹² analyzed what effect the addition of ketorolac to the dermal anesthesia solution would have on the overall incidence and severity of back pain after laboring epidural placement and delivery. These authors reported that the addition of 6 mg ketorolac to 3 mL 1% lidocaine dermal anesthetic solution resulted in a decrease in the incidence and severity of back pain in the postpartum period as compared with a similar group receiving 1% lidocaine solution alone for dermal anesthesia prior to entry of the epidural needle through the skin.⁹²

Other complications associated with epidural catheters are similar to those associated with spinal anesthesia and have already been discussed. As with spinals, the overall risk of PDPH is low. For placement of epidural catheters, the PDPH rate is 1% to 2%. However, epidural needles are large in diameter compared with spinal needles. Although the goal of an epidural catheter technique is to avoid puncture of the dura, an inadvertent rent created by a

17-gauge Tuohy is a rather large dural perforation and is referred to as a “wet tap” for the quite brisk free flow of CSF that can escape through the needle. With such a rent in the dura, the incidence of PDPH can be as high as 75% in young patients. Epidural catheters are also more likely to place a patient at risk for neuraxial anesthesia complications than the single passage of a smaller-gauge spinal needle because the catheter acts as a foreign body that remains within the patient. The catheter causes mechanical tissue disruption, acts as a physical irritant, may provide a path for infection, and will cause tissue trauma on removal, perhaps as much trauma as that associated with catheter placement. Therefore, although complications are rare overall, patients must be followed closely in the postoperative period for signs and symptoms of neurologic compromise such as spine ache, root pain, weakness, and bowel or bladder dysfunction.

Combined Spinal and Epidural Anesthesia

First described in 1937, the combined spinal epidural (CSE) anesthesia technique has risen in popularity and is used successfully for orthopedic, urologic, and gynecologic surgeries and for providing postoperative pain relief. It also has gained favor in the obstetric suite for providing anesthesia and analgesia for labor and delivery and for cesarean section.⁹³⁻⁹⁷

CSE anesthesia and analgesia offers the advantages of both spinal and epidural techniques while reducing or eliminating the associated disadvantages.^{5,53} The CSE technique is appropriately used in any setting in which the practitioner plans a spinal or epidural anesthetic and desires to exploit the advantages of each technique, usually the quicker onset of the spinal anesthetic combined with the flexibility of an epidural catheter.

History and Development

In 1937, Soresi described the sequential injection of local anesthetic, first into the epidural space, then into the subarachnoid space, using the same small-gauge spinal needle. Soresi described placing an epidural needle (without a stylet) into the epidural space using a hanging-drop technique and injecting 7 to 8 mL of procaine, then advancing the needle into the subarachnoid space, where he injected 2 additional mL of procaine. He reported the anesthesia lasted between 24 to 48 hours. His experience using this technique in more than 200 patients led him to state that “by combining the two methods many of the disadvantages of both methods are eliminated and their advantages are enhanced to an almost incredible degree.”⁹⁸

In 1979, Curelaru reported application of the CSE technique in 150 patients. He used a two-puncture technique; he placed an epidural catheter first, using a standardized epidural needle, followed by a subarachnoid puncture, using a spinal needle one or two interspaces below the level of the epidural puncture. Advantages of the technique included “the possibility of obtaining

a high-quality conduction anesthesia, virtually unlimited in time, the ability to extend over several anatomic regions the surgical field, minimal toxicity, the absence of postoperative pulmonary complications, and the economy." Disadvantages included "the need for two vertebral punctures, the longer induction time of anesthesia, and some difficulty in finding the subarachnoid space after catheterization of the epidural space."⁹⁹

Finally, in 1982 Coates⁹⁵ used a single-space technique in which a long spinal needle was inserted through the epidural needle to provide the spinal component of the CSE technique.⁹⁴ Coates stated that the technique was "simple, reliable and quick to perform." He was, however, concerned that "the theoretical hazards of this technique include the possible passage of the epidural catheter through the hole in the dura mater and the possibility of subarachnoid effects from epidurally injected drugs by passage through the hole in the dura." Eldor⁹⁶ described finding metallic particles while using the needle-through-needle technique, supposedly formed by abrasion of the inner surface of the epidural needle by the passage of the spinal needle. They were concerned that these particles might be introduced into the epidural space. In addition, they were concerned that uneven distribution of the spinal local anesthetic was possible. The delay, they theorized, inherent in introducing the epidural catheter after intrathecal administration of local anesthetic could affect the spread of the anesthetic. These concerns led to the development of a combined spinal-epidural needle with two separate conduits to allow the epidural catheter to be placed first, followed by the spinal puncture. Because the needle had two conduits, it allowed both techniques to be performed with one puncture at one interspace. This innovation led to the development of several needle types, each of which sought to improve on the others.

Equipment and Techniques

Two-Level Technique

The two-level technique is unique in that each component is performed separately at two different interspaces. An epidural catheter is inserted first, followed by a spinal anesthesia needle

placed one or two interspaces lower. The primary advantage of this technique is the ability to insert and test the epidural catheter first, then place the spinal anesthetic needle. Once the spinal needle is placed, no delay occurs in positioning the patient, which may be an important factor when using a hyperbaric spinal anesthetic solution. Prior placement of the epidural catheter is not entirely benign. Potential problems include the inability to distinguish the epidural test dose from the spinal block, inability to differentiate the epidural test dose from CSF, epidural catheter laceration by the spinal needle, misdirection of the spinal needle by the catheter, inability to obtain CSF because of compression of the dural sac by the test dose, and an increased risk of dural puncture by the epidural catheter.⁹¹ Other disadvantages include increased discomfort, tissue trauma, and morbidity associated with multilevel interspinous space penetration (e.g., backache, epidural venous laceration, hematoma, infection, and technical difficulties).⁹⁷

Single-Level Technique: Needle Through Needle

First described in 1982, the needle-through-needle technique involves insertion of an epidural needle at the appropriate interspace and then using the epidural needle as a guide for the spinal needle.^{92,93} A small (25-, 27-, or 29-gauge) pencil-point spinal needle is inserted through the epidural needle into the subarachnoid space, and local anesthetic is injected. The spinal needle is removed, and an epidural catheter is threaded into the epidural space. The epidural needle is removed, and the catheter is secured. The main advantages are related to performance of a single interspace insertion (e.g., less tissue trauma, backache, and associated morbidity). Disadvantages include the possibility of inadequate spinal block if catheter placement is delayed, potential for increased nerve-root trauma if paresthesias occur during catheter insertion, and the inability to reliably test the catheter with a preexisting spinal block. Inability to obtain CSF because of inadequate spinal needle length is a risk avoided by using the appropriate specialized needles.

Specialized Needles

Eldor⁹⁶ was the first to develop and patent a combined spinal-epidural needle with two channels, one for the epidural catheter, the other for the spinal needle. The needle is placed at the selected interspace, the epidural catheter is inserted through its designated conduit, and then the spinal needle is placed through its conduit. Once CSF is obtained, the chosen local anesthetic is injected, and the needle is removed. The catheter is taped in place, and the patient is positioned. Purported advantages and disadvantages are similar to those described for the single-level technique. Although the risk of metallic particle formation may be reduced, the risk of trauma to the interspinous ligaments is increased because of a larger needle diameter.

Several other needles have been developed, all seeking to minimize or eliminate potential problems.⁹⁶ To reduce external size, decrease needle abrasion, and allow for a direct angle of approach to the dura, a Tuohy needle was modified with a separate back-eye at the bend of the needle, thereby permitting straight passage of the spinal needle. These needles are subject to their own limitations and failure rates as well. The spinal needle can miss the back-eye hole and exit the epidural needle through the main orifice, as occurs in the needle-through-needle technique.

Sequential Technique

Rawal et al.⁹⁴ described a single-level “sequential” technique that was developed to minimize the hypotensive effects of the spinal component of CSE anesthesia for cesarean section. An epidural needle is placed at the selected interspace, and a low-dose (7.5 mg of hyperbaric bupivacaine) spinal anesthetic is placed using the needle-through-needle technique. The spinal needle is removed, the catheter is inserted and taped in place, and the patient is placed in the supine position with a left lateral tilt. After 15 minutes, the block is extended by titrating epidural local anesthetic until the desired level is achieved (1.5 to 2 mL for each unblocked segment). Although this technique takes longer to perform, it has been shown to decrease the frequency and severity of the hypotension seen with spinal anesthesia. This technique has also been applied in other types of surgery.

Agents

As discussed previously, local anesthetic agents and their concentration are chosen depending on the effects desired. Appropriate anesthetics for the spinal component include isobaric or hyperbaric 5% lidocaine with or without epinephrine, hyperbaric 0.75% (spinal) bupivacaine, and isobaric or hyperbaric 1% tetracaine. Appropriate anesthetics for the epidural component include 2% lidocaine with or without epinephrine, 0.5% or 0.75% bupivacaine, 2% or 3% 2-chloroprocaine, and 1% ropivacaine. The concentration of these agents may be adjusted to provide postoperative analgesia in combination with opioids such as morphine and fentanyl. All agents should be preservative free to reduce or eliminate any neurotoxic effects. Note that the bupivacaine liposome injectable suspension (EXPAREL) is not listed as it is only approved for infiltration and not for central neuraxial administration.

Management of CSE Anesthesia

Although the CSE technique may be used in any type of surgical procedure in which a spinal or epidural would be acceptable, this technique may be particularly well suited to providing analgesia and anesthesia in obstetric patients. The CSE technique offers several potential advantages over conventional epidural anesthesia and analgesia.⁹³

- Rapid onset of the intrathecal component for women who are in the later stages of labor and in significant pain and distress
- The use of intrathecal opioids (e.g., fentanyl, sufentanil, morphine, and meperidine) in early labor; the minimal-to-absent motor block associated with intrathecal opioids allows the patient to ambulate while in labor

The CSE technique for the laboring patient usually involves the placement of an epidural needle at the selected (usually lumbar) interspace, followed by the placement of the spinal needle using the needle-through-needle technique. Intrathecal opioids (5–15 mcg of sufentanil or 25–50 mcg of fentanyl) may be given alone or in combination with a small dose (2.5 mg of bupivacaine) of local

anesthetic, saline, or both. The spinal needle is withdrawn, and the epidural catheter is inserted. The epidural needle is removed, and the catheter is taped in place. The catheter can be activated at any time if supplemental analgesia or anesthesia is required. Standard testing of the epidural catheter before use is always recommended.

The CSE technique also can be used to provide anesthesia for cesarean section if required. If the patient already has an epidural catheter in place, a test dose (3 mL 1.5% lidocaine with 1 : 200,000 epinephrine) is given to rule out intrathecal and intravascular placement. After a negative test dose, incremental administration of 2% lidocaine, 0.5% bupivacaine, or 3% 2-chloroprocaine can be used to establish a level of surgical anesthesia.

If a catheter has yet to be placed, and if time allows, the anesthetist can proceed as with any new patient. After the spinal needle is placed, an intrathecal dose of local anesthetic (12–15 mg of 0.75% bupivacaine) with or without opioid (10–15 mcg of fentanyl, 0.2–0.3 mg of preservative-free morphine, or both) is given. The catheter is inserted and taped in place. The spinal anesthetic will set up quickly and allow for urgent (but maybe not emergent) delivery.

Despite the utility and flexibility of the CSE technique, several concerns related to its use exist. The first of these concerns is related to the use of intrathecal sufentanil and its associated hypotension.¹⁰⁰ Controversy exists with regard to whether intrathecal sufentanil causes clinically significant changes in blood pressure and fetal heart rate (fetal bradycardia). Purported mechanisms include pain relief, mild sympatholysis, and uterine hypertonus.^{101–103} Studies show no differences in outcome between CSE using intrathecal sufentanil and epidural anesthesia.^{104,105}

A second concern with CSE analgesia is the ability to ambulate after receiving intrathecal narcotics. The concern is related to possible motor weakness if low-dose local anesthetic is added and regarding the effects on blood pressure.¹⁰⁶ Hypotension appears within the first 30 minutes after intrathecal fentanyl but remains stable through ambulation and follow-up doses of epidural local anesthetic. Studies demonstrate the safety of allowing ambulation with no apparent deleterious effects.¹⁰⁷

A third concern with CSE technique in laboring patients is related to complications. Overall, the complications of itching and

hypotension, although bothersome, do not appear to significantly affect outcome or patient satisfaction.⁸⁹ CSE anesthesia is associated with faster onset, denser motor block, lower anxiety, lower preoperative and intraoperative pain scores, and greater patient satisfaction preoperatively. There were no significant differences in the incidence or severity of hypotension or nausea, the need for supplemental analgesics, or the postoperative assessments of intraoperative pain, anxiety, and satisfaction.¹⁰⁸ However, there is some data to indicate that when a CSE technique is used where intrathecal bupivacaine (3.125 mg) plus 5 mcg fentanyl is injected preceding epidural placement, CSE provides better first stage analgesia and less requirement for supplemental bolus epidural injections.¹⁰⁹

Complications of CSE Anesthesia

Spinal and epidural anesthesia both have their own associated complications as discussed. The CSE technique has the same complications and some additional unique complications. Therefore, as always, vigilance is prudent.

Failure to Obtain a Subarachnoid or Epidural Block

The failure rate for subarachnoid block alone ranges from 3.1% to 17%. With the single-level CSE technique for anesthesia, the range is 0% to 24.5%, and for the two-level technique, the range is 1.6% to 4%.¹¹⁰⁻¹¹² Failure with the single-level CSE technique may occur because the epidural needle is not in the epidural space, because the epidural needle is off midline, because the spinal needle is too short (or dull) and does not penetrate the dura, or because the angle of approach of the spinal needle is too oblique to puncture the dura. The overall failure rate of the epidural catheter has also been shown to be lower when the CSE technique is used as compared to when a conventional catheter is used. In a 2016 study by Groden et al.¹¹¹ they noted that catheter failure was approximately two times higher in the conventional epidural placement group compared to when the CSE technique was used. These same investigators noted that mean time to replacement between the groups was also

significantly prolonged in the CSE group.

One of the most important considerations is the length of the spinal needle, specifically, the length of needle that extends beyond the tip of the epidural needle.⁹⁷ Studies have shown an increased success rate when the tip of the spinal needle extends 7 to 15 mm beyond the tip of the epidural needle.^{112,113} The angle at which the spinal needle approaches the dura may also be important. As the spinal needle exits a standard epidural needle tip, the angle caused by the epidural needle's curve may be 4 to 5 degrees or more.¹¹⁴ This factor, combined with inadequate needle length, may result in failure to obtain CSF. This situation has led to the development of a modified Tuohy needle that has a separate back-eye at the bend of the needle to allow for a straight-on approach to the dura. Pan¹¹⁵ determined that the success rate for the needles exiting the correct hole ranged from 50% to 67%. The success rate can be improved to 81% to 94% by bending the spinal needle slightly in the direction of the epidural needle bevel and to 91% to 96% by orientating the epidural needle bevel upward.

Failure rates may also be directly related to level of experience with the technique and are not easily correctable. The problem of spinal needle displacement during connection of the syringe, aspiration, or injection of the local anesthetic has led to the development of "locking" devices that fix the spinal needle in the epidural needle once the dura has been punctured. Their efficacy has not yet been confirmed.

Catheter Migration

Another problem with the needle-through-needle technique is the possibility of catheter migration through the dural puncture caused by the introduction of the spinal needle.¹¹⁴ Studies that assessed the risk of catheter migration through a dural puncture site demonstrated little to no risk if the dural puncture was made with a 25-gauge or smaller spinal needle, but an increased risk if the dural puncture was made by a larger (18-gauge) Tuohy needle.¹¹⁶⁻¹¹⁸ Many factors may result in catheter placement in, or migration into, the subarachnoid space, including patient movement, undetected dural puncture with the epidural needle with subsequent catheter placement, and (least likely) diffusion of local anesthetic from the

epidural space into the subarachnoid space through the dural puncture. The prudent practitioner is advised to adopt a conservative approach that includes a high index of suspicion and frequent aspiration and testing of the catheter.

However, even the question of when to test the epidural catheter can be problematic. The purpose of the epidural catheter test dose is to rule out inadvertent placement or migration of the catheter into the subarachnoid space or into an epidural vein. A preestablished subarachnoid block may preclude the ability to reliably test for subarachnoid catheter placement and mask intravascular placement. To date, no published studies have demonstrated reliable detection of inadvertent subarachnoid catheter placement in someone with a preexisting spinal block.

Increased Spinal Level After Epidural Administration

The CSE technique is known to cause an increased spread of spinal anesthesia after injection of solutions through the epidural catheter. Although controversial, several theories may help explain this phenomenon. The first, the “volume effect” theory, states that the volume of fluid injected into the epidural space compresses the subarachnoid space and the CSF within it, thereby increasing the spread of the intrathecal local anesthetic. This effect has been documented clinically and by the use of contrast media and radiography. The second theory presupposes a “leak” or flow of local anesthetic from the epidural into the subarachnoid space through the dural puncture. This effect also has been demonstrated clinically and by radiography.^{119,120} Other radiographic studies have been unable to confirm these results.^{118,121}

Metallic Particles

Eldor and Levine¹¹⁰ noted the production of metallic particles when passing a spinal needle through a Tuohy epidural needle. Subsequently, Eldor^{122,123} has implied that scratches in the spinal needle and metallic particles may be associated with an increase in aseptic meningitis and cancer in patients who have received CSE anesthesia via the needle-through-needle technique. No studies

have been published to support these assertions, but several studies have examined the issue of metallic particle formation.¹²⁴ These studies used electron microscopy, atomic absorption spectrography, photomicrography, and microscopy; none were able to detect metallic particle formation.^{118,125}

Postdural Puncture Headache

Conflicting evidence exists regarding whether a greater risk of PDPH is associated with the CSE technique compared with conventional epidural anesthesia and analgesia. Both techniques involve the placement of an epidural needle, with its attendant risk of dural puncture. In addition, the CSE technique involves a dural puncture, usually with a small-gauge, pencil-point spinal needle. Because this type of spinal needle is associated with an extremely low incidence of PDPH, one would expect an equally low incidence with the CSE technique. A review of the literature on the CSE technique shows a PDPH rate between 0% and 2.3% in laboring patients.¹²⁶ Theoretic reasons for a low incidence with the CSE technique include the following:

- The epidural needle serves as an introducer for the smaller-gauge spinal needles and allows for a straight approach at the dura.
- CSF leakage through the dural puncture is abated because of the presence of the epidural catheter and fluids, which increases pressure in the epidural space.
- The spinal needle penetrates the dura at a slight angle, which may help dural fibers seal the hole on withdrawal.

Studies suggest that the use of intrathecal opioids as part of the CSE technique may offer a protective effect from PDPH.^{127,128} In addition, the success rate in obtaining CSF may be higher when the patient is in the sitting position, rather than the lateral position. The sitting position allows for correct midline placement of the epidural needle and makes it more likely that CSF will be obtained with the spinal needle (higher hydrostatic pressure). Both these factors contribute to minimization of the number of dural punctures and may decrease the risk of PDPH.

Infection

The incidence of infectious complications associated with epidural and spinal anesthesia has always been considered to be very low, in the range of 0% to 0.04%.^{30,129,130} However, perhaps because of close monitoring of this newer technique, an increase has occurred in the number of case reports of patients who have developed complications that may be associated with the use of the CSE technique. Bouhemad et al.¹³¹ cite several cases (three between 1994 and 1998) of bacterial meningitis associated with the use of CSE. The authors believed that potentially infectious skin matter was first introduced into the epidural space during the insertion of the epidural needle and was then introduced into the CSF by the passage of the spinal needle into the subarachnoid space. Because the CSE technique requires invasion of both the epidural and subarachnoid spaces, strict aseptic technique should be practiced. As with other complications associated with the use of CSE, further study of this area is warranted.

Neurologic Injury

Neurologic injury associated with spinal and epidural anesthesia is also very low, ranging from 0.02% to 0.1%, and is usually transient in nature.⁵ Although there does not appear to be any increased risk inherent in the CSE technique as compared with either spinal or epidural anesthesia alone, there have been several case reports of cauda equina syndrome in patients who underwent CSE anesthesia.^{132,133} In none of these cases was the cause ever identified. Possible causes include preexisting spinal deformity (present in one case), use of lidocaine (present in one case), and an intrathecal catheter (never proved or disproved).

A final concern with the use of the CSE technique is paresthesia on epidural catheter insertion. A preexisting spinal block may mask a significant paresthesia on catheter insertion and result in neurologic injury. Paresthesias during epidural catheter placement range in frequency from 20% to 44%.¹³⁴ However, studies show no significant difference in the frequency of paresthesias reported for either technique.^{112,134}

Caudal Anesthesia

Caudal anesthesia can be thought of as a distal approach to the epidural space. Therefore, anesthetics administered or catheters placed via the caudal route will act as epidural administered anesthetics, but first on the sacral dermatomes. A caudal technique is useful for perirectal surgery, urologic surgery, and orthopedic surgery of the lower extremity. Caudal techniques are especially useful in pediatrics but also can be used for labor and delivery and for chronic pain states. With the success of lumbar epidural catheters for labor and delivery, caudal anesthesia is rarely used in this population currently and is less likely to be used in the adult population in general. After the age of 12, sacral anatomy changes and bone growth makes identification of the epidural space by this approach difficult and the spread of anesthesia less reliable.⁸ Therefore, caudal anesthesia is most often used in combination with a light general anesthetic to augment postoperative analgesia in preadolescent pediatric patients.

Equipment and Techniques

The patient can be placed either prone or in a lateral position. The posterior iliac spines and the sacral hiatus are identified. Positioning the patient prone with the legs slightly apart, the heels rotated outward, and a pillow under the buttocks facilitates the palpation of the cornua of the sacral hiatus. In the lateral, Sims, or knee-chest position, identification of the cornua can be enhanced by adjusting the amount of hip flexion. Excess flexion can stretch the skin, making landmark identification difficult. An assistant is often useful when one is positioning patients who are anesthetized.

In pediatric patients, general anesthesia is usually induced, the airway and IV access secured, and the patient turned prone or placed in a lateral decubitus position. After aseptic preparation is performed, the index and second fingers of one hand are placed on the cornua of the sacrum, with the hand cephalad and against the patient's back. A 22- to 25-gauge short needle attached to a 10-mL syringe filled with local anesthetic is inserted midline between the

cornua at a steep angle to the skin into the sacral hiatus. Alternatively, a 20-gauge over-the-needle IV catheter is sufficiently long enough for the block, and the catheter can be passed into the epidural space while the needle is removed. This allows the anesthetist better control when administering the local anesthetic. The needle is inserted, with the bevel of the needle directed toward the sacrum. As the membranes are penetrated and the ventral canal of the sacrum is entered, a popping sensation can be felt. At this point the needle angle is lowered parallel to the sacrum and the spinal canal. The needle is advanced into the epidural space for a distance of 1 to 3 cm, but no farther than the second sacral interspace. The second sacral interspace lies 1 to 2 cm below a line drawn between the posterior iliac spines. The needle position is evaluated for entrance into the subarachnoid space or epidural veins via gentle aspiration and examination for CSF or blood return through the needle. Once the appropriate location of the needle is verified, the anesthetic is incrementally injected as with an epidural. During injection, the skin area above the end of the needle is palpated. Bulging over the needle tip indicates subcutaneous or superficial injection rather than injection into the epidural space. If the needle is in the subperiosteal area, resistance to injection is felt, and the needle must be repositioned.

Agents

In children, 0.5 to 1 mL of solution per kilogram of body weight is injected to reliably achieve a level of analgesia to the umbilicus. Bupivacaine or ropivacaine, in concentrations of 0.125% to 0.5%, are usually administered with epinephrine 1 : 200,000, to a maximum dose of 2.5 mg/kg body weight. These dosing regimens have been shown effective for children undergoing subumbilical surgical procedures, providing analgesia or anesthesia for the lower extremities and the abdomen, urogenital surgery, inguinal hernia repair, or orthopedic procedures with analgesia that lasts 3 to 5 hours postoperatively.^{8,135,136} Clonidine 1 mcg/kg of body weight added to the local anesthetic has been shown to be comparable with opioids that are added to enhance analgesia. Clonidine has fewer side effects than caudal opioids (e.g., delayed recovery, respiratory depression, and nausea).¹³⁷ Some patients may be unable to tolerate

the loss of lower-extremity motor control. These patients should be identified before the anesthetic is administered and be offered another technique. For example, infants too young to walk greatly benefit from caudal analgesia, but toddlers may be frightened by their inability to move their legs. Ropivacaine may have benefits over bupivacaine, because analgesia in the postoperative period is equivalent, but ropivacaine offers shorter duration of motor blockade and less risk of CNS and cardiotoxicity.^{8,135-138}

In adults, the principles of epidural drug administration should be followed, with use of a 3-mL test dose and incremental injections and aspiration. Only 12 to 15 mL is necessary for sacral anesthesia, and up to 20 to 30 mL offers sufficient spread for lower-extremity procedures to approximately the 10th thoracic dermatome. The spread of drug, duration of anesthesia, and desired level of anesthesia are less predictable than with epidural anesthesia because of the variability in the volume, content, and leakage of the caudal canal. The maximum recommended dose of lidocaine or mepivacaine is 10 mg/kg of body weight and 2.5 mg/kg of body weight for bupivacaine.⁸ All agents injected into the epidural or subarachnoid spaces should be preservative free.

Management of Caudal Anesthesia

Caudal anesthesia, like epidural anesthesia, is adaptable to a continuous catheter technique. However, if a Tuohy needle is used, the angle of the tip must be kept in mind when one attempts to pass the catheter into the epidural space. Management is similar to that with an epidural catheter.

Complications of Caudal Anesthesia

Caudal anesthesia has complications that are very similar to those of epidural anesthesia. The caudal canal has a sacral epidural venous plexus with vessels that can be unintentional recipients of a needle or catheter tip, with subsequent IV injection of local anesthetic. Dural puncture is also possible, although the dural sac usually ends in adults at the lower border of L2, and in infants the sac can extend to S4. High spinal punctures are less likely but have been reported. In addition, the anatomy of caudal anesthesia is

variable enough, especially in adults, to cause a high failure rate (10% to 15%) as the needle is unintentionally inserted into false passages. The proximity of the caudal canal to the rectum theoretically makes infection a potential risk, although clinically significant infection is rarely reported.^{8,139} The risk of infections, perhaps, will best be shown to be minimized with the use of chlorhexidine solutions instead of povidone-iodine solutions.¹⁴⁰

In 1899, Alice Magaw described the job of an anesthetist and best summarized the reality of the practice of regional anesthesia. She stated, "While one should be competent in the theoretical part of this important work, there is nothing so helpful to the anesthetist as the hard school of practical experience."¹⁴¹

Summary

Regional anesthesia techniques are a vital part of modern anesthesia practice. Our ability to understand and apply neuraxial anesthesia continues to evolve. These techniques are increasingly being used for all types of anesthetics, including many outpatient procedures. Their utility in providing for perioperative pain management has greatly enhanced our ability to provide comfort to our patients.

Regional Anesthesia

Upper and Lower Extremity Blocks

Jennifer Lynn Thompson

The benefits of peripheral nerve block techniques are numerous and include decreased incidence of nausea and vomiting, decreased postoperative pain and need for postoperative analgesics, better communication with and easier positioning of the patient, reduction in hospital stay, and increased patient satisfaction.¹⁻⁴

However, general anesthesia and regional anesthesia techniques are not exclusive, and often the most comprehensive care occurs when they are used in conjunction with one another.

The use of long-acting local anesthetics, peripheral nerve stimulators (PNSs), ultrasonography, and the placement of peripheral nerve catheters have significantly altered the landscape with respect to the practice of regional anesthesia and pain management. The best strategy for achieving maximum successful conduction block may be to use a combination of these techniques.² This chapter aims to present the key concepts and evidence relating to the use of peripheral nerve blockade.

Selection of Regional Anesthesia Techniques

When regional anesthesia is chosen for management of pain, the technique should be thoroughly discussed with the patient. During the informed consent process, the patient must understand the benefits, risks, potential complications and any alternatives that may be available before a specific technique is selected. Regional anesthesia is used extensively for surgical procedures involving the extremities or the lower abdomen, for the management of labor pain, for the management of obstetric procedures, and for the control of chronic pain syndromes. Frequently, regional anesthesia techniques are used in combination with other interventions to provide analgesia or anesthesia during surgical or obstetric procedures. These techniques provide the patient with additional anesthesia options when selecting an anesthetic for surgical or obstetric procedures. It is not only the preferred technique for obstetrics, but for many other types of procedures.⁵⁻¹⁰

The administration of regional anesthesia to patients with a difficult airway or a full stomach presents both benefits and potential risks. The use of regional anesthesia permits the patient to retain upper airway and pharyngeal reflexes while providing surgical anesthesia as long as the sedation is reduced to a minimum. Furthermore, blockade of the sympathetic nervous system theoretically results in increased gastric and intestinal motility, decreasing residual gastric contents. However, this benefit may be negated by the perception of pain and anxiety that accompanies injury. If hypotension develops, the patient may have increased nausea and vomiting. Regional anesthesia should not be considered an alternative to securing the airway. If the patient's airway cannot be secured in a safe manner in an emergent situation, use of a regional anesthetic should be avoided. The airway concerns must be addressed before the anesthetic technique is initiated so that the patient's safety is maximized.² A list of peripheral nerve blocks and their indications can be found in [Table 50.1](#).

TABLE 50.1**Peripheral Nerve Blocks and Their Indications**

Interscalene	Analgesia to the shoulder and upper arm
Supraclavicular	Analgesia to the entire upper extremity distal to the shoulder
Infraclavicular	Analgesia to the elbow and below
Axillary	Analgesia distal to the elbow
Selective blocks at the elbow and wrist	Analgesia to various areas of the wrist and hand
Intercostal	Analgesia to the chest and upper abdominal wall
Transversus abdominis plane	Analgesia to the anterior abdominal wall
Psoas compartment	Anesthesia or analgesia to the entire hip, thigh and medial aspect of the lower leg
Femoral	Analgesia to the anterior thigh and knee, medial aspect of the lower leg
Fascia iliaca	Analgesia to the hip, femoral shaft and knee
Sciatic	Analgesia below the knee sparing the area of the medial side of the lower leg (saphenous distribution)
Popliteal	Analgesia for surgery below the knee sparing the area of the medial side of the lower leg
Ankle	Anesthesia or analgesia to the foot and distal ankle

Contraindications

Contraindications to the selection of regional anesthesia techniques are few, and some remain controversial. Absolute contraindications include patient refusal, uncorrected coagulation deficiencies, and infection at the site of the block.⁴ The most significant absolute contraindication to regional anesthesia is patient refusal. Each patient must be informed of the acceptable techniques that will provide analgesia or anesthesia. The discussion must include the advantages and disadvantages of each proposed technique, as well as the risk involved. The patient's questions should be answered completely. This level of communication helps the practitioner uncover misconceptions while educating the patient about regional anesthesia.⁴

Another absolute contraindication to regional anesthesia is systemic anticoagulation. Certain medications and systemic diseases can cause alterations in the coagulation profile. The long-term or extended use of aspirin products or nonsteroidal antiinflammatory drugs (NSAIDs) can prolong bleeding time without significantly altering other laboratory data. The patient's medical and pharmacologic history may provide information about increased bleeding time. Asking the patient about frequent bruising

without injury may reveal the first indication of a problem. If injury to a large epidural vessel were to occur during the performance of either a spinal or an epidural technique, significant bleeding could develop in the epidural space. A similar injury to the axillary artery might result in a hematoma that would produce further complications. Injury to a large vessel in the neck during an interscalene technique could result in compromise of the airway.⁴

Despite the benefits of peripheral nerve block, there is no scientific consensus for its specific use in the anticoagulated patient; therefore the overarching guidelines for the use of regional anesthesia (including neuraxial blocks and peripheral nerve blocks) in patients receiving anticoagulation are generally followed. Due to the variations in depth, diffusion of local anesthetic agents, and the possibility of local compression during performance of peripheral nerve blocks, the safety of the technique should be further investigated. Guidelines for the use of regional techniques in a patient receiving anticoagulation therapy are given in [Chapter 38, Table 38.7](#).

Finally, if the patient has an active infectious process present near the location at which regional anesthesia is to be performed, another type of anesthetic should be chosen due to the risk of spreading or seeding infection. Sepsis and systemic infection are considered relative contraindications and the risk to benefit ratio should be carefully weighed before peripheral blockade is performed.⁴

Patients with a history of a documented local anesthetic allergy should undergo further evaluation in a controlled situation by an allergist. If a regional technique is used in a patient with an allergy, a local anesthetic that is unrelated to the suspected agent should be selected. For example, if the patient is allergic to an ester anesthetic, an amide anesthetic agent should be chosen. A true allergy to local anesthetic agents is rare and the problem may be caused by a preservative in the anesthetic solution or by a metabolic product of local anesthetic hydrolysis (para-aminobenzoic acid). If local anesthetics are administered, then the patient should be medicated with histamine-1 and histamine-2 receptor blockers.¹¹⁻¹³

Patients who have difficulty understanding the procedures to be performed or who are unable to cooperate with the practitioner

should undergo another type of anesthesia. Patients with chronic neurologic disorders must be well informed of the potential effects of the regional anesthetic technique. Clear documentation of any deficits prior to the procedure is essential. The regional anesthetic may not cause an increase in the patient's symptoms; however, if symptoms of the disorder increase or deterioration results, the regional anesthetic technique may be identified as the cause of the **Problem** (Box 50.1).^{14,15}

Contraindications to Peripheral Nerve Blockade

Absolute Contraindications

- Patient refusal
- Infection at injection site
- Coagulopathy or other bleeding diathesis

Relative Contraindications

- Uncooperative patient/psychiatric disease
- Preexisting neurologic disease

Complications of Peripheral Nerve Blockade

General complications associated with regional anesthesia include local anesthetic systemic toxicity (LAST), direct nerve injuries, vascular injury or hematoma, and infection.^{4,16} Each individual block has specific complications and risks and will be discussed later in the chapter.

The potential of an intravascular injection is increased when local anesthetics are injected into the tissues around nerves and blood vessels. It is especially important to be prepared for a LAST reaction when performing peripheral blocks because high volumes are frequently injected into vascular areas. A complete discussion of the management of LAST is given in [Chapter 10](#). A functional intravenous line and all the necessary equipment and drugs for the treatment of LAST must be immediately available prior to administration of any regional block.¹⁶

The anesthetist must also be prepared to manage complications that occur after the block has been established or during the postanesthesia recovery period. The choice of needle type may play a role in peripheral nerve injury when the injury is caused by intraneural injection. Nerve fascicles migrate away from the needle tip, especially when using a short-beveled needle. The use of a long-beveled needle, which tended to impale the nerve, resulted in a greater number of injuries, especially if the needle tip was oriented transversely to the nerve fibers. Patients with preexisting nerve pathology, such as diabetic neuropathy, are at increased risk for prolongation of the block and local anesthetic neurotoxicity. The absence of a motor response to peripheral nerve stimulator (PNS) does not exclude the possibility of intraneural needle placement, and seeking nerve stimulator confirmation of apparent intraneural needle position noted on ultrasound can lead to unnecessary trauma to the nerve.¹⁷

Significant bleeding events from vascular puncture are uncommon in patients without known bleeding diathesis, or those receiving therapeutic anticoagulation. Although spinal hematoma is

the most significant hemorrhagic complication of regional anesthesia due to the catastrophic nature of bleeding into a fixed and noncompressible space, the associated risk after plexus and peripheral techniques remains undefined. For patients undergoing deep plexus or peripheral block, the American Society of Regional Anesthesia and Pain Medicine (ASRA) suggests following the recommendations regarding neuraxial techniques be similarly applied. The ASRA guidelines discussing regional anesthesia and antiplatelet and anticoagulant medications are listed in [Chapter 38, Table 38.7](#).¹⁸

Local inflammation is an infrequent occurrence with the use of a peripheral nerve block technique; however, bacterial colonization rates of the catheter are high. Even so, the incidence of local infection, abscess formation, and sepsis is rare. The use of strict aseptic technique is vital.¹⁶

Discharge Information

A useful tool to provide patients who have received a regional anesthetic is a discharge information sheet ([Box 50.2](#)). This sheet provides the patient with information about the nature of the anesthetic and what to expect as the block resolves. Most importantly, it should alert the patient to contact the anesthesiologist in the event of certain symptoms that may occur after discharge, which may indicate a potential complication of the regional anesthetic.

Regional Anesthesia Discharge Information Sheet

What Is Regional Anesthesia?

Regional anesthesia is the injection of a local anesthetic (such as Novocain) near the nerves that sense pain from the area of your body that had surgery. Regional anesthesia is the same as a dentist injecting local anesthesia into your mouth—it numbs an area of your body so that procedures won't hurt.

What Should I Expect After Regional Anesthesia?

After regional anesthesia, the area of your body that had surgery will be numb for several hours. In fact, the area may be numb for up to 24 hours. The block will wear off slowly, and your first sensations will be a tingling feeling in the area that was numb.

What Should I Do When the Block Starts to Wear Off?

As soon as you develop any feeling in the numb area, begin taking the pain medications that has been prescribed for you. It is much easier to treat pain before it begins than try to catch up after it has started.

What Should I Be Careful About After Regional Anesthesia?

Because part of your body is numb, you won't know if you injure it. You should take care to protect that part of your body from being bumped, cut, and otherwise harmed, and you should look at it frequently to make sure it isn't injured. You should also avoid lying on the numb area while you sleep.

What Complications Should I Watch for After Regional Anesthesia?

The site of your body where the injection was made will be sore for a few days. This pain should go away with any over-the-counter pain-relief medicine (e.g., Tylenol, Advil). It is not uncommon for the area that was numb to have strange sensations (e.g., mild numbness, tingling) for a few days after the block.

If you experience any of the following changes, you should immediately phone your health care provider:

- Sensation doesn't begin to return to the numb area after 24 hours.
- The area that was numb regained sensation but is becoming numb again.
- The skin in the numb area turns blue or feels cool.
- There is persistent pain in the area that was numb, even several

days after the surgery.

Electrical Stimulators in Regional Anesthesia

Peripheral nerve stimulators are valuable tools in the practice of regional anesthesia. Although ultrasound-guided blocks have become more common, nerve stimulator techniques may still be used for select blocks or as an adjunct to an ultrasound technique.¹⁹

Electrical stimulator devices provide a controlled stimulating pulse of variable amplitude that is administered through a conducting device. Location of neural fibers is improved without the need for eliciting repeated paresthesias. Specialized shielded needles have been designed to localize the distribution of the stimulating charge to the tip of the needle. This characteristic reduces confusion from wide-field stimulation of the area around the nerve, thereby enhancing the isolation of the appropriate nerve fibers.²⁰

The negative lead is attached to the skin with an electrocardiogram electrode, and the positive lead is attached to the needle. Most electrical devices are equipped with an adjustable amplitude from 0 to 5 mA, with a digital readout of the amplitude. The needle must be advanced slowly, and the amplitude of the unit is adjusted as the needle approaches the nerve.^{19,20}

When this technique is used, the stimulator should not be turned on until the needle has entered the skin. This measure reduces the discomfort experienced by the patient during the initial advancement of the needle. The patient must be instructed to identify discomfort verbally and to not move during the advancement of the needle.^{19,20} The use of light sedation helps the patient tolerate the procedure, maintain sufficient alertness to respond to the stimulus, and be cooperative.

Use of an electrical stimulator device can assist the practitioner during the administration of nerve block anesthesia to patients with sensory perception difficulties or neural degeneration, such as that experienced during end-stage renal disease.¹⁹ Such a device can be used for enhancing any technique, including ultrasound-guided nerve block, in which identification of specific nerve roots improves

the success of the block and reduces the amount of medication required for anesthesia of the nerve root.

During a brachial plexus block, the stimulator is adjusted to deliver 2 mA after the needle has been introduced into the subcutaneous tissues. As the needle approaches the sheath, the amplitude is continuously reduced and the needle is adjusted so that the muscle response to the stimulus is maintained. When the needle enters the sheath, the amplitude should be reduced to 0.5 mA. The lower amplitude decreases the discomfort experienced by the patient while enhancing the ability to accurately identify the neurovascular bundle. The goal is maintenance of motor stimulation with minimal amplitude, thereby approximating the needle tip to the target nerve. When a motor response is elicited with less than 0.2 mA, there is a chance the tip is intraneural and the practitioner should not proceed with injection.¹⁹

Patients may complain of aching or weakness along the path of the stimulated nerve after the regional anesthesia is terminated. This phenomenon is seen after the posterior tibial or the common peroneal nerves are stimulated. Severe or prolonged discomfort occurs when the stimulus is delivered over a long period or at a high current. The response to a stimulus with a lower amplitude is often adequate and results in less discomfort. Placement of the negative electrode has been important in the enhancement of electrotranslocation of the nerve. If the path of the nerve fiber is located under the negative electrode, a lesser stimulus produces a significant response.^{19,20}

Ultrasound-Guided Regional Anesthesia

The technology and clinical understanding of anatomic sonography has evolved greatly over the past decade. In anesthesia departments throughout the United States, ultrasound-guided regional anesthesia (UGRA) has become a routine technique and has arguably become the gold standard for performing regional anesthetic nerve blocks.^{21,22} Direct visualization of the distribution of local anesthetics with high-frequency probes can improve the quality and avoid complications of peripheral nerve blocks. Ultrasound guidance enables more accurate needle position and monitoring of the distribution of the local anesthetic in real time. The advantages over conventional guidance techniques, such as nerve stimulation and paresthesia elicitation, are significant. The key requirement for successful regional anesthetic block is to ensure optimal distribution of local anesthetic around nerve structures. This goal is most effectively achieved under sonographic visualization. Advantages of using ultrasound-guided techniques are noted in [Box 50.3](#).^{23,24} When compared with other forms of nerve localization, UGRA decreases performance time and onset time, and therefore decreases the time for surgical readiness from regional anesthesia. The quality of peripheral nerve block is also improved and fewer blocks require supplementation or conversion to general anesthesia compared to blocks placed with PNS. Additionally, the use of ultrasound guidance reduces the incidence of paresthesia, as well as vascular punctures.²⁵

Advantages of Using Ultrasound Guidance for Nerve Blocks

- Direct visualization of the nerves and adjacent anatomic structures
- Observing the local anesthetic spread in real time
- Detecting variations in anatomy

- Faster onset times
- Lower incidence of supplemental anesthesia or conversion to general anesthesia
- Improvement in block quality
- Use of lower, more precise doses of local anesthetics
- Possible increase in safety
- Less painful administration compared with nerve stimulator techniques
- Improved patient satisfaction

Empirically, by allowing for the use of smaller volumes of local anesthetic, as well as visualization of the real-time interaction of the needle, the nerve, and the local anesthetic, it appears the risk of LAST or neuronal toxicity will be reduced.^{16,23,26} An interesting report noted that novice trainees learn the technique at variable rates but generally require 28 supervised trials before competency is achieved.²⁷

A medical ultrasound machine operates at frequencies between 2 and 13 MHz. The average wavelength of an ultrasound beam is less than 1 mm. This limits the use of ultrasound technology to structures that are 1 mm in diameter or larger. In general, higher-frequency ultrasound probes (10–13 MHz) are best suited for visualizing structures less than 4 cm deep from the skin. For deeper structures, lower-frequency ultrasound probes (2–5 MHz) are more clinically useful.²³

The handheld probe emits and collects the ultrasound waves in a fan-shaped beam, which is represented on the display screen in a two-dimensional plane. The on-screen vertical axis represents the distance an anatomic structure or block needle is from the ultrasound probe, whereas the horizontal axis represents the distance to the right or left of the center of the probe. Therefore the ultrasound waves are used to construct an image of the “slice” of tissue centered on and beneath the ultrasound probe, much like

single images on a computed tomography (CT) scan.²³

The standard ultrasound image is rendered in shades ranging from white to black, depending on the amount of energy that returns to the probe from structures being examined. Hyperechoic tissues reflect a large amount of the ultrasound waves back to the probe and therefore appear white. Hypoechoic tissues reflect fewer ultrasound waves and therefore appear as shades of gray. Anechoic areas do not reflect ultrasound waves and therefore appear black. The amount of reflection of ultrasound waves back to the probe is dependent on the amount of resistance to passage of the waves through a particular tissue. This characteristic is known as *acoustic impedance*. Differences in acoustic impedance at tissue interfaces results in the ability to identify specific anatomic structures. Understanding these concepts, along with a thorough knowledge of anatomy, will allow the practitioner to identify structures on ultrasound. For example, bone has much greater acoustic impedance as compared to soft tissue; therefore the interface between these two tissues will produce a hyperechoic image. Veins appear as a round, easily compressible anechoic structure, whereas arteries are pulsatile and not as easily compressible. Nerves may appear either hyper- or hypoechoic depending on their location in the body.²⁸

Ultrasound images can produce transverse (short-axis, cross-sectional) views or longitudinal (long-axis, parallel) views. In a short-axis view, cylindrical structures, such as nerves or vessels appear as circles. By rotating the ultrasound transducer 90 degrees, a long-axis view of the same structure produces a linear view.²³

The orientation of the needle to the ultrasound probe during the administration of a regional anesthetic block is typically described in relationship to the image plane. The in-plane or axial/longitudinal approach allows the entire length of the needle (including the tip) to be visualized within the plane of the ultrasound image. In contrast, the out-of-plane, or tangential/short axis approach allows only the cross section of the needle to be visualized as a hyperechoic dot where it pierces the plane of the ultrasound image (Fig. 50.1). The in-plane approach is favored when possible because it permits visualization of the entire length of the needle at all times; however, the anatomy associated with

certain blocks may necessitate the use of the out-of-plane approach.²³

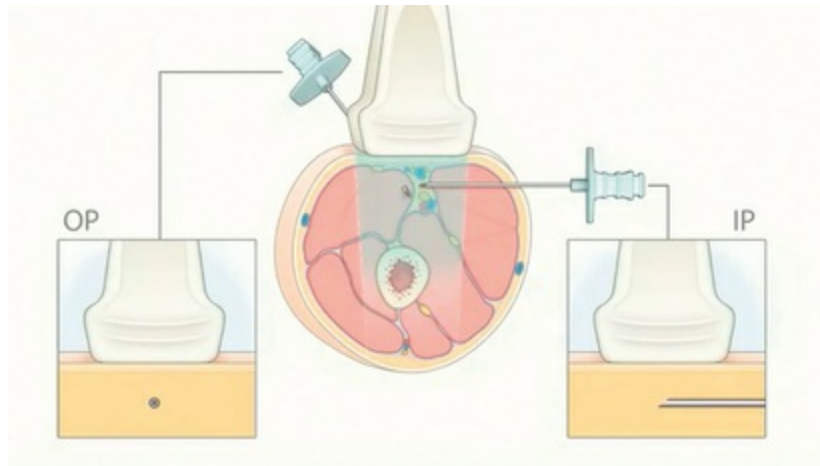

FIGURE 50.1 In-plane (IP; axial/longitudinal) and out-of-plane (OP; tangential/short axis) needle orientation and the image representation on ultrasound.

The basic movements when scanning with the ultrasound probe are often referred to as the *ART maneuvers* (Fig. 50.2):

FIGURE 50.2 The “ART” maneuvers for the ultrasound probe. Alignment (A): Sliding the transducer along the skin over a structure helps to identify it and define its lengthwise course. Rotation (R): Rotation of the probe clockwise or counterclockwise allows for viewing structures on both a long and short axis view. Tilting (T): A tilt of the probe in either direction can optimize image quality by maximizing the angle of incidence of the beam to the target structure.

Brachial Plexus Anesthesia

Applied Anatomy of the Brachial Plexus

An understanding of brachial plexus anatomy is mandatory if effective clinical application of regional block techniques of the upper extremity is to be achieved. This includes familiarity with muscle, facial, and vascular anatomy in relation to the origin and distribution of the brachial plexus. The brachial plexus is a large network of nerves that extend from the neck through the axilla and innervate the upper extremity (Fig. 50.3). It is composed of ventral rami (roots), trunks, divisions, cords, and their terminal branches. The supraclavicular portion of the plexus, including the five primary ventral rami and the three nerve trunks and their six divisions, lies in the posterior triangle of the neck. The infraclavicular portion of the plexus, including the three cords and their four terminal branches, lies in the axilla. These nerves combine, divide, recombine, and divide again as they pass between the anterior and middle scalene muscles, through the posterior triangle of the neck, and into the axilla, where they end in the five terminal branches that supply the upper extremity. The resulting nerve pathway, when pictured and contemplated in two dimensions and without the associated bone, muscle, and vascular structures, often leads to difficulty in understanding and applying this textbook anatomy in the clinical setting. When learning brachial plexus blockade, the value of augmenting written material with an apprenticeship with experienced anesthetists cannot be overestimated.³⁰⁻³²

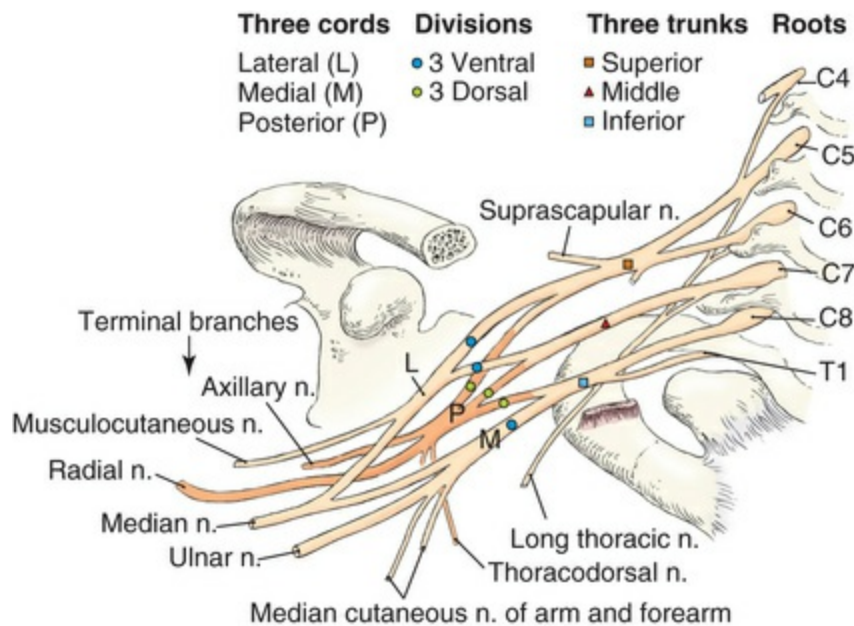

FIGURE 50.3 Derivation of the brachial plexus from the cervical spine. *n.*, Nerve.

The archetypal brachial plexus is formed by the rami from the fifth (C5) to the eighth (C8) cervical nerves and the first thoracic (T1) nerve. In a small percentage of individuals, the fourth cervical (C4) or the second thoracic (T2) nerve or a combination of the two contributes to the plexus. After the nerve roots pass the lateral border of the scalene muscles, they reorganize into trunks. The rami from C5 and C6 combine to form the superior or upper trunk, and the ramus from C7 continues alone as the middle trunk. The rami from C8 and T1 combine to form the inferior or lower trunk, which lies on the first rib posterior to the subclavian artery. The nerve trunks are enveloped by a fascial “sheath,” the origins of which are from the posterior fascia of the anterior scalene muscle and the anterior fascia of the middle scalene muscle. This forms a closed space at this level known as the *interscalene space*, or, more generally as the *sheath of the brachial plexus*.^{30–32}

Cadaver studies have demonstrated the existence of extensive velamentous septa that can form compartments around the contents of this sheath. These septa appear to be incomplete and therefore may not function as mechanical barriers to the spread of local anesthetics. Indeed, a single injection of local anesthesia into this sheath commonly produces complete block of the upper extremity. Nevertheless, anatomic variations do exist, and it is possible that in certain individuals, septa occur that isolate nerves,

resulting in so-called “patchy blocks” by preventing exposure to the injected local anesthetic. It has also been shown that injection even outside the sheath can produce neural blockade, albeit with a considerably greater latency period. Failure to allot a sufficient amount of time to perform an upper extremity block and in particular to allow it to “set up” generally produces an unsatisfactory result.³⁰⁻³²

At the lateral border of the first rib and posterior to the clavicle, each of the three trunks divides into ventral and dorsal divisions. These divisions are of significant clinical importance to application and evaluation of brachial plexus blockade because the ventral divisions generally supply the ventral (flexor) portion of the upper extremity, and the dorsal divisions generally supply the dorsal (extensor) portions. As these divisions enter the axilla, the three posterior divisions combine to form the posterior cord, the anterior divisions of the superior and middle trunks combine to form the lateral cord, and the anterior division of the inferior trunk continues to become the medial cord. At that point, the cords are named according to their position in relation to the axillary artery. At the lateral border of the pectoralis minor muscle, each of these cords divides into two branches that reorganize to form the peripheral nerves of the upper extremity. The lateral cord divides and generates the musculocutaneous nerve and the lateral root of the median nerve. The medial cord divides and generates the ulnar nerve and the medial root of the median nerve. The posterior cord divides to generate the axillary and the radial nerves.³⁰⁻³²

Understanding the anatomic relationships that result as the nerve cords give rise to the terminal nerve branches and knowing the areas of the upper extremity these branches innervate are of paramount importance in the clinical application, evaluation, and supplementation of brachial plexus block. The branches of the lateral and medial cords (median, ulnar, and musculocutaneous nerves) predominantly supply the ventral portions of the upper extremity, and the branches of the posterior cord (radial and axillary nerve) predominantly supply the dorsal portions. However, in certain areas of the upper extremity, such as the posterior portion of the fingers and hand, there exists considerable cutaneous representation of the “predominantly ventral” median

and ulnar nerves.³⁰⁻³²

The radial nerve (C5 to C8 and T1) is the major nerve supply to the dorsal extensor muscles, such as the triceps, of the upper limb below the shoulder. It supplies sensory innervation to the extensor region of the arm, forearm, and hand. The musculocutaneous nerve (C5 to C7) supplies the flexor muscles, such as the biceps, brachialis, and coracobrachialis, of the ventral portion of the arm. It supplies sensory innervation to the lateral aspect of the forearm between the wrist and elbow as the lateral antebrachial cutaneous nerve. The median and ulnar nerves pass through the arm and provide sensory and motor innervation to the forearm and hand. The median nerve (C6 to T1) is better represented than the ulnar nerve in the forearm, where it supplies most of the flexor and pronator muscles. It also supplies sensory innervation to the ventral portion of the thumb, the first and second fingers, the lateral half of the third finger, and the palm of the hand. The ulnar nerve (C8 and T1) is better represented than the median nerve in the hand, where it supplies motor innervation to most of the small flexor muscles. It has no sensory innervation of the forearm but supplies sensation to the medial part of the third finger, the entire fourth finger, and the remaining portion of the palm of the hand.³⁰⁻³²

Approaches to Brachial Plexus Block

Frequent injury of the hand, arm, and shoulder, combined with the accessibility of the nerves of the brachial plexus, has encouraged the development of regional anesthesia techniques for surgical procedures of the upper extremity, as well as the diagnosis and control of pain.²⁸ The widespread use of upper-extremity regional anesthesia is the result of numerous factors, including the availability of equipment to locate and deliver local anesthetics to the nerves of the plexus, the development of local anesthetics that can be applied alone and in combination to produce an appropriate duration of action for the procedure at hand, and the variety of techniques and approaches that can be used.

The four primary approaches for anesthetizing the brachial plexus are interscalene, supraclavicular, infraclavicular, and axillary. The requirement for anesthesia of the upper arm and shoulder is most often accomplished through use of the interscalene

approach. If coverage of the shoulder is not needed, the supraclavicular approach is one of the most consistent and efficient techniques to block all portions of the upper extremity. However, the superior portion of the lung is close to the needle insertion site, and inadvertent puncture can potentially cause a pneumothorax. The infraclavicular block is a safe and simple technique for providing surgical anesthesia of the lower arm, with an efficacy comparable to other approaches. Advantages of the infraclavicular approach include a lower likelihood of tourniquet pain and more reliable blockade of the musculocutaneous and axillary nerves when compared with a single-injection axillary block.^{33,34} Because of the ease of performance, the relatively high success rate and low incidence of complications, and the ability to produce anesthesia of the forearm and hand, the other frequently used technique is the axillary approach.

The decision to use regional anesthesia as compared with general anesthesia (which may be viewed by the surgeon as failure-free and more expedient) for elective and emergency surgical procedures of the upper extremity requires a strong commitment to and expertise in the use of these techniques. As with any regional anesthetic block that does not provide adequate anesthesia, the need to immediately convert to general anesthesia is possible.

There are multiple approaches to local anesthetic block of the brachial plexus. The choice of approach should be based on several factors, including patient considerations, the location of the planned surgical intervention, and especially the skill and experience of the anesthesia practitioner. Although surgical site and practitioner preference often drive the decision regarding the technique that is used, the patient's body habitus, comfort, and coexisting disease and the nature and location of the injury are as important, if not more so, as these other concerns. Patient-related considerations should be weighed in the context of the risk of potential complications associated with a given approach, technique, and local anesthetic solution.³⁴ [Table 50.2](#) lists the approaches to the brachial plexus and tips.

TABLE 50.2**Approaches to the Brachial Plexus**

Approach	Clinical Tips	Ultrasound Tips
Interscalene	<ul style="list-style-type: none"> • Best for surgeries of the shoulder • The ulnar nerve is often spared • To better visualize the scalene muscles, have the patient forcibly inhale • Slightly posterior and caudal needle approach 	<ul style="list-style-type: none"> • Blocks at the level of the roots/trunks • Superficial block • Tilting the transducer has a great effect on the image quality • Anatomic variations include direct nerve root penetration of the anterior scalene muscle
Supraclavicular	<ul style="list-style-type: none"> • Immediately medial to the first rib is the cupola of the lung • Risk of pneumothorax 	<ul style="list-style-type: none"> • Blocks at the level of the divisions • The brachial plexus appears just lateral to the subclavian artery • Needle may require multiple redirections to allow for local anesthetic spread throughout the divisions
Infraclavicular	<ul style="list-style-type: none"> • Abduction of the arm, while not necessary, may allow for easier identification of the axillary artery • Brachial plexus depth is 2.5–3 cm in slender patients • If punctured, the axillary artery may be difficult to compress 	<ul style="list-style-type: none"> • Blocks at the level of the cords • Injecting on the posterior cord will result in a more complete block • The needle crossing two muscle fascial planes makes this blocks more painful than others.
Axillary	<ul style="list-style-type: none"> • The arm must be abducted • Musculocutaneous nerve must be blocked separately • Risk of local anesthetic systemic toxicity (LAST) 	<ul style="list-style-type: none"> • Blocks at the terminal branches • Median, radial and ulnar nerve lie around the axillary artery • Musculocutaneous nerve lies deep to the belly of the coracobrachialis muscle

Interscalene Approach.

The interscalene approach to the brachial plexus was first described in 1970 by Dr. Alon Winnie. The interscalene approach is the most proximal brachial plexus block and is typically used to provide anesthesia for surgical procedures involving the shoulder and proximal humerus. It is the only technique that can provide adequate anesthesia and analgesia to the shoulder and the rest of the upper extremity. It is important to note that the ulnar nerve and its peripheral distribution to the forearm and hand is often spared with this technique.³⁵

With the patient in the supine or a lateral position, the anesthetist asks the patient to lower the shoulder on the side of the proposed anesthetic and surgery site to pull the shoulder away from the brachial plexus, intentionally trying to stretch the neck muscles and improve visualization and access. The patient's head can then either be turned so that the patient looks away from the area of the anesthetic or remain in a neutral position. The cricoid cartilage ring is then palpated just below the thyroid cartilage. This anatomic landmark correlates to the vertebral body of C6 and the corresponding area of the transverse process called *Chassaignac's*

tubercle. If firm pressure is applied, it is possible to feel the transverse process of C6 and to elicit a paresthesia in most patients. A straight line is drawn posteriorly to cross over the sternocleidomastoid (SCM) muscle, and the lateral border of the SCM is palpated. If this border is difficult to assess, the patient can be asked to raise the head against gentle resistance and then relax. Posterior to this border is the anterior scalene muscle; after rolling the fingers over the belly of the muscle, the anesthetist palpates for the groove between the anterior and middle scalene muscles (interscalene groove) with two fingers (Fig. 50.4). This is the level of the trunks of the brachial plexus (Fig. 50.5). If the patient is instructed to take a fast, deep breath through their nares, the scalenus muscles will contract and the groove is easier to identify. It is worth noting that the external jugular vein often overlies the interscalene groove at the level of C6.^{35,36}

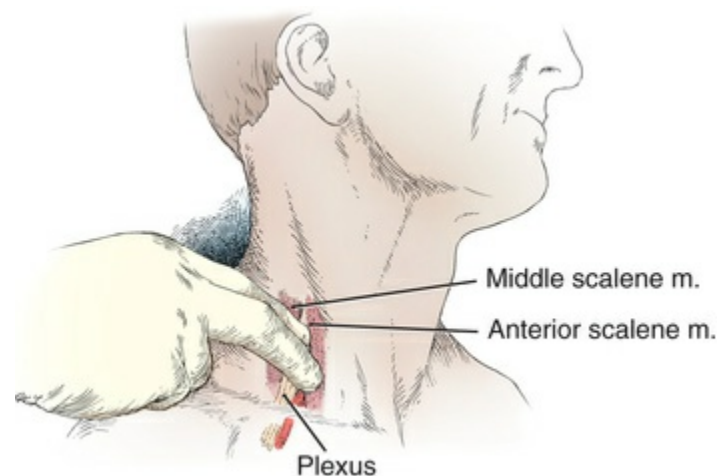

FIGURE 50.4 Technique for identifying the anterior and middle scalene muscles and the major vessels so the interscalene perivascular technique can be accomplished.
m., Muscle.

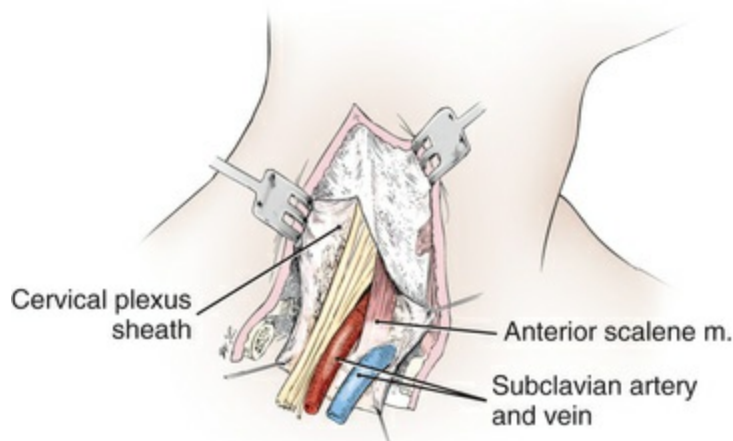

FIGURE 50.5 Three trunks of the cervical plexus are revealed lying alongside the subclavian vessels. *m.*, Muscle.

After cleansing the patient's skin, an intradermal skin wheal of local anesthetic is made at this point on the groove. A 22-gauge, insulated B-bevel needle, usually $\frac{1}{2}$ inches long, is inserted gently through the skin wheal perpendicularly to the skin and then angled slightly posterior and caudad. The needle is attached to the nerve stimulator and an intravenous extension tube with an anesthetic-filled syringe, and slowly advanced until the desired motor twitch response is elicited. The nerve stimulator current is lowered to minimize excessive current to the patient and to ensure proper needle position. After gentle aspiration is negative for blood or cerebrospinal fluid, a test dose of 1 mL of local anesthetic solution is injected. A fade will be observed in the quality of the motor twitch experienced by the patient. This indicates that the needle is probably within the brachial plexus sheath. If no subjective symptoms of local anesthetic systemic toxicity are present, incremental injections of 3 to 5 mL of local anesthetic, each followed by aspiration to detect blood, are administered until the intended volume is given. In adult patients, the volume is usually 25 to 35 mL.³⁴⁻³⁶

Potential Problems.

Due to its close proximity to the injection site the phrenic nerve is also blocked, resulting in ipsilateral diaphragmatic hemiparesis with the interscalene approach. Although the healthy patient is rarely symptomatic, the provider should use caution and consider

this when caring for a patient with significant pulmonary compromise. Other problems that may arise include subarachnoid or epidural injection, intravascular injection (especially in the vertebral artery) and, rarely, pneumothorax (Fig. 50.6).³⁴⁻³⁶

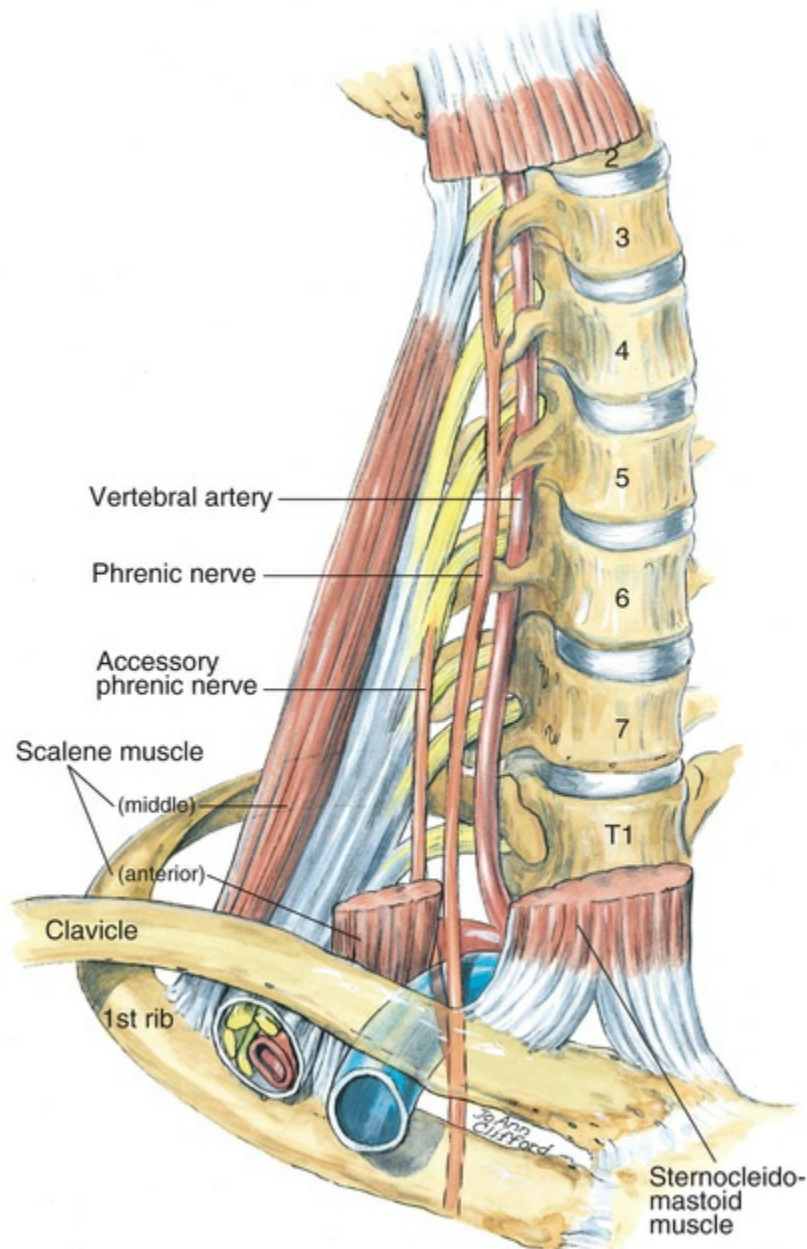

FIGURE 50.6 Note the proximity of both the phrenic nerve and the vertebral artery to the location of the interscalene block. (From Farag E, Mounir-Soliman L. *Brown's Atlas of Regional Anesthesia*. 5th ed. Philadelphia: Elsevier; 2017:30.)

Ultrasound-Guided Interscalene Block.

The patient is placed in the supine position with the head rotated toward the nonoperative side and a high-frequency ultrasound probe is placed at the level of the first rib. The anchoring landmarks to be visualized are the subclavian artery and the first rib. The ultrasound probe is then slid from the first rib up to the level of, or just below, the cricoid cartilage, where the brachial plexus is visualized as a group of hypoechoic circular structures lying between the anterior and middle scalene muscles (Fig. 50.7). Alternatively, the probe is placed at the cricoid cartilage and scanned from medial to lateral, over the SCM muscle, until the scalene muscles, as well as the roots of the brachial plexus within the scalene groove, are identified. The needle is inserted posterior to the plexus, in-plane to the ultrasound beam, with the tip of the needle coming to rest in close proximity to the roots of the brachial plexus (Fig. 50.8). Local anesthetic solution is injected under direct observation. The local anesthetic solution should create an expanding hypoechoic area that surrounds and engulfs the nerve plexus (Fig. 50.9).³⁴⁻³⁶

FIGURE 50.7 **A**, Transverse view of the brachial plexus at the lateral border of the sternocleidomastoid muscle, at the level of the posterior interscalene space between the anterior and the median scalene muscles. **B**, Structures labeled and the needle tip is near the roots of the brachial plexus. *ASM*, Anterior scalene muscle; *MSM*, median scalene muscle.

Continuous Catheter Technique.

Postoperative pain control after upper extremity surgery requires adequate analgesia not only at rest but also for incident pain. Especially after joint surgery, mobilization is required, as is the need to assess neurologic function. The use of brachial plexus catheters for the surgical anesthetic can have significant benefits by reducing postoperative analgesic requirements, including superior control of incident pain, and can be extended to aid in postoperative rehabilitation of the patient.³⁷

Continuous administration of local anesthetics via a brachial plexus catheter inserted at the cervical level can markedly improve analgesia and decrease opioid requirements. The advent of cheaper and more reliable pump technology has given rise to a significant growth in the use of continuous peripheral nerve blocks, especially continuous brachial plexus blocks.³⁷

Under strict sterile technique, a 22-gauge, insulated block needle should be advanced at the level of C6, or the cricoid cartilage, into the anterior and middle scalene groove and directed 45 degrees in a caudal, dorsal, and medial angle to reduce the risk of a punctured vertebral artery or inadvertent subarachnoid or epidural placement. The practitioner may feel a slight “pop” as the needle enters the sheath. Before placement of the catheter, the patient should be instructed to report any paresthesia experienced. Use of an insulated needle and a nerve stimulator or ultrasound technology may allow more accurate placement, reduce the risk of intraneuronal injection and trauma, and reduce time for placement of the catheter. When the desired motor stimulation is identified (i.e., movement in the upper or lower arm) the current should be gradually reduced to 0.5 mA with continued stimulation to ensure close proximity to the neural target. Normal saline, 5 to 10 mL, should then be injected incrementally with intermittent aspiration to guard against accidental intravascular injection. The addition of normal saline will expand the sheath and allow for the passage of the continuous catheter. The catheter should be inserted 3 to 5 cm and secured at the skin. Local anesthetic solution in a volume of 30

to 35 mL should now be injected incrementally, with intermittent aspiration to guard against accidental intravascular injection and to ensure that the continuous catheter works. Continuous infusions of 0.125 to 0.25 mL at a rate of 4 to 6 mL/hr have been shown to be effective.³⁷⁻³⁹

Supraclavicular Approach.

The patient is positioned supine with the head facing the nonoperative side. In addition, some practitioners may place the patient's bed in a 30- to 45-degree head-up position. The area above and including the clavicle on the surgical side is cleansed and draped.

The pulsations of the subclavian artery in the plexus are behind and below the clavicle, just above the superior surface of the first rib; the artery is palpated behind the midpoint of the clavicle. The anesthetist uses the nondominant hand to palpate for pulsations behind and 1 to 2 cm above the clavicle at this point and uses the dominant hand to place a skin wheal of local anesthetic immediately lateral to this site. Through the skin wheal, the 22-gauge, insulated B-bevel needle, attached to a nerve stimulator, is advanced perpendicularly to the skin, inward, and caudad until a motor twitch is noted in the distal upper extremity (Fig. 50.10). The nerve stimulator current is lowered to minimize excessive current to the patient and to ensure proper needle position. After gentle aspiration is negative for blood, a test dose of 1 mL of local anesthetic solution is injected. A fade will be observed in the quality of the motor twitch experienced by the patient. This indicates that the needle is probably within the brachial plexus sheath (Fig. 50.11). If no subjective symptoms suggesting toxicity reactions are present, incremental injections of 3 to 5 mL of local anesthetic followed by aspiration to detect blood are administered until the intended volume is given. In adult patients, the volume is usually 25 to 35 mL.^{39,40}

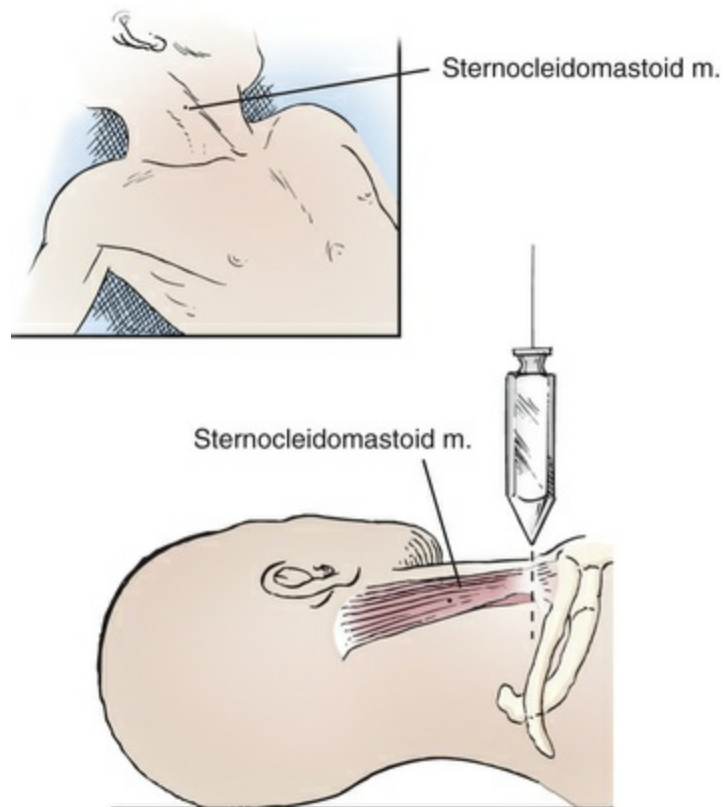

FIGURE 50.10 The patient is placed in the supine position with the head supported and turned toward the opposite shoulder. *m.*, Muscle.

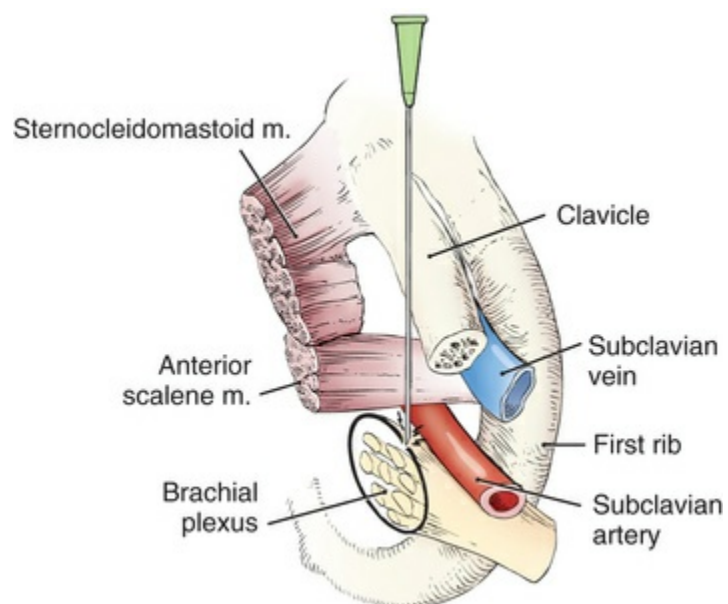

FIGURE 50.11 The needle enters the sheath of the brachial plexus at the farthest possible distance from the subclavian artery. *m.*, Muscle.

Potential Problems.

The most important complication associated with a supraclavicular approach is pneumothorax. The pleura of the lung is immediately inferior to the first rib, and careful needle placement, as described previously, is imperative. If landmarks are difficult to define, if the patient is very thin, or if the pleura of the lung is unusually high, the incidence of pneumothorax may increase. The development of a hematoma after unintentional subclavian artery puncture may be difficult to compress and must be closely observed. The anesthetist should watch for the onset of Horner syndrome (i.e., triad of miosis, partial ptosis, and loss of hemifacial sweating) as a positive sign of a successful block.⁴⁰

Ultrasound Guided Supraclavicular Block.

The supraclavicular approach is the first described method for anesthetizing the brachial plexus. Due to its high complication rate with a blind technique, it quickly fell out of favor with the advent of alternative approaches. However, the more recent use of ultrasound guidance has brought this old technique back into use.⁴¹ Performance of a supraclavicular block under ultrasound guidance has been shown to provide a block that is faster in onset, lasts longer, is safer, and is of better quality than when a nerve stimulator technique is used.⁴²

The ultrasound probe is rested on the clavicle and scanned medial and lateral until the anechoic, pulsatile subclavian artery is observed above the level of the first rib. Superolateral to the artery, the divisions of the brachial plexus can be viewed as a “grape-like” cluster of hypoechoic oval structures. Deep to the subclavian artery, the first rib may be viewed as a hyperechoic line with shadowing below (Fig. 50.12). After local skin infiltration, the needle is inserted just above the clavicle with a slight cephalad angle in a lateral to medial direction. It is best to position the needle tip at the junction of the first rib and the subclavian artery (often referred to as the *corner pocket*) and deposit local anesthetic until the hypoechoic spread can be seen surrounding the nerves. A volume of 30 to 35 mL should be sufficient, although markedly lower doses have been recommended to reduce the risk of complications.⁴¹

FIGURE 50.12 Transverse view of the brachial plexus lateral to the subclavian artery at the level of the first rib. SA, Subclavian artery; BP, divisions of the brachial plexus, which are reflected as hypoechoic structures.

Infraclavicular Approach.

The infraclavicular approach to brachial plexus blockade is most useful for patients undergoing procedures of the elbow, forearm, or hand. It is sometimes referred to as a *high axillary block* and is appropriate when an axillary block is preferred but the patient is unable to abduct the arm for placement. Unlike the axillary block, the infraclavicular approach blocks the musculocutaneous and axillary nerves more consistently.^{37,43}

Whereas various approaches are described in the literature, the lateral approach, due to its reduced risk of axillary artery and pleural puncture, will be described here. The patient is positioned supine with the head neutral or turned to the nonoperative side and the arm either straight at their side or with the hand on the abdomen. The skin is prepped and draped in a sterile manner. The anesthetist identifies the medial aspect of the coracoid process and a 22-gauge needle is inserted through a skin wheal 2 cm caudad and 2 cm medial from this location in a vertical parasagittal plane. The first twitch response noted is usually from the musculocutaneous nerve resulting in elbow flexion. A more distal response in the

hand, either flexion or extension, is required to successfully achieve complete anesthesia of the hand.^{37,43} A technique is described in the literature for identifying which cord the needle is nearest by close examination of the 5th digit (pinkie). Stimulation of the lateral cord will result in lateral movement of the pinkie, flexion represents the medial cord and extension, the posterior cord.⁴⁴ Incremental dosing of approximately 20 to 30 mL of local anesthetic is usually sufficient for the block.^{37,43}

Potential Problems.

The benefit of the infraclavicular block is the lack of neuraxial or pulmonary complications. However, the risk of hematoma from puncture of the axillary artery or vein may be difficult to tamponade due to its location. Care should be taken to avoid vascular puncture.^{37,43}

Ultrasound Guided Infraclavicular Block.

Position the ultrasound probe just medial to the coracoid process and perpendicular to the clavicle. The axillary artery is visualized as a round pulsatile anechoic structure and the compressible axillary vein usually lies caudad to the artery. With the left side of the ultrasound screen oriented as cephalad, the cords are identified as follows: the lateral cord at 9 to 10 o'clock; the medial cord at 4 to 5 o'clock; and the posterior cord at 6 to 7 o'clock. Using an in-plane approach, the needle is inserted cephalad to the probe and advanced caudad at a 30-degree angle posterior to the axillary artery toward the posterior cord for the most complete block. A test dose of D5W can be performed prior to local anesthetic injection to visualize spread and confirm needle tip placement. Injection of 20 to 25 mL of local anesthetic around the posterior cord will usually produce a sufficient block.^{37,45}

Axillary Approach.

The axillary approach to anesthesia of the brachial plexus is best suited to surgical procedures at or below the elbow (hand and forearm). However, an injury to the hand or forearm such as a fracture, which also limits the range of motion of the extremity because of patient discomfort, reduces the versatility of this

approach. Under these conditions, patient comfort must be weighed against the need for profound anesthesia of the hand or forearm, often in the presence of a full stomach and the desire to avoid general anesthesia. In this instance, an infraclavicular block should be considered instead.⁴³

The patient is placed in the supine position, with the arm to be blocked abducted 90 degrees from the body. The forearm is flexed to 90 degrees and rested parallel to the long axis of the body. The anesthetist uses the index and third fingers to identify the axillary artery, starting at the lateral margin of the pectoralis major muscle high in the axilla. Insertion in the mid to lower axilla is just as effective; however, it reduces the chances that a local anesthetic will reach the point at which the musculocutaneous nerve leaves the sheath. A well-defined, localized pulsation of the axillary artery is more important to successful blockade than the point at which needle insertion occurs within the axilla. After appropriate preparation of the skin, a local anesthetic intradermal skin wheal is raised just proximal and superior to the palpating index finger. During needle insertion, moderate digital pressure should be applied to the artery to minimize the distance between the skin and subcutaneous tissue and the neurovascular bundle. An appropriate needle connected to a sterile extension tubing and syringe containing 50 mL of local anesthetic is inserted through the skin wheal. At this point the technique diverges, depending on the end-point used to determine when the needle tip lies within the sheath. These end-points include the loss-of-resistance technique or penetration of the axillary artery (transarterial technique).^{34,46}

Potential Problems.

Axillary block complications are infrequent due to the distance of this block from the neuraxis. Depending on the technique utilized, systemic uptake of local anesthetic and subsequent toxicity appears to be the most concerning and frequent complication.⁴⁷

Loss-of-Resistance Technique.

The loss-of-resistance technique uses a distinct change in tissue resistance, often described as a *pop*, as the needle penetrates the fascia and enters the sheath. After the axillary artery is identified, a

22-gauge, $\frac{1}{2}$ -inch, short-bevel (B-bevel) needle is inserted medial to the artery at approximately a 90-degree angle to the skin (Fig. 50.13). Use of a short-bevel needle enhances the loss-of-resistance sensation on penetration of the sheath; however, the drag associated with the attachment of an extension tubing decreases this sensation. Some practitioners disconnect the extension tubing and observe the free needle for a pulsatile movement associated with the needle tip's close proximity to the axillary artery. This is considered a further indication of correct needle placement within the sheath, but it does not guarantee proper placement. The needle is then advanced medially an additional half to 1 inch just inferior to the axillary artery.³⁴

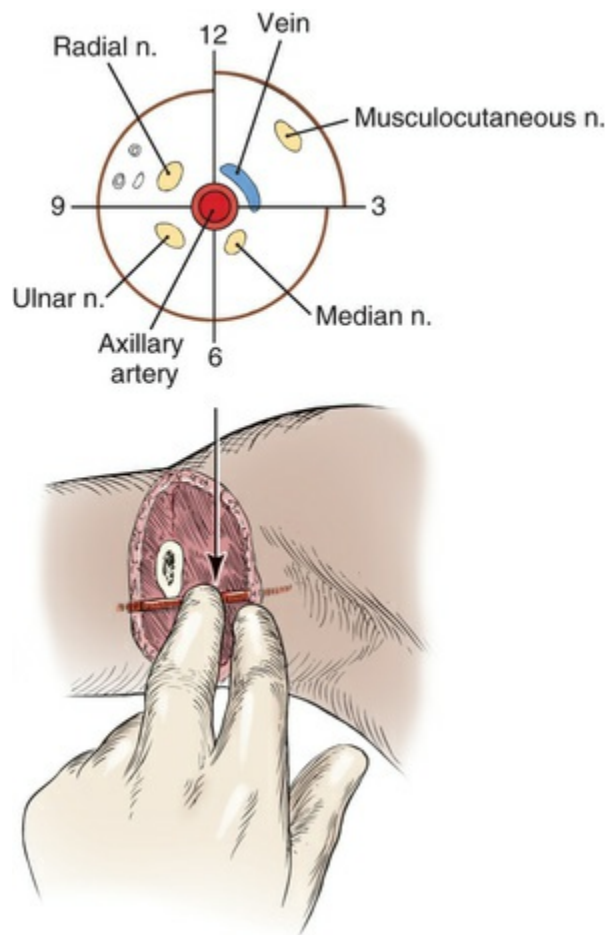

FIGURE 50.13 Identification of the axillary artery in preparation for the axillary block. *n.*, Nerve.

Before local anesthesia is injected, the patient is instructed to

immediately inform the anesthetist if symptoms indicative of rapid intravascular uptake or direct intravascular injection occur. These include dizziness, tinnitus, metallic taste in the mouth, circumoral numbness or tingling, visual disturbances, and muscle twitching. If epinephrine has been added to the local anesthetic to reduce vascular absorption of the solution, the patient may also be instructed to report the sensation of having a “rapid” heartbeat.³⁴

The needle is held fixed in position, and an assistant gently aspirates the syringe while the operator observes for blood in the extension tubing, which would indicate that the needle has entered the axillary artery or vein. In the absence of frank blood in the aspirate, a 3- to 5-mL test dose of the local anesthetic solution is injected and the patient observed and queried for the existence of any of the vascular warning symptoms for a minimum of 1 minute. Barring an untoward event, the remainder of the local anesthetic solution is injected in 5-mL increments, with each injection preceded by gentle aspiration and observation for blood in the extension tubing. During the injection, firm pressure should be applied with several fingers to the area immediately behind the needle insertion site to prevent retrograde flow of the anesthetic solution. Injection of each 5 mL of local anesthetic should be considered a “test dose,” because unrecognized penetration of the artery or rapid uptake of the local anesthetic remains a possibility throughout the procedure.³⁴

When 40 mL of the local anesthetic solution has been injected, the needle is withdrawn to the level of the skin in preparation for field block, if desired, of the musculocutaneous, medial brachial cutaneous, and intercostobrachial nerves (Fig. 50.13). These nerves may require individual blockade because they exit the sheath high in the axilla (musculocutaneous and medial brachial cutaneous) or lie outside the sheath altogether (intercostobrachial). If care is taken to apply continuous digital pressure immediately below the site of needle insertion during injection of a 40-mL bolus of local anesthetic solution, and the arm is adducted after injection, anesthesia of the musculocutaneous nerve and its terminal distribution, the lateral antebrachial nerve (sensory innervation to the lateral forearm from the elbow to the wrist), can be achieved.³⁴

Before the needle is withdrawn from the skin, the

musculocutaneous nerve can be independently blocked by injecting 3 to 5 mL of the remaining local anesthetic into the body of the coracobrachialis muscle. The coracobrachialis muscle is located immediately superior to the axillary artery and inferior to the biceps brachialis muscle. After block of the musculocutaneous nerve has been performed, the needle is again withdrawn to the level of the skin and redirected inferior and perpendicular to the artery into the subcutaneous tissue.³⁴

The remaining 3 to 5 mL of local anesthetic is injected into the subcutaneous tissue as the needle is advanced to the hub. This subcutaneous “bracelet” of local anesthetic produces conduction block of the medial brachial cutaneous and intercostobrachial nerves necessary to prevent discomfort if a tourniquet is to be used. After completion of the block, the arm is immediately adducted and held close to the body to promote the cephalad spread of the local anesthetic solution, which can be obstructed by the abducted humeral head.³⁴

Transarterial Technique.

The transarterial technique uses intentional penetration of the axillary artery and aspiration of blood as the end-point for determining that the needle is within the sheath. After the axillary artery is identified, a local anesthetic skin wheal is raised directly above the artery at the planned point of needle insertion (see [Fig. 50.13](#)). A 22-gauge needle is inserted perpendicularly to the skin and advanced slowly until blood is aspirated into the extension tubing by an assistant, who provides gentle aspiration of the syringe. The needle is then advanced along the same plane until blood can no longer be aspirated because the bevel has exited the posterior wall of the artery. Care must be taken to avoid advancing the needle through the posterior wall of the sheath after the artery is exited, which would result in deposition of the local anesthetic outside the sheath ([Fig. 50.14](#)).^{34,46}

FIGURE 50.14 Axillary block: needle insertion.

Before local anesthetic is injected, the patient is instructed to immediately inform the anesthetist if symptoms indicative of rapid intravascular uptake or direct intravascular injection occur. The needle is held fixed in position, and an assistant gently aspirates the syringe while the operator observes for blood in the extension tubing, which would indicate that the needle has entered the axillary artery or vein. In the absence of frank blood in the aspirate, a 3- to-5 mL test dose of the local anesthetic solution is injected, and for a minimum of 1 minute, the patient is observed for and queried regarding the existence of any of the symptoms previously noted.

If signs and symptoms associated with local anesthetic systemic toxicity are absent, then the remainder of the local anesthetic solution is injected in 5-mL increments, with each injection preceded by gentle aspiration and observation for blood in the extension tubing. To prevent retrograde flow of the anesthetic solution, firm pressure with several fingers should be applied to the area immediately behind the needle insertion site during the injection. Injection of each 5 mL of local anesthetic should be

considered a “test dose,” because unrecognized penetration of the artery or rapid uptake of the local anesthetic remains a possibility throughout the procedure. When 40 mL of the local anesthetic solution has been injected, the needle is withdrawn to the level of the skin in preparation for field block, if desired, of the musculocutaneous, medial brachial cutaneous, and the intercostobrachial nerves, as noted previously.^{34,46}

Ultrasound-Guided Axillary Block.

With an ultrasound-guided axillary block, the patient is positioned supine and a high-frequency ultrasound probe is placed in the axilla at the crease formed by the pectoralis major and biceps muscles with the ultrasound beam positioned perpendicular to the axillary artery. The anchoring landmarks to be visualized are the axillary artery and the terminal nerve branches of the plexus located in a variable fashion around the axillary artery. The median nerve can be readily visualized because it is located in close proximity to the axillary artery and tracks down to the cubital area of the elbow. The ulnar nerve is located medial to the artery and remains closer to the skin surface than the median nerve as it tracks down to the proximal forearm. The radial nerve is located just below the artery (Fig. 50.15).⁴⁷

FIGURE 50.15 Transverse view of the axillary segment of the brachial plexus. AA, Axillary artery; AV, axillary vein;

Bi, biceps muscle; *CB*, coracobrachialis muscle; *H*, humerus; *M*, median nerve; *MC*, musculocutaneous nerve; *R*, radial nerve; *TM*, triceps muscle *U*, ulnar nerve.

A 22-gauge, 2-inch needle is inserted anterior to the plexus in-plane to the ultrasound beam (Fig. 50.16) and advanced until the needle tip comes to rest in close proximity to the terminal branches of the brachial plexus; 20 to 30 mL of local anesthetic is injected under direct observation. The local anesthetic solution should create an expanding hyperechoic area that surrounds and engulfs the nerve plexus (Fig. 50.17).⁴⁷

FIGURE 50.16 Needle inserted in-plane in the axilla.

FIGURE 50.17 Transverse view of the axillary portion of the brachial plexus with a needle positioned just below the axillary artery and the formation of a hyperechoic area as a result of local anesthetic injection. AA, Axillary artery; M, median nerve; R, radial nerve; U, ulnar nerve.

The musculocutaneous nerve is located between the coracobrachialis and pectoralis major muscles and is usually separated from the radial, median, and ulnar nerves at the level of the axilla (see Fig. 50.15). It generally cannot be blocked by the injection of local anesthetic into the axillary sheath, but may be blocked independently using a 2-inch, 22-gauge needle in an in-plane or out-of-plane position relative to the ultrasound beam approach. The musculocutaneous nerve will appear as a large, singular hyperechoic structure with small, internal hypoechoic fascicles. A volume of 5 to 10 mL of local anesthetic solution is injected under direct observation.⁴⁷

Selective Blocks at the Elbow

Several other blocks of the upper extremity can be of benefit and may become techniques of choice, especially in outpatients. Selective blocks at the elbow and wrist permit the surgeon to complete the procedure while minimizing the amount of anesthesia administered. The blocks at the elbow and wrist are primarily sensory blocks. The patient retains the ability to move the hand during the procedure. Reduction of the area anesthetized, the amount of sedation administered, and the potential for complications minimizes the patient's stay in the outpatient center.

The use of selective nerve blocks of the upper extremity avoids the use of a general anesthetic when the regional anesthetic technique fails to completely block all the nerves that innervate the surgical site.^{45,48-50}

Each nerve that supplies sensory branches to the arm can be blocked at the elbow and the wrist. Use of a nerve locator at the level of the elbow (for the median and radial nerves) and at the level of the wrist (for the ulnar and median nerves) can improve the success rate of the block.

When a tourniquet is used during the surgical procedure, the intercostobrachial nerve and the brachial cutaneous nerve should be blocked in the axilla. These blocks provide sufficient anesthesia to permit the patient to tolerate a tourniquet. The coracobrachial muscle can also be blocked at the level of the shoulder to provide anesthesia so the patient may better tolerate the tourniquet.⁴⁵

Ulnar Nerve Block at the Elbow

As the ulnar nerve traverses the ulnar sulcus of the humerus, it is tightly fixed within the groove. Performing a regional anesthetic technique in this location can increase the risk of nerve entrapment. The volume of the solution should be limited to reduce the amount of pressure exerted on the nerve and the ischemia that could develop from injection of a large volume (greater than 3 mL).³²

The technique should be performed 1 to 2 cm proximal to the sulcus. The patient's elbow is flexed 90 degrees, and the medial condyle of the humerus is identified. A finger is placed in the ulnar sulcus, extending approximately 1 cm proximal to the condyle (Fig. 50.18). The insertion point for the needle is between the medial condyle of the humerus and the olecranon process of the ulna. The needle is inserted at a 45-degree angle to the skin and perpendicularly to a line drawn between the medial condyle and the olecranon process. If a paresthesia is elicited on introduction of the needle, the needle is withdrawn approximately 1 mm, and 2 to 3 mL of the solution is injected. If a paresthesia is not elicited, the volume of the solution can be increased. The total volume of the local anesthetic solution is 3 to 5 mL. The onset of action is determined by the local anesthetic used for the procedure. Epinephrine can be used at this level; however, this agent delays

the onset.^{45,48–50}

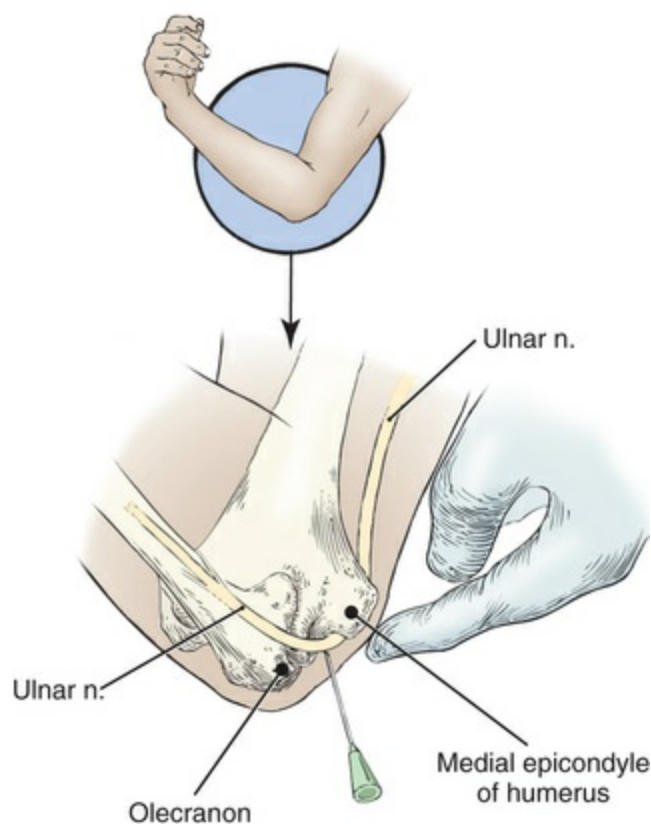

FIGURE 50.18 Technique of ulnar block at the elbow. The patient's elbow is flexed 90 degrees, and the medial condyle of the humerus is identified. *n.*, Nerve.

Median Nerve Block at the Elbow

Anesthesia of the forearm and hand can be achieved by a combination of median and ulnar nerve block as either a supplement to another technique or as a primary anesthetic technique. The combination of median and ulnar nerve block provides adequate anesthesia for procedures on the cutaneous portions of the lower forearm, the hand, and the second, third, and fourth fingers. The median nerve block can be used to supplement a partially successful brachial plexus block. It should be avoided in patients with carpal tunnel syndrome, if neuritis is present, or if the artery is perforated. If anesthesia is administered to two of the three nerves in the foramen, limited function of the hand remains.^{48,49}

The median nerve block is performed by positioning the patient's arm on a stable surface with the elbow slightly flexed. A line is drawn from the medial to the lateral condyles of the humerus on the anterior surface of the elbow. The brachial artery is then identified as it crosses this line (Fig. 50.19). A short B-bevel needle is inserted slightly medial to the brachial artery to a depth of 0.5 to 0.75 cm. Median nerve blocks at the elbow can be facilitated with the use of a nerve locator. When the nerve locator is used, a stimulus of low amplitude elicits a response along the path of the median nerve. If a nerve locator is not used, a paresthesia can be elicited by fan-wise movement of the needle. Identification of the median nerve is necessary for a successful block. Local anesthetic solution (3 to 5 mL) is injected after the nerve is located. As the needle is withdrawn through the fascia, an additional 1 to 2 mL of solution is injected to block cutaneous branches of the nerve.^{50,51}

FIGURE 50.19 Performance of median nerve block, positioning the patient's arm on a stable surface with the elbow slightly flexed. After the brachial artery is identified, a short B-bevel needle is inserted slightly medial to the brachial artery. *m.*, Muscle; *n.*, nerve.

Radial Nerve Block at the Elbow

Anesthetizing the radial nerve can be used as an adjunct to axillary perivascular techniques. This block also can be used for surgery of the forearm and hand that is within the distribution of the radial nerve or in conjunction with other nerve blocks.

With the elbow extended and stabilized on a firm surface, the brachioradialis muscle and biceps tendon are identified. The radial nerve is located in the groove formed by the fascial border of the brachioradialis muscle (see Fig. 50.19) on the lateral edge and the biceps tendon medially. A line is drawn between the medial and lateral condyles. A short B-bevel needle is inserted along the medial border of the brachioradialis muscle toward the lateral condyle at the point at which the line between the condyles crosses the facial groove. The needle is directed toward the anterior aspect of the lateral condyle so that gentle contact occurs. After contact with the condyle, the needle is withdrawn 2 mm. Local anesthetic solution (3 to 5 mL) is injected. This procedure is repeated two or three times while the needle is moved slightly more proximally for each injection. As the needle is withdrawn into the subcutaneous tissue, 3 to 5 mL of local anesthetic is injected.^{50,51}

An alternate approach to the radial nerve requires identification of the lateral border of the brachioradialis muscle. Measuring 3 to 5 cm proximal from the lateral condyle along the border of the brachioradialis muscle enables palpation of the radial nerve as it parallels the humerus. The nerve is adherent to the bone at this level and can be easily injured during trauma or during the performance of the regional anesthesia. By slight movement of the nerve, a paresthesia can be elicited. A short B-bevel needle is inserted in a plane perpendicular to the humerus and advanced to the proximity of the identified radial nerve. Because of its fixation against the humerus, the needle must be advanced slowly and the position evaluated to avoid injury to the nerve.^{50,51}

Selective Blocks at the Wrist

Selective blocks of the ulnar, median, and radial nerves at the wrist can be used for supplying limited anesthesia for the outpatient or as a supplement to brachial plexus anesthesia. Procedures that require

a motor block in addition to the sensory blockade should be accomplished by use of another anesthesia technique. Epinephrine is not included in solutions used in nerve blocks below the elbow because of the relatively small blood vessels of the wrist, hand, and fingers and the risk of compromising circulation to these areas.^{50,51}

Ulnar Block at the Wrist

With the wrist slightly flexed and stabilized on a firm surface, the ulnar flexor muscle of the wrist is identified (Fig. 50.20). A line is then drawn across the forearm at the level of the styloid process of the ulna. A short B-bevel needle is inserted perpendicularly to the skin on the radial side of the ulnar flexor muscle of the wrist, where it is crossed by the line. At this location, the needle is slightly lateral to the ulnar artery, and a small deviation medially can place the needle over the artery. The ulnar artery can be palpated when the wrist is moderately extended. However, severe extension causes the artery to collapse. After the needle is inserted, 2 to 4 mL of local anesthetic solution is injected. An additional 2 mL is injected as the needle is withdrawn from the deep fascia. The dorsal branch of the ulnar nerve is blocked by injection of 3 to 5 mL of local anesthesia in a half-ring around the ulnar aspect of the wrist. The needle is placed subcutaneously at the radial margin of the ulnar flexor muscle of the wrist and advanced to the midportion of the dorsal aspect of the wrist.^{50,51}

FIGURE 50.20 With the patient's wrist slightly flexed and stabilized on a firm surface, the ulnar flexor muscle of the wrist is identified. A short B-bevel needle is inserted perpendicular to the skin on the radial side of the ulnar flexor muscle of the wrist. *n.*, Nerve.

Median Block at the Wrist

The wrist is stabilized on a firm surface and slightly flexed against resistance. When the wrist is flexed, the long palmar muscle and the radial flexor muscle of the wrist are easily identified (see [Fig. 50.20](#)). A line is drawn across the wrist that parallels the proximal crease. A short B-bevel needle is inserted perpendicularly to the skin between the two tendons to a distance of 0.5 to 1 cm. The carpal tunnel is a tightly confined space. The nerve is located in the superficial portion of the carpal tunnel. A paresthesia can be elicited during the performance of the procedure. If the sensation persists, the needle must be withdrawn and repositioned. Local anesthetic solution (2 to 5 mL) is injected within the carpal tunnel, and another 2 to 3 mL is injected after the needle is withdrawn from the fascia of

the carpal tunnel.^{50,51}

Radial Block at the Wrist

The sensory fibers of the radial nerve to the hand are superficial branches at the wrist. Anesthesia of the radial fibers is achieved through the injection of a subcutaneous ring of local anesthetic solution, beginning at the radial flexor muscle of the wrist and extending to the dorsal surface of the ulnar styloid (Fig. 50.21). The formation of a continuous ring of local anesthetic around the wrist should be avoided when this procedure is accomplished in conjunction with an ulnar block because circulation to the hand could be compromised.

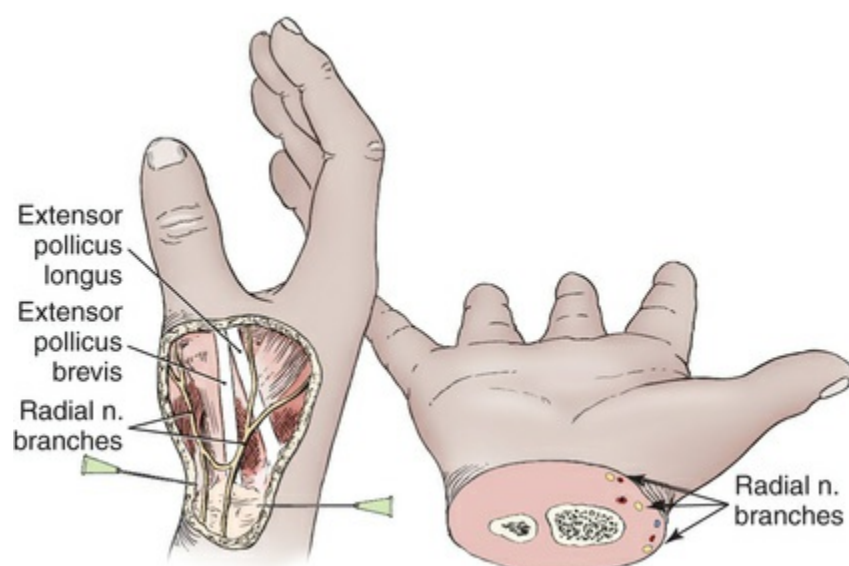

FIGURE 50.21 Anesthesia of the radial fibers is achieved by injecting a subcutaneous ring of local anesthetic solution at the radial flexor muscle of the wrist, extending to the dorsal surface of the ulnar styloid. *n.*, Nerve.

Another approach to anesthesia of the radial nerve is the identification of the brachioradialis muscle proximal to the wrist. Approximately 6 to 8 cm proximal to the wrist, 5 to 7 mL of local anesthetic solution is injected under the brachioradialis muscle. This technique is the least well tolerated of all the supplemental blocks, and it is associated with limited success.^{50,51}

Intravenous Regional Anesthesia (Bier Block)

Intravenous regional block is a technically simple, safe, and rapid means of producing surgical anesthesia of the extremity. The technique is best suited for upper extremity (hand and wrist) soft-tissue surgical procedures of 1 hour or less; however, it has also been used for lower extremity surgical procedures of the foot and ankle. The factor limiting the duration of anesthesia to approximately 1 hour is most commonly discomfort produced by the tourniquet required to initiate and maintain the block. Use of a dual tourniquet system and preoperative and or intraoperative administration of small doses of opioids may extend this time limit to the maximum tourniquet time of 2 hours. The greatest risk associated with intravenous regional anesthesia (IVRA) is the potential for rapid transfer of a large volume of local anesthetic from the extremity to the central circulation in the event of an improperly fitted or inflated tourniquet or tourniquet failure. Therefore it is important to have emergency equipment, medications, and monitors immediately available when this block is administered. Because of the rapid onset of the block and the limited duration, it is almost always performed in the operating area, where the emergency items needed are readily available. The necessity for intravenous access and manipulation of the affected extremity, the prerequisite for a tourniquet, and the density and duration of the block influence the clinical application of this technique.⁵²⁻⁵⁴

Intravenous Regional Anesthesia: Upper Extremity Block

A small-bore (23–25 gauge) intravenous catheter is placed in a distal vein of the affected extremity and secured in place, and a heparin lock is attached and flushed with normal saline. The preferred location for access to the venous system of the upper extremity is the dorsum of the hand; however, forearm and antecubital fossa

veins have been used. Evidence suggests that use of forearm or antecubital fossa veins increases the possibility of a partial or complete failure of the block when the hand or wrist is the surgical target. It is reasonable to assume that consideration should be given to the area on which surgery is to be performed with regard to access to the venous system because attainment of surgical anesthesia is predicated on the adequate spread of the injected local anesthetic. The patient is placed supine, and several layers of a suitable padding material are wrapped around the arm in preparation for application of the tourniquet. Although a single tourniquet can be used, a dual tourniquet is recommended because it provides a means to extend the length of the block after the initial onset of tourniquet pain.⁵²⁻⁵⁴

After application of the tourniquet, the extremity is elevated and exsanguinated. Exsanguination is accomplished by wrapping an Esmarch bandage at close overlapping intervals tightly around the arm, starting at the fingertips and continuing until the bandage overlies the tourniquet itself. In cases in which application of an Esmarch bandage would cause undue discomfort, exsanguination by simple elevation of the extremity for a minimum of 5 minutes may be attempted. This method may or may not result in adequate block. In addition, an air-inflated splint may be used as an alternative to the Esmarch bandage. After exsanguination, the proximal tourniquet is inflated to 250 mm Hg or 100 mm Hg above systolic blood pressure, and the Esmarch bandage is removed. A total of 50 mL of 0.5% lidocaine is then injected via the intravenous catheter. The local anesthetic should be free of preservatives (e.g., methylparaben, metabisulfite) and contain no vasoconstrictor. The patient should be carefully monitored during the injection for signs of local anesthetic toxicity. At the conclusion of the procedure, the cuff may be deflated for as long as 20 minutes after injection of the local anesthetic. This allows enough time for substantial amounts of the drug to diffuse into the tissues; therefore the drug released systemically will not reach toxic levels.⁵²⁻⁵⁴

An alternative block technique uses an additional “tourniquet” (Penrose drain) applied at midforearm in the manner used to start an intravenous line after primary distal tourniquet inflation. Half of the 50-mL volume of local anesthetic is injected with the forearm

tourniquet in place; the tourniquet is removed, and the remaining local anesthetic is injected. This technique results in a faster onset and a denser block. Numerous additives to the local anesthetic have been tested, including opiates, clonidine, muscle relaxants, and ketorolac. Ketorolac appears to be the only agent that provides a significant clinical benefit. The addition of 15 to 30 mg of ketorolac to the local anesthetic solution can provide a degree of postoperative analgesia without increasing the risk of postoperative bleeding.⁵²⁻⁵⁴

Intravenous Regional Anesthesia: Lower Extremity Block

Indications for IVRA of the lower extremity include orthopedic surgery of short duration on the foot, removal of fixation plates and screws from the bones below the knee, and foreign body removal from the foot.

Two significant differences exist between IVRA of the upper and lower extremities. First, the local anesthetic volume (and dose) for IVRA of the lower extremity is approximately double that used for the arm. This obviously increases the risk of local anesthetic systemic toxicity resulting from leakage under the inflated cuff and from release of a large bolus dose of local anesthetic when the cuff is deflated. Second, in order to occlude the arterial inflow at the thigh level (femoral artery), the tourniquet pressure must be higher than in the arm (usually 350 to 400 mm Hg), which increases the occurrence and intensity of tourniquet pain.

Two separate 9-cm-wide tourniquet cuffs (adult patient) are applied, and care must be taken that the pneumatic parts of the tourniquets surround the thigh by more than 1.5 turns. Otherwise, the technique is similar to that described for IVRA of the arm.

During brief surgical procedures of the foot or the ankle, the distal tourniquet cuff may be applied on the calf, clearly below the head of the fibula (away from the peroneal nerve), and the proximal cuff left on the thigh. The local anesthetic solution is injected with the distal tourniquet cuff inflated; therefore the volume and the dose can be the same as for the arm of an adult, that is, 35 to 45 mL of 0.5% lidocaine. The proximal tourniquet is usually not inflated

but can be rapidly inflated in the event the distal tourniquet fails.^{51,54}

Intercostal Nerve Blocks

The use of the intercostal nerve block has increased in the past several years. The anatomic landmarks are easily identified, thereby facilitating the performance of the block. The procedure is not extremely painful, has a high rate of success, has a low incidence of complications, and provides the patient with significant analgesia. The most common complications are pneumothorax and toxicity from the local anesthetic. The patient who has pain with respiratory effort is able to cough and breathe deeply with reduced discomfort. In the outpatient or ambulatory care setting, surgical procedures can be accomplished with the aid of this regional anesthesia technique.⁵⁵

The use of multiple-level intercostal nerve block can lead to the highest local anesthetic plasma levels of any regional techniques. The high vascularity of the area and large intercostal veins contribute to high plasma levels of local anesthetic. The high plasma concentration can produce toxicity with lower-than-toxic injected doses.

Intercostal nerve block is used for supplementing balanced anesthesia techniques to increase tolerance of the surgical procedure. Sufficient analgesia can be provided to permit the performance of surgical procedures involving the abdominal wall without the need for supplemental blocks. For more involved procedures, additional anesthesia may be required.

Intercostal nerve block can provide analgesia for postoperative pain control when epidural analgesia is not desired or possible. The procedure can provide analgesia during or after chest-tube insertion to limit the patient's discomfort. The landmarks are easily identified in most patients. The procedure can be accomplished with the patient prone, in the lateral position, or sitting comfortably with the upper body supported over a table or a stand. Having obese patients sit up enables easier identification of landmarks. One advantage of using multiple-level intercostal nerve blocks is the reduction in the amount of pain medication required to facilitate normal respiration in the postoperative period. These factors result in a reduction in the potential development of respiratory

depression related to the use of intravenous or intramuscular opioids, especially in obese patients.

The intercostal nerve emerges from the intervertebral foramen and follows the rib in the costal groove. This groove is located on the anteroinferior aspect of the rib. The intercostal artery and vein accompany the nerve in the groove. Medial to the posterior angle of the rib, the neurovascular bundle lies between the pleura and the internal intercostal fascia. As the nerve passes the angle of the rib, it begins to run between the two layers of the internal intercostal muscle. At the midaxillary line, the nerve branches send sensory fibers anteriorly and posteriorly to supply skin and subcutaneous tissue. Fibers also provide motor and sensory innervation to the bundles of the superior rectus muscle in the upper abdomen.^{55,56}

Positioning the patient may require modification to facilitate breathing during the procedure. The area of pain may have to be splinted, or other measures may need to be taken to reduce pain-induced movement during the procedure. Ideally the patient should be positioned in the prone position with the arms hanging down. This position pulls both scapulas away from the midline and permits the practitioner to perform the block as the nerve root begins to travel in the intercostal groove.

The block can be performed with the patient lying on the unaffected side with the arm extended over the head. This technique is helpful in obese patients and in patients experiencing severe pain, especially when such a patient is prone. When the patient is in the lateral position, preservation of circulation in the downward arm must be preserved.

During the postoperative period the supine position can be used with the anterior approach to the intercostal nerve. This position is less satisfactory, and it is associated with a higher incidence of complications.

The rib is palpated posterior to the midaxillary line in the prone patient so that the appropriate landmarks can be identified. In this position, the rib becomes superficial to the muscle bodies. The lateral border of the sacrospinal muscle must be identified before the block is attempted. The sacrospinal muscle lies approximately 7 to 10 cm from the midline.

With a small-gauge (27- to 30-gauge) needle, a skin wheal is

raised over the point chosen for the injection. A 22-gauge, B-bevel needle is then inserted perpendicularly to the rib through the skin wheal and advanced until contact with the rib occurs. The needle is slowly walked caudad off the rib. As the edge of the rib is cleared, the needle is advanced another 2 to 3 mm (Fig. 50.22). The needle should be gently aspirated for verification of needle placement. Use of a “free needle,” as described in brachial plexus anesthesia, can facilitate the maneuverability of the needle and increase control.

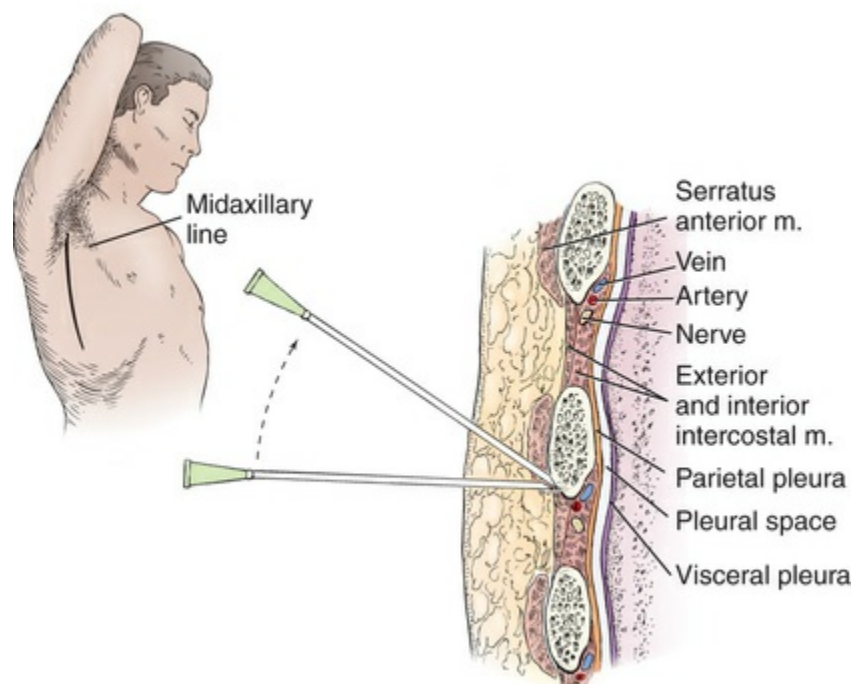

FIGURE 50.22 A 22-gauge, B-bevel needle is inserted perpendicular to the rib and advanced until contact is made with the rib. The needle is slowly walked caudad off the rib. *m.*, Muscle.

Once the needle is in the appropriate location, 3 to 5 mL of the local anesthetic solution is injected. The procedure can be repeated for anesthesia at each dermatome level. If resistance is encountered during the injection, the injection should be terminated and the needle repositioned. If the patient begins to cough or move, the needle position should be reevaluated before injection. Advancing the needle several millimeters can place the needle within the nerve itself, resulting in severe pain or direct injury to the nerve.

Procaine, bupivacaine, tetracaine, and lidocaine have all been

used for blocking the intercostal nerves, with varying effects. Because the goal is to provide the patient with extended pain relief, a longer-acting agent is most commonly used. An injection of 3 mL of bupivacaine (0.5%) into the tissues surrounding the intercostal nerve provides the patient with 3 to 9 hours of anesthesia and analgesia. Patient factors such as temperature, presence of infection, and the response to local anesthetics affect the duration of action. Epinephrine 1 : 200,000 or 1 : 400,000 should be added to the local anesthetic solution. Bupivacaine's duration of action may be unchanged; however, the rise in the plasma concentration of the local anesthetic is slowed. The addition of epinephrine to tetracaine or lidocaine prevents the rapid absorption of the anesthetic and increases the duration of action. With the use of epinephrine, increased vasoconstriction occurs, an effect that reduces absorption of the local anesthetic. The increased contact time between the neural tissue and the local anesthetic increases the amount of local anesthetic present to be absorbed into the neural fibers.

The likelihood of complications, such as pleural injection and pneumothorax, can be reduced by use of a short B-bevel needle. To avoid an intraneural injection, the needle is directed cephalad as it passes over the ridge of the rib. A symptomatic pneumothorax can occur; however, use of a single 22-gauge, short-beveled needle reduces the risk. A leak created by this needle can be minimal. When a larger or A-bevel needle is used, the risk of complications is increased.

In most patients, a small leak of air does not cause a symptomatic pneumothorax. Most patients are able to compensate for any reduced ventilatory capacity, and the pneumothorax resolves without intervention. In a small percentage of patients, intervention is needed for relief of the discomfort and dyspnea. Radiologic studies should be performed after completion of the procedures so that the status or occurrence of a pneumothorax can be established. The studies can be used during follow-up evaluations and therapy if required.^{55,56}

The use of intercostal nerve block has enhanced the practice of anesthesia and pain control. This technique provides the patient with increased flexibility in the control of pain and reduces the need for opioids. In the ambulatory surgery center, this technique offers

increased options to the patient who desires a regional anesthetic technique.⁵⁵

Transversus Abdominis Plane Block

Transversus abdominis plane (TAP) blocks have been demonstrated to provide analgesia in both the general surgery and the obstetric populations. It provides unilateral analgesia to the skin, muscles, and parietal peritoneum of the anterior abdominal wall. It can be done bilaterally to provide analgesia for hernia repair, caesarian section, hysterectomy, and other lower abdominal procedures.^{55,57}

Ultrasound-Guided Transversus Abdominis Plane Block

The abdominal wall between the iliac crest and the subcostal margin consists of the external oblique, internal oblique, and transversus abdominis muscles. The transversus abdominis is the deepest muscle layer, and below it lies the peritoneum. The TAP block is used to place local anesthetic in the lateral abdominal wall between the internal oblique and the transversus abdominis muscles. The objective is to block the segmental nerves within this plane (T9–12 and L1) with a single injection of local anesthetic. The patient is placed in the supine position with the ultrasound probe positioned transversely between the margin of the twelfth rib and the anterior superior iliac spine. A 21-gauge, 4-inch needle is inserted using an in-plane to the ultrasound beam approach. The needle is inserted through the muscle layers until the tip lies between the internal oblique and transversus abdominis muscles (Fig. 50.23). Loss of needle resistance may be appreciated when the needle penetrates the external oblique muscle and again when penetration of the internal oblique occurs; 20 mL of local anesthetic may be injected bilaterally.^{55,57}

FIGURE 50.23 Anatomy of the transversus abdominis plane block. *AC*, Abdominal contents; *EO*, external oblique muscle; *IO*, internal oblique muscle; *TA*, transversus abdominis muscle.

Lower-Extremity Block

Lower-extremity nerve blocks are well described and can provide high-quality anesthesia and analgesia for lower-extremity surgical procedures. Lower-extremity nerve blocks, although underused, have significant advantages as compared with central neuraxial techniques, especially in the ambulatory setting.

Advantages of lower-extremity nerve blocks include reduced recovery room admissions; decreased nausea, vomiting, and urinary retention; and improved postoperative analgesia. These benefits include shortened hospital stays, decreased probability of hospital admission, and an overall reduction in hospital costs and patient charges.^{58,59}

Anatomy of the Lumbar Plexus

The lumbar plexus is formed from the first, second, third, and fourth lumbar nerve roots (ventral rami). Contributions to the plexus originate in the twelfth thoracic nerve in some patients. The plexus is formed in front of the quadratus lumborum muscle and behind the psoas major muscle (Fig. 50.24). As the major branches from the plexus begin their descent into the leg, the muscle bodies and the connecting fascia tightly bind them.

FIGURE 50.24 Location of the lumbar plexus. *m.*, Muscle.

The lateral femoral cutaneous nerve is formed from the second and third lumbar nerves and is the first to leave the compartment. It emerges from the lateral border of the psoas major at its midpoint. The nerve then traverses the iliac muscle obliquely toward the anterior iliac spine. The lateral femoral cutaneous nerve passes under the lateral border of the inguinal ligament and provides the sensory innervation to the lateral aspect of the thigh ([Fig. 50.25](#)).

FIGURE 50.25 Origin and position of the nerves of the lower extremity. *n.*, Nerve.

The obturator nerve arises from the second, third, and fourth lumbar nerves as an extension of the lumbar plexus. It emerges from the medial border of the psoas major at the level of the sacroiliac joint and is covered by the external iliac artery and vein. The nerve passes into the pelvis minor and runs anteroinferiorly to the obturator canal, which it traverses near the obturator vessels. Due to the proximity of the nerve to the external iliac artery, it can be injured during surgical procedures. This nerve is frequently injured when patients undergo extensive pelvic surgery. The obturator nerve is primarily a motor nerve to the adductor muscles of the upper leg that has some mixed sensory fibers to the hip, the medial aspect of the femur, and the skin and soft tissue of the medial aspect of the thigh proximal to the knee.⁵⁸⁻⁶⁰

The third and largest nerve in the lumbar plexus is the femoral nerve, which is formed from the contributions of the second, third, and fourth lumbar nerve roots. This nerve forms and appears at the junction of the middle and lower third of the psoas major muscle. It remains within the groove of the psoas major and the iliac muscles

and runs deep under the inguinal ligament, where it comes to lie anterior to the iliopsoas muscle and lateral to the femoral artery.

The femoral nerve has two branches: the anterior and the posterior bundles. This formation usually occurs just after the nerve passes under the inguinal ligament but may occur before it passes under the ligament. The anterior branch provides innervation to the anterior surface of the thigh and the sartorius muscle. The posterior branch provides innervation to the quadriceps muscles, the knee joint, and its medial ligament, and is the origin of the saphenous nerve. The femoral nerve is bound by several structures above and below the inguinal ligament. Above the inguinal ligament, the iliaca fascia encapsulates the femoral nerve laterally, the psoas fascia medially, and the transverse fascia anteriorly. The posterior border of this capsule or sheath is made up of the bony structure of the pelvis.⁵⁸⁻⁶⁰

As the femoral nerve joins the femoral artery and enters the leg, the iliopsoas fascia forms the posterolateral wall. The inguinal ligament and the fascia lata form the anterior wall, and the iliopectineal fascia forms the medial wall of the capsule. Winnie et al.⁶¹ suggested that the neural sheath originating with the femoral artery, in conjunction with the fascial attachments, form a structure similar to the neural sheath in the brachial plexus. With this anatomic design, anesthesia can be provided for the lower extremity through techniques used in upper extremity anesthesia.

Psoas Compartment Block

Immediately after emerging from the intervertebral foramina, the nerve roots form the lumbar plexus. Blockade of the lumbar plexus as a unit can be accomplished by injecting local anesthetic into the fascial sheath surrounding the plexus. This can be done at the level of the psoas compartment.⁵¹ This approach attempts to block the plexus as it lies in the fascial plane bordered medially by the vertebral column, dorsally by the quadratus lumborum muscle, and ventrally by the psoas major muscle.

The patient is placed in either the lateral or sitting position. If placed in the lateral position, the patient should be in a relaxed but curled position similar to that used for spinal or epidural anesthesia, with the operative side uppermost (Fig. 50.26).

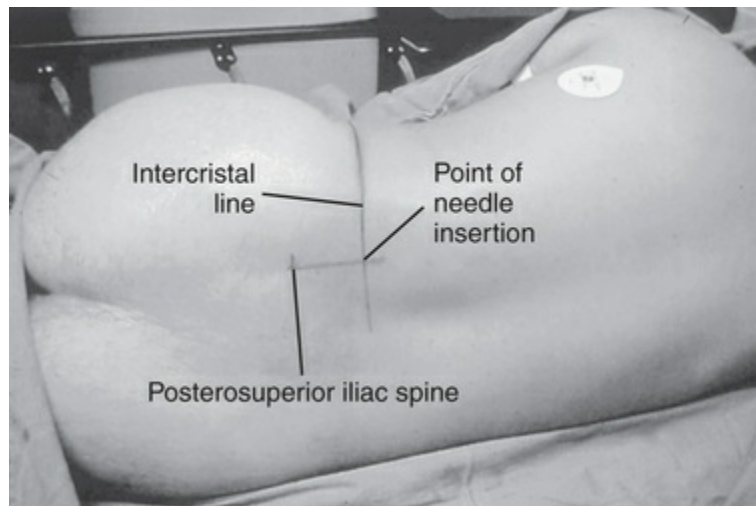

FIGURE 50.26 Lumbar plexus (psoas compartment) block.

From the spinous process of L4, a 3-cm line is drawn caudally in the interspinal line. From the end of this line, a 5-cm line is drawn perpendicularly and laterally toward the side to be blocked, usually ending at the medial edge of the iliac crest. This spot identifies the point of needle insertion. A 120-cm insulated block needle is used. A skin wheal is raised, and the needle is inserted perpendicularly to all planes and advanced until contact with bone is made, which identifies the transverse process of L5 and usually occurs at a depth of 5 to 10 cm.⁵¹

The needle is then withdrawn, redirected slightly cephalad, and advanced until it slides over the transverse process of L5. Using the loss-of-resistance technique, the psoas compartment is usually encountered at the depth of 8 to 12 cm. The tip of the needle now lies in the psoas compartment. Needle placement can be confirmed with the aid of a nerve stimulator, by checking for stimulation of the quadriceps muscles, by eliciting paresthesias into the thigh, or by advancing the needle slightly into the psoas muscle and reconfirming a loss of resistance while withdrawing the needle slightly into the psoas compartment.

After the needle is properly placed, and after careful aspiration, 30 to 40 mL of local anesthetic is injected in 5-mL divided doses. It is often helpful to have the patient remain in the lateral position for a few minutes after injection to limit the spread of the drug.⁵¹

Femoral Nerve Block

Whereas not effective as a sole anesthetic, the use of a femoral nerve block is recommended for postoperative analgesia following knee surgery. The use of a continuous femoral nerve block can facilitate rehabilitation and reduces side effects as compared to continuous epidurals.^{58,62,63}

After the patient is positioned supine, the groin is prepared and draped by use of aseptic technique. The site of injection is 1 cm lateral to the femoral artery and 1 cm inferior to the inguinal ligament. The identified area is prepped and draped and then infiltrated with 2 to 3 mL of 1% lidocaine solution subcutaneously. A 22-gauge, 4-cm insulated B-bevel needle is advanced perpendicularly to the skin just lateral to the artery until the femoral nerve is located with the aid of a PNS. With a stimulation frequency of 2 Hz, the intensity level is set at 1 mA until quadriceps twitch or patellar “snap” is elicited, then decreased to less than 0.5 mA. Local anesthetic solution (20 to 30 mL) is injected in 3- to 5-mL increments, with intermittent syringe aspiration. Digital pressure can be applied firmly but gently distal to the needle. This action assists in limiting the distal spread of the anesthetic solution by forcing it proximal into the channel formed by the neural sheath and other structures.^{58,62,63} Winnie et al.⁶¹ indicated that the total volume of anesthetic solution required to maximize the block must exceed 20 mL. Volumes of less than 20 mL provide a spotty and unpredictable block. Increasing the volume of the solution to 30 mL increases the ability of the solution to block all three nerves (femoral, obturator, and lateral femoral cutaneous), which would be considered a three-in-one block.⁵⁸ Bupivacaine (0.5%), ropivacaine (0.5%), and lidocaine (1.5%) are commonly used for this procedure. Anesthesia to the sciatic distribution does not occur with this technique. If the surgical procedure requires anesthesia along the sciatic distribution, a separate procedure must be performed (Fig. 50.27).^{62,63}

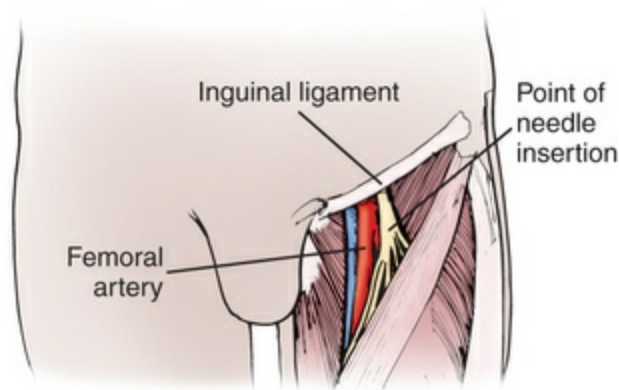

FIGURE 50.27 Femoral nerve block.

Ultrasound-Guided Femoral Nerve Block

The femoral nerve emerges just below the inguinal ligament, lateral to the femoral artery, and deep to the fascia iliaca. The patient is positioned supine with the groin exposed. The ultrasound probe is placed axially anywhere between the inguinal crease and the inguinal ligament. The anchoring landmarks for visualization are the femoral artery and vein and the femoral nerve (Fig. 50.28). The femoral nerve will appear triangular, hyperechoic, and lateral to the femoral artery. The fascia lata and the fascia iliaca may also be visualized as hyperechoic lines. A 22-gauge, 2-inch needle is inserted from lateral to medial in the transverse plane of the image, in-plane to the ultrasound beam. Once the fascia iliaca is pierced and needle tip is visualized close to the femoral nerve, 20 mL of local anesthetic is injected.⁵⁸

FIGURE 50.28 Transverse view of the femoral nerve lateral to the femoral artery and femoral vein. *FA*, Femoral artery; *FN*, femoral nerve; *FV*, femoral vein.

Continuous Femoral Nerve Block

Extension of the anesthesia and analgesia provided by a femoral nerve block through use of a continuous catheter technique after surgical procedures of the femur and knee has grown in popularity and application. The success rate is high as long as the surgical procedure does not extend beyond the innervations of the femoral nerve. The landmarks are readily identifiable and include the femoral artery and the femoral crease immediately inferior to the inguinal ligament.⁶⁴

The patient is placed in the supine position and the skin is thoroughly prepped with an antiseptic solution and draped. The practitioner stands on the side to be blocked. The needle insertion site is located at the lateral border of the femoral artery (approximately 1 cm lateral to the arterial pulse) in the femoral crease. A 17-gauge, $\frac{3}{8}$ -inch insulated needle connected to a nerve stimulator set at 1 mA is inserted and advanced in the sagittal plane at a 45- to 60-degree cephalad angle. The technique is similar to single-injection femoral nerve block except for the more acute

cephalad angle of needle insertion to facilitate threading of the catheter. Following a quadriceps muscle twitch (patellar twitch) at 1 mA, the current is reduced to 0.5 mA, and the twitch response is reestablished. If a quadriceps twitch is not elicited after initial needle placement, the needle should be withdrawn and redirected slightly more lateral to the femoral artery until the desired twitch response is achieved. An initial bolus of local anesthetic (15 to 20 mL) is injected slowly after negative aspiration for blood, and the catheter is then threaded 5 to 10 cm beyond the tip of the needle. The nerve stimulator can be connected to the catheter to confirm that the tip lies in close proximity to the femoral nerve. The catheter is then secured by one of several mechanisms. Kits available for continuous nerve block often contain a securing device, but the catheter may be secured through use of a suture and/or a clear dressing applied over the catheter. The continuous infusion of local anesthetic is initiated immediately after the bolus injection at a rate of 8 to 10 mL/hr. Typical local anesthetics and concentrations used for this purpose are ropivacaine 0.2% and bupivacaine 0.25%.⁶⁴

Strict aseptic technique should be adhered to during placement and maintenance of the catheter, and it has been recommended that the catheter be removed after 48 hours. In addition, as with all peripheral nerve blocks, complaints of pain during needle insertion or injection suggest intraneural penetration. In this event, the needle should be withdrawn and redirected. Insertion of the needle medially is likely to produce femoral artery and or vein penetration. If this occurs, constant pressure should be applied to the site for a period of not less than 2 to 3 minutes prior to another attempt at locating the nerve. The patient should be counseled with regard to the extended loss of sensation and motor control of the extremity and what action to take in the event of a potential complication upon discharge (see [Box 50.2](#)).⁶⁴

Fascia Iliaca Compartment Block

The fascia iliaca compartment block is an anterior lumbar plexus approach with a puncture point distant from the neurovascular sheath. A nerve stimulator is not necessary for this procedure. Initially described in children in 1989, fascia iliaca compartment block is widely used for postoperative analgesia after lower limb

surgery in children and adults and provides effective postoperative analgesia after hip, femoral shaft, or knee surgery. Compared with three-in-one block, it provides a faster and more consistent simultaneous blockade of the lateral femoral cutaneous and femoral nerves. The fascia iliaca compartment block is performed as described by Dalens et al.⁶⁵ and others.^{66,67} With the patient in a supine position, a projection of the inguinal ligament is drawn on the skin from the pubic tubercle to the anterior superior iliac spine and trisected. The puncture site is marked 1 cm caudal to the point at which the lateral meets the middle third of the inguinal ligament line. After disinfecting the skin using topical 10% povidone-iodine, a short-bevel needle (24 gauge, 50 mm) is inserted at a 90-degree angle to the skin. An initial loss of resistance is felt as the needle tip crosses the fascia lata. The needle is advanced at the same angle until a second loss of resistance is felt as the fascia iliaca is pierced (a paresthesia is not intentionally elicited), and 30 mL of local anesthetic is injected.⁶⁵⁻⁶⁷

Sciatic Nerve Block

Sciatic nerve blocks, in combination with lumbar plexus or femoral block, provide complete anesthesia and postoperative analgesia for lower-extremity surgery. Contrary to common belief, a sciatic nerve block is relatively easy to accomplish.⁶⁸ In a 2003 review of outpatients undergoing complex knee surgery, it was noted that among the patients who received a combination sciatic nerve block with a femoral nerve block, a lower incidence of nursing interventions for pain occurred in the step-down unit.⁵⁹ In addition, patients had fewer hospital admissions and were more satisfied with their surgical procedures.^{59,68}

Anatomy of the Sciatic Nerve

The sciatic nerve, formed by the fourth lumbar through the third sacral roots, is the continuation of the upper division of the sacral plexus and is the largest nerve trunk in the body. It supplies the muscles of the back of the thigh, the skin of the leg, and the muscles of the lower leg and foot. It passes out of the pelvis through the great sacrosciatic foramen, below the piriform muscle. It descends

between the major trochanter and the tuberosity of the ischium to the lower third of the thigh. At the cephalad portion of the popliteal fossa, it divides into the tibial and common peroneal nerves.³¹

Technique of Sciatic Nerve Block

Although posterior and lateral popliteal approaches to the sciatic nerve are performed most commonly for ankle and foot surgery, and higher approaches to the sciatic nerve are performed more commonly for surgery below, above, and at the knee, there is no clinical evidence to support one particular sciatic approach over another. The classic approach to the sciatic nerve will be described in this chapter. The indications for a given approach are based on the specific surgical requirement.^{59,69,70}

After standard monitors are placed, the patient is positioned in the Sims position with the operative leg positioned superiorly and flexed at the knee. A line is drawn from the posterior superior iliac spine to the greater trochanter of the femur. A second line is drawn from the sacral hiatus to the greater trochanter, and a third line is drawn perpendicular to and bisecting the first line. The intersection of the second and third lines is the point of needle entry (Fig. 50.29). The identified area is prepped, draped, and then infiltrated with 2 to 3 mL of 1% lidocaine solution subcutaneously. A 22-gauge, 10-cm insulated B-bevel needle, inserted perpendicularly to the skin, is advanced until the posterior tibial nerve distribution is elicited with the aid of a PNS. A stimulation frequency of 2 Hz and an intensity level of 1 mA is used until a plantar flexion motor response is elicited. The intensity level is decreased to less than 0.5 mA as long as motor response is still present. Local anesthetic solution (10 mL) is injected in 5-mL increments, with intermittent syringe aspiration. The needle is redirected laterally and advanced until peroneal nerve distribution is elicited with the aid of a PNS. A stimulation frequency of 2 Hz and an intensity level of 1 mA is used until a dorsal flexion motor response is elicited. The intensity level is decreased to less than 0.5 mA as long as motor response is still present. Local anesthetic solution (10 mL) is injected in 5-mL increments, with intermittent syringe aspiration. Bupivacaine (0.5%), ropivacaine (0.5%), and lidocaine (1.5%) are commonly used for this procedure.^{68,70}

FIGURE 50.29 Sciatic nerve block.

Popliteal Fossa Approach to the Sciatic Nerve Block

The sciatic nerve block at the level of the popliteal fossa can be used to block the distal leg and foot. Patient's presenting for surgery including the ankles, toes, Achilles tendon, tibia or fibula would be good candidates for this block. The popliteal fossa approach is based on the use of the three anatomic landmarks that define the posterior popliteal fossa: the popliteal crease, the medial border of the femoris biceps muscle laterally, and the tendon of the semitendinous muscle medially.^{71,72}

A line is drawn joining the medial border of the femoris biceps muscle laterally and the lateral border of the semitendinous muscle medially at the level of the popliteal crease. From the middle of this line, a perpendicular line is extended 15 cm cephalad. The site of insertion of the needle is 1 cm laterally. A 10-cm insulated needle connected to a nerve stimulator is introduced through a skin wheal of local anesthesia at a 45- to 60-degree anterosuperior angle. The sciatic nerve is usually located at a depth of 1 to 2 cm in an adult. After careful aspiration, 30 to 40 mL of a local anesthetic is injected (Fig. 50.30).^{71,72}

FIGURE 50.30 Popliteal nerve block. (From Farag E, Mounir-Soliman L. *Brown's Atlas of Regional Anesthesia*. 5th ed. Philadelphia: Elsevier; 2017:138.)

Ultrasound-Guided Popliteal Fossa Approach to Sciatic Nerve Block

The popliteal artery and vein can be located with the ultrasound probe placed in the popliteal region of the knee parallel to the flexor crease. The tibial nerve can usually be visualized at this level, just lateral and/or superficial to the popliteal vessels. Lateral to the nerve lies the biceps femoris muscle. Medial to the nerve lie the semimembranosus and semitendinosus muscles. Once the tibial nerve is identified at the flexor crease, the ultrasound probe is slid slowly proximal. The tibial nerve is joined by the common peroneal nerve approximately 5 to 10 cm above the flexor crease to form the sciatic nerve (Fig. 50.31). A 22-gauge, 2-inch needle is inserted lateral to the nerve, in-plane to the ultrasound beam, and advanced until the needle tip is adjacent to the nerve; 20 mL of local anesthetic is then injected under direct observation to envelope the

tibial and common peroneal nerves (Fig. 50.32).^{71,72}

Ankle Blocks

The ability to administer anesthesia to patients who require surgery of the foot offers valuable additional regional block options. Either a complete or partial block of the foot can provide adequate anesthesia for many of the surgical procedures performed by podiatrists and orthopedic surgeons. The nerves are easy to locate, and the procedures can be rapidly accomplished. This tool can prove invaluable in the care of certain patients, such as those with gangrene of the foot or those with diabetes who have foot ulcers, in whom a local anesthetic procedure would be inadequate.^{72,73}

Anatomy of the Ankle

The ankle block is performed by anesthetizing the five nerves at the level of the ankle: the tibial nerve, the sural nerve, the superficial peroneal nerve, the deep peroneal nerve, and the saphenous nerve.

Tibial Nerve.

The tibial nerve arises from the nerve roots of the fourth and fifth lumbar roots, along with the first, second, and third sacral roots. It is the larger of the two branches of the sciatic nerve. The path of this nerve lies on the medial side of the Achilles tendon. It passes into the ankle with the posterior tibial artery (Fig. 50.33). At the level of the ankle, this nerve lies behind the posterior tibial artery and between the tendons of the long flexor muscles of the toes and the long flexor muscles of the great toe. The nerve is covered by the flexor retinaculum. Several branches leave the neural bundle at the level of the medial malleolus. Two of the branches, the medial and the lateral plantar nerves, traverse the ankle, following under the cover of the abductor hallucis. They provide sensory innervation to the foot.^{51,60}

FIGURE 50.33 Path of the posterior tibial nerve, with the posterior tibial artery past the Achilles tendon. *m.*, Muscle.

Sural Nerve.

The sural nerve is formed from the union of a branch of the tibial nerve and the common peroneal nerve. This nerve travels superficially with the short saphenous nerve behind the lateral malleolus into the ankle, where it provides the sensory innervation to the posterior portion of the sole of the foot, as well as to the posterior portion of the heel and the portion of the Achilles tendon immediately above the ankle (Fig. 50.34).^{51,60}

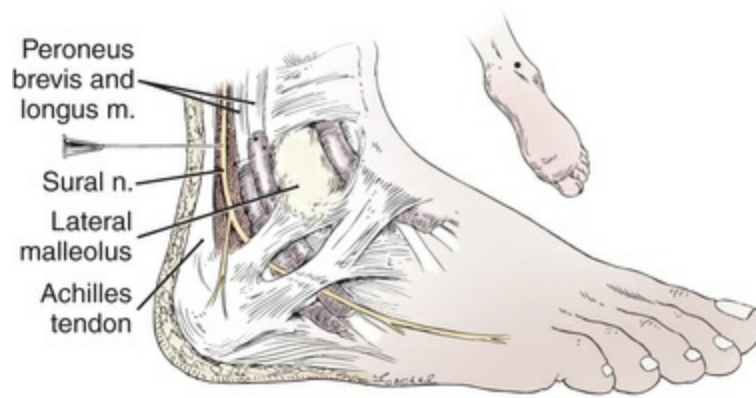

FIGURE 50.34 Path of the sural nerve behind the lateral malleolus into the ankle. *m.*, Muscle; *n.*, nerve.

Superficial Peroneal Nerve.

The superficial peroneal nerve arises from the roots of the fourth and fifth lumbar nerve roots, as well as the first and second sacral nerve roots. The nerve becomes superficial in the middle two-thirds of the lower leg and remains subcutaneous as multiple branches proceed into the dorsum of the foot. Just above the ankle ([Fig. 50.35](#)) the nerve begins to branch; for this reason, a single injection site does not provide sufficient anesthesia.^{51,60}

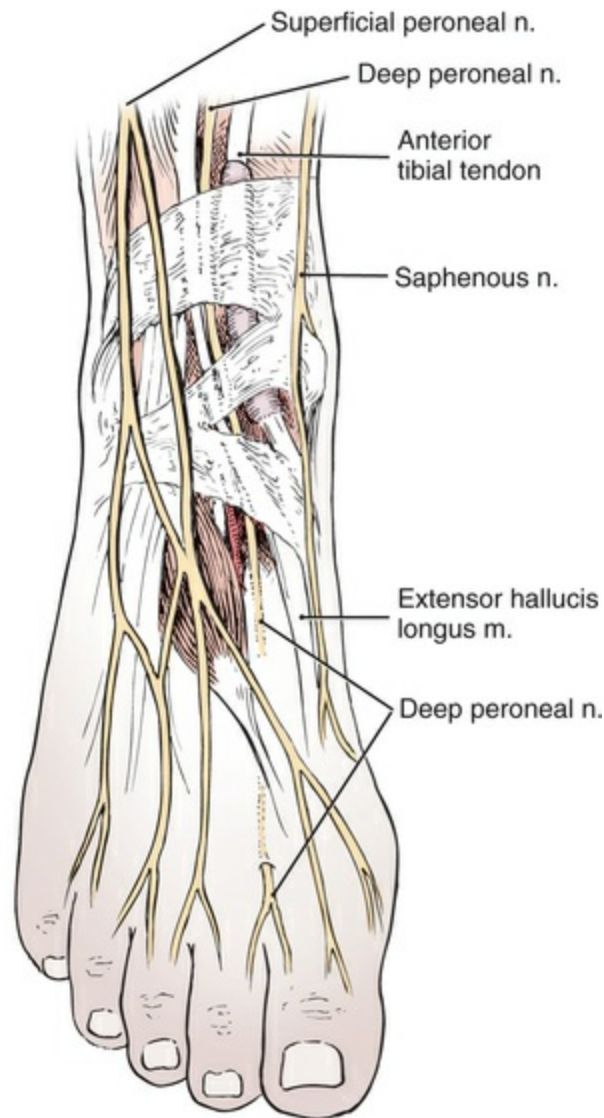

FIGURE 50.35 The superficial peroneal nerve proceeds to the dorsum of the foot subcutaneously through multiple branches. *n.*, Nerve.

Deep Peroneal Nerve.

The deep peroneal nerve arises from the same nerve roots as the superficial peroneal nerve. However, it remains within the protection of the anterior tibial muscle and the long extensor muscle of the great toe (see Fig. 50.35) as it traverses the leg and into the ankle. As it crosses the ankle, it is covered by the extensor retinaculum. The deep peroneal nerve provides innervation to the short extensors of the toes and provides sensory innervation to the skin on the lateral side of the hallux and on the medial side of the second digit. The nerve and the artery cross each other, so the nerve

lies lateral to the anterior tibial artery and medial to the long extensor muscle of the great toe that is in the ankle. This nerve is frequently missed when regional anesthesia is administered to the ankle.^{51,60}

Saphenous Nerve.

The saphenous nerve is the terminal branch of the femoral nerve and travels subcutaneously from the lateral side of the knee joint. It follows the greater saphenous vein to the medial malleolus and provides sensory innervation to the medial side of the malleolus and the skin of the medial aspect of the lower leg (see Fig. 50.35). If the block of the saphenous nerve is inadequate, the patient is unable to tolerate a tourniquet above the ankle.^{51,60}

Ankle Block Technique

The approach to both the sural and the posterior tibial nerves can be enhanced by placing the patient in the prone position. However, this is not always the most comfortable position. Therefore the patient should be placed in the most comfortable position that permits sufficient mobility of the foot. Rotation of the foot from side to side can be facilitated by turning the patient onto either side or elevating the foot on towels or pillows. The posterior tibial artery is palpated at the level of the superior portion of the medial malleolus. After the artery is located, the needle is inserted lateral to the artery in a line drawn from the superior portion of the medial malleolus to the lateral malleolus across the Achilles tendon. If the artery is not palpated, the needle is inserted lateral to the Achilles tendon at the level of the superior portion of the medial malleolus. The needle is advanced toward the medial malleolus and lateral to the position of the posterior tibial artery. As the needle is advanced toward the outer aspect of the medial malleolus, a paresthesia may be elicited. If this occurs, 5 mL of the anesthetic solution is injected with the needle held in position, and an additional 3 mL is injected as the needle is withdrawn. If a paresthesia is not elicited, the medial malleolus is gently contacted with the needle tip and withdrawn 2 mm from the bone. The anesthetic solution is slowly injected at this position, and the location is gently massaged after

the injection.^{73,74}

With the patient in the same position, the line from the medial malleolus across the Achilles tendon is identified on the lateral malleolus. The needle is inserted under the skin along the lateral border of the Achilles tendon in the plane with the line that is between the medial and lateral malleoli. The needle is advanced subcutaneously toward the superior edge of the lateral condyle, and 5 mL of solution is injected in the subcutaneous tissues as the needle is withdrawn. The solution must reach the superior edge of the lateral malleolus to anesthetize all the fibers of the sural nerve.

The patient is then placed in the supine position, and the anterior aspect of the ankle is prepared for the block. For anesthetizing the deep peroneal nerve, a line is drawn from the superior edge of the medial malleolus to the superior border of the lateral malleolus across the anterior portion of the ankle. The tendons of the anterior tibial muscle and the long muscles of the great toe are identified by having the patient flex the foot against resistance. Where the line crosses the midpoint between the two tendons, the needle is inserted toward the tibia (Fig. 50.36). As the needle advances through the fascia, a paresthesia may be elicited. If the paresthesia is not obtained, the needle is slowly advanced until the needle gently contacts the tibia. As the needle is withdrawn from contact with the tibia, 5 mL of anesthetic solution is injected. The needle is then withdrawn through the fascia, and an additional 3 mL of solution is injected.^{73,74}

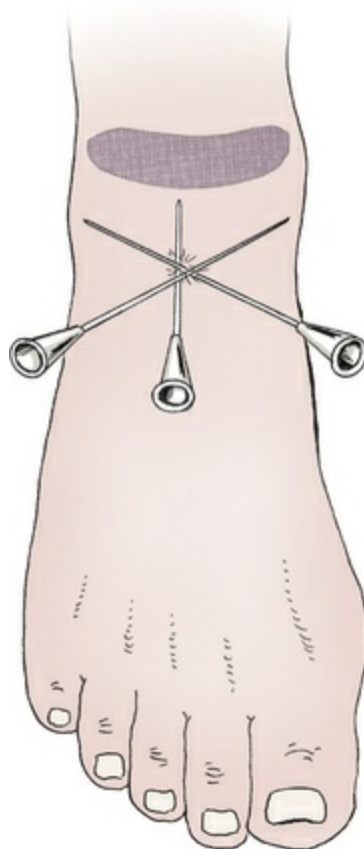

FIGURE 50.36 Direction and redirection of the needle in the ankle block technique.

With the needle remaining in the subcutaneous tissue, the needle direction is changed. The needle is advanced toward the inferior border of the lateral malleolus. The superficial peroneal nerve is located in subcutaneous tissue at this level. While the needle is being withdrawn, 5 mL of anesthetic solution is injected. A subcutaneous ring develops that should reach the lateral malleolus.^{73,74}

The needle is withdrawn to the midpoint, and the needle direction is again changed. The needle is redirected to the inferior border of the medial malleolus. The saphenous nerve is in the subcutaneous tissue, superficial to the saphenous vein. If the needle is not superficial, the saphenous vein is entered; 5 mL of solution is injected toward the medial malleolus. As the needle is withdrawn, 3 mL is injected. The deep peroneal and the posterior tibial nerves are the only nerves of the ankle that do not exist within the subcutaneous tissue.^{73,74}

Summary

Regional anesthesia techniques for upper- and lower-extremity blocks can be invaluable for specialized surgical procedures and immediate and long-term pain relief. There are a wide variety of techniques to achieve regional anesthesia: subarachnoid, epidural, caudal, brachial plexus, lumbar plexus, selective block of the upper- and lower-extremity nerves, intravenous infusion, intercostal nerve block, and specialized trauma techniques. Placement of these blocks can be facilitated by technology such as the PNS and ultrasonographic nerve location. Regional block may be used alone or in combination with general anesthesia and offers patients and surgeons excellent options for safe, effective anesthesia and analgesia.

Obstetric Anesthesia

Brian J. Kasson

Parturients who request or require obstetric anesthesia services represent a unique challenge to anesthesia providers. Techniques for providing pain relief during labor and delivery are continuously being refined in an effort to provide the best care possible to this uniquely vulnerable patient population. A thorough understanding of the anatomic and physiologic changes that occur during pregnancy and the anesthetic considerations associated with such changes are necessary for a safe and effective anesthetic course.

Anatomic and Physiologic Changes During Normal Pregnancy

The physiologic changes seen in pregnancy occur as a result of increased metabolic demands and hormonal and anatomic changes. These changes begin early in pregnancy and continue into the postpartum period. These marked changes have significant implications for the anesthesia provider.

Cardiovascular Changes

Cardiovascular changes begin as early as the fourth week of pregnancy and then continue into the postpartum period.¹ The heart rate (HR) is increased by 20% to 30% at term. This increase begins in the first trimester and peaks by 32 weeks of gestation.² Normal HR variability does not appear to be changed until late in pregnancy, when tachyarrhythmias are more common.³ Cardiac output increases by approximately 40% over nonpregnant values.⁴ This increase in cardiac output begins in the fifth week of pregnancy and results from an increase in stroke volume (SV) (20%–50%) and, to a lesser extent, HR.⁵ Cardiac output increases consistently throughout pregnancy.⁶ Some studies previously indicated cardiac output decreased in the third trimester, but these results were likely due to aortocaval compression from studying subjects in the supine position.⁷ At term, approximately 10% of the cardiac output perfuses the gravid uterus.^{8,9} When a woman is in labor, cardiac output increases during uterine contractions as a result of autotransfusion from the contracting uterus to the central circulation.¹⁰

Immediately after delivery, cardiac output increases as much as 80% above prelabor values. This occurs because of the autotransfusion of blood into central circulation from the contracting uterus and increased venous return from aortocaval decompression. As a result, patients with preexisting cardiac anomalies are at an increased risk for decompensation in the immediate postpartum period. Cardiac output gradually returns to baseline within 14 days as HR and SV normalize.¹¹

During pregnancy, the diaphragm rises, shifting the heart up and to the left, making the cardiac silhouette appear enlarged on x-ray examination. The ventricular walls thicken and end-diastolic volume increases. A physical examination of the pregnant patient may appear to elicit abnormal findings. A benign grade 1 or 2 systolic murmur or a third heart sound may be heard on auscultation.¹² These findings would not be unusual; however, if the systolic murmur is greater than grade 3 or accompanied by chest pain or syncope, further evaluation is necessary. Diastolic murmurs and cardiac enlargement are considered pathologic. Normal pregnancy may also result in signs of cardiac abnormality such as exercise intolerance, shortness of breath, and edema.

Total blood volume increases 25% to 40% throughout pregnancy, in part to prepare for the normal blood loss associated with delivery. Plasma volume increases 40% to 50% whereas red blood cell (RBC) volume increases by only 20%.¹³ As a result, a relative or dilutional anemia is commonly seen as the plasma volume increases to a greater extent relative to the actual RBC volume. The increased plasma volume is likely caused by circulating levels of progesterone and estrogen resulting in enhanced renin-angiotensin-aldosterone activity.¹⁴ RBC volume increases as a result of elevated erythropoietin levels seen after the eighth week of gestation.¹⁵ Normal blood loss for vaginal delivery is less than 500 mL, and for an uncomplicated cesarean section, the blood loss is 800 to 1000 mL. Normal blood losses at delivery are generally well tolerated in the healthy parturient as a result of these compensatory mechanisms. In labor each contraction moves 300 to 500 mL of blood from the contracting uterus to the central circulation.¹⁶ Pregnant women have greater baroreflex-mediated changes in HR at term than at 6 to 8 weeks postpartum.¹⁷ In the presence of adequate neuraxial analgesia and little sympathetic stimulation, there is often a corresponding decrease in maternal HR during uterine contractions due to the transiently increased preload.

Systemic vascular resistance (SVR) decreases as much as 21% by the end of a term pregnancy, owing in large part to decreased resistance in the uteroplacental, pulmonary, renal, and cutaneous vascular beds.^{18,19} At term gestation 10% of the cardiac output perfuses the low resistance intervillous space of the uterus. Baseline

central sympathetic outflow is twice as high in normal, term pregnant women as in nonpregnant women.²⁰ The venous capacitance system loses tone, allowing pooling of the larger blood volume. This decrease in SVR results in minimal overall systolic blood pressure change during normal pregnancy, despite the increased blood volume.²¹ A decrease in diastolic blood pressure of up to 15 mm Hg may occur, resulting in a decrease in mean pressure.

Aortocaval Compression

In the early 1950s, a syndrome involving supine hypotension was identified in term or near-term pregnant women.^{22,23} This syndrome is caused by compression of the vena cava and aorta by the gravid uterus, which restricts venous return to the heart when the parturient lies in the supine position. Compression can be more severe when the abdomen is tense or when the uterus is larger than normal, as in polyhydramnios or multiple gestation pregnancies. This decreased venous return results in a significant reduction in SV and, ultimately, cardiac output. The resultant hypotension can be severe enough to cause loss of consciousness in some women. Maximal decreases in blood pressure may require up to 10 minutes to develop; however, some women experience the decrease almost immediately. The normal physiologic responses to aortocaval compression are tachycardia and vasoconstriction of the lower extremities. Despite this attempted compensation, uterine blood flow and therefore fetal oxygenation are reduced.²⁴ Fig. 51.1 depicts changes in aortocaval compression with changes in position.

FIGURE 51.1 Effects of left uterine displacement on the diameter of the abdominal aorta and vena cava.

In addition to compressing the vena cava, the gravid uterus may compress the abdominal aorta. For this reason, supine hypotensive syndrome is more correctly referred to as *aortocaval compression*. When the abdominal aorta is compressed, upper-body blood pressure remains relatively normal, whereas blood pressure distal to the site of aortic compression (uterus and lower extremities) may be significantly reduced.

Compression of the aorta and vena cava can usually be relieved by shifting the uterus to the left (left uterine displacement) or by lying on the side.²⁵ Left uterine displacement can be accomplished by rotation of the operating room table 15 degrees to the left or by placing a 15-cm-high wedge under the parturient's right hip and back, as shown in Fig. 51.1. Most anesthetists have been shown to underestimate the angle of tilt they provide, so care should be taken to ensure adequate left uterine displacement.²⁶ In women with an exceptionally large uterus, greater displacement may be necessary

to be effective.

There has been much debate regarding the optimal position for performing neuraxial anesthesia for labor analgesia and cesarean delivery. Many clinicians feel that the lateral position is optimal to facilitate both maternal and fetal hemodynamics. Researchers have found that cardiac index is improved in both the left and right lateral positions when compared to the sitting flexed position in healthy pregnant women. However, when umbilical Dopplers were monitored in the same group as a surrogate for healthy fetal blood flow, no differences were identified.²⁷ Although positioning for neuraxial anesthesia may influence maternal hemodynamic variables, there were no differences in healthy fetal blood flow indices among positions, suggesting that these changes are not clinically significant.

Hematologic Changes

In general, the parturient is said to be in a hypercoagulable state. Because of the parturient's hypercoagulable state, concentration of factors VII through IX and fibrinogen are increased, whereas fibrinolytic activity is decreased.²⁸ In the nonpregnant state, fibrinogen levels average from 200 to 400 mg/dL. Late in pregnancy, fibrinogen levels are normally at least 400 mg/dL and may be as high as 650 mg/dL. These increased levels place the parturient at risk for thromboembolic events, which remain one of the leading causes of maternal mortality. The platelet count remains stable or is decreased slightly in the third trimester. The prevalence of maternal thrombocytopenia (platelet count less than $150 \times 10^9/L$) in normal pregnancy has been shown to be 11.6%²⁹ and is not associated with increased morbidity or mortality. The pathogenesis is not well understood but may involve factors such as hemodilution and/or accelerated platelet clearance.^{30,31} The white blood cell count rises in pregnancy. In the third trimester, the mean is 10,500/mm³, and in labor it may increase to 20,000 to 30,000/mm³.³²

Respiratory Changes

The respiratory changes that accompany normal pregnancy are of particular importance to the anesthesia provider. Capillary

engorgement in the upper airway results in a narrowed glottic opening and edema in the nasal and oral pharynx, larynx, and trachea. These changes carry over into labor, as has been shown by the Mallampati score changing as labor progresses.³³ Airway tissues are susceptible to damage and bleeding during placement of airway adjuncts. For this reason, nasal intubation in the parturient should generally be avoided. A 6.5–to 7.0-mm cuffed oral endotracheal tube is recommended when intubation is necessary. Obese patients with enlarged breasts may benefit from the use of a short-handled laryngoscope.

Term pregnancy is accompanied by an increase in oxygen (O_2) consumption by up to 33% at rest and 100% or more during the second stage of labor. Minute ventilation at term is increased by 50%. This is primarily due to a 40% increase in tidal volume, whereas the respiratory rate remains unchanged or increases by only 10%.³⁴ By 12 weeks' gestation the normal arterial partial pressure of carbon dioxide ($PaCO_2$) decreases to approximately 30 to 32 mm Hg and remains in this range throughout pregnancy.³⁵ Metabolic alkalosis is rarely seen because there is a compensatory decrease in the serum bicarbonate from 26 to 22 mEq/L. The normal arterial partial pressure of O_2 is greater than 100 mm Hg.

The functional residual capacity (FRC), expiratory reserve volume, and residual volume are decreased primarily as a result of upward pressure on the diaphragm, with results functionally similar to restrictive lung disease. The FRC plays an important role in preserving O_2 saturation during periods of hypoventilation or apnea. The decrease in FRC (20%) combined with the increase in O_2 consumption in pregnancy commonly results in rapid arterial desaturation in the apneic pregnant patient.³⁶ Morbid obesity, labor, and sepsis exaggerate this effect. For this reason, preoxygenation with 100% O_2 prior to induction of general anesthesia (GA) is important. Closing capacity (CC) does not change, which results in a decreased FRC/CC ratio often leading to small-airway closure before the tidal volume has been exhaled. This mechanism may explain the reduction in O_2 saturations seen in parturients during natural sleep. When compared with nonpregnant controls, whose average oxygen saturation during sleep was 98.5%, healthy near-

term pregnant women averaged only 95.2%, with temporary desaturations below 90% not being uncommon.³⁷ The increased cardiac output and a shift to the right in the oxyhemoglobin dissociation curve help to maximize oxygen delivery.

Minute ventilation can increase up to 300% during contractions and cause maternal PaCO₂ to drop below 15 mm Hg. This alkalemia can cause hypoventilation between contractions, resulting in hypoxemia. Some evidence indicates that hyperventilation may cause a decrease in uterine blood flow. However, in animal studies, this finding has usually been associated with stressful events such as intubation and invasive procedures. In pregnant, laboring human volunteers, hyperventilation to a PaCO₂ of 20 mm Hg does not appear to harm the fetus. Specifically, the fetus does not develop hypoxia or acidosis as determined by analysis of a scalp blood sample. However, in the presence of a complicated labor with preexisting fetal compromise, the effects could be detrimental.³⁸

Nervous System Changes

Beginning in the first trimester pregnant women have an increased sensitivity to local and general anesthetics.³⁹ The exact mechanism remains unclear, but animal studies have demonstrated a variable reduction in the minimum alveolar concentration (MAC) of inhalation agents in rabbits chronically exposed to progesterone.⁴⁰ In pregnant rats, the effects of endorphins on pain thresholds are also demonstrated, which may also be an important factor.⁴¹ Additionally, research and clinical experience have demonstrated an increase in the sensitivity of nerves to local anesthetics during pregnancy.⁴² Mechanical changes within the epidural space may also play a role in the increased block height seen in pregnancy.⁴³ Epidural veins become engorged as a result of increased intraabdominal pressure and cause a decrease in the volume of both the epidural and subarachnoid spaces.

Gastrointestinal Changes

The parturient is at increased risk for regurgitation and aspiration of gastric contents because of anatomic and physiologic changes associated with pregnancy. A significant number of pregnant

women, and women immediately postpartum, have gastric volumes in excess of 25 mL and gastric pH below 2.5.⁴⁴ Ultrasound has demonstrated solid food in the stomach of almost two-thirds of women in whom neuraxial analgesia had been instituted and in the stomach of more than 40% of laboring women who had not eaten in 12 to 24 hours.⁴⁵ Increased levels of gastrin during pregnancy result in greater gastric volume and lower pH. Upward displacement of the stomach by the gravid uterus may result in mechanical obstruction to outflow through the pylorus, delayed gastric emptying, and increased intragastric pressure. Elevated levels of progesterone, a smooth-muscle relaxant, also decrease gastric motility and cause a reduction in lower-esophageal sphincter tone. This explains the heartburn frequently experienced by pregnant women. Gastrointestinal changes do not completely normalize until several weeks postpartum.

The onset of labor is accompanied by a further reduction in the rate of gastric emptying in part due to pain and the use of parenteral opioids. Practice guidelines (2007) allow for the ingestion of a moderate amount of clear fluids in uncomplicated laboring patients. Uncomplicated patients undergoing elective cesarean delivery may have modest amounts of clear liquids up to 2 hours prior to induction of anesthesia. The same guidelines state that patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes, difficult airway), or patients at increased risk for operative delivery (e.g., nonreassuring fetal heart rate [FHR] pattern) may have further restrictions of oral intake.⁴⁶ Administration of nonparticulate antacids, H₂ receptor antagonists (to increase gastric pH), and metoclopramide (to promote gastric emptying, reduce nausea and vomiting, and increase lower esophageal sphincter tone) may be beneficial prior to cesarean section and should be considered. The use of these drugs is advocated when a general anesthetic becomes necessary. When a general anesthetic is used, a rapid sequence induction with cricoid pressure using a cuffed endotracheal tube is necessary from the twentieth week of gestation extending to the immediate postpartum period.

Hepatic Changes

During pregnancy, levels of aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase increase to the upper limits of nonpregnant normal levels. Serum albumin concentration decreases and may result in increased free fractions of highly protein-bound drugs. Serum cholinesterase activity decreases by 30% or more during the first or second trimester. Although activity recovers slightly by term, it remains reduced compared with prepregnant values. Despite these decreases in cholinesterase activity, clinically relevant prolongation of the duration of action of drugs that depend on cholinesterase for elimination, such as succinylcholine and remifentanyl, is uncommon in women with genotypically normal cholinesterase enzymes.

Renal Changes

During pregnancy, increased cardiac output leads to increased renal plasma flow and increased glomerular filtration rate (GFR). Creatinine clearance rises to 140 to 160 mL/min. As a result, the level of blood urea nitrogen decreases to approximately 8 mg/dL and creatinine decreases to approximately 0.5 mg/dL. Urinary excretion of glucose is common in the absence of disease and is attributable to increased GFR and reduced renal absorption. The urinary excretion of protein in normal pregnancy is slightly elevated toward the upper limits of normal. The gravid uterus may occasionally produce mechanical obstruction of a ureter. A summary of the physiologic changes in pregnancy at term appears in [Box 51.1](#) and [Table 51.1](#).

Key Points Regarding Physiologic Changes in Pregnancy

- Cardiac output increases mostly because of an increase in stroke volume and, to a lesser extent, an increase in heart rate.
- Blood volume is markedly increased and prepares the parturient for the blood loss associated with delivery.
- Plasma volume is increased to a greater extent than red blood cell volume, resulting in a dilutional anemia.

- Minute ventilation increases 45%, and this is due mostly to an increase in tidal volume.
- Oxygen consumption is markedly increased; carbon dioxide production is similarly increased.
- Pregnant women have an increased sensitivity to local anesthetics and a decreased minimum alveolar concentration (MAC) for all general anesthetics.
- Platelet count remains stable or decreases slightly; coagulation factors and fibrinogen are increased, resulting in a hypercoagulable state in pregnancy.
- Aortocaval compression results in profound hypotension and can be relieved by left uterine displacement.
- All pregnant women are at increased risk of aspiration because of the anatomic and physiologic changes to the gastrointestinal system and should be considered to have a full stomach after week 12 of gestation.
- Pregnancy and labor are associated with significant airway changes that can result in a difficult intubation. This highlights the importance of a comprehensive airway evaluation prior to general anesthesia.

TABLE 51.1

Summary of the Physiologic Changes in Pregnancy at Term

Parameter	Change	Amount
Heart rate	↑	20%–30%
Stroke volume	↑	20%–50%
Cardiac output	↑	40%
Systemic vascular resistance	↓	20%
Total blood volume	↑	25%–40%
Plasma volume	↑	40%–50%
Red blood cell volume	↑	20%
Coagulation factors	↑↑	
Platelets	No change or ↓	
Minute ventilation	↑	50%
Tidal volume	↑	40%
Respiratory rate	↑	

Uterine Blood Flow

The uterus undergoes tremendous changes during pregnancy. The uterus enlarges, and its blood flow increases to meet both uterine and fetal metabolic demands. Uterine blood flow is supplied by two uterine arteries that are thought to be maximally dilated throughout pregnancy. Placental blood flow on the uterine side is supplied via the maternal arcuate, radial, and spiral arteries. The spiral arteries expel blood into the intervillous space. The maternal venous sinuses receive blood from the intervillous space and return it to the general circulation. Uterine blood flow at term increases to a maximum of 800 mL/min, accounting for approximately 10% of maternal cardiac output. Of this, approximately 150 mL/min supplies nutritive flow to the myometrium, and 100 mL/min flows to the decidua (the lining of the uterus); the remainder flows to the intervillous space.

The fetus sends O₂-poor blood to the placenta via two umbilical arteries. These vessels perfuse capillary networks within placental villi that protrude into the pool of maternal blood. Placental villi are small, fingerlike projections, the purpose of which is to maximize the placental surface area in contact with maternal blood. Each villus contains a capillary network that exchanges respiratory gases, nutrients, and wastes with maternal blood (Fig. 51.2). Both O₂ and CO₂ diffuse through placental tissue readily and are considered to be “perfusion limited,” meaning their transfer to the fetus is limited only by the perfusion of the placenta, not by the rate of diffusion of the gases. Therefore, decreases in maternal uterine artery blood flow or increases in placental vascular resistance decrease fetal oxygenation.

FIGURE 51.2 Cross section of the uteroplacental interface and the maternal and fetal blood supply.

Autoregulation of intervillous blood flow does not seem to occur. Thus the uteroplacental perfusion is solely dependent on maternal blood pressure. The spiral arteries, however, do constrict in response to α -agonists (e.g., phenylephrine). However, human studies indicate phenylephrine does not appear to be harmful to the fetus when used at clinically relevant doses.⁴⁷ Patients with preeclampsia can develop placental insufficiency at systolic pressures greater than 100 mm Hg. Unlike patients who receive neuraxial anesthesia, patients receiving inhalation anesthesia seem to maintain adequate placental blood flow, despite somewhat reduced blood pressure; this may be a function of altered uterine blood flow, altered fetal O₂ requirements, or both.

Placental Transfer and Fetal Effects of Drugs

Placental transfer of free (non-protein-bound) drug is dependent on the magnitude of the concentration gradient, the molecular weight, lipid solubility, and state of ionization. Drugs with molecular weights greater than 1000 Daltons (Da) cross the placenta poorly, whereas drugs with weights less than 500 Da cross easily. Most drugs that are administered to the parturient are relatively small compounds and are thus able to cross to the placenta readily.

However, size is only one of the determinants of permeability.

Transfer of drugs from the maternal circulation to the fetal unit is determined primarily by diffusion. Factors that favor diffusion include low molecular weight, high lipid solubility, low degree of ionization, and low protein binding. Cell membranes consist primarily of phospholipids such that a drug's degree of lipid solubility favors its passage through a cell membrane. Highly lipid-soluble drugs such as fentanyl cross readily. On the other hand, ionized drugs are polar and water soluble, which inhibits diffusion through lipophilic cell membranes. Local anesthetics are examples of variably ionized basic compounds, whereby the degree of ionization is dependent on the ambient pH; the more alkaline the pH, the greater the degree of nonionization. It is the nonionized portion that crosses phospholipid membranes readily. Nondepolarizing muscle relaxants are an example of large, ionized drugs that are not affected by ambient pH because of the quaternary groups in their structure and are inhibited from crossing the placenta.

When a drug enters the fetal circulation, a variety of factors minimize the effects on the fetus. First among them is dilution. Before reaching the fetus, a drug is diluted in intervillous blood, absorbed by the placenta, further diluted in placental blood, and then circulated to the fetus. Once in the fetus, the drug is distributed within the fetal intravascular volume and redistributed to fetal tissues. Umbilical venous blood from the placenta must first pass through the liver on the way to the fetal heart. The resultant increase in maternal hepatic enzyme activity likely reduces serum drug levels before entering the general fetal circulation. Other factors limit the effects of maternally administered drugs on a fetus. Approximately one-fifth of the fetal cardiac output returns directly to the placenta because of shunt flow through the foramen ovale and ductus arteriosus. This shunted blood does not circulate, and any drug it contains does not have a systemic fetal effect.

The acid-base status of the fetus may affect the accumulation of a drug. A fetus who has become acidotic will alter the degree of ionization of a drug, potentially resulting in "ion trapping" leading to accumulation. For a complete discussion of fetal ion trapping see [Chapter 10](#).

Labor and Delivery

Pain in Labor and Delivery

First-stage labor pain is primarily the result of cervical distension, stretching of the lower uterine segment, and possibly, myometrial ischemia. The resultant nonspecific nociceptor visceral stimulation is carried to the central nervous system (CNS) by afferent unmyelinated C fibers that enter the cord at the T10, T11, T12, and L1 segments (Table 51.2 and Fig. 51.3). Thus, the pain of first-stage labor is frequently described as nonlocalized aching or cramping. Second-stage labor begins when cervical dilation is complete and the presenting part descends into the pelvis. Compression and stretching of the pelvic musculature and perineum produce pain that is mediated by somatic afferent fibers carried via the pudendal nerves that enter the spinal cord at the S2, S3, and S4 levels. A neuraxial anesthetic that extends from T10 to the sacral nerve roots can be effective in relieving the pain of both first- and second-stage labor.

TABLE 51.2

Pain Pathways During Labor

Area	Innervation	Comments
Uterus and cervix	T10 to L1–L2	Pain impulses carried by visceral afferent type C fibers
Perineum	S2–S4	Pain impulses carried by somatic nerve fibers; pudendal nerves

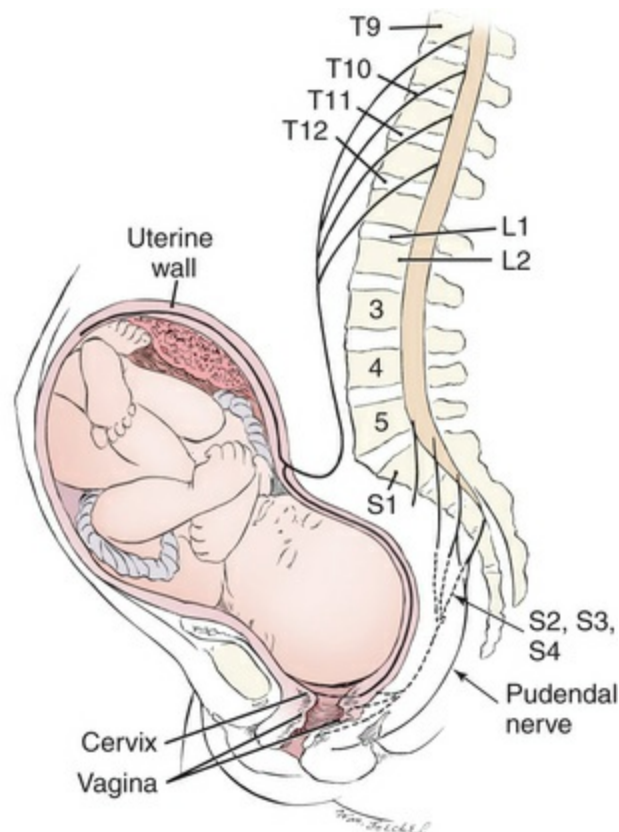

FIGURE 51.3 Lower thoracic, lumbar, and sacral regions of the spine showing spinal cord, nerve roots, and sensory innervation to the uterus, cervix, and vagina.

The experience of pain is a highly individualized phenomenon, and pain tolerance varies widely among patients. Many factors outside a parturient's control are also related to the perception of pain; these range from the presence or absence of social support to physical factors such as fetal presentation. Labor and vaginal delivery can be described as a process in which three essential components must work in concert. First, the fetus must be properly positioned and of an appropriate size to ensure passage through the bony pelvis, dilating cervix, and vagina. Second, the uterus must contract regularly and effectively. Third, the pelvic outlet itself must be configured in a way that the fetus can pass. A flaw in any of these three elements can result in a difficult, painful, and prolonged labor. A few women are able to tolerate labor and delivery without significant discomfort; others experience pain in excess of their ability to cope. When women choose labor analgesia, it can make the birth process more enjoyable and provide the opportunity to better control their bodies and environment, thereby

allowing them to maintain personal dignity.

Stages of Labor and Delivery

Labor is defined as progressive dilation of the cervix in response to uterine contractions. Although sporadic and irregular third-trimester contractions are common, labor is not said to begin until those contractions are regular and result in a change to the cervix. Labor is generally divided into three stages. First-stage cervical changes consist of effacement and dilation. The first stage is further divided into at least the latent and active phases. The latent phase is of variable duration and is defined as the period between the onset of labor and the point at which the cervix begins to rapidly change. Active phase usually begins at 2 to 3 cm dilation and is the period during which the cervix undergoes its maximum rate of dilation.

The second stage begins at full cervical dilation (10 cm) and ends with delivery of the fetus. The third stage encompasses the delivery of the placenta. The length of time it takes to progress through these stages is dependent on parity, effective uterine contractions, the size and type of pelvis, and fetal presentation. The Friedman curve is used to track the normal progress of labor (Fig. 51.4). Cervical dilation normally progresses 1 to 1.2 cm/hr during the active phase of labor. When labor progress no longer follows the normal pattern, it is considered a “dysfunctional labor,” and may require the use of oxytocin to augment contractions.

nulliparous patients in labor. *accel.*, Acceleration; *decal.*, deceleration; *sec.*, second. (Redrawn with modifications from Miller RD, et al. *Miller's Anesthesia*. 8th ed. Philadelphia: Elsevier; 2015:2335.)

Intrapartum Fetal Evaluation

Intrapartum FHR monitoring is now used routinely in the United States. Although continuous or intermittent FHR monitoring is not a specific predictor of fetal well-being, it is the most readily available method for the assessment of fetal condition. Intermittent monitoring can be performed using a manual stethoscope known as a fetoscope. Continuous FHR monitoring is accomplished using either external Doppler ultrasonography or an internal fetal electrocardiography electrode. The internal method requires ruptured amniotic membranes and a partially dilated cervix through which the electrode can be inserted. The continuous FHR is recorded in a two-channel format with the FHR displayed directly above a graphic representation of the uterine contractions. In this way, it is possible to relate FHR changes to uterine activity. The most commonly used scaling is a paper speed of 3 cm/min on the horizontal axis and 30 beats/min per centimeter of paper for the FHR (vertical axis).⁴⁸ In this manner each sequential vertical line is 10 seconds apart and every sixth vertical line (bold) represents a period of 1 minute.

Uterine contractions are monitored either externally via a tocodynamometer or internally with an intrauterine pressure catheter attached to a transducer placed between the fetus and uterine wall. Data obtained from external contraction monitoring is limited to temporal elements such as contraction duration and interval, and cannot be used to estimate contraction strength. External monitoring is subject to a great deal of artifact from maternal movement and errors in transducer placement. Internal contraction monitoring is more reliable and allows for precise determination of intrauterine pressure and, hence, contraction strength. Its use is also predicated on ruptured amniotic membranes and a partially dilated cervix. Internal pressure monitoring is commonly seen with high-risk parturients or those in whom labor augmentation with oxytocin is being used. Most

commercially available intrauterine pressure catheter systems also allow for the infusion of fluids into the amniotic space (amnioinfusion), which is thought to reduce the risk of fetal aspiration of meconium-stained amniotic fluid.⁴⁹

Fetal pulse oximetry has been introduced but is largely investigational at this time. A wide range in normal values has been reported, and use of oximetry has not been shown to decrease overall cesarean section rates, making its ultimate benefit questionable.⁵⁰

Information about the baseline status of a fetus should be obtained during the preanesthetic assessment. The FHR can also reveal information about the fetal response to anesthetic interventions. This information is useful before neuraxial anesthetic placement, for assisted or operative delivery, and for nonobstetric surgery during pregnancy. Current American Association of Nurse Anesthetists (AANA) practice guidelines state that the Certified Registered Nurse Anesthetist (CRNA) shall be aware of the fetal status prior to each anesthetic intervention and that the fetal status be monitored and documented in the patient's record.⁵¹

Changes in Fetal Heart Rate

The individual components of the FHR pattern do not occur alone and changes generally evolve over time. Therefore, a full description of a FHR tracing requires a qualitative and quantitative description of baseline rate, variability, presence of accelerations or decelerations, and trends over time.⁵² In the presence of a normally functioning uteroplacental unit, fetal oxygenation is limited primarily by uterine blood flow. As stated, uterine arteries are maximally dilated in pregnancy, which results in the inability of the uterus to autoregulate blood flow. Decreases in maternal blood pressure and uterine artery blood flow ultimately compromise placental blood flow, resulting in fetal hypoxia and acidosis, which can be manifested as FHR changes. The normal FHR ranges from 110 to 160 beats per minute (bpm). An immature fetus has a higher HR. Tachycardia is defined as a HR greater than 160 bpm in a term fetus. It can result from fetal asphyxia, fetal arrhythmias, maternal fever, chorioamnionitis, and maternally administered drugs such as terbutaline and atropine. Ephedrine can increase both FHR and

variability if given to the parturient in large enough doses.⁵³ Fetal bradycardia is present when the FHR is less than 110 bpm. Bradycardia can be caused by maternally administered drugs, hypoxia (fetal or maternal), or fetal head or cord compression.

Variability

Fetal heart rate variability is thought to be the single best indicator of fetal wellbeing because it likely indicates adequate fetal oxygen reserve. Variability is the result of interaction between the fetal sympathetic and parasympathetic autonomic nervous systems. Baseline variability is defined as fluctuations in the FHR of two cycles per minute or greater that are irregular in amplitude and frequency.⁵² It is quantified by measuring the amplitude from peak to trough in beats per minute. Variability is described as absent, minimal (less than 5 bpm), moderate (6–25 bpm), and marked (greater than 25 bpm). In general, baseline FHR variability increases with advancing gestational age. Variability represents an intact CNS and normal cardiac function. Hypoxia causes fetal CNS depression, which results in decreased variability. Other causes of decreased variability include fetal sleep, acidosis, anencephaly, drugs (CNS depressants or autonomic agents), and defects of the fetal cardiac conduction system. For example, administration of opioids to the mother, can decrease FHR variability for up to 30 minutes.⁵⁴ Maternal magnesium sulfate administration may also attenuate FHR variability.⁵⁵ Variability refers to the baseline FHR and, as such, does not include accelerations or decelerations. Beat-to-beat variability can be accurately assessed only by direct FHR monitoring with a fetal scalp electrode. Examples of absent and moderate FHR variability are shown in [Fig. 51.5](#).

FIGURE 51.5 **A**, Normal intrapartum fetal heart rate (FHR) tracing. The infant had Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. **B**, Absence of variability in a FHR tracing. Placental abruption was noted at cesarean delivery. The infant had an umbilical arterial blood pH of 6.75 and Apgar scores of 1 and 4, respectively. **C**, Early FHR decelerations. After a normal spontaneous vaginal delivery, the infant had Apgar scores of 8 and 8, respectively. **D**, Late FHR decelerations. The amniotic fluid surrounding this fetus was meconium stained. Despite the late FHR decelerations, the variability remained acceptable. The infant was delivered by cesarean delivery and had an umbilical venous blood pH of 7.30. Apgar scores were 9 and 9, respectively. **E**, Variable FHR decelerations. A tight nuchal cord was noted at low-forceps vaginal delivery. The infant had Apgar scores of 6 and 9, respectively. Numerical scales: *Left upper panel margin*, FHR in beats per minute; *left lower panel margin*, uterine pressure in mm Hg; *right lower panel margin*, uterine pressure in kilopascal (kPa) (From Chestnut DH, et al. *Chestnut's Obstetric Anesthesia*, 5th ed. St. Louis: Elsevier; 2014:153.)

Accelerations and Decelerations

An acceleration is an abrupt increase in the FHR above baseline. Accelerations occur in response to fetal movement and indicate adequate oxygenation. A FHR pattern is said to be reactive when there are two or more accelerations in a 20-minute period. Decelerations are classified as early, variable, or late.

Early Decelerations.

Early decelerations occur in concert with uterine contractions. The deceleration begins when the contraction begins, and it returns to baseline when the contraction ends. An early deceleration occurs with each uterine contraction and has the same appearance from one contraction to the next. Compression of the fetal head resulting in vagal stimulation is thought to be the cause of early decelerations. Early decelerations have the following characteristics:

- Occur with each uterine contraction
- Start and end with the contraction
- Gradually decrease in rate and then end in a return to baseline
- Are uniform in appearance
- Are associated with a mild decrease in FHR (20 bpm or less)
- Are accompanied by a loss in beat-to-beat variability during the deceleration

Variable Decelerations.

Variable decelerations are the most frequent FHR changes related to labor and are described as a sudden decrease in FHR that occurs irrespective of uterine contractions.⁵⁶ Variable decelerations are abrupt in both onset and recovery and vary in occurrence, onset, depth, duration, and appearance. Beat-to-beat variability is normally present during the decelerations. Variable decelerations are thought to be caused by a baroreflex-mediated response to umbilical cord compression and are often considered to be a non-ominous sign for neonatal outcome. Alternatively, if the fetus is compromised, then the recovery phase of the deceleration may be delayed. Variable decelerations have the following characteristics:

- Vary in appearance, duration, depth, and shape
- Demonstrate abrupt onset and recovery
- Maintain beat-to-beat variability with the deceleration

Late Decelerations.

Late decelerations begin late in the contraction and represent uteroplacental insufficiency. The lowest point of the deceleration occurs after the peak of the contraction. Like early decelerations, they are smooth in both onset and recovery. Late decelerations are

normally repetitive. Beat-to-beat variability may or may not be present during the deceleration, depending on the degree of fetal hypoxia and myocardial depression. Late decelerations are nonreassuring and should be investigated for potential causes.⁵⁷ Fig. 51.5 shows a FHT with late decelerations and minimal variability.

Late decelerations have the following characteristics:

- Occur with each uterine contraction
- Low point of the deceleration after the peak of the contraction
- Gradually decrease in rate and end in a return to baseline
- Are uniform in appearance
- Vary in depth according to the strength of the uterine contraction
- May or may not be accompanied by beat-to-beat variability

Categories for the Evaluation of Fetal Heart Rate

The American College of Obstetrics and Gynecologists recommends a three-tiered system to evaluate FHR tracings. Category I FHT are considered normal and include normal baseline HR and moderate variability with absent variable and late decelerations. Category I tracings predict normal acid-base balance. Category II FHT include all tracings that are not classified as category I or III. Category II tracings do not predict abnormal acid-base status and warrant continued observation. Category III tracings include those with fetal bradycardia or absent variability accompanied by recurrent late or variable decelerations. Category III tracings predict abnormal acid-base status and require prompt intervention.⁵⁸

Anesthetic Considerations in the Presence of Nonreassuring FHT

If the FHR tracing recorded during the preanesthesia assessment suggests hypoxia, caution should be used in making the decision to proceed with neuraxial analgesia. Careful consideration must be given to the severity of the fetal compromise and to the possibility that it may be worsened by anesthetic intervention. However, the obstetrical team may request a neuraxial anesthetic for a patient

with a nonreassuring FHT in anticipation of a possible urgent and unplanned operative vaginal delivery or cesarean section.

Intrauterine resuscitation describes interventions that can be used by the obstetrical staff and anesthesia provider to improve the condition of a compromised fetus in utero. These interventions include changing maternal position, rapid infusion of intravenous (IV) fluids, discontinuing oxytocin, IV pressor support in the presence of maternal hypotension, the use of tocolytic agents and maternal oxygen administration to correct maternal hypoxia.⁵⁹

Analgesia for Labor and Vaginal Delivery

Intravenous Analgesia in the Parturient

Although less effective than neuraxial analgesia, systemic medications can be used for labor pain relief when neuraxial analgesia is unavailable, refused, or contraindicated. However, the use of systemic medications presents several disadvantages. The pain relief they afford is often inadequate, and both fetal and maternal respiratory depression, nausea, vomiting, and decreased lower esophageal sphincter tone may result. Controlled, randomized trials investigating neuraxial versus IV analgesia in labor are difficult to design and execute due to high protocol failure rates. In a systematic review of studies involving over 9600 women that compared neuraxial analgesia to opiates, neuraxial techniques offered better pain relief and a reduced risk of fetal acidosis. On the other hand, neuraxial analgesia was associated with a longer second stage labor and an increased incidence of assisted vaginal delivery.⁶⁰

Because opioids are lipid soluble and relatively small (less than 500 Da), they rapidly cross the placenta to gain access to the fetal circulation and may result in fetal depression. A neonate's blood-brain barrier is less developed and its ability to metabolize narcotics is less mature when compared to an adult. Opioids can be administered by IV bolus or patient-controlled analgesia (PCA). The advantage of PCA is it allows the parturient greater control over drug dosing and has resulted in greater patient satisfaction. However, in one study PCA was compared with nurse-administered boluses, and there was no difference in pain scores or maternal and fetal side effects.⁶¹ The use of parenteral narcotics in early labor has declined as the practice of obstetric anesthesia has evolved to include those patients in early labor as acceptable candidates for neuraxial analgesia.

Meperidine

Meperidine is administered as a parenteral opioid for labor analgesia. A typical dose is 50 to 100 mg intramuscular (IM) and can be repeated every 4 hours. Meperidine crosses the placenta easily and has been recovered from the fetus within 2 minutes of IV administration. The maternal half-life of meperidine is 2.5–3 hours. Like all opioids, it can cause neonatal respiratory depression, although less so than morphine. Because of differences in pH and protein binding, the level of meperidine in the fetus is likely to be higher than the maternal blood level. Normeperidine is an active metabolite of meperidine with an elimination half-life of 30 hours. Normeperidine remains in the neonate for several days after delivery and may lead to depression of neonatal behavioral assessment scores. Both meperidine and normeperidine can be antagonized by naloxone.

The overall analgesic effect of meperidine in labor is marginal. In a random trial of 102 women acetaminophen 1000 mg IV was found to provide similar analgesia when compared to IV meperidine 50 mg. The incidence of maternal side effects was 64% in the meperidine group and 0 in the acetaminophen group.⁶²

Fentanyl

The pharmacologic profile of fentanyl, that is, its high potency and short duration of action, make it a reasonable choice for labor. It is highly lipid soluble and protein bound and can be detected in fetal circulation after 1 minute of IV administration. Depressant effects, including a reduction in beat-to-beat variability, have been seen.⁶³ Fentanyl can be administered IM, IV or most commonly by PCA. Dosages used for labor analgesia range from 25 to 100 mcg IV in hourly increments⁶⁴ or PCA bolus 25–50 mcg with a lockout interval of 3 to 6 minutes and a 4-hour limit of 1–1.5 mg.⁶⁵

Morphine

Morphine has been used in early labor to provide analgesia and sedation but is no longer widely accepted due to high rates of maternal sedation, neonatal depression, and an undesirable prolonged duration.⁶⁶ Morphine crosses the placenta easily and, in animal studies, crosses the fetal blood-brain barrier more readily

than in adults.⁶⁷

Butorphanol and Nalbuphine

Butorphanol and nalbuphine are opioid agonist-antagonists that are associated with a “ceiling effect” whereby incrementally higher doses do not result in increasing respiratory depression. They may also result in less nausea and vomiting than pure opioids. Agonist-antagonists have typically been used in first-stage latent-phase labor to provide sedation and a period of maternal rest. A typical butorphanol dose for labor is 1 to 2 mg IV or IM. Butorphanol is five times as potent as morphine and has a half-life of 3 hours.

Unlike morphine, butorphanol increases pulmonary artery pressure and myocardial work.⁶⁴ Butorphanol has no active metabolites. The nalbuphine dose in labor is 5 to 10 mg IV, IM, or subcutaneous (SC) and is equivalent to morphine 10 mg. Nalbuphine results in a greater reduction in FHR variability compared with meperidine.⁶⁸ Because these compounds possess significant antagonist properties, their use in opioid-dependent patients should be avoided.

Remifentanil

Remifentanil is an ultra–short-acting opioid receptor agonist. It is rapidly hydrolyzed by plasma and tissue esterases to an inactive metabolite. The context-sensitive half-life remains short (3.2 min) regardless of prolonged administration times.⁶⁹ This unique pharmacokinetic profile makes it suitable for PCA use in labor. It crosses the placenta readily but is similarly rapidly redistributed and metabolized by the fetus.⁷⁰ Douma et al.⁷¹ compared remifentanil, fentanyl, and meperidine PCA's in labor and found that remifentanil PCA was associated with the greatest reduction in pain scores; however, the relief was described as mild to moderate. The same group has found that remifentanil PCA is less effective when compared with standard epidural labor analgesia.⁷² A PCA bolus of 0.25 mcg/kg with a lockout interval of 2 minutes and a background infusion of 0.025–0.05 mcg/kg per min is common.^{63,73,74} Use of remifentanil during labor is a relatively new technique that appears to have an acceptable safety profile. However, its use mandates careful monitoring due to the potential for adverse

maternal events.⁷⁵

Ketamine

Ketamine is a derivative of phencyclidine and an N-methyl-D-aspartate (NMDA) receptor antagonist that produces a dissociative anesthetic effect. It produces profound analgesia at subhypnotic doses. Its use as a labor analgesic is limited, however, by its short duration of action and high incidence of amnesia. **Low-dose ketamine preserves airway reflexes while causing somatic analgesia, sedation and occasionally a dreamlike state.** Satisfactory labor analgesia has been described by using a continuous infusion of ketamine at 0.2 mg/kg per hr.⁷⁶ Small intermittent IV doses of ketamine can be used to supplement a suboptimal neuraxial anesthetic when replacement or adjustment is not possible. Ketamine doses of 0.2 to 0.5 mg/kg produce rapid analgesia with a dose-dependent duration of action of approximately 5 to 15 minutes.

Ketamine has sympathomimetic properties that result in increased HR, blood pressure and cardiac output which may be desirable in a hypovolemic parturient. The hyperdynamic effects, however, may be problematic in the parturient with hypertension or preeclampsia. It is the agent of choice for induction in the patient with acute asthma requiring urgent cesarean section. The emergence delirium and hallucinations limit the effectiveness of ketamine for routine use in obstetrics. Uterine arterial blood flow does not decrease after ketamine administration. Ketamine is lipid soluble and crosses the placenta easily. Neonatal depression has not been demonstrated after maternal ketamine doses of up to 1 mg/kg. Doses larger than 1 mg/kg may result in neonatal respiratory depression, muscular hypertonicity, and lower Apgar scores.⁷⁷

Nonpharmacologic Methods

A multitude of nonpharmacologic techniques are currently in use but, as Wong has stated, the effectiveness of these techniques generally lack rigorous scientific study and conclusions regarding their efficacy cannot be made.⁷⁸ Nonpharmacologic alternatives include hydrotherapy, hypnotherapy, massage, movement, and

positioning. Although maternal satisfaction is without a doubt influenced by the degree of pain endured, it is influenced to a greater extent by whether the actual birth event met the mother's personal expectations.⁷⁹ The role of an obstetric anesthesia provider is to support laboring women such that they can make informed choices that meet their individual expectations, while at the same time ensuring the safety of both the mother and infant.⁸⁰

Neuraxial Analgesia for Labor and Vaginal Delivery

Neuraxial analgesia is currently the best method of pain relief for labor and delivery. When properly placed and dosed, a neuraxial anesthetic is the only modality available that can provide complete relief from labor pain with minimal depression of the parturient or fetus. Common neuraxial anesthetics include epidural, combined spinal-epidural (CSE), and spinal techniques. The American College of Obstetricians and Gynecologists (ACOG) has stated that, absent medical contraindications, maternal request is sufficient reason to provide labor analgesia.⁸¹ However, labor is a prerequisite for neuraxial analgesia and is defined as regular uterine contractions that result in cervical dilation and effacement.

Early initiation of neuraxial anesthesia may be considered for anesthetic or obstetrical complications.⁸² These patients include those with morbid obesity, severe scoliosis or known difficult airway. Obstetrical indications for early placement include multiple gestation pregnancies and severe preeclampsia. Early initiation allows for better cooperation with positioning during placement and adequate time to confirm proper block function. If cesarean section becomes urgently necessary the indwelling epidural catheter can be used for anesthesia, reducing the need for a general anesthetic.

Absolute contraindications to neuraxial anesthesia include patient refusal, inability to cooperate, uncorrected severe hypovolemia, uncorrected coagulopathy or pharmacologic anticoagulation, elevated intracranial pressure secondary to a mass, or infection at the site of insertion. There are many relative contraindications such as stable preexisting CNS disease, chronic

severe headaches or back pain, untreated bacteremia, and severe stenotic valvular lesions. Patients with these and other preexisting conditions should undergo careful preanesthetic evaluation and consultation that takes into consideration the risks and benefits of the proposed procedure. With recognition and proper optimization of these preexisting conditions, patients can often safely receive neuraxial anesthesia.

Historically, the platelet count at which a neuraxial anesthetic could be safely administered has been considered to be greater than $100,000 \times 10^9/L$. However, contemporary practice surveys indicate that most practitioners are comfortable providing a regional anesthetic with the platelet count as low as $80,000 \times 10^9/L$.⁸³ Careful consideration of thrombocytopenic parturients should include a thorough history and physical examination for signs and symptoms of coagulopathy with an emphasis on previously administered medications including herbal supplements. A review of laboratory findings should include all prior platelet counts (to establish any trends) as well as other relevant laboratory findings.

Patients receiving prenatal and/or intrapartum antithrombotic or thrombolytic therapy require special consideration. Normal pregnancy is associated with a hypercoagulable state that, alone or in combination with certain pathologic conditions, can predispose parturients to thromboembolic events. Conditions that may require anticoagulation therapy in the obstetric population include deep vein thrombosis, antiphospholipid antibody syndrome, factor V Leiden mutations, and protein S and C deficiencies. The concern with neuraxial anesthetics is the potentially catastrophic complication of epidural hematoma. Epidural hematoma results from uncontrolled bleeding in the nondistensible epidural space, which, if untreated, can cause ischemic injury to the cord resulting in persistent neurologic dysfunction. Epidural hematoma is a rare complication that is estimated to occur in less than 1 in 150,000 epidural and 1 in 220,000 spinal anesthetics.⁸⁴ The American Society of Regional Anesthesia and Pain Medicine has published consensus statements in an effort to guide practitioners in the management of these complex patients.⁸⁵

Preprocedure Preparation

History and Physical.

It is optimal to complete the history and physical for every patient whose plan includes a neuraxial anesthetic early in the labor process, often before the regional anesthetic is indicated. An early history and physical allows for recognition of potential problems and provides time for additional work-up if necessary. Valuable time can also be saved with a previously completed history and physical if an anesthetic intervention becomes urgently necessary.

The history should include questions regarding pertinent systemic diseases, as well as the obstetric history and course of the current pregnancy. Particular attention should be directed toward problems with previous pregnancies, deliveries, or anesthetics. A review of the patient's medical record to include previous analgesic interventions, such as IV narcotics, should be performed. The physical examination should include an inspection of the back, heart, and lungs, as well as an airway examination. It has been demonstrated that the airway examination can change during labor.³² Therefore a repeat examination is indicated immediately before administering anesthesia in labor regardless of prior examination results.

The maternal vital signs and fetal condition should be documented. This includes dilation, effacement, station, FHR, membrane status, and variability. The obstetric history includes gestational age and the parturient's gravidity (i.e., number of conceptions) and parity (i.e., number of live births). Obtaining a platelet count before the institution of neuraxial anesthesia in healthy patients with uncomplicated pregnancies has not been shown to reduce overall complication rates.⁸⁶ However, in the presence of hypertensive disorders or coagulopathies with anesthetic implications, the elective anesthetic should generally be delayed until appropriate laboratory results (e.g., coagulation studies, platelet count) are available. In the absence of comprehensive prenatal care, obtaining baseline laboratory values may be indicated due to the possibility of undiagnosed medical conditions.

Informed Consent.

Those who provide anesthesia for laboring women have an

obligation to obtain informed consent prior to the procedure. The elements of informed consent include a description of the procedure, the risks, benefits, potential complications, and alternatives. However, there are several issues unique to obstetric anesthesia that can complicate informed consent. The first involves capacity and whether a woman in great pain and distress has the ability to understand and reason.⁸⁷ There is evidence to indicate that women retain the ability to assimilate information and make good decisions despite the pain of labor. Jackson et al.⁸⁸ found that most women in active labor were able to voluntarily consent and that their ability to understand was not affected by pain, premedication, or duration of labor. Affleck et al.⁸⁹ determined that recall of risks by parturients is similar to the recall of risks by other patients and does not appear to be affected by parity or the reported level of pain.

A second confounding issue with regard to informed consent is caring for the pregnant minor. Competence describes the legal authority to make a decision and is recognized in the United States as occurring at 18 years of age. However, various state laws make exceptions (emancipation) for minors who are free of parental care, control, and custody. This may occur when a minor is married, a member of the military, or a high school graduate. Becoming pregnant does not necessarily constitute emancipation. With respect to obstetric anesthesia, it is best to include the legal guardian of a minor patient in the informed consent process. Anesthesia providers must have a working knowledge of various local, state, and federal guidelines, as well as their institutions' applicable policies and procedures.

Informed consent should include those risks that are reasonably foreseeable, but it does not have to include every possible risk. Material risks are those that a reasonable person would want to be made aware of before deciding on a recommended therapy.⁹⁰ They include risks that commonly occur, as well as those risks that are rare but may result in severe morbidity and mortality. There exists no distinct and inclusive list of potential risks and complications; however, several surveys of practitioners demonstrate some consensus regarding what should be disclosed.^{91,92}

Drugs and Equipment.

It is the provider's responsibility to ensure that the anesthesia equipment available in the obstetric area is consistent with other anesthetizing locations in the facility.⁹³ An oxygen source, a positive pressure apparatus capable of delivering 100% oxygen, and an appropriate suction assembly must be present at every location where neuraxial anesthesia is provided. Emergency airway supplies such as face masks, oral and nasal airways, laryngeal mask airways, laryngoscope handle/blades, endotracheal tubes and stylet, and an Eschmann intubating stylet need to be immediately available. Carbon dioxide monitoring can be accomplished with a qualitative carbon dioxide detector. **Emergency drugs** include an induction drug (for terminating a local anesthetic-induced seizure), succinylcholine, ephedrine, epinephrine, phenylephrine, naloxone, atropine, calcium chloride (for treating magnesium sulfate overdose), and sodium bicarbonate. The equipment should be checked prior to each anesthetic.

As services are often provided at each bedside in a labor and delivery unit, an "epidural" cart that contains routine supplies, as well as emergency equipment and drugs, is preferred. A standard "crash cart" with a defibrillator and a supply of intralipid 20% to treat intravascular injection of local anesthetics should be readily available (see [Chapter 10](#) for a complete discussion of local anesthetic toxicity). Noninvasive automatic blood pressure monitoring and pulse oximetry are required in each labor and delivery room. In addition to proper drugs and equipment, a knowledgeable assistant is essential for the safe insertion of a neuraxial anesthetic. An obstetric nurse who can assist with FHR monitoring and positioning is desirable. IV access is required prior to initiating a neuraxial anesthetic and should be maintained throughout its duration. IV insertion sites should take into consideration the vigorous arm movement that can occur during second-stage labor. The dilute concentrations of local anesthetic commonly used in labor analgesia today result in significantly less sympathetic blockade and hypotension compared with traditional high-dose blocks.⁹⁴ As a result, the administration of a fixed volume of IV fluid is not required before neuraxial analgesia is initiated.⁸⁶

Local Anesthetics

Bupivacaine.

Bupivacaine is an amino-amide local anesthetic with a relatively long duration of action and the ability to produce a differential block whereby sensory fibers are blocked more readily than motor fibers. When compared with lidocaine, there is less tachyphylaxis during long-term administration. In lower doses, it has limited placental transfer, as well as minimal neonatal effects. These characteristics have made it the **most commonly used local anesthetic in obstetric anesthesia**. Bupivacaine is marketed as a racemic mixture of the S⁻ and R⁺ isomers. Refractory cardiac arrest has been associated with high concentrations of bupivacaine inadvertently administered intravascularly. It is more difficult to resuscitate patients who experience bupivacaine-induced cardiac arrest when compared with other local anesthetics. The exact cause remains unclear; however, evidence suggests that toxicity occurs primarily at sodium channels, and there may be qualitative differences in cardiotoxicity caused by low- and high-potency local anesthetics.⁹⁵ The epidural administration of 0.75% bupivacaine has been prohibited for use in obstetrical anesthesia due to its increased potential for toxicity. Clinical techniques to reduce the incidence of cardiac toxicity include fractional dosing (less than 5 mL), frequent aspiration for blood during injection, and use of a test dose. The use of low concentrations for continuous epidural infusion and low doses (less than 15 mg) for spinal anesthesia are not associated with cardiac toxicity.⁹⁶

Lidocaine.

Lidocaine is an amino-amide local anesthetic that has been used extensively in obstetric anesthesia for decades. It has a rapid onset and an intermediate duration of action. When given in the epidural space, it produces a dense motor block when combined with epinephrine, which makes it well suited for epidural anesthesia for cesarean section. This dense motor block, however, makes it less desirable for labor analgesia. Lidocaine administered in the subarachnoid space is potentially neurotoxic.⁹⁷ In 1991 four cases of cauda equina syndrome were reported after the use of lidocaine in

small-diameter catheters designed for continuous spinal anesthesia. In all four cases, there was initial evidence of a focal sensory block, and to achieve adequate analgesia, a dose of local anesthetic was given that was greater than that usually administered with a single-injection technique. The authors postulated, and subsequent data substantiated, that the combination of maldistribution and a relatively high dose of local anesthetic resulted in neuronal injury.⁹⁸ Transient neurologic symptoms consisting primarily of lower extremity pain also have been attributed to 5% hyperbaric lidocaine⁹⁹ (see [Chapter 10](#)). For this reason, obstetric anesthesia providers **do not use lidocaine in the subarachnoid space.**

2-Chloroprocaine.

Chloroprocaine is an amino-ester local anesthetic that is rapidly metabolized by ester hydrolysis. As such, its potential to produce cardiac and CNS toxicity after inadvertent IV administration is low. It has a rapid onset and brief duration of action. Chloroprocaine is used primarily in obstetric anesthesia to rapidly produce a surgical block in the presence of a preexisting epidural in the case of an emergency cesarean section. However, the epidural administration of chloroprocaine has been shown to reduce the effectiveness of subsequently administered epidural morphine, possibly by antagonism at the opioid receptors.¹⁰⁰ Neurotoxicity has been reported after inadvertent spinal administration of large doses intended for the epidural space but was likely a result of the low pH and/or the preservatives.¹⁰¹

Ropivacaine.

Ropivacaine is an amino-amide local anesthetic that is produced as the pure levorotatory enantiomer and is structurally similar to bupivacaine. It has a propyl group attached to the aromatic ring as opposed to bupivacaine, which has a butyl group attached to the ring. Ropivacaine was developed largely to address the cardiac toxicity associated with bupivacaine and when equivalent masses of drug are compared, appears to be less toxic. Both levobupivacaine and ropivacaine have a clinical profile similar to that of bupivacaine, and the minimal differences observed are mainly related to different anesthetic potency, with bupivacaine >

levobupivacaine > ropivacaine.^{102,103} When clinical dosing is adjusted for the decreased potency the toxicity advantage of ropivacaine is diminished.¹⁰⁴ Although equipotent doses of ropivacaine have been shown to produce less motor block when compared with bupivacaine, it has not been shown to influence the mode of delivery, the duration of labor, or neonatal outcome.¹⁰⁵

The potential cardiotoxicity of ropivacaine are limited to animal models and in vitro preparations, and they have found either an advantage for ropivacaine in regard to toxicity or no difference between ropivacaine and bupivacaine. It is possible that ropivacaine is less cardiotoxic than bupivacaine at high doses, but at the more dilute concentrations clinically relevant to obstetric anesthesia, this difference is less likely to be important.¹⁰⁶ Synthetic opioids increase the potency of amide local anesthetics. Significantly longer labor analgesia can be achieved with ropivacaine–sufentanil and levobupivacaine–sufentanil, and ropivacaine is associated with comparatively less motor blockade. Labor duration after epidural analgesia has been found to be shorter when bupivacaine–sufentanil combinations are used and there is a low incidence of instrumental delivery.¹⁰⁷

Neuraxial Anesthetic Placement

Strict aseptic technique must always be used during the insertion of neuraxial anesthetics. This includes preprocedural hand hygiene, wearing of sterile gloves, cap and mask (new for each case), removal of rings and watches, and sterile draping of the back. A newly opened single-use container of preparation solution should be used for skin surface disinfection. Chlorhexidine gluconate in an alcohol base should be considered the antiseptic of choice. When compared with other commonly used antiseptic solutions, it is effective against a wider array of pathogens, has a greater degree of potency, shows a more rapid onset of action with an extended duration of effect, and has fewer and less severe localized skin reactions.¹⁰⁸ In addition, the efficacy of chlorhexidine gluconate is maintained in the presence of protein-based organic compounds such as blood and other body fluids. A sterile occlusive dressing should then be placed over the catheter insertion site.

Baseline blood pressure and pulse oximetry should be obtained

preprocedure then measured at regular intervals once neuraxial dosing is begun. Typically, blood pressure is monitored every 2 minutes for 15 minutes, then every 5 minutes for another 15 minutes, thereby enabling the early detection and treatment of neuraxial anesthesia–induced hypotension. It is preferable to remain in the anesthetizing location during this time to monitor the proper onset and progression of the neuraxial block and to enable prompt recognition and treatment of potentially catastrophic complications such as with total spinal anesthetic or local anesthetic systemic toxicity.

The sitting position is often easiest for the laboring parturient to assume and maintain and normally offers the anesthetist the maximum interspace width. On the other hand, the use of the lateral position has been found to reduce the incidence of intravascular catheter placement.¹⁰⁹ The lateral position can make identification of the midline more difficult due to skin shifting and requires meticulous attention to shoulder position. The upper shoulder naturally rotates anteriorly resulting in a concomitant rotation of the vertebral column that, if not corrected, can result in anatomical distortion. The lateral position may also help limit movement if the patient is having a difficult time with positioning. Occasionally, obstetrical emergencies such as fetal head entrapment, prolapsed umbilical cord, and footling breech presentation may preclude the use of the sitting position for neuraxial anesthesia placement.

It has long been observed that the failure rate associated with epidural anesthetics is greater in the obese patient. At the same time, neuraxial anesthetics are particularly desirable in obese parturients because of their increased cesarean section rates and concerns surrounding potential airway difficulty. The distance between the skin and the epidural space increases as the body mass index (BMI) increases, which can make epidural insertion more difficult.¹¹⁰ However, morbid obesity, when considered alone, is not a predictor of difficult block placement. In a study of 427 morbidly obese patients receiving neuraxial anesthetics, four variables were evaluated to determine whether they could predict difficult insertion. The authors found that only the ability to palpate bony landmarks and the patient's ability to flex her back were significant

predictors of difficulty, whereas BMI and the practitioners experience level were not predictive.¹¹¹ Prelabor consultation for women with a BMI greater than 50 kg/m² should be considered where an anesthesia plan can be made after a focused history and physical exam. Neuraxial anesthesia for the morbidly obese parturient should include a thorough check of equipment for appropriate size, consideration of early placement and anticipation of difficulty with prolonged labor and the likelihood of cesarean delivery. Frequent evaluation of the block and communication with all caregivers is paramount.⁸²

The use of ultrasound imaging as an aid in the placement of neuraxial anesthetics is a relatively new and growing technique. The placement of neuraxial anesthetics relies primarily on palpation of underlying anatomy and visualization of surface landmarks and is therefore an essentially blind technique. Preprocedure imaging and, eventually, real-time ultrasound guidance, may ultimately improve clinical practice and the ability to teach these techniques.¹¹² Ultrasound imaging is particularly useful in determining the skin to epidural space depth, the location of the midline, and the precise interspace. Palpation alone, regardless of BMI, is a relatively ineffective method for determining vertebral interspace, which is of particular importance when performing techniques that involve dural puncture.¹¹³ Morbidly obese patients or those with a history of difficult block placement may benefit from this technique.¹¹⁴

The type of epidural catheter used influences the anesthetic. Spiral wire-embedded flexible polyurethane catheters with a soft tip have been shown to result in fewer paresthesias and intravascular placements when compared with nylon catheters.¹¹⁵ Previous comparisons between multiple- and single-orifice catheters focused on standard nylon (stiff) designs and found an advantage favoring multiple-orifice catheters. A study comparing both versions (single orifice and multiple orifice) of soft catheters has found no difference.¹¹⁶ Multiple-orifice closed-end catheters are less prone to obstruction and likely result in better spread of local anesthetic in the epidural space.¹¹⁷

Historically, when larger doses of local anesthetic were used, a bolus of IV fluids was given prior to placement of the regional analgesic in an effort to reduce the incidence and magnitude of

hypotension. However, when dilute concentrations of local anesthetics combined with lipid-soluble narcotics are used to initiate neuraxial analgesia for labor and are combined with efforts to reduce aortocaval compression, the incidence of hypotension is approximately 5%.¹¹⁸ Zamora et al.¹¹⁹ found that a 1-liter preload did not provide added protection against hypotension but likely resulted in decreasing contraction frequency and was associated with delays in providing analgesia.

Test Doses

High cephalic spread of a neuraxial block remains one of the most common causes of anesthesia related maternal mortality in obstetrics.¹²⁰ A test dose is intended to identify epidural catheters that are inadvertently inserted into either the subarachnoid space or an epidural vein. First, it is essential to aspirate for blood or cerebrospinal fluid (CSF) after placement of the epidural catheter and before every manually administered dose. However, negative aspiration does not conclusively indicate that the catheter is not in the subarachnoid or intravascular space. Therefore the epidural test dose is designed to reveal inadvertent subarachnoid or intravascular injection of local anesthetic without producing systemic toxicity or widespread subarachnoid block. The test dose is the minimum amount of drug required to produce a modestly detectable effect when injected either intrathecally or systemically. A commonly administered test dose is 3 mL of lidocaine 1.5% with epinephrine 1 : 200,000. This 45-mg dose of lidocaine, if unexpectedly administered in the subarachnoid space, will produce a noticeable, but manageable, spinal anesthetic within 3 to 5 minutes while having no appreciable effect when given in the epidural space.

When administered intravascularly, lidocaine 45 mg will often result in early signs and symptoms of modest systemic toxicity such as circumoral numbness, lightheadedness, or auditory changes. The previously mentioned test dose also includes 15 mcg of epinephrine that, when given intravascularly into an epidural vein, has been shown to reliably increase HR in nonpregnant patients. The maternal HR should be monitored continuously using either pulse oximetry or electrocardiogram (ECG) during administration of the

test dose to detect these HR changes. In the laboring parturient, increases in HR are a less specific indicator of intravascular injection because of the changes in HR that normally occur during uterine contractions. Even when a test dose is carefully timed to be administered between contractions, it lacks both sensitivity and specificity. As a result, it is not universally accepted for use in obstetric anesthesia. Furthermore, concern exists that epinephrine may cause significant uterine artery constriction in a small number of patients, resulting in a decrease in fetal O₂ delivery.¹²¹

Some practitioners believe that by using multiple-orifice catheters in combination with incrementally administered (every 3–5 min) small doses (less than 5 mL) of dilute (less than 0.125%) local anesthetic, an epinephrine containing test dose is unjustified for labor analgesia. Careful aspiration of the epidural catheter for blood or CSF alone, without the administration of a test dose, may be effective in revealing an intrathecal or intravascular catheter.¹²² If a parturient receiving a continuous epidural infusion of dilute local anesthetic remains comfortable, the catheter must, by default, be in the epidural space. However, if the catheter was intravascular, the parturient would have inadequate analgesia, and, if it were intrathecal, a significant motor block would ensue.¹²³

Observing for blood or CSF while aspirating from the epidural catheter had a 0% false-positive rate and a 0.2% false-negative rate in over 1000 women in whom 60 intravascular or subarachnoid catheter placements were performed.¹²⁴ However, a test dose with epinephrine is necessary when administering larger and more concentrated doses such as those given in an epidural for cesarean delivery.¹²² Ideally, the administration of every epidural dose should be considered a “test dose” in which the catheter is carefully aspirated and incrementally injected. In summary, every precaution to ensure proper placement of the epidural catheter should be employed including the use of minimum effective doses, careful aspiration, and incremental injection, coupled with the use of intravascular markers when large doses are used. Epinephrine remains the most widely used and studied marker, but its reliability is impaired in the face of β -blockade, advanced age, and active labor. As an alternative, the use of subtoxic doses of local anesthetics themselves can produce subjective symptoms in

unmedicated patients. Fentanyl has also been confirmed to produce sedation in pregnant women when used as an alternative. The use of ultrasound observation of needle placement and injection may be useful. Constant vigilance and suspicion are still needed along with a combination of as many of these safety steps as practical.^{125,126}

Anesthetic Effects on the Progress of Labor

It is likely that women who request early labor analgesia have more pain than women who do not, and pain is a marker for risk of cesarean delivery.¹²⁷ In a systematic review of 10 trials that enrolled over 2300 patients in which the effects of epidural versus parenteral opioids in labor were examined, Halpern et al.¹²⁸ found that epidural labor analgesia was not associated with increased rates of instrumented vaginal delivery or cesarean section. Not surprisingly, patient satisfaction and neonatal outcomes were better after epidural when compared with parenteral opioid analgesia. Another systematic review of seven existing trials found that epidural analgesia using low concentrations of bupivacaine and fentanyl was unlikely to increase the risk of cesarean section but may increase the risk of instrumented vaginal delivery.¹²⁹ Although women in those studies had a longer second-stage labor, they had better pain relief. It could be argued that the increased risk of instrumented vaginal delivery was the result of obstetricians choosing this method more frequently because of the presence of a functioning epidural.¹³⁰ It has been postulated that early initiation of neuraxial analgesia (less than 4 cm) may increase the incidence of labor dystocia and cesarean section. However, a 2009 large study from China involving almost 13,000 patients found no difference in the duration of labor or cesarean section rate when primiparous women were randomized to receive epidural analgesia at 1 cm dilation versus 4 cm or more dilation.¹³¹ Overall, the use of epidural analgesia does not increase the risk of cesarean section. It may affect the incidence of forceps delivery, but it depends on the medications used. Epidural analgesia does prolong labor, although the clinical significance of this prolongation has not been shown.¹³²

Epidural Analgesia for Labor

Epidural analgesia remains a popular, safe, and effective means of providing analgesia for labor. The use of an indwelling epidural catheter gives the anesthetist the ability to produce a segmental block of varying density that can be adapted to the patient's changing requirements. This is accomplished by changing the volume and concentration of local anesthetic administered. Dosing an epidural with dilute concentrations of local anesthetic often results in satisfactory labor analgesia without producing significant motor block. When necessary, the same labor epidural can be converted to a surgical anesthetic that includes a dense motor and sensory block by administering a larger volume of a more concentrated local anesthetic.

Combining a lipid-soluble opioid allows a decrease in concentration of local anesthetic without compromising analgesia while at the same time preserving motor function. Decreasing the dose of both drugs minimizes the potential complications and side effects of each. An epidural for labor analgesia is optimally inserted at the L2–L3 or L3–L4 interspace to allow for effective blockade of the T10 to L1 dermatomes necessary for analgesia in first-stage labor. Analgesia for second-stage labor and subsequent repair, if needed, requires an extension of the block to include the S2 to S4 dermatomes that innervate the perineum and vagina. Adequate analgesia must be balanced against loss of the sensation of labor, which is not desirable during the second stage, and motor block, which is bothersome to the mother during labor and prevents effective pushing during second stage.

Although the small amount of epinephrine present in a test dose should be safe for a healthy fetus, the larger amounts present in the volume of local anesthetic used in epidural infusions carry some risk of umbilical artery constriction in some parturients.¹³³

Epinephrine-containing local anesthetics also result in significantly enhanced motor block. For these reasons, routine use of epinephrine-containing solutions for labor analgesia is not recommended, especially in the preeclamptic patient.

To avoid aortocaval syndrome, after epidural analgesia has been instituted, the patient should be instructed to avoid the supine position. A hip roll, wedge, or pillow should be used to maintain a

left or right lateral position. Following the initial and all subsequent doses, the patient should not be left unattended for at least 20 minutes. The anesthetist should remain aware of cervical dilation and the progress of labor after the epidural catheter has been placed. Communication with the obstetric personnel is important to prevent the use of a drug, dose, or concentration of local anesthetic that is inappropriate for the patient's circumstances.

Maintaining Epidural Analgesia for Labor and Delivery

Although it is possible to maintain epidural analgesia with intermittent bolus administration, this technique is associated with periods of analgesia alternating with periods of pain, as well as frequent provider interventions. Hypotension occurs less often when a continuous infusion is used as a result of fewer changes in the level of sympathetic blockade. Continuous infusion results in less total local anesthetic administered (when compared with intermittent boluses), more effective analgesia, and significantly reduced workload. There is also no need for the careful incremental administration of local anesthetic associated with bolus doses.

The parturient's analgesia level and degree of motor block should be frequently assessed and changes in the infusion rate and/or concentration made as needed. An epidural catheter originally sited in the epidural space can potentially migrate into the subarachnoid or intravascular space. If the epidural catheter enters the subarachnoid space some time after placement during a continuous infusion, the resulting gradual increase in motor block can be easily recognized. Alternatively, if the catheter enters the intravascular space, the patient will have a loss of analgesia without overt symptoms of systemic toxicity.

Infusions of bupivacaine (0.0625% to 0.125%) or ropivacaine (0.1% to 0.2%) with fentanyl (1 to 3 mcg/mL) or sufentanil (0.3 to 0.5 mcg/mL) at infusion rates of 8 to 12 mL/hr are commonly used. Lower concentrations may be effective as long as adequate spread is achieved. However, maintaining an adequate sensory level with lower concentrations may necessitate an increased infusion rate of 10 to 15 mL/hr. In most women, this dilute concentration is

associated with minimal motor block, although the block will become denser as the infusion is maintained over time. A higher concentration may be needed as labor intensifies or in women who experience greater pain.

The epidural infusion should be maintained as the parturient transitions to second-stage labor provided the block is stable and effective and adequate motor function has been preserved. The ideal block provides effective analgesia for uterine contractions, dense analgesia of the perineum for delivery, and little motor block. If motor block hinders pushing or if sensory block prevents the parturient from sensing contractions and therefore effectively prevents pushing, the epidural infusion may be decreased or changed to a more dilute solution. Additionally, the block can be supplemented during second-stage labor if additional perineal analgesia is required. This can be accomplished by injecting a relatively large 6 to 10 mL volume of bupivacaine 0.25%, lidocaine (1% to 2%), or 2-chloroprocaine 2%. Fentanyl (50 to 100 mcg) can be added to the aforementioned bolus to further enhance analgesia. Instrumented vaginal delivery generally requires a denser block, in which case lidocaine 2% with epinephrine 1 : 200,000 can be used with or without the addition of fentanyl.

Patient-Controlled Epidural Analgesia

Patient-controlled epidural analgesia (PCEA) is an alternate technique that allows the parturient to self-administer bolus doses as needed. It is normally initiated after analgesia has been established with either an epidural or a CSE technique. When compared with continuous epidural infusion, PCEA has several distinct advantages.¹³⁴ It reduces the number of unscheduled interventions required by the anesthetist, the total dose of drug used, and lower extremity motor block, all without sacrificing effective analgesia. Maternal satisfaction would be expected to increase due to enhanced control, but this has not been consistently shown to be the case. The best combination of variables (e.g., background infusion rate, bolus dose, and lockout interval) has yet to be established. The use of a background infusion likely reduces breakthrough pain but has been shown to result in an increase in total local anesthetic used.¹³⁵ Background infusion rates of

bupivacaine (0.125%) or ropivacaine (0.2%) between 2 and 10 mL/hr have been used effectively. Bolus doses greater than 5 mL may provide superior analgesia compared with smaller boluses.¹³⁴ PCEA may also presumably limit the number of epidural catheter disconnections and reconnections necessary to manually bolus a catheter, hence reducing the potential exposure to pathogens and catheter contamination.

Programmed Intermittent Epidural Boluses

There is evidence to indicate that there may be more widespread distribution of local anesthetic solution within the epidural space when large volumes are injected as a bolus compared with a slow infusion.¹³⁶ Automated epidural infusion pumps capable of administering programmed intermittent boluses have been recently introduced. With this technique, a bolus dose is automatically administered at regular intervals as opposed to a continuous infusion. Optimal dosing regimens are being studied at this time, but some evidence indicates that larger boluses timed more widely apart appear to increase effectiveness. Wong et al.¹³⁷ found that extending the programmed intermittent bolus interval and volume from 15 minutes to 60 minutes, and 2.5 mL to 10 mL, respectively, decreased overall bupivacaine consumption without decreasing patient comfort or satisfaction.

Combined Spinal-Epidural

The CSE is a commonly used technique that many practitioners feel provides superior analgesia for labor and vaginal delivery. A CSE combines the best attributes of both techniques while minimizing their respective disadvantages. Analgesia obtained from the spinal component is uniformly effective and has a rapid onset. The epidural catheter allows the analgesia to be prolonged as required and provides the ability to convert the block to a surgical level if operative delivery is indicated.

Several methods have been described for performing the block, including the early technique of spinal needle insertion and removal immediately followed by epidural insertion at the same or different level. Most practitioners now use the “needle through the

needle” technique in which the epidural space is identified with an epidural needle followed by placement of a longer small-gauge spinal needle through the existing epidural needle. Care must be taken to avoid displacing the spinal needle during injection. The spinal needle is then withdrawn and an epidural catheter is placed. The needle through the needle technique provides the additional benefit of confirming proper epidural needle location. If the epidural needle is not inserted in the midline of the epidural space, the subsequently placed spinal needle will not likely penetrate the dura and CSF flow will not be obtained. Fig. 51.6 shows the proper orientation of both the spinal and the epidural needles during a CSE technique.

FIGURE 51.6 The proper orientation of both the spinal and epidural needles during the needle-through-needle combined spinal-epidural (CSE) technique. (From Birnbach DJ, et al. *Textbook of Obstetric Anesthesia*. Philadelphia: Churchill Livingstone; 2000:166.)

The spinal component of a CSE can be dosed with either a lipid-soluble narcotic alone or in combination with isobaric bupivacaine. Narcotics are commonly used alone in early first-stage labor. For example, fentanyl (15 to 25 mcg) or sufentanil (10 mcg) in the subarachnoid space can provide analgesia for up to 2 hours with no motor block. Local anesthetic is often combined with the narcotic in late first-stage labor to produce a rapid-onset analgesia with minimal motor block. Isobaric bupivacaine 0.25% 1 mL (2.5 mg)

combined with fentanyl or sufentanil provides a denser analgesia than narcotic alone. Consideration should be given to initiating an epidural infusion before resolution of the spinal component to avoid the need for bolus dosing the epidural catheter.

Spinal Analgesia

In contemporary practice, a single-shot spinal is rarely an appropriate anesthetic choice for a patient in labor due to its finite duration and lack of flexibility. The technique can often be performed rapidly, and it is generally reserved for multiparous patients in advanced second-stage labor when delivery is clearly imminent or for those exhibiting poor control who can then have an epidural placed with better cooperation. It is also suitable in parturients who have labored without anesthesia and require an instrumented vaginal delivery or those who have delivered without anesthesia and require an extensive perineal repair. In rare cases, multiple single-shot spinal anesthetics, placed every 2 to 3 hours, have been used in parturients with conditions that preclude epidural placement such as a previous history of spinal surgery in which the epidural space has likely been surgically obliterated.

Continuous spinal anesthesia (CSA) using a macro-bore epidural catheter is an option in certain high-risk patients such as the extremely morbidly obese, those with previous spinal surgery or deformity, or those whose dura has been inadvertently punctured with the epidural needle. A CSA may be particularly indicated in a high-risk parturient after failed attempts at a conventional neuraxial anesthetic due to the increased morbidity and mortality associated with GA. The morbidly obese parturient is at greater risk for cesarean delivery, as well as greater risk of failed regional technique.¹³⁸ To perform a CSA, an epidural needle is used to identify the subarachnoid space and the epidural catheter is then intentionally threaded into the subarachnoid space. This spinal catheter can then be dosed as a spinal anesthetic using isobaric bupivacaine (0.25%) in 0.5-mL to 1-mL increments for labor analgesia. A CSA is not considered a first-line technique because it is clearly associated with an increased risk of postdural puncture headache. There has been some evidence to indicate that a catheter left in situ in the subarachnoid space for at least 12 hours results in

fewer postdural puncture headaches.¹³⁹ It is postulated that the epidural catheter creates a localized inflammatory response where it passes through the dura, which results in decreased CSF leakage when the catheter is ultimately removed. However, in a subsequent trial of 97 patients with accidental dural puncture (ADP) who were randomized to either a CSA or a repeat of the block, no difference in the incidence of headache or blood patch was found.¹⁴⁰ If a CSA is used, block level must be carefully monitored and all caregivers in contact with these patients should be notified that the “epidural” catheter is actually subarachnoid in order to prevent accidental overdose. It is also necessary to clearly label the catheter as a spinal catheter.

Microcatheters (27- to 32-gauge) were developed for use in the early 1990s specifically for this purpose but were found to result in an unacceptably high incidence of cauda equina syndrome.⁹⁷ The low-flow velocity through the very small-diameter catheter resulted in poor mixing of the lidocaine local anesthetic that was used at the time, creating a pool of concentrated local anesthetic in close proximity to the nerve roots. Microcatheters were subsequently removed from the market by the Food and Drug Administration (FDA).¹⁴¹

Regional Opioids for Labor Analgesia

The combination of dilute local anesthetics with low-dose opioids allows for the reduced dose of both agents that ultimately results in decreased motor block while preserving acceptable analgesia and minimizing side effects. The agents work by binding to separate and distinct receptors. Local anesthetics work at the nerve axon whereas neuraxial opioids bind to receptors in the substantia gelatinosa within the dorsal horn of the spinal cord. These receptors are stimulated by the administration of opioids via the subarachnoid or epidural routes. Epidurally administered opioids are believed to be absorbed into the CSF, and ultimately the spinal cord, to exert their action on spinal opioid receptors. When opioids are administered within the epidural or subarachnoid space, they are known to possess a “ceiling effect” whereby increasing the dose beyond conventional regimens does not result in an increased duration or quality of analgesia. Common side effects are, however,

more severe and prolonged at the increased dose levels.

Side effects of epidural and subarachnoid opioid administration include respiratory depression, itching, urinary retention, nausea, and vomiting. IV doses of an opioid antagonist (naloxone) or agonist-antagonist (nalbuphine) are effective at reducing or eliminating the undesirable effects without antagonizing the analgesia and are often more effective against pruritus than an antihistamine.

Fentanyl.

When used in combination with local anesthetics, fentanyl in epidural doses of 50 to 100 mcg and subarachnoid doses of 10 to 25 mcg produces good to excellent analgesia in 5 to 10 minutes. Administration of these doses, repeated as often as every 90 minutes in women in labor, has been shown not to affect Apgar scores, umbilical cord blood analysis, or neurobehavioral test results for up to 24 hours after delivery.¹⁴²⁻¹⁴⁴ Fentanyl 100 mcg in the epidural space has been shown to be undetectable in breast milk.¹⁴⁵ When opioids are used alone, much higher doses are needed to provide labor analgesia, and even these higher doses are not entirely effective during the second stage of labor. When analgesia from fentanyl administration is at its peak, serum fentanyl levels are lower than those known to produce equivalent analgesia after IV administration. In fact, most women have undetectable plasma fentanyl levels after receiving 100 mcg of epidural fentanyl.¹⁴⁶

The duration of action of fentanyl in the epidural space is 60 to 140 minutes. Because fentanyl is so much more lipid soluble than morphine, it is absorbed into neural tissue faster; therefore it has a faster onset and shorter duration of action when compared with morphine. As a result, the cephalad migration of fentanyl is much less than that of morphine; therefore, fentanyl is associated with a significantly lower incidence of CNS side effects. This is likely why respiratory depression has rarely been reported following subarachnoid or epidural administration of fentanyl in conventional doses.

For continuous epidural infusion, fentanyl concentrations up to 2.5 mcg/mL of local anesthetic can be used without adversely

affecting neonatal respiration or neurobehavioral scores.¹⁴⁷ Bupivacaine (up to 0.125%) or ropivacaine (up to 0.2%) with 1 to 2 mcg/mL of fentanyl is a widely used combination.¹⁴⁸

Sufentanil.

Sufentanil (5 to 10 mcg) can be combined with bupivacaine or ropivacaine to initiate analgesia for first stage labor. When added to a continuous epidural infusion the concentration is normally 0.3 to 0.5 mcg/mL. Because sufentanil is commercially prepared in a concentration of 50 mcg/mL and clinically relevant doses used in neuraxial anesthesia are significantly lower, care must be taken when using sufentanil to avoid medication errors.

Morphine.

Morphine is more ionized and therefore less lipid soluble as compared with fentanyl or sufentanil. When administered in the epidural or subarachnoid space it has a slow onset of action of 30 to 60 minutes and, when used alone for labor analgesia, is not associated with a high degree of maternal satisfaction. It is this pharmacologic profile that makes it a poor choice for use in labor analgesia. However, morphine is uniquely suited for use as a postoperative analgesic when neuraxial anesthesia is utilized for cesarean section (see next section). Optimal analgesia and less pruritis is produced with an intrathecal dose of 0.075-0.15 mg.

Anesthesia for Cesarean Section

Birth by cesarean section now accounts for over 30% of all deliveries, and it is performed over 1.5 million times annually in the United States.^{149,150} Common indications include cephalopelvic disproportion, nonreassuring fetal status, arrest of dilation, malpresentation, prematurity, prior cesarean delivery, and prior uterine surgery. The choice of anesthesia depends on maternal status, urgency of the surgery, condition of the fetus, and the patient's desires. This fact highlights the need for strong communication between the obstetrician, nursing staff, and anesthesia provider. The use of neuraxial anesthesia for cesarean section has increased dramatically along with a commensurate decrease in the use of GA.¹⁵¹ Neuraxial anesthesia has significant advantages including decreased risk of mortality from failed intubation and aspiration of gastric contents, better neonatal outcomes from the use of less depressant agents, and the ability of the mother to be awake for the delivery. Evidence also suggests that general anesthetic agents are associated with apoptosis of fetal brain neurons in animal models.¹⁵²

Regardless of the anesthetic technique used, left uterine displacement should be provided as soon as possible. The table should be rolled to the left or a wedge placed under the right hip of the patient in order to shift the uterus off the inferior vena cava and abdominal aorta, thereby preserving fetal oxygenation. Fetuses delivered of mothers with left uterine displacement have a lower incidence of CNS depression and acidosis than those delivered of mothers in the supine position.¹⁵³ In an awake parturient with a neuraxial anesthetic, it is not a requirement to secure the upper extremities to the armboards. The lower extremities, however, should be secured to prevent unintentional movement from the table.

Blood loss during cesarean section is usually between 500 mL and 1000 mL. However, the reported range of blood loss is great—in one study, from 164 to 1438 mL.¹⁵⁴ Many factors affect the volume of blood lost during cesarean section, including surgical time, surgical technique, blood pressure, fetal lie, fetal size,

placental implantation, maternal coagulation status, and the ability of the uterus to contract after the placenta has been delivered. Visual estimation of blood loss is inaccurate and often complicated by the presence of large volumes of amniotic fluid and variably saturated sponges. Normal amniotic fluid volume is approximately 700 mL (range 300 mL to 1400 mL) and should be accounted for when estimating blood loss.¹⁵⁵

Neuraxial Anesthesia for Cesarean Section

A dermatome level of T4 is required to provide effective anesthesia for cesarean section. This level of block can result in profound sympathectomy that frequently causes maternal hypotension and, if untreated, fetal compromise. Common measures to minimize hypotension include left uterine displacement, IV fluid administration, and vasopressor use.

A nonparticulate antacid should be administered preoperatively for aspiration prophylaxis. An H₂-receptor antagonist and metoclopramide can also be used preoperatively to increase gastric pH and enhance emptying. Anxiolytics are normally not administered preoperatively in order to minimize fetal depression. Prophylactically administered antibiotics have been traditionally withheld until cord clamping in an effort to prevent fetal transmission and the obscuring of any subsequent neonatal sepsis workup. However, antibiotics administered preincision have been shown to decrease the surgical site infection rate from 6.4% to 2.5%, making the practice much more common.¹⁵⁶ Requirements for standard monitoring remain the same as with any anesthetic; however, blood pressure should be assessed at least every 1 minute for the first 20 minutes or until the patient's condition has stabilized. Left uterine displacement is an essential aspect of positioning to preserve maternal cardiac output and, ultimately, utero-placental exchange.

The routine supplemental use of oxygen in the absence of preexisting fetal compromise or maternal hypoxemia has not been shown to be of any maternal or neonatal benefit in spite of its common practice.¹⁵⁷ Although supplemental oxygen may reduce postoperative nausea and vomiting after GA, its administration

during cesarean section with neuraxial anesthesia does not decrease the incidence or severity of intraoperative or postoperative nausea or vomiting.¹⁵⁸ Oxygen administration during elective cesarean section appears to increase oxygen free radical activity in both the mother and fetus. However, the intervention was neither beneficial nor harmful to the neonate's short-term clinical outcome as assessed by Apgar scores.¹⁵⁹ Consideration, however, should be given to the use of end-tidal CO₂ monitoring made possible by the use of sampling nasal cannula for those patients susceptible to intraoperative respiratory compromise or in those who have been provided IV sedation.

Spinal Anesthesia for Cesarean Section

Single-shot spinal anesthesia has become the most commonly used anesthetic technique for cesarean delivery because it offers many distinct advantages. This technique has a rapid onset of action and provides a more reliable block and uses smaller and therefore less toxic doses of local anesthetic when compared with epidural anesthesia. Its simplicity and rapid onset make it suitable for all but the most emergent cesarean deliveries when compared with GA. It is considered an economical anesthetic insofar as its rapid onset functions to decrease overall operating room times. Drawbacks include its fixed duration of action and rapid onset of sympathectomy with resultant hypotension. **Hyperbaric bupivacaine (0.75% 13 mg) is effective in 95% of patients (ED₉₅) and provides 90 to 120 minutes of surgical anesthesia.** In practice, neither the patient's height, weight, nor BMI correlates to the ultimate block level obtained.¹⁶⁰ The compound curvature of the spine in the supine position serves to limit the upward spread of the block when hyperbaric local anesthetics are used. A series of studies has determined that decreasing the bupivacaine dose results in less hypotension but is associated with an increased risk of intraoperative pain, a shorter duration of effective anesthesia, and a slower onset.¹⁶¹

When a spinal anesthetic is used to produce the T4 block needed for cesarean section, hypotension has been shown to occur in up to 80% of patients despite left uterine displacement.¹⁶² Maternal

hypotension results mainly in nausea and vomiting but, if severe and untreated, may lead to a decreased level of consciousness, uteroplacental hypoperfusion and cardiovascular collapse. The goal should be to prevent and effectively treat hypotension before these complications arise.

Administering crystalloids to increase intravascular volume has traditionally been used in an effort to prevent hypotension but has been shown to be minimally effective, possibly due to its rapid redistribution from the intravascular space.^{163,164} The 2014 multicenter, randomized, double-blinded CAESAR section surgical techniques (CAESAR) trial demonstrated the efficacy of a mixed 500 ml 6% hydroxyethyl starch (HES) 130/0.4 + 500 ml Ringer's lactate (RL) preload in significantly reducing hypotension, compared to a 1-l RL preload, without adverse effects on coagulation and neonatal outcomes in healthy parturients undergoing caesarean delivery under spinal anaesthesia.¹⁶⁵ Despite these findings, the routine use of HES continues to be debated because of its disadvantages including cost, potential allergic reactions, and pruritus.

The timing of the fluid administration has also been investigated comparing preloading (prior to anesthetic placement) with coload (given rapidly at the time of intrathecal injection). It appears that crystalloid coload is somewhat effective compared with crystalloid preloading (not effective), provided the infusion rate and volume are high enough during the first 5 to 7 minutes after spinal injection when the sympathetic block is being established.¹⁶⁶ On the other hand, the timing of a colloid administration does not appear to change its degree of effectiveness.¹⁶⁷ Current evidence suggests that combining a prophylactic vasopressor regimen with HES preloading, HES coload, or crystalloid coload is the best method of preventing maternal hypotension after the initiation of spinal anesthesia. Crystalloid preloading is clinically ineffective and thus should no longer be used.

Ephedrine and phenylephrine are vasopressors commonly used to treat maternal hypotension. Ephedrine is a synthetic, nonselective, noncatecholamine sympathomimetic. Doses of 5 to 15 mg intravenously are used to treat acute decreases in blood

pressure. The duration of ephedrine's cardiovascular effects varies with the dose given. The effect of a 5- or 10-mg IV dose usually persists for 5 minutes. Tachyphylaxis can occur with repeated administration of small doses, resulting in a noticeably reduced clinical effect after subsequent dosing. Ephedrine is metabolized in the liver, and up to 40% is excreted unchanged by the kidneys. It has an elimination half-life of 3 hours.

Ephedrine causes direct β stimulation and indirect α stimulation through the release of endogenous norepinephrine. It has long been used in obstetric anesthesia because it was thought to affect uterine artery blood flow less than direct acting vasoactive drugs in pregnant ewes.¹⁶⁸ However, evidence suggests that ephedrine crosses the placental barrier and stimulates fetal β -adrenergic receptors, raising the fetal metabolic rate and results in a depression of fetal acid-base status.¹⁶⁹ Although the ultimate clinical relevance of this effect has yet to be defined, many practitioners are now using phenylephrine as a first-line vasopressor to treat maternal hypotension.⁴⁷ Hypotension is a primary cause of intraoperative nausea and vomiting in the early period after spinal anesthesia. Hypotension may lead to cerebral hypoperfusion, which is thought to activate the vomiting center. It has also been suggested that hypotension results in gastrointestinal hypoperfusion with the subsequent release of emetogenic substances such as serotonin. Optimum use of vasopressors to prevent hypotension significantly reduces the incidence of intraoperative nausea and vomiting.¹⁷⁰

Phenylephrine is a direct-acting α_1 -adrenergic agonist that results in vasoconstriction and increased peripheral vascular resistance. It can result in a reflex bradycardia with a subsequent decrease in cardiac output. Based on early animal studies, α -agonists were thought to decrease uterine artery blood flow,¹⁶⁸ but phenylephrine has been shown to be safe for the treatment of maternal hypotension during regional anesthesia when given in the conventional dose range.¹⁷¹ Neonatal blood gas values and Apgar scores remain within normal limits in all healthy subjects after the administration of 80-mcg or 100-mcg bolus doses of phenylephrine.¹⁷² Phenylephrine can be administered by either bolus dosing or continuous infusion; however, the optimal regimen for each has yet to be determined. Many practitioners now feel that

the maternal HR should play a role in the selection of a vasopressor. There is evidence to indicate that during phenylephrine infusion there is a dose-dependent decrease in cardiac output that parallels a decrease in HR.¹⁷³ When the HR is at baseline or above, phenylephrine may be used. When the HR is below baseline, ephedrine will increase the blood pressure and HR without further reductions in cardiac output. A 2012 systematic review supports the favorable effects of phenylephrine over ephedrine as the first-line vasopressor for treating maternal hypotension for parturients undergoing cesarean section.¹⁷⁴

Maternal complaints of nausea, vomiting, and visceral pain occur occasionally even in the presence of an adequate T4 block. It is common practice to add opioids to hyperbaric bupivacaine for cesarean section spinal anesthesia to provide additional intraoperative and postoperative analgesia without affecting the block height. **Intraoperative block quality can be significantly improved with the addition of fentanyl (10 to 20 mcg) or sufentanil (2.5 to 5 mcg).** The onset of these lipid-soluble opioids is 5 to 10 minutes with an effective duration of 60 to 90 minutes. In addition to either fentanyl or sufentanil, morphine can be added to provide long-acting postoperative analgesia. Morphine has an onset of action of 60 to 90 minutes that coincides with the effective duration of fentanyl or sufentanil such that, when used in combination, the patient has uninterrupted opioid analgesia intraoperatively and for 12 to 18 hours postoperatively.

After the placenta has been delivered, oxytocin should be given as directed by the obstetrician. Pitocin is the clinically available synthetic equivalent of oxytocin, a naturally occurring hormone synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. In the mature uterus of a pregnant woman, oxytocin causes an increase in the frequency and strength of uterine contractions. Endogenous oxytocin release occurs with stimulation of the cervix, vagina, and breasts.

The half-life of oxytocin varies from 4 to 17 minutes. It is metabolized by liver, kidney, and plasma enzyme pathways in the parturient. Commercially available preparations of oxytocin contain a preservative that may cause systolic and especially diastolic hypotension, flushing, and tachycardia when infused at high

doses.¹⁷⁵ The amount of oxytocin added to the IV solution should be tailored to the volume of solution remaining in the bag, the flow rate of the IV, and the patient's condition. If an unusually large blood loss results in hypotension, and fluid resuscitation is required, it may be helpful to infuse the oxytocin at an appropriate rate and to start a second IV line for administering fluid volume at a rapid rate. If the solution with the added oxytocin is infused rapidly enough to replace intravascular volume, it is possible that the high dose of oxytocin may cause further hypotension. In some cases, the obstetrician may choose to administer oxytocin directly into the uterine muscle to maximize its effect.

Transversus abdominal plane blocks can be used to provide postoperative analgesia in patients who are not candidates for intrathecal morphine, when neuraxial anesthesia is contraindicated, or in those who receive GA.¹⁷⁶ The sensory nerves that supply the anterior abdominal wall course through the fascial plane between the internal oblique and the transversus abdominis muscles. Local anesthetics injected into this plane block sensory impulses from the anterior abdominal wall and are effective in relieving the pain associated with a Pfannenstiel incision.¹⁷⁷ A suggested technique for spinal anesthesia for cesarean section is outlined in [Box 51.2](#).

Spinal Anesthesia Technique for Cesarean Section

- Nonparticulate oral antacid no more than 1 hour prior to surgery
- Administer an IV preload (colloid) or coload (crystalloid or colloid)
- Apply standard monitors and record preprocedure vital signs
- Record preprocedure fetal heart tones
- Consider oxygen administration
- Perform lumbar puncture at L3–L4
- Sitting or lateral position

- Small-gauge (24- or 25-gauge) non-cutting needle (e.g., Sprotte, Whitacre, Pencan)
- Hyperbaric bupivacaine 15 mg in 8.25% dextrose (12–15 mg)
- Add fentanyl 20 mcg for intraoperative analgesia
- Add preservative-free morphine 150 mcg for postoperative analgesia
- Supine position with left uterine displacement
- Monitor blood pressure every 1 minute at least until birth
- Confirm block level (T4) prior to surgical start
- Treat hypotension with phenylephrine; if maternal heart rate decreases below baseline or blood pressure is not increased, use ephedrine
- Administer oxytocin as directed at delivery

Epidural Anesthesia for Cesarean Section

An epidural inserted in the operating room for an elective cesarean section is not often the technique of choice because it has a slower onset and requires a higher milligram dose of local anesthetic to achieve a surgical level of anesthesia when compared with a spinal anesthetic. However, an epidural catheter does provide the flexibility to extend the duration of the anesthetic when a prolonged surgical time is anticipated. The slower-onset sympathectomy associated with an epidural may make treating the resultant hypotension easier and can be of value in patients who are particularly susceptible to abrupt changes in blood pressure. Attention to correct catheter placement and dosing safety is required when this technique is used due to the increased volume and concentration of local anesthetic needed to obtain a surgical block. After a negative test dose and careful aspiration for blood

and CSF, lidocaine 2% with epinephrine 1 : 200,000 can be used when dosed in 3- to 5-mL increments. A total volume of approximately 20 to 25 mL is required to obtain a T4 level.

When a parturient with an epidural in place for labor analgesia requires a cesarean section, the indwelling epidural catheter should be used to provide surgical anesthesia. Because larger volumes of more concentrated local anesthetic are required to produce surgical anesthesia and unrecognized epidural catheter movement into either the intrathecal or intravascular space is always a possibility, careful aspiration and incremental dosing is again important. The selection of local anesthetic is largely determined by the urgency required for delivery. The addition of sodium bicarbonate 1 mEq/10 mL to lidocaine 2% with epinephrine 1 : 200,000 will hasten the onset of anesthesia when a rapid conversion to surgical anesthesia is necessary. Commercially prepared lidocaine containing epinephrine has a low pH in order to preserve the epinephrine. The addition of sodium bicarbonate immediately prior to use increases the biologically active non-ionized fraction of drug.¹⁷⁸ This combination normally results in approximately 90 to 120 minutes of surgical anesthesia. Sodium bicarbonate cannot be added to bupivacaine as it results in precipitation when the pH is raised. 2-Chloroprocaine is rapidly metabolized by ester hydrolysis and, as a result, is associated with a very low incidence of toxicity; it can be used to rapidly convert a labor epidural to a surgical anesthetic with little concern of toxicity but will likely require intraoperative augmentation because it has an effective duration of approximately 45 minutes. The efficacy and duration of epidural morphine analgesia is diminished when administered after 2-chloroprocaine. The precise mechanism of this interaction is unknown but may be the result of opioid receptor antagonism.¹⁰⁰

In the presence of a well-functioning epidural used for labor analgesia, the total volume required to raise the block level from the existing T10 to the required T4 is approximately 10 to 15 mL. Conversion of a labor epidural to a surgical anesthetic can be initiated in the labor room in an emergency. Careful attention should be directed toward the existing analgesia level, incremental dosing, and maternal vital signs while in the labor room. On arrival to the operating room, the block level can be assessed and

additional doses provided as required during the surgical preparation.

Breakthrough pain in labor requiring multiple epidural doses is a significant predictor of subsequent failure of surgical anesthesia and highlights the need to replace inadequately functioning epidural catheters before an unplanned cesarean is required.¹⁷⁹

Efforts should be directed toward avoiding the situation of a failed epidural in the operating room. This includes early recognition and replacement of poorly performing labor epidurals. However, if an inadequate epidural is identified in the operating room, and the fetal status allows, consideration should be given toward replacing the epidural to a different interspace or replacing the epidural with a CSE technique in which the spinal is injected with a reduced dose and the epidural is subsequently used to augment the level as needed. In the scenario of a recently dosed inadequate epidural, a superimposed conventionally dosed single-shot spinal anesthetic can often produce an unpredictable, and frequently higher than expected, block level. Alternatively, the inadequate epidural can be given time to absorb and resolve before a single-shot spinal.

Ultimately, a general anesthetic may be required. A suggested technique for converting an epidural that is used for labor analgesia to one that provides anesthesia for cesarean section is given in

Box 5133

Converting an Epidural in Use for Labor Analgesia to a Cesarean Anesthetic

- Administer nonparticulate oral antacid no more than 1 hour prior to surgery.
- Discontinue continuous epidural infusion.
- Administer an IV coload (crystalloid).
- Apply standard monitors and record preprocedure vital signs.
- Record preprocedure fetal heart tones.
- Consider oxygen administration.

- Place in supine position with left uterine displacement.
- Carefully aspirate epidural catheter for blood and cerebrospinal fluid.
- Administer lidocaine 2% with epinephrine 1 : 200,000 and sodium bicarbonate 1 mEq/10 mL local anesthetic (total dose 10 to 15 mL).
- Administer 3 mL and observe maternal heart rate (HR) for 60 seconds and level of block for 3 to 5 minutes.
- If no sign of subarachnoid or intravascular injection, administer 3 to 5 mL and observe for 3 to 5 minutes.
- Treat hypotension with phenylephrine; if maternal HR decreases below baseline or blood pressure is not increased, use ephedrine.
- Confirm block level (T4) prior to surgical start.
- Administer 3 to 4 mg preservative-free morphine (0.5 mg/mL 6 to 8 mL) via the epidural catheter after the umbilical cord is clamped for postoperative analgesia.
- Administer oxytocin as directed at delivery.

Combined Spinal-Epidural for Cesarean Section

As with labor analgesia, the CSE technique for cesarean section can provide several advantages over either technique when used alone. A lower spinal dose can be used, resulting in a decreased incidence of hypotension, whereas the epidural can be augmented to increase the block height or prolong the duration if necessary. The technique, however, is not without its disadvantages. Because the spinal component is injected prior to placement of the epidural catheter, if difficulty is encountered with catheter placement, the patient could remain in the sitting position for a prolonged time, resulting in lower block height. The presence of a dense spinal block makes evaluating subsequent test doses for subarachnoid injection less reliable. If a lower spinal dose is used and the block is

not adequate for surgery, subsequent epidural dosing will delay the start of surgery. Some practitioners advocate the CSE technique after attempts with a spinal have been unsuccessful. An epidural needle has a larger diameter and may be less likely to deflect from its intended direction around dense ligaments or bone.

General Anesthesia for Cesarean Section

General anesthesia may be indicated despite the numerous disadvantages of the technique when compared with regional anesthesia. GA allows for better control of the airway and improved hemodynamic control, making it useful in cases of existing or expected hypovolemic shock or maternal cardiac disease. GA is a necessary choice when a neuraxial anesthetic is not in place and a surgical delivery is urgent enough to preclude its placement or when contraindications, such as patient refusal or coagulopathy, are present. It is also an alternative when a failed neuraxial technique occurs. Neuraxial techniques have progressively eclipsed GA for use in cesarean section primarily in an effort to reduce maternal mortality resulting from airway complications.¹⁵¹ However, GA is likely safer today compared to the 1970s and 1980s due to the use of supraglottic airway devices, video laryngoscopes and difficult airway algorithms.¹⁸⁰ Practical steps to decrease the use of GA include referral and evaluation of high-risk parturients early in pregnancy to optimize their medical condition and plan for anesthetic management, considering early neuraxial anesthetic placement to ensure proper functioning, and promptly replacing epidural catheters that are providing suboptimal labor analgesia.¹⁸¹

The Difficult Airway.

An airway evaluation is an important part of the preparation for anesthesia in any patient and even more so in the parturient. Airway problems occur with more frequency in obstetric patients compared to non-pregnant patients; failure to intubate has been reported to occur as frequently as 1 in 250 obstetric patients.¹⁸² This is true in part because of the soft-tissue edema often present in the hypopharynx. A patient's airway may also significantly change

during her labor and, as such, should be evaluated again prior to an operative delivery. Breast enlargement and cephalad displacement of the thorax can make maneuvering the laryngoscope into the mouth difficult, necessitating the use of a short-handled laryngoscope. Placement of a rolled towel along the thoracic spine or under the shoulders helps to elevate the chest off the operating table. This makes it possible to extend the neck and position the head more optimally, facilitating insertion of the laryngoscope blade and improving visualization of the glottis. The external auditory meatus can be aligned with the sternal notch by utilizing a ramp built with blankets. This position can facilitate oral tracheal intubation in the obese parturient. Positioning of the obese parturient for laryngoscopy is shown in [Fig. 51.7](#).

FIGURE 51.7 Positioning for the obese parturient for laryngoscopy. **A**, Standard positioning. **B**, Improved positioning with the elevation of the torso and head. (From Hagberg CA. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Elsevier; 2013:844.)

Airway difficulties resulting in a failure to oxygenate and ventilate remain an avoidable cause of anesthesia-related mortality in the obstetric population.¹⁸³ Although rapid-sequence induction is the technique most commonly used to minimize the risk of gastric aspiration during induction of GA, it is *not* normally indicated if the laryngoscopist has doubts about his or her ability to intubate the patient. In such a case, an alternative method, such as awake intubation, may be necessary. Blind nasal intubation should be performed cautiously, if at all, in the parturient, who commonly has swollen nasal mucosa that are prone to bleeding. The anesthetist

should be familiar with and be able to perform interventions as outlined in the algorithm below (Fig. 51.8).

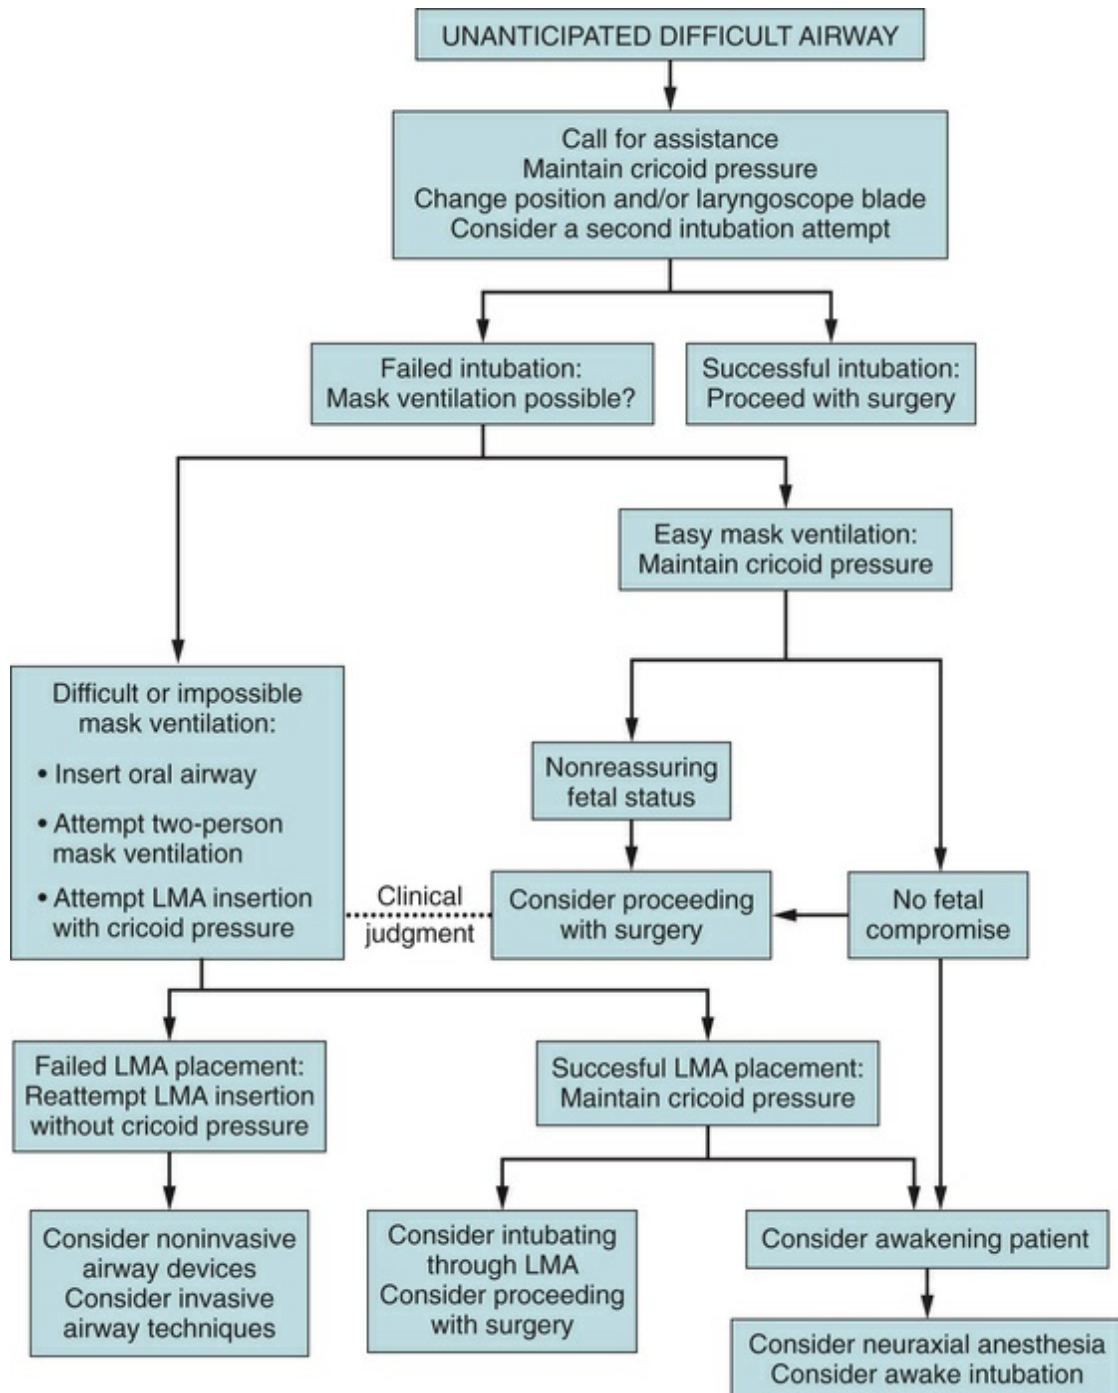

FIGURE 51.8 Unanticipated difficult airway algorithm adapted for use in obstetric anesthesia. It is intended as a guide only. Practitioner's skill set and judgment should guide clinical decisions. *LMA*, Laryngeal mask airway. (From Chestnut DH, et al. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 5th ed. St. Louis: Elsevier; 2014:701.)

Induction.

Induction of GA requires a rapid-sequence technique using cricoid pressure after denitrogenation and preoxygenation for 3 minutes has occurred. The **standard induction agent in the healthy parturient is propofol (2 to 2.5 mg/kg)**. As expected, propofol produces neonatal depression but is rapidly redistributed and cleared from the neonate, resulting in a rapid emergence.^{184,185}

Ketamine (1 mg/kg) or etomidate (0.3 mg/kg) are especially useful in patients who have airway disease or are hemodynamically unstable. Ketamine has been associated with lower analgesic demands during the first 24 hours postoperatively.¹⁸⁶ The indirect sympathomimetic effects of ketamine help to support blood pressure until adequate intravascular volume can be replaced.

The induction of anesthesia should be delayed until all preparation for surgery is complete and the surgical staff indicates they are ready. The operating surgeon should be instructed to delay incision until confirmation of correct endotracheal tube placement is made. The incision is only made after verification by capnography, auscultation of breath sounds over the chest, and bilateral chest expansion. The reasoning behind this practice is to minimize fetal exposure to depressant drugs.

Succinylcholine (1 to 1.5 mg/kg) remains the muscle relaxant of choice during induction of GA in the parturient. When succinylcholine is contraindicated, a fast-acting nondepolarizer may be judiciously administered, or an awake intubation may be attempted. **Rocuronium (0.5 to 1.0 mg/kg) can be used.** Although intubation can be accomplished quickly with a fast-onset nondepolarizing muscle relaxant, the duration of action will be longer than with succinylcholine. Pregnancy is associated with fewer fasciculations and less succinylcholine-related muscle pain; therefore, a defasciculating dose of a nondepolarizing muscle relaxant is often not required.

Maintenance of Anesthesia.

GA can be maintained with a volatile inhalational agent with or without nitrous oxide. The predelivery goal of at least 0.80 MAC should be delivered with a relatively high fresh-gas flow rate

consisting of 50% oxygen/50% nitrous oxide to ensure adequate anesthesia and minimize intraoperative awareness. If fetal distress is present or if maternal O₂ saturation is below 97%, high concentrations of O₂ may be used without nitrous oxide. Administering 100% O₂ does result in improved fetal oxygenation compared with 50% O₂, but questions have been raised about the danger of free radical activity in neonates born to women administered greater than 50% O₂.¹⁸⁷ Comparisons of Apgar scores, umbilical venous O₂ tension, time to breathing, and resuscitation efforts in neonates has revealed that infants born to women given 100% O₂ before delivery have slightly better outcomes.¹⁸⁸ Maternal hyperventilation should be avoided during mechanical ventilation because a PaCO₂ less than 20 mm Hg can result in decreased uterine blood flow and a shift of the oxyhemoglobin dissociation curve to the left. Maternal PaCO₂ should be maintained at the normal term pregnancy range of 30 to 32 mm Hg.

The use of bispectral index (BIS) monitoring remains controversial in that even the most rapid application before an emergency cesarean section takes some time, and its use has not been shown to conclusively prevent recall in all cases.¹⁸⁹ When used, a target BIS score of less than 60 can be obtained at a MAC of approximately 0.8 or above.

Volatile inhalational agents are tocolytic and result in decreased uterine contractility and tone that can result in increased postdelivery blood loss. The uterus continues to contract in response to oxytocin provided the MAC is less than 1.0.¹⁹⁰ In the presence of uterine atony and hemorrhage, their concentration can be decreased at delivery and anesthesia supplemented with narcotics and benzodiazepines as needed. The routine use of intraoperative muscle relaxation is generally not necessary and can be left to the surgeon's preference. Immediately after delivery, the recently distended abdominal musculature is quite flaccid and the surgical team should be accustomed to performing cesarean sections on spontaneously ventilating patients. In the absence of neuromuscular relaxation, the anesthetic depth can be better adjusted to the patient's requirements according to respiratory rate and depth. Intraoperative awareness from inadequate anesthesia

may be less likely to occur in a patient who is not surgically relaxed.

Infants delivered by cesarean section under GA are more likely to be depressed and to require active resuscitation compared with those delivered with a neuraxial anesthetic and therefore an individual other than the anesthesia provider who is trained in neonatal resuscitation should be present at delivery.¹⁹¹ The length of time from uterine incision to delivery has been shown to correlate with the degree of neonatal acidosis.¹⁹² The interval should be recorded. An interval of 3 minutes seems to be the critical value as neonates delivered later than 3 minutes after uterine incision are more likely to be depressed.¹⁹³ At the completion of surgery, the patient is extubated awake (i.e., following commands) after full recovery of neuromuscular function has been confirmed and extubation criteria have been met. A suggested method for providing GA for cesarean section is given in [Box 51.4](#).

General Anesthesia for Cesarean Section

- Discuss the operative plan with the multidisciplinary team.
- Perform preanesthetic assessment and obtain informed consent.
- Prepare necessary medications and equipment.
- Place patient supine with left uterine displacement.
- Secure 16- or 18-gauge intravenous access. Send blood specimen for baseline laboratory measurements; consider type and screen (or crossmatch) if risk factors for peripartum hemorrhage are present.
- Administer metoclopramide 10 mg and/or ranitidine 30 mg intravenously more than 30 minutes before induction, if possible.
- Administer a nonparticulate antacid orally less than 30 minutes before induction.
- Administer antibiotic prophylaxis if necessary (with 60 minutes prior to incision).

- Initiate monitoring.
- Perform a team “time-out” to verify patient identity, position, and operative site; procedure to be performed; and availability of special equipment, if needed.
- Provide 100% oxygen with a tight-fitting face mask for 3 minutes or longer, when possible, for denitrogenation/preoxygenation. Otherwise, instruct the patient to take four to eight vital-capacity breaths immediately before induction of anesthesia.
- After the abdomen has been prepared and operative drapes are in place, verify that the surgeon and assistant are ready to begin surgery.
- Initiate rapid-sequence induction.
- Cricoid pressure 10 Newtons while awake; increase to 30 Newtons after loss of consciousness.
- Propofol 2 to 2.5 mg/kg and succinylcholine 1 to 1.5 mg/kg; wait 30 to 40 seconds. Perform tracheal intubation. Confirm correct placement of endotracheal tube.
- Provide maintenance of anesthesia.
- Use isoflurane, sevoflurane, or desflurane (approximately 1 MAC) in 100% oxygen, or oxygen/nitrous oxide (up to 50%).
- Treat hypotension (e.g., phenylephrine, ephedrine).
- If additional muscle relaxant (e.g., rocuronium, vecuronium) is necessary, titrate dose according to response to peripheral nerve stimulator.
- Observe delivery of infant.
- Administer a bolus and/or a continuous infusion of oxytocin; consider other uterotonic agents (e.g., methylergonovine, 15-methyl prostaglandin F_{2α}, misoprostol) if uterine tone is

inadequate. Monitor blood loss and respond as necessary.

- Adjust maintenance technique after delivery of the infant.
- Administer a reduced concentration of a volatile halogenated agent (0.5 to 0.75 MAC).
- Supplement anesthesia with nitrous oxide and an intravenous opioid.
- Consider administration of a benzodiazepine (e.g., midazolam) if the potential for recall is significant.
- Perform extubation when neuromuscular blockade is fully reversed and the patient is awake and responds to commands.
- Evaluate postoperative issues (e.g., pain, nausea).

IV, intravenously; *MAC*, minimum alveolar concentration.

Complications of Regional Anesthesia

Hypotension

Hypotension is a frequent complication of obstetric neuraxial anesthesia and results from a rapid-onset sympathectomy and subsequent decreased venous return and decreased cardiac output. Hypotension commonly manifests as maternal nausea and vomiting and can impair uterine perfusion. Maternal hypotension of sufficient magnitude and duration results in uteroplacental hypoperfusion and fetal acidemia. It has been defined as a 20% decrease from baseline or a systolic pressure less than 100 mm Hg. Blood pressure should be monitored at least every 2 minutes following the initiation of neuraxial anesthesia until stabilized. Efforts to reduce the incidence of hypotension include left uterine displacement, IV fluid administration, and the use of vasopressors.

Nausea and Vomiting

Nausea and vomiting is a common occurrence during labor and delivery. The causes are often multifactorial and include pain, delayed gastric emptying, administration of parenteral opioids, visceral traction with exteriorization of the uterus, and motion during transport. The aggressive treatment of hypotension can prevent nausea and vomiting from occurring. Some clinicians believe that a sympathetic block results in unopposed gastrointestinal vagal stimulation, which predisposes the patient to nausea. Opioids administered in either the epidural or subarachnoid space improve block quality and do not increase intraoperative nausea.

Multimodal approaches combining antiemetics with different mechanisms of action may be more effective than single drugs when treating nausea and vomiting.¹⁹⁴ **Metoclopramide (10 mg IV)** is a prokinetic that likely reduces the incidence of intraoperative nausea and vomiting. It can be given preoperatively or at cord clamp.¹⁹⁵ The serotonin receptor antagonist **ondansetron (4 mg IV)** may be more effective compared with metoclopramide in preventing intraoperative nausea.¹⁹⁶ Granisetron 1 mg appears to be

ineffective reducing the incidence of intraoperative nausea and vomiting during elective cesarean section.¹⁹⁷ Scopolamine transdermal patches have been shown to significantly reduce the incidence of post-cesarean section nausea and vomiting resulting from regional anesthesia.¹⁹⁸ Transdermal scopolamine begins to be effective in 2 to 4 hours. Although this onset time is long, the duration of action (48 hours or longer) and simplicity of the scopolamine patch make it an attractive choice for parturients with a strong history of postoperative nausea and vomiting. Side effects include dry mouth and dizziness, which, for some patients, will outweigh the benefits of scopolamine.

Postdural Puncture Headache

Postdural puncture headache (PDPH) is a significant source of morbidity among parturients who receive neuraxial anesthesia.¹⁹⁹ PDPH most commonly results from ADP with a large bore (16- to 18-gauge) epidural needle during attempted epidural placement. ADP has been reported to occur in 1% to 2% of epidural placements and results in a PDPH in 80% to 86% of women.²⁰⁰ The resulting large dural defect provides a source for CSF to leak from the subarachnoid space to the epidural space. The loss of intracranial pressure causes caudad displacement of the cranial contents and traction on meningeal structures when the patient assumes a head-up position. The hallmark of a PDPH is this postural component. The headache is relieved when the patient is supine and returns upon sitting or standing. Cerebral venous dilation also occurs in response to intracranial hypotension and contributes to the PDPH symptoms. PDPH symptoms commonly include frontal and occipital pain radiating to the neck or shoulders. Nausea, vertigo, and low back pain are also seen. Ocular dysfunction as a result of a cranial nerve VI (abducens nerve) palsy is less common and can result in double vision and a deviated gaze.²⁰¹

Postdural puncture headache is not the only cause of significant headache after regional anesthesia in the obstetric patient. In a retrospective review of 95 women who experienced a headache more than 24 hours after delivery, Stella et al.²⁰² found that tension/migraine and preeclampsia/eclampsia accounted for over 70% of reported headaches whereas a diagnosis of PDPH was made

in 16%. More serious causes of postpartum maternal headache include meningitis and intracranial pathology such as cortical vein thrombosis and subarachnoid hemorrhage.

The incidence of PDPH is inversely related to age and seen infrequently in those older than 70 and younger than 10 years old. Women appear to be slightly more susceptible than men, and pregnancy may increase the incidence. In general, large-diameter needles are more likely to be associated with PDPH when compared with small-diameter needles.

With spinal anesthesia, the incidence of PDPH is significantly reduced with the use of pencil-point needles (e.g., Pencan, Sprotte, Whitacre) compared with beveled cutting needles (e.g., Quincke) (Fig. 51.9). In a retrospective study of 366 obstetric patients, the incidence of PDPH after the use of a Sprotte needle was 1.5%, compared with 9% after the use of a beveled Quincke needle of similar gauge.²⁰³

FIGURE 51.9 Physical characteristics of four different types of spinal and epidural needles. Needle diameters are not to scale.

Some evidence indicates that the bevel orientation relative to the dural fibers plays a role. Electron microscopy has confirmed that the collagen fibers composing the dura are primarily oriented longitudinally.²⁰⁴ Penetrating the dural fibers along their vertical axis may result in less CSF leakage compared with horizontal bevel

orientation. The angle at which the needle approaches the dura may also modify the amount of CSF leakage and therefore the incidence of PDPH; however, the angle of approach is most often dictated by anatomy, and therefore it is difficult for the anesthetist to modify effectively.

When ADP occurs during epidural placement, there has been some evidence to indicate that placing a subarachnoid catheter reduces the incidence of PDPH and the requirement for epidural blood patch (EBP).^{139,205} However, in a 2012 study of 97 women randomly assigned to either a repeat of the epidural procedure or converting to continuous spinal analgesia there was no difference in the incidence of PDPH or the requirement for EBP.¹⁴⁰ Interestingly, those in the repeat epidural group experienced a 9% ADP as a result of the second attempt. Based on these results, it would appear prudent to use spinal analgesia to provide rapid and reliable labor analgesia and to avoid the significantly increased chance of a second ADP.

The use of air as opposed to saline in the loss of resistance technique may also be associated with greater PDPH rates. Aida et al.²⁰⁶ studied 3700 patients who received epidural anesthesia and found that 100 experienced an ADP. PDPH occurred in 67% of the patients in the air group as opposed to 10% in the saline group. A head computed tomography (CT) scan was done in all 100 PDPH patients and identified supraspinal intrathecal air bubbles in 78% of those with PDPH indicating that intraventricular air plays a role in PDPH symptoms.

Treatment

Patients should be given a choice of treatments ranging from conservative to aggressive. PDPH can be a mild irritation for a few days, or it may be debilitating. Conservative treatment is appropriate for mild headaches and includes bed rest, caffeine and oral analgesics. Although aggressive hydration is not contraindicated, there is little evidence to indicate increased fluid intake affects CSF production.²⁰⁷ Caffeine is a cerebral vasoconstrictor that can be transiently effective in relieving the symptoms of PDPH that result from cerebral vasodilation. Epidural administration of preservative free saline has been proposed to

increase epidural pressure thereby temporarily reducing CSF outflow.²⁰⁸ However, its effectiveness is limited and the available evidence does not support the use of epidural saline at this time.¹⁹⁹

Patients with PDPH who are unresponsive to conservative therapy for 24 hours should be considered for an EBP. This procedure has an estimated treatment success rate of 75%.²⁰⁹ After resolution of the neural blockade has been confirmed, an EBP is performed by placing an epidural needle in the epidural space, preferably at the same interspace as the dural puncture or one interspace below. When viewed under fluoroscopy, an autologous blood/dye combination spreads one spinal segment below and 4 spinal segments above point of injection.²¹⁰ Once the needle is in place, an assistant performs a peripheral venipuncture and draws 20 mL autologous blood using strict aseptic technique. The blood is then slowly injected into the epidural space. The ideal volume for injection appears to be between 15 and 20 mL.²¹¹ If back pain develops, the injection is temporarily stopped. If the discomfort passes quickly, slow injection of the target volume of 15 to 20 mL may continue until discomfort returns. After the desired volume is injected, the Tuohy needle is withdrawn, and the patient should remain at rest for at least 1 hour.²¹²

The mechanism of action of an EBP appears to be twofold. First, the epidural blood covers the dural defect with a fibrin clot, and second, the injected volume of blood applies pressure to the dura, decreasing the relative total volume of CSF.

Prophylactic blood patch is a technique in which autologous blood is injected through the epidural catheter following delivery and immediately prior to its removal. However, its use is controversial for several reasons. Immediately after delivery the patient likely has yet to develop a headache, and, as a result, she may then receive an unnecessary treatment. In addition, the absolute sterility and precise location of an indwelling epidural catheter cannot be determined. Lastly, prophylactic blood patches do not appear to consistently influence the incidence or severity of PDPH.²¹³

Local Anesthetic Systemic Toxicity

Local anesthetic systemic toxicity (LAST) during epidural

anesthesia can result from inadvertent intravascular injection into an epidural vein or accumulation from repeated dosing. The signs and symptoms of LAST are directly related to the serum concentration and increase in severity as the concentration rises. Early signs of systemic toxicity include circumoral numbness, lightheadedness, and visual and auditory disturbances although both neurologic and cardiovascular signs may occur simultaneously. Unconsciousness, seizures, and cardiovascular depression/collapse follow as plasma concentrations increase further.

Necessary measures to prevent LAST during epidural anesthesia include aspiration of the catheter for blood prior to injection, use of an appropriate test dose, fractionated dosing, and vigilance for clinical signs of toxicity. The incidence of venous cannulation with an epidural catheter is approximately 6% in the obstetric population.²¹⁴ In a 2009 review of randomized controlled trials, Mhyre et al.²¹⁵ identified effective strategies to reduce the incidence of venous cannulation that included insertion in the lateral as opposed to the sitting position, using single-orifice rather than multi-orifice catheters, using wire-embedded polyurethane (soft) rather than nylon (hard) catheters, and limiting the depth of insertion to less than 6 cm.

Clearly, the initial intervention when any signs or symptoms of LAST occur is discontinuation of the injection of local anesthetic. Early recognition of a positive response to a test dose often halts the progression of symptoms. If signs and symptoms of LAST escalate to seizure activity, both mother and fetus are at risk for hypoxia. Rapid response involves the administration of benzodiazepines to end the seizure and support of ventilation and oxygenation. Emergency drugs and airway equipment should be on all epidural insertion carts. Advanced cardiac life support is provided symptomatically per guidelines. Careful evaluation of the maternal and fetal status should dictate decisions regarding obstetric management. The American Society of Regional Anesthesia and Pain Medicine has issued a practice advisory on local anesthetic systemic toxicity, and it is presented in detail in [Chapter 10](#).²¹⁶

Rescue treatment with **20% lipid emulsion** has been shown to be effective in treating local anesthetic-induced cardiotoxicity. The

precise mechanism of action remains unknown but may involve the exogenous lipid providing an alternate binding site for the lipid-soluble local anesthetic, often referred to as the *lipid sink theory*. Although the timing, dose, and duration has yet to be firmly established, its low cost, simplicity of use, and apparent lack of significant side effects leads to the recommendation that 20% lipid emulsion be available wherever regional anesthesia is used.²¹⁷ Guidelines for lipid use and a checklist for managing LAST should be readily available.²¹⁸

Total Spinal Block

Total spinal anesthesia is a complication that results from the excessive and unintended cephalic spread of local anesthetic within the subarachnoid or epidural space. It can follow the inadvertent injection of a large “epidural” dose of local anesthetic into the subarachnoid space after unrecognized subarachnoid catheter placement or migration of a previously placed epidural catheter into the subarachnoid space. Unintentionally high or total spinal block also can result from a single-shot spinal anesthetic performed after a failed epidural block. It is thought that the large amount of previously placed epidural local anesthetic migrates through the dural hole made by the spinal needle. A total spinal block is normally rapid in onset and preceded by complaints of dyspnea, difficult phonation, and hypotension. Bradycardia can occur resulting from blockade of the sympathetic innervation to the heart, which is located at the T1-T4 spinal cord segment. In the presence of these symptoms, consideration should be given to alternative diagnoses that include anaphylactic shock, eclampsia, or amniotic fluid embolus.

Accidental Subdural Injection

Rarely an epidural catheter may be inadvertently placed in the subdural space between the dura and arachnoid membranes.²¹⁹ Subdural injection presents as an excessively high sensory block with little motor involvement and is normally unilateral and delayed in onset by 10 to 25 minutes.²²⁰ The magnitude of the block is significantly greater than would be anticipated if the catheter

were located in the epidural space. Hypotension caused by extensive sympathetic block is usually the primary problem and is treated with vasopressors as needed. If the block is sufficiently extensive to compromise respiration or airway maintenance, endotracheal intubation may be necessary. This complication is uncommon and likely unpreventable. The possibility of delayed respiratory compromise emphasizes the necessity for close monitoring after epidural administration.

Cardiac Arrest in Pregnancy

Cardiac arrest in pregnancy has been estimated to occur in less than 1 : 20,000 women and, although rare, presents specific challenges to the obstetrical care team. In a recent consensus statement from the Society of Obstetric Anesthesia and Perinatology several important recommendations were made to improve resuscitation in maternal cardiac arrest.²²¹

In addition to standard American Heart Association (AHA) advanced cardiac life support (ACLS) guidelines, it is recommended for patients in the third trimester that hand placement during compressions be 2 to 3 cm higher on the sternum than in nonpregnant patients.²²² Manual left uterine displacement is necessary when the uterus is palpable above the umbilicus and is best performed by using two hands from the patients left and pulling leftward and up. Resuscitation drugs should be administered consistent with standard ACLS guidelines as none are contraindicated during maternal cardiac arrest.²²³

A perimortem cesarean delivery is required to improve maternal and fetal survival if return of spontaneous circulation does not occur within minutes of the arrest.²²⁴ This makes direct oxygenation of the neonate possible and has resulted in substantially improved venous return in the mother, ultimately allowing for improved success of resuscitation.²²⁵ The goal of a perimortem cesarean section during cardiac arrest is uninterrupted chest compressions and delivery no more than 5 minutes after the onset of cardiac arrest.²²⁶ Because transport to the operating room is time consuming and impairs quality chest compressions, it is recommended the procedure be performed in the labor room.²²⁷

Neurologic Injuries

Neurologic complications following labor and delivery are uncommon and may be associated with labor, delivery, positioning or neuraxial anesthesia.²²⁸ In a retrospective review of observational studies, Ruppen et al.²²⁹ found the incidence of persistent neurologic injury in obstetric patients who received epidural anesthesia to be 1 in 240,000 and the rate of transient (less than 1 year duration) neurologic injury to be 1 in 6700. Obstetrical nerve injuries related to childbirth involve pressure and stretching of peripheral nerves by the descending fetus and are identified by the appearance of a single peripheral neuropathy. Alternatively, neuraxial anesthesia–related injuries involve a spinal nerve root and, hence, follow a dermatomal distribution. Although neuraxial anesthesia is often cited as the cause of postpartum nerve injuries, careful identification and evaluation of the defect can indicate otherwise. The American Society of Regional Anesthesia and Pain Medicine has published a practice advisory on neurologic complications that discusses this topic further.²³⁰ Fig. 51.10 illustrates both peripheral nerves conducting sensory innervation and spinal dermatome distribution.

FIGURE 51.10 The dermatomal (right leg) and peripheral (left leg) sensory nerve distributions useful in distinguishing central from peripheral nerve injury. (In Chestnut DH, et al. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 5th ed. St. Louis: Elsevier; 2014:743. From Redick LF. Maternal perinatal nerve palsies. *Postgrad Obstet Gynecol*. 1992;12:1-6.)

Obstetric Complications

Postpartum Hemorrhage

Approximately 4% of all parturients who deliver vaginally experience postpartum hemorrhage (PPH), and the incidence appears to be increasing.^{231,232} Aggressive recognition and treatment has the potential to prevent the development of serious PPH.²³³

Postpartum hemorrhage may occur as a result of uterine atony (accounting for 80% of all postpartum bleeding), placental retention, abnormalities of the uterus, lacerations of the cervix or vaginal wall, uterine inversion, and abnormalities of coagulation. Uterine atony is associated with multiparity, prolonged infusions of oxytocin before delivery, polyhydramnios, and multiple gestation.²³⁴ PPH has been defined as an estimated blood loss of greater than 500 mL after vaginal delivery and greater than 1000 mL during cesarean section.

The ACOG has made recommendations for the prevention and treatment of PPH that includes the use of uterotonic agents such as oxytocin followed by methylergonovine, prostaglandins, and misoprostal when oxytocin is ineffective.²³⁵ An example of a flow chart for managing obstetric hemorrhage is shown in Fig. 51.11.

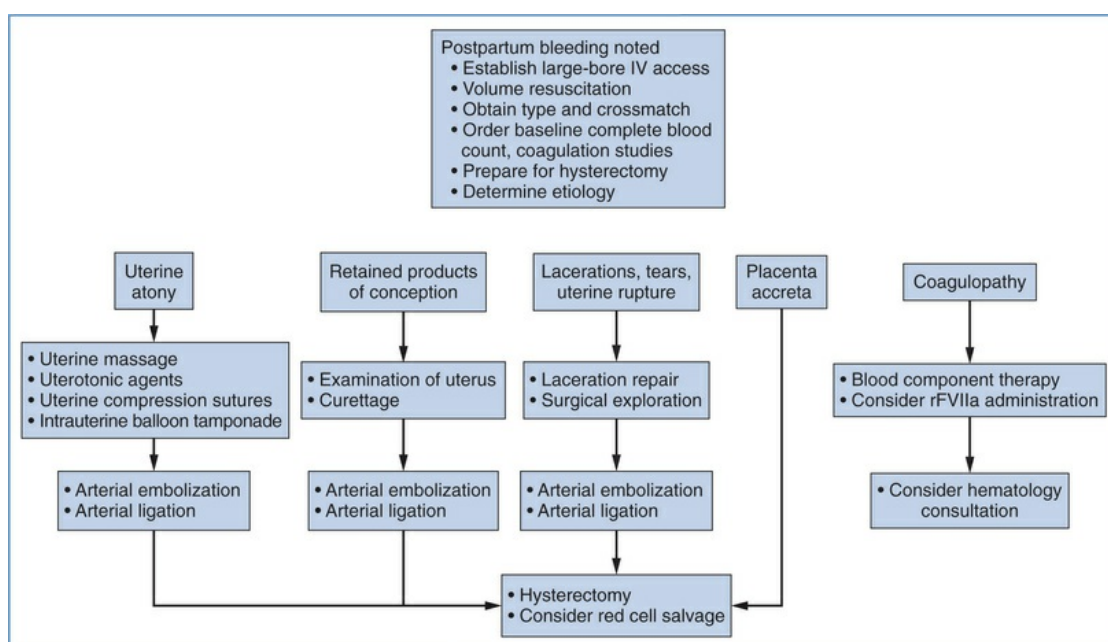

FIGURE 51.11 Management options for postpartum hemorrhage. (From Chestnut DH, et al. *Chestnut's Obstetric Anesthesia*. 5th ed. St. Louis: Elsevier; 2014: 889.)

When oxytocin does not adequately stimulate uterine contraction, another uterotonic, an ergot alkaloid (Methergine) can be used. Because of their potent vascular effects, ergot alkaloids are not administered intravenously. Ergot alkaloids normally cause an increase in blood pressure, central venous pressure, and pulmonary capillary wedge pressure and should be used with caution in patients with preexisting elevated blood pressure. An intramuscular dose of **Methergine 0.2 mg** is commonly administered for stimulating uterine contractions.

Following the use of oxytocin and ergot alkaloids, prostaglandin F_{2a} (e.g., Carboprost, Hemabate; 250 mcg) can be administered either intramuscularly or directly into the uterine muscle. Prostaglandins are potent stimulators of uterine contractions but can cause nausea, bronchospasm, and increased pulmonary vascular resistance. If **uterine atony continues, misoprostol 800 to 1000 mcg** can be administered rectally, vaginally, or orally.

Antifibrinolytic agents such as tranexamic acid strengthen fibrin clots by inhibiting enzymatic fibrinolysis, and they have shown early promise when used in combination with uterotonic agents.^{234,236}

Institution-specific massive transfusion protocols and policies can be invaluable in coordinating communication between anesthesia, blood bank, and intensive care staff. Regardless of the approach, planning for the management of PPH should be an integral part of an obstetric anesthesia practice.²³⁷ Although historically controversial due to the risk of amniotic fluid embolus and Rh incompatibility, the use of intraoperative cell salvage is now accepted and should be considered in the setting of massive intraoperative obstetrical hemorrhage. Cell salvage should start after delivery of the placenta, and use of a leukocyte depletion filter improves safety.^{238,239}

A retained placenta or placental fragments can precipitate postpartum hemorrhage and are often removed manually. Nitroglycerin, a potent uterine relaxant with a relatively short duration of action, can be used to provide uterine relaxation

necessary for placental extraction.²⁴⁰

When hemostasis is not achieved despite the use of pharmacologic adjuncts, the obstetric staff may place an intrauterine balloon. The device is specifically designed for this purpose, and it is placed in the uterine cavity and filled with saline in order to exert a tamponade effect. Balloon tamponade is a minimally invasive and rapidly applied approach that can be used alone or as a temporizing measure while other resources are being mobilized.²⁴¹

Anesthetic Implications

Anesthesia for uterine exploration can be accomplished with a variety of methods including the use of an epidural catheter, a single-shot spinal “saddle block,” or a general anesthetic. The choice of technique is dependent on the patient's condition and the urgency of the proposed procedure. Under normal circumstances, the continuous epidural infusion is routinely discontinued at completion of delivery and repair; however, the epidural catheter should remain in place until the maternal patient is stable. In this manner, if a postpartum surgical intervention becomes necessary, reestablishing epidural anesthesia is an option.

Preeclampsia

Description

Preeclampsia is a pregnancy-specific multisystem disorder of unknown etiology. The disorder affects approximately 5% to 7% of pregnancies, and it is a significant cause of maternal and fetal morbidity and mortality.²⁴² The incidence of preeclampsia has increased by 25% in the United States over the last 20 years.²⁴³ The pathophysiology appears to involve deranged placental angiogenesis leading to constricted myometrial arteries with exaggerated vasomotor responsiveness, superficial placental implantation and placental hypoperfusion.²⁴⁴ Mediators secreted by the placenta cause widespread endothelial dysfunction resulting in multisystem organ dysfunction.²⁴⁵

Preeclampsia is defined as systolic hypertension of 140 mm Hg or

higher or diastolic blood pressure of 90 mm Hg or higher after 20 weeks gestation, accompanied by proteinuria.²⁴⁶ In the absence of proteinuria, the diagnosis can be made when new-onset hypertension is accompanied by a platelet count less than 100,000/ μ L, impaired liver function and/or severe persistent right upper quadrant pain, progressive renal insufficiency, pulmonary edema or new-onset cerebral or visual disturbances.²⁴⁶

The primary cause of hypertension related maternal mortality is cerebral hemorrhage. Pulmonary edema, renal failure, hepatic rupture, cerebral edema, and disseminated intravascular coagulation (DIC) are also associated with preeclampsia. Eclampsia is the onset of seizures in a patient with signs and symptoms of preeclampsia.

Pathophysiology

The precise pathogenesis of preeclampsia is complex and not well understood but likely involves a failure in normal placental angiogenesis resulting in decreased placental perfusion. Placental function worsens as the pregnancy progresses, often resulting in intrauterine growth restriction. The hypoperfused placenta releases factors into the maternal circulation that damage the maternal endothelium, resulting in system-wide manifestations.

The upper airway edema normally associated with pregnancy can be more pronounced in the preeclamptic patient. The decreased colloid osmotic pressure associated with urinary protein loss combined with increased vascular permeability predisposes the parturient to pulmonary edema. CNS effects include headache, hyperexcitability, and hyperreflexia. Thrombocytopenia occurs in up to 20% of women and is related to the severity of the disease process. Increased vascular tone results from hypersensitivity to endogenous catecholamines. Systemic vascular resistance is increased, ultimately resulting in end organ ischemia. Plasma volume is normal in mild disease but may be reduced by up to 40% in severe disease.²⁴⁷ Hepatocellular necrosis results in hepatic enlargement, which ultimately can lead to hepatic capsule rupture. Proteinuria occurs as a result of glomerular capillary endothelial destruction. There is now evidence to indicate that a woman who has had preeclampsia during pregnancy is at an increased risk of

later-life cardiovascular disease.²⁴⁶

Obstetric Management

Delivery is at present, the only definitive way of ending the disease process of preeclampsia. The obstetrical decision to deliver is based on the presence of complicating factors such as uncontrolled severe hypertension, eclampsia (seizures), pulmonary edema, placental abruption or evidence of nonreassuring fetal status. For preeclamptic parturients, the mode of delivery (cesarean section or vaginal) is determined by fetal gestational age, fetal presentation, cervical status and maternal and fetal condition.²⁴⁶ In the absence of severe features a 24–48 hour trial of corticosteroids may be administered to enhance fetal lung maturity.

Obstetric treatment is directed toward preventing eclampsia (seizures), avoiding decreases in uteroplacental blood flow, and maximizing organ perfusion. **Magnesium sulfate is routinely used to prevent seizures in severe preeclampsia both before and after delivery.** Magnesium sulfate (which is also used as a tocolytic) causes venous dilation, mild CNS depression, a decrease in the rate of hepatic fibrin deposition, and a reduction in uterine activity. Decreasing fibrin deposition prevents further decay in organ perfusion and often greatly decreases liver pain. Hypertension can be treated to prevent maternal complications such as intracranial hemorrhage and hypertensive myocardial ischemia. There is no evidence to indicate that treating the hypertension changes the underlying maternal disease process.

Anesthetic Implications

Regional analgesia and anesthesia are generally preferred for both spontaneous vaginal delivery and cesarean section in the preeclamptic patient when neuraxial techniques are not otherwise contraindicated. Historically there was concern that neuraxial techniques, especially spinal anesthesia, would result in severe hypotension refractory to fluids and vasopressors due to the chronic volume depletion associated with preeclampsia. In reality, prospective studies have shown that parturients with preeclampsia actually experience less severe and less frequent hypotension

compared to normotensive controls.^{248,249} These findings indicate that spinal anesthesia can be safely administered to severely preeclamptic patients and that spinal induced hypotension can generally be treated safely.²⁴⁴

Early epidural placement for labor analgesia is encouraged in severely preeclamptic patients because it provides a means for rapid anesthesia if an urgent cesarean section is required, thereby avoiding the potential use of GA. Although the use of epidural anesthesia for cesarean section in preeclampsia likely results in a lower requirement for vasopressors when compared to spinal,²⁴⁹ the difference is small and of little clinical significance. Therefore, when no epidural catheter is present, a spinal anesthetic is generally preferred for the severely preeclamptic parturient because of its rapid onset which may be of value in an urgent setting.

Spinal anesthesia is also preferred over GA when not contraindicated. Uncontrolled hypertension in response to laryngoscopy is a major cause of hemorrhagic stroke in severely preeclamptic parturients.²⁵⁰ Airway edema normally associated with pregnancy is exaggerated and can add to the risk of failed or difficult intubation. Labetalol is generally considered to be the first-line drug in treating hypertension during anesthesia. Treatment of systolic blood pressures above 160 mm Hg should be a guide in order to avoid intracranial bleeding.²⁵¹ Esmolol has also been safely used during induction without significant neonatal effects.²⁵² Opioids administered prior to delivery are normally avoided because they can result in undesirable neonatal and maternal respiratory depression. Maternal respiratory depression can become a significant issue in the event of a failed intubation. Control of blood pressure during induction of GA demands both careful planning and skill.

Nondepolarizing muscle relaxants are markedly potentiated in women with preeclampsia who have therapeutic levels of magnesium. Magnesium sulfate reduces the onset time of rocuronium and prolongs the total recovery time by approximately 25%.²⁵³ If a nondepolarizing muscle relaxant is indicated, a decreased dose should be used and the response should be carefully monitored with a peripheral nerve stimulator.

Thrombocytopenia in preeclampsia is common and results from

endothelial dysfunction that stimulates excess platelet activation and consumption. There is no universally accepted platelet count for a safe neuraxial anesthetic but practice guidelines and expert opinion indicate most practitioners require a platelet count of 75,000 or $80,000 \times 10^9/L$ ^{85,254} (see section on [Neuraxial Analgesia for Labor and Delivery](#)). In the setting of severe preeclampsia complicated by thrombocytopenia it may also be advantageous to confirm normal partial thromboplastin (PTT) and prothrombin (PT) times prior to initiating neuraxial anesthesia.

HELLP Syndrome

HELLP syndrome consists of *hemolysis, elevated liver enzymes, and a low platelet count* and is a complication of preeclampsia. From 5% to 10% of women with preeclampsia develop HELLP syndrome and it is associated with a progressive and often sudden deterioration in maternal and fetal condition. Clinical signs of HELLP syndrome include epigastric pain, upper abdominal tenderness, proteinuria, hypertension, jaundice, nausea, and vomiting. Rarely, HELLP syndrome may result in hepatic rupture. Some experts believe that a degree of compensated DIC is present in all patients with HELLP syndrome. Due to increased maternal morbidity and mortality, the presence of HELLP syndrome is generally considered to be an indication for immediate delivery.²⁴⁶

Obesity

Obesity affects over 20% of pregnancies and is associated with significant increases in obstetric and anesthesia related morbidity.²⁵⁵ Obese parturients are more likely to experience prenatal hypertensive and hyperglycemic disorders. Labor is often complicated by fetal macrosomia, prolonged duration, failed induction and increased cesarean delivery rates.⁸² Cesarean sections are also characterized by increased complication rates such as prolonged operative times, infectious complications and thromboembolic events.²⁵⁶

Neuraxial catheter techniques are clearly indicated for labor analgesia because they can offer complete pain relief without respiratory depression while providing a ready option for

anesthesia if cesarean or instrumented delivery becomes necessary. They are, however, associated with more difficult insertion and higher complication rates.²⁵⁷ Early placement of the anesthetic may be considered to allow for enhanced maternal cooperation and adequate time for troubleshooting thereby reducing the possibility of a general anesthetic and related potential airway difficulties. Early prenatal consultation and examination is advised and effective communication between all members of the care team is of great importance.

Abnormal Placental Implantation

Placenta Previa

Placenta previa is present when the placenta has implanted on the lower uterine segment and either partially or completely covers the opening of the cervix. Placenta previa has an incidence of up to 1%, and the mortality rate for those with it approaches 1%. Risk factors include uterine scars from prior uterine surgery, prior placenta previa and advanced maternal age. It most often results in painless vaginal bleeding prior to the onset of labor that can result in hemodynamically significant blood loss. The risk of bleeding increases if the placenta is disturbed by manual examination of the cervix. Postpartum bleeding is often increased as well because the lower uterine segment, where the placenta previa was implanted, does not contract as well as the remainder of the uterus. Three variations of placenta previa are shown in [Fig. 51.12](#). The diagnosis of placenta previa is made by ultrasound and normally indicates cesarean delivery.

FIGURE 51.12 Three variations of placenta previa. (From Gabbe SG, et al. *Obstetrics: Normal and Problem Pregnancies*. 6th ed. Philadelphia: Elsevier; 2017:457.)

Placenta Accreta

The placenta normally implants into the endometrium. Placenta accreta is the abnormal growth of the placenta onto the myometrium and placenta increta describes abnormal placental growth into the myometrium. In placenta percreta the placenta grows completely through the myometrium into the surrounding structures such as bowel, bladder or ovaries (Fig. 51.13). Overall, rates are directly related to the number of prior uterine scars (cesarean deliveries) and the presence of placenta previa. In patients with known placenta previa, placenta accreta was found to be present in 3%, 11%, 40%, 61%, and 67% for first, second, third, fourth, and fifth or more repeat cesarean deliveries.²⁵⁸ Delivery of patients with placenta accreta is often complicated by massive intraoperative hemorrhage. Treatment at the time of delivery can include surgical techniques such as uterine artery embolization and preoperative planning should include the possibility of cesarean hysterectomy.

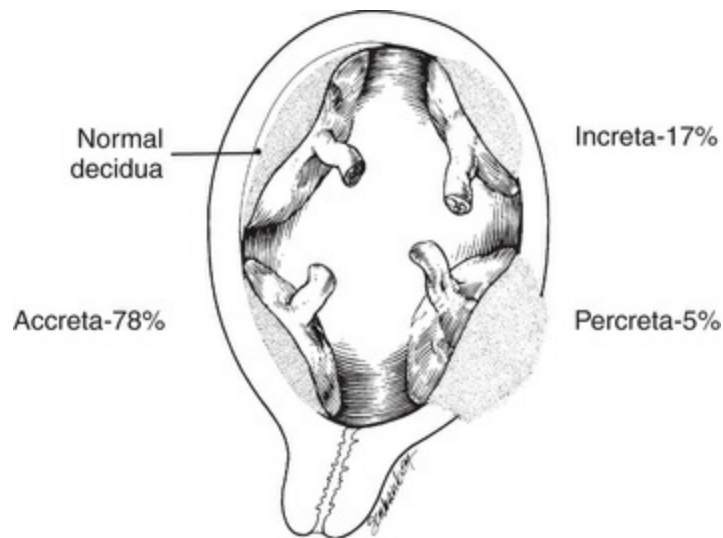

FIGURE 51.13 An example of placenta increta, percreta, and accreta. (From Gabbe SG, et al. *Obstetrics: Normal and Problem Pregnancies*. 7th ed. Philadelphia: Elsevier; 2017:457.)

Placental Abruption

Placental abruption occurs when the placenta begins to separate from the uterus before delivery. This allows bleeding to occur behind the placenta and jeopardizes fetal blood supply. Placental abruption results in hemorrhage, uterine irritability, abdominal pain, and fetal hypoperfusion. Open venous sinuses in the uterine wall may allow amniotic fluid to enter the maternal circulation, resulting in an increased incidence of DIC. The reported incidence of abruption in the general population varies widely but is much higher in women with hypertension (up to 23% among women with preeclampsia).

In cases of placental abruption without fetal distress, vaginal delivery may still be possible. Because fetal distress can occur without warning, the anesthetist should be prepared to administer anesthesia for an emergency cesarean section. Performing a preanesthetic evaluation as soon as the diagnosis of placental abruption becomes known and confirming adequate IV access is recommended. If the mother is unstable or if fetal distress is present, operative delivery is necessary. Although placental abruption does not usually result in sudden blood loss, a large volume of trapped blood may become apparent at delivery. Consideration should be given to the parturient's existing volume

status and potential for increased intraoperative blood loss.

Amniotic Fluid Embolus

Amniotic fluid embolism is rare and may occur during labor, vaginal, or operative delivery and it is occasionally associated with placental abruption. Signs and symptoms of amniotic fluid embolism include anxiety, dyspnea, hypoxia, hypotension, cardiovascular collapse and coagulopathy. The pathogenesis is likely related to an anaphylactoid reaction to the amniotic fluid and not purely an embolic event.²⁵⁹ Clinical management is supportive and includes airway management, hemodynamic resuscitation, and appropriate treatment of coagulopathy.

Prematurity

Premature delivery is a significant cause of fetal morbidity and mortality, and it is implicated in more than 50% of all perinatal deaths. Premature labor and delivery occurs before 37 weeks' gestation. Late preterm births, defined as those of 34 to 36 weeks' gestation, compose approximately 70% of all preterm births. Fetal birth weight below 1500 g is considered very low-birth-weight and is associated with the greatest risk of long-term complications.²⁶⁰ Severe morbidity associated with preterm delivery includes respiratory distress syndrome, intracranial hemorrhage, and hyperbilirubinemia. A diagnosis of preterm labor can be facilitated by measuring fetal fibronectin which is a protein normally undetected before 35 weeks' gestation.²⁶¹

The ability to stop premature labor can allow the fetal lungs additional time to mature. Delaying delivery for 24 to 48 hours can allow for the administration of corticosteroids and antibiotics which promote fetal lung maturation and decrease maternal chorioamnionitis. Drugs used to prevent and suppress preterm labor include magnesium sulfate, calcium channel blockers, and β -sympathomimetics.

There is evidence to indicate that bacterial colonization of fetal membranes and amniotic fluid triggers an inflammatory response in the mother and fetus that leads to preterm labor and associated long-term neurologic and respiratory complications in the neonate.

This raises questions about the desirability of prolonging pregnancy in this context. Combined with 2012 meta-analyses that fail to demonstrate improvements in neonatal outcome with tocolytic therapy, as well as a poor maternal/fetal side-effect profile, the case for continued use of these drugs needs to be questioned.²⁶²

Neuraxial analgesia is indicated when a vaginal delivery is planned as it provides excellent relaxation of the pelvic musculature, thereby reducing the incidence of intracranial trauma. Deliveries involving infants with very low-birth-weight (< 1500 g) or those in the breech position are normally performed via cesarean section. The choice of anesthetic technique is directed toward avoiding fetal trauma and maintaining utero placental perfusion.

Anesthesia for the Pregnant Patient Undergoing a Nonobstetric Procedure

Occasionally anesthesiologists must provide anesthesia care for a pregnant woman having nonobstetric emergency procedures. Approximately 1% to 2% of pregnant women will require a surgical procedure. The most common procedures are appendicitis, ovarian cysts, trauma, and cervical cerclage. Although there are theoretical concerns involving the teratogenicity of anesthetic agents as a result of animal studies, there is no clear information applicable to humans regarding the toxicity of specific agents. Animal studies involving multiple exposures to anesthetic agents suggest CNS neuronal apoptosis and associated expressed abnormalities.²⁶³ Anesthesia management issues in pregnancy include appreciating the alterations in maternal physiology, maintenance of uterine perfusion and prevention of premature labor. Goals for intraoperative management include maintaining maternal oxygenation, avoiding hyperventilation, and hypotension. Virtually all anesthetic agents rapidly cross the placenta and exhibit fetal effects with the exception of muscle relaxants, which cross the placenta with difficulty due to their charged status. It is realistic to monitor FHR after approximately 20 weeks' gestation. When monitored intraoperatively, the FHR normally displays decreased variability and likely does not reflect poor acid-base status. Alternatively, intraoperative fetal bradycardia is a more ominous sign and should be investigated for treatable causes. Organogenesis occurs in the first trimester and is avoided if at all possible for surgical procedures, as is the third trimester when premature labor is the primary issue. The maternal airway changes that accompany normal pregnancy favors regional anesthesia techniques when possible.

Cervical cerclage is a surgical intervention used to prevent second trimester fetal loss due to cervical incompetence and is generally performed between 12 and 26 weeks' gestation. Sutures are placed in the cervical os to prevent further dilation and ultimately premature delivery. The superficial nature of the

procedure often makes a spinal anesthetic a suitable choice. Key points are noted in [Box 51.5](#).

Key Points for the Pregnant Patient Undergoing Nonobstetric Procedure

- A significant number of women undergo anesthesia and surgery during pregnancy for procedures unrelated to delivery.
- Maternal risks are associated with the anatomic and physiologic changes of pregnancy (e.g., difficult intubation, aspiration) and with the underlying maternal disease.
- The diagnosis of abdominal conditions often is delayed during pregnancy, which increases the risk of maternal and fetal morbidity.
- Maternal catastrophes involving severe hypoxia, hypotension, and acidosis pose the greatest acute risk to the fetus.
- Other fetal risks associated with surgery include increased fetal loss, increased incidence of preterm labor, growth restriction, and low birth weight. Clinical studies suggest that anesthesia and surgery during pregnancy do not increase the risk of congenital anomalies.
- It is unclear whether adverse fetal outcomes result from the anesthetic, the operation, or the underlying maternal disease.
- No anesthetic agent is a proven teratogen in humans, although some anesthetic agents, specifically nitrous oxide, are teratogenic in animals under certain conditions.
- Many anesthetic agents have been used for anesthesia during pregnancy, with no demonstrable differences in maternal or fetal outcome.
- The anesthesia management of the pregnant surgical patient should focus on the avoidance of hypoxemia, hypotension, acidosis, and hyperventilation.

- When performing a maternal laparoscopy, the use of an open technique or a Veress needle to enter the abdomen is desirable.
- Monitor maternal ETCO₂ to avoid fetal hypercarbia and acidosis.
- Low pneumoperitoneum pressures (between 10 and 15 mm Hg) should be used.
- Limit the extent of Trendelenburg or reverse Trendelenburg positions and initiate any position slowly.
- Monitor fetal heart rate and uterine tone preoperatively and postoperatively.
- Tocolytic agents should not be used prophylactically but should be considered when evidence of preterm labor is present.

Neonatal Resuscitation

All labor and delivery personnel, including anesthetists, should be trained in basic neonatal resuscitation. The anesthetist in clinical practice may participate in neonatal resuscitation, but his or her primary responsibility is attending to the care of the mother. An individual other than the anesthetist should be assigned responsibility for care of the newborn at every delivery.

Approximately 15% of newborns require resuscitation, but this can generally be predicted from known risk factors. Tactile stimulation of the newborn will often result in spontaneous respiration. If spontaneous respiration is delayed after stimulation, initiation of assisted ventilation should begin.

The Apgar scoring system is widely used to assess newborns. The score is derived from five parameters including HR, respiratory rate, muscle tone, reflex irritability, and color. The assessment is performed at 1 minute and again at 5 minutes. The score is used to guide resuscitation. A score of 8 to 10 is considered normal, 4 to 7 indicates moderate distress or impairment, and 0 to 3 indicates the need for immediate resuscitation.

If the parturient has received prenatal care, there may be previous knowledge or suspicions of a congenital anomaly that can be used to guide resuscitation. In the event of little or no prenatal care, this information may be unavailable.

Most newborns do not require neonatal resuscitation. However, approximately 10% of newborns require some type of resuscitative assistance at birth. The vast majority will require assisted ventilation only. Approximately 1% will require major interventions such as intubation, chest compressions, or emergency medications. The AHA guidelines for neonatal resuscitation are summarized in [Box 51.6](#).

Neonatal Resuscitation Guidelines

- Initial evaluation of the newborn with emphasis on heart rate and respirations. Pulse oximetry should be used for evaluation of oxygenation because assessment of color is often unreliable.

- To avoid hypothermia, preterm babies less than 28 weeks' gestation should be wrapped immediately after birth, up to their neck and without drying, and kept wrapped under radiant heat until their temperature has been verified in the neonatal intensive care unit (NICU). For these infants, delivery room temperature should be maintained at least at 26°C.
- Ventilatory resuscitation should begin with air rather than 100% oxygen in term infants receiving resuscitation at birth with positive pressure ventilation. If, despite effective ventilation, there is no increase in heart rate or if oxygenation, best guided by pulse oximetry, remains unacceptable, a higher concentration of oxygen should be considered. Oxygen saturation during labor and just after birth is approximately 60% and will increase to \pm 90% after 10 minutes.
- Positive pressure ventilation (PPV) is an extremely important and effective intervention that should be initiated if the infant is apneic or gasping or if the heart rate is less than 100 bpm after 30 seconds of administering the initial steps of resuscitation. Prompt improvement in heart rate is the best indicator of adequate ventilation. The T-piece resuscitator is specifically used for neonatal resuscitation and is the device of choice.
- In births with meconium-stained amniotic fluid, suctioning of the oropharynx and nasopharynx before delivery of the shoulders is no longer recommended. In babies born through meconium-stained fluid, available evidence does not support or refute the routine endotracheal intubation and suctioning, even if they are depressed at birth, and the current practice should not be changed.
- Detection of exhaled carbon dioxide, in association with clinical assessment, for example, increasing heart rate, is the most reliable method for confirming endotracheal tube placement in infants with spontaneous circulation. Colorimetric exhaled CO₂ detectors are useful in identifying airway obstruction during facemask ventilation in preterm infants.

- Chest compressions are indicated when the heart rate is less than 60 bpm despite adequate ventilation for 30 seconds. In the newly born infant, the standard compression:ventilation ratio is 3 : 1.
- If the arrest is clearly due to a cardiac etiology, a higher compression:ventilation rate (e.g., 15 : 2) may be considered. Compressions should be delivered on the lower third of the sternum at a depth of one-third of the anteroposterior diameter of the chest. The two thumb-circling hands method is recommended because this process allows for better control of the depth of compressions.
- The use of drugs is rarely indicated because the most important and effective step is establishing adequate ventilation. If emergency drugs are required, they can be given by three possible routes: venous (e.g., umbilical vein), endotracheal tube, and intraosseous. If the heart rate remains less than 60 bpm despite adequate assisted ventilation for 30 seconds and chest compression for an additional 30 seconds, then the administration of epinephrine at the dose of 0.01 to 0.03 mg/kg, intravenously or 0.05 to 0.1 mg/kg via the tracheal route.
- The use of therapeutic hypothermia, both whole-body hypothermia and selective head-cooling, may reduce the risk of death and disability in infants with moderate-to-severe hypoxic-ischemic encephalopathy. Hypothermia is recommended as a treatment for neonates with suspected asphyxia. Hypothermia should be induced, lowering temperature to 33.5°C to 34.5°C within 6 hours of birth, continuing it for 72 hours, and then rewarming over at least 4 hours. Treated infants should be followed up on a long-term basis.
- Health care providers may consider not initiating neonatal resuscitation when there are factors associated with almost certain infant death or unacceptable morbidity, or both. The parents must be included in the decision-making process regarding initiating or withholding resuscitation of their infant, particularly in situations when the prognosis is uncertain and morbidity rate is very high. Discontinuing continuous and

adequate resuscitation after 10 minutes, if there are no signs of life, is justifiable.

Summary

Nurse anesthetists play a major role in providing obstetric anesthesia care. The practice of obstetric anesthesia has the additional challenge of assuring the safety of the newborn. Advances in monitoring and prenatal care have allowed for continuous refinements in regional and, when necessary, GA management of these patients. A thorough knowledge of the physiologic changes associated with pregnancy, anesthetic techniques, and potential complications associated with labor and delivery will help the anesthetist to make calculated decisions to help ensure the highest quality of care.

Neonatal Anesthesia

Sass Elisha, Karrey Lynn Terry

The neonatal period is defined as the first 28 days of extra-uterine life. Anesthesia for the neonate may be required as the result of a life-threatening illness or medical conditions requiring surgical intervention. The neonate is particularly vulnerable to external stressors and the anesthetic plan must be tailored to help mitigate physiologic stress, which serves to improve neonatal morbidity and mortality. The differences between neonatal and adult anatomy and physiology, however, are clearly greatest during this transitional period, especially if birth occurs before term. The neonate that is born prematurely does not compensate physiologically as effectively as the full-term infant. Therefore the anesthetist must have a thorough understanding of normal growth and development, the anatomic and physiologic differences during various stages of maturation, and how immature organ systems affect anesthetic pharmacokinetics and pharmacodynamics. Anesthetic management of the neonate requires integration of this specialized knowledge and refinement of acquired technical skills.

In the past neonates, and in particular those that were preterm, or “sick” neonates, were anesthetized with the “Liverpool Technique,” which consisted of oxygen, nitrous oxide, and curare. Volatile anesthetics and opioids were not used, and the “stable” state that resulted was due to a sympathetic system stimulation. However, since 1987, our understanding of neonatal physiology, particularly neurobiology, has led to an active program of research in the field of neonatal anesthesia. Neonates, term and preterm, respond to painful stimuli.¹ Signs of distress are clearly evident when neonates are exposed to painful stimuli. The behavioral, physiologic, and humoral signs are similar to those seen in older children and adults.² Therefore, all neonates require general or regional anesthesia when surgery is necessary. There is a tenfold increased

incidence of morbidity and mortality in neonates as compared with older pediatric patients.³ Neonates and infants younger than 12 months old exhibit the highest rate of adverse events during the postoperative period. Preterm infants are more prone to developing respiratory complications. Postoperatively, apnea is a common occurrence in young infants who are less than 60 weeks' post-conceptual age and observation for 24 hours is necessary.^{4,5} In pediatric medicine, the term *post-menstrual age* is preferred as compared to post-conceptual age to describe the child's age during the perinatal period. A description of terms related to the perinatal period are listed in [Box 52.1](#).

Terminology Used During the Perinatal Period

- Gestational age: Time in weeks between the first day of the last menstrual period and the day of delivery (weeks).
- Chronological age: Time that has elapsed since birth (days, weeks, months or years)
- Postmenstrual age: Gestational age + chronological age (weeks)
- Corrected age: Chronological age reduced by the number of weeks born before 40 weeks' gestation (weeks, months)

American Academy of Pediatrics. Age Terminology During the Perinatal Period, *Pediatrics* 2004;114;1362-64

Developmental Considerations

Fetal Circulation

The fetal circulatory system relies on the placenta for delivery of oxygen and transport of carbon dioxide (CO₂). The chorionic villus is the functional unit of the placenta. Normally, fetal blood is separated from the maternal blood in the placenta by a thin layer of cells known as *syncytial trophocytes*. Oxygen, CO₂, and small nonionized particles readily pass through this layer, whereas substances with a larger molecular weight are prevented from diffusing across the syncytial trophocytes. Fetal circulation is characterized by high pulmonary vascular resistance (uninflated atelectatic lungs and hypoxic vasoconstriction) and low systemic circulatory resistance (high flow and low impedance of the placental vessels). Fetal deoxygenated blood travels down the aorta and through the internal iliac arteries, arriving in the placenta via paired umbilical arteries. The umbilical arteries divide, forming the arterioles, capillaries, and venules of the intervillous placental space. Oxygenated blood is delivered to the fetus from the placenta via a single umbilical vein. This oxygenated blood bypasses the lungs by flowing through extracardiac (ductus arteriosus, ductus venosus) and intracardiac (foramen ovale) shunts, forming a parallel circulation. The ductus venosus routes oxygenated blood away from the sinusoids of the liver. The oxygenated blood in the inferior vena cava is directed by the eustachian valve toward the atrial septum and passes through the foramen ovale (FO) to enter the left side of the circulation. Oxygenated blood passes into the left ventricle and exits the aorta, supplying the coronary arteries. Blood entering the pulmonary artery from the right ventricle flows to the aorta via the ductus arteriosus. Only 5% to 10% of the combined ventricular output flows through the pulmonary circulation.

Transitional Circulation

The transitional circulation is established at the time of birth. With the cessation of placental blood flow, aortic pressure increases.

Clamping of the umbilical vein doubles systemic vascular resistance. Pulmonary vascular resistance (PVR) falls with lung expansion, and increasing partial pressure of arterial oxygen (PaO_2) produces pulmonary vasodilation, resulting in further decreases in PVR. These changes in systemic and pulmonary blood flow produce corresponding changes in intra-cardiac pressure. Decreases in right atrial pressure with accompanying increases in left atrial pressure change the direction of blood flow through the FO, resulting in the functional closure of the FO as left atrial pressure increases. The FO may reopen if right atrial pressure is greater than left atrial pressure (e.g., pulmonary hypertension), permitting venous blood to flow from right to left. Within a period of 2 to 3 months, the FO will undergo permanent closure, which is also known as *anatomic closure*. Up to 25% of adult patients may demonstrate a probe patent FO at autopsy.⁴ Closure of the ductus arteriosus (DA) is precipitated in part by the increase in systemic vascular resistance (SVR) and decrease in PVR. In utero, prostaglandins maintain the patency of the DA. Within a few hours after birth, the muscular wall of the DA constricts, preventing retrograde blood flow from the aorta into the pulmonary artery. This functional closure (thrombosis) occurs within 1 to 8 days. Anatomic closure (fibrosis of the DA) requires 1 to 4 months. Closure of the DA is influenced by elevations in the systemic PaO_2 that occur after birth. The majority of portal blood flow continues to enter the ductus venosus (DV) after interruption of umbilical vein blood flow. Although the cause of the initiating mechanisms of DV closure is unknown, the muscular wall of the DV begins to constrict within 1 to 3 hours of birth. Blood flow is directed into the liver, and portal venous pressure increases.

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN) is the result of an abnormal early adaptation to the perinatal circulatory transition. PPHN is characterized by a sustained elevation of PVR; decreased perfusion of the lungs; and continued right-to-left shunting of blood through the DA. When PVR remains high after

birth, right (and sometimes left) ventricular function and cardiac output are depressed. Moderate or severe PPHN is believed to affect up to 2 to 6 per 1000 live births, and complicates the course of 10% of all infants admitted to neonatal intensive care. These circulatory abnormalities are also responsible for an 8% to 10% risk of death and a 25% risk of long-term neurodevelopmental morbidity. Significant pulmonary hypertension may also develop in neonates and young infants as a result of bronchopulmonary dysplasia (BPD) or cardiac disease. Pulmonary hypertension affects roughly one-third of infants with moderate-to-severe BPD.⁵⁻⁷

During fetal development, PVR is high but rapidly decreases at birth to near-normal levels, allowing the lungs to become a gas-exchanging organ. Before anatomic closure of the DA and FO, fetal circulation may be reestablished and persist. Persistent PPHN manifests as increases in PVR and accompanying pulmonary hypertension, which produces a right-to-left shunt across the FO and the DA, with resulting cyanosis. The presence of congenital cardiovascular or pulmonary disease inhibits functional and anatomic closure of these aforementioned fetal shunts. Persistent fetal circulation is common in preterm infants and infants with metabolic derangements (e.g., asphyxia, sepsis, meconium aspiration, congenital diaphragmatic hernia). Hypoxemia, acidosis, pneumonia, and hypothermia are primary precipitating factors of PPHN. Oxygenation, correcting acidosis, and maintenance of normothermia will attenuate the increase in PVR. Continual increases in pulmonary vascular pressure and resistance will precipitate the development of right ventricular hypertrophy (cor pulmonale). Although pulmonary vasodilators may have some utility in decreasing pulmonary vascular resistance, concurrent reductions in SVR can occur and may worsen shunting.

The primary aim of PPHN therapy is selective pulmonary vasodilation. Treatment of pulmonary hypertension includes optimization of lung function, oxygen delivery, and support of cardiac function. Optimal lung inflation is essential because PVR is increased when the lungs are underexpanded or overexpanded, independent of lung disease. The use of lung recruitment strategies, such as high-frequency ventilation and exogenous surfactant administration, is particularly important in infants with PPHN

associated with parenchymal disease, but has limited impact in infants with primary vascular disease. Correction of severe acidosis and avoidance of hypoxemia are important because they both stimulate pulmonary vasoconstriction. Maintaining a normal hematocrit is also important to ensure adequate oxygen-carrying capacity while avoiding polycythemia, because hyperviscosity can increase PVR. Treatment includes inhaled nitric oxide, phosphodiesterase-5 inhibitors sildenafil/tadalafil, milrinone, endothelin receptor antagonist bosentan, and prostanoids such as prostacyclin, iloprost, or treprostinil.^{5,7}

Growth and Development

Cardiovascular System

The myocardium of the newborn is structurally and functionally immature. The neonatal heart contains the essential architectural elements of the adult heart; however, there are cellular disorganization and fewer myofibrils. Although the ventricles are of equal size and shape, the contractile components (sarcoplasmic reticulum and T-tubule system) are immature. Accordingly, the neonatal heart is less capable of generating a response to an increase in resistive load (increase in stroke volume [SV]) and is dependent on free ionized calcium for contractility. Despite this immaturity, the neonatal heart is capable of limited increases in SV up to left atrial pressures of 10 to 12 mm Hg when afterload remains low. This information suggests that the neonatal heart is operating near the peak of the Frank-Starling curve because there is a limited reserve to increases in both preload and afterload.

During maturation, the left ventricle will hypertrophy through an increase in the number and size of myofibrils. This maturation is a consequence of left ventricular contraction against a higher postnatal systemic pressure. Acute increases in afterload (e.g., acidosis, hypothermia, pain) will produce further reductions in cardiac output. In the immediate postnatal period, left ventricular compliance is low. The neonate may develop congestive heart failure because the stiff left ventricle will not stretch to accommodate large fluid loads. Left ventricular distention from volume overload compresses the adjacent right ventricle, producing additional embarrassment to cardiac output. Likewise, ventilation with high peak pressure will produce left ventricular dysfunction and progressive overload of the right ventricle.

Owing to the immaturity of the contractile elements of the neonatal myocardium, the belief is that pediatric cardiac output is highly dependent on heart rate. Atropine may be administered to decrease the potential of bradycardia. However, marked increases in heart rate fail to a large extent to produce further increases in cardiac output. Although the neonatal myocardium is not as

compliant as in an older child or adult, increased preload does not increase SV to the same degree. However, volume expansion (VE) remains important, albeit to a smaller extent than in the adult, in increasing SV. The combination of hypovolemia and bradycardia produce dramatic decreases in cardiac output that threaten organ perfusion. Epinephrine rather than atropine increases contractility and heart rate and is warranted for the treatment of bradycardia and decreased cardiac output in pediatric patients. The baroreceptor reflex is not completely developed, limiting the neonate's ability to compensate for hypotension with the reflex tachycardia as would be expected in the older child and adult.

Autonomic innervation of the neonatal heart is predominantly controlled by the parasympathetic nervous system; the sympathetic nervous system is immature at birth. Parasympathetic predominance produces bradycardia that may occur with minor clinical interventions such as pharyngeal suctioning and laryngoscopy. Marked variation in the newborn heart rate and rhythm occur secondary to changes in autonomic tone. The electrocardiogram (ECG) recording in the newborn reflects the immaturity of the conduction system. The ECG axis is shifted to the right but shifts to the left with maturation and accompanying hypertrophy of the left ventricle. The P wave is evident; the PR is less than 0.12 seconds and increases until adolescence. T waves are upright in the recorded chest leads, reflecting right ventricular domination. The newborn heart rate averages 120 beats per minute (bpm) during the first day of life, increasing to 160 bpm at 1 month of age, then steadily decreasing to an average of 75 beats by the adolescent period. Sleep may produce heart rates lower than 100 bpm, whereas pain increases the rate up to 200 bpm.

Blood pressure increases immediately after birth, rising to a mean systolic pressure of 70 to 75 mm Hg within the first 48 hours. Blood pressure is lower in the preterm infant. As the heart rate decreases with maturation, there is an accompanying increase in blood pressure. The American Heart Association defines pediatric hypotension in relation to the systolic blood pressure as shown in [Box 52.2](#). [Table 52.1](#) shows general values for heart rate and blood pressure at various ages.

Systolic Blood Pressure Values Defining

Hypotension in the Pediatric Patient

- < 60 mm Hg in term neonates (0 to 28 days)
- < 70 mm Hg in infants (1 month to 12 months)
- < 70 mm Hg + (2 × age in years) in children 1 to 10 years
- < 90 mm Hg in children >10 years of age

From Pediatric Advanced Life Support: 2016 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Accessed 2016 at <https://eccguidelines.heart.org/index.php/circulation/cpr-ecc-guidelines-2/part-12-pediatric-advanced-life-support/>

TABLE 52.1

Age-Related Changes in the Cardiovascular System

Age	Heart Rate	Systolic BP	Diastolic BP
Neonate	140	70–75	40
12 months	120	95	65
3 yr	100	100	70
12 yr	80	110	60

BP, Blood pressure.

Fetal hemoglobin is the predominant hemoglobin species in the newborn, contributing between 70% and 90% of the total. A normal hemoglobin range at birth is approximately 18 to 20 g/dL. Fetal hemoglobin has a higher affinity for oxygen than adult hemoglobin. In utero, this increased oxygen affinity facilitates oxygen uptake as fetal blood circulates through the placenta, increasing the binding of oxygen to fetal hemoglobin and allowing the fetus to exist in an environment with a relatively low PaO₂. There is a rapid change in the fetal hematopoietic physiology due to increased oxygen concentrations after birth. The increased arterial oxygen content results in a decrease in erythropoietin activity, as well as in the rate of hematopoiesis. A decrease in erythropoiesis and decreased life span of the newborn's red blood cells (RBCs) produces a progressive decrease in hemoglobin, which peaks approximately between 3 and 4 months of age. The period of “physiologic anemia of infancy” does not compromise the oxygen delivery to tissues,

because the oxyhemoglobin dissociation curve shifts to the right and red blood cell concentrations of 2,3-diphosphoglycerate increase (Fig. 52.1). Fetal hemoglobin is replaced by adult hemoglobin during the first 3 to 6 months, producing a rightward shift of the oxyhemoglobin dissociation curve as compared to the neonatal period.

FIGURE 52.1 Schematic representation of oxyhemoglobin dissociation curves with different oxygen affinities. *Top arrows*, Direction of rightward shifting of the oxyhemoglobin dissociation curve (and P50) after birth. By 10 weeks of age, the adult position of the curve is reached. *PaO₂*, Partial pressure of oxygen; *SpO₂*, oxygen saturation. (From Davis PJ, Cladis FP. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia: Elsevier; 2017:60.)

It is important to note that premature infants may experience a dramatic fall in hemoglobin because of insufficient body stores of iron. Premature infants should receive iron and vitamin K prophylaxis, because the concentration of vitamin K–dependent clotting factors (II, VII, IX, and X) are 20% to 50% of adult levels.⁸ Premature infants have lower levels of vitamin K–dependent clotting factors. Maternally ingested drugs such as warfarin and isoniazid may precipitate the development of a coagulopathy.

The newborn's blood volume is dependent on the time of cord clamping (transfusion from the placenta). Delaying umbilical cord

clamping in premature infants for 30 seconds stabilizes transitional circulation, decreases the need for inotropic medications and reduces blood transfusions, necrotizing enterocolitis (NEC), and intraventricular hemorrhage.⁹ Blood volume is approximately 80 to 90 mL/kg but may be as high as 100 mL/kg in the premature neonate. The intravascular volume decreases 25% in the immediate postnatal period with the loss of intravascular fluid. Blood volume increases over the next 2 months, peaking at 2 months of age. [Table 52.2](#) provides an estimate of circulating blood volume development.

TABLE 52.2
Estimated Blood Volumes by Age

Age Group	Volume (mL/kg)
Premature	90–100
Newborn (less than 1 month of age)	80–90
Infants 3 months to 3 years of age	75–80
Children older than 6 years of age	65–70
Adults	65–70

Respiratory System

In utero, fetal lung development begins with the formation of lung buds, which occurs during the first few weeks after conception. During organogenesis which occurs in the second trimester, creation of distinct bronchi and bronchopulmonary segments extend downward to the terminal bronchioles. There are 10 to 20 million terminal sacs, which, after elongation, begin to develop into alveoli after birth. The process of alveolar formation is accelerated between 12 and 18 months postnatally, and increases to 200 to 300 million between 8 and 10 years of age.

Type II pneumocytes are responsible for the production and secretion of surfactant, which begins between 22 and 26 weeks, and concentrations peak between 35 and 36 weeks' gestation. Surfactant decreases surface tension within the alveoli to decrease alveolar collapse. This relationship can be explained by the Law of Laplace as shown in the equation which follows. In the absence of adequate pulmonary surfactant such as in a premature neonate, alveoli become stiff and noncompliant as depicted in [Fig. 52.2](#). Severe atelectasis decreases alveolar surface area available for oxygen and

carbon dioxide exchange. Increased physiologic dead space and ventilation perfusion mismatch cause hypoxia and hypercarbia, necessitating mechanical ventilation. The treatment for infantile respiratory distress syndrome includes synthetic surfactant, continuous positive airway pressure (CPAP), and mechanical ventilation.¹⁰

FIGURE 52.2 An idealized state showing the reciprocal relationship between resistance and compliance; gas flow is preferentially delivered to the most compliant regions, regardless of the rate of inflation. Static and dynamic compliance are equal. (From Davis PJ, Cladis FP. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia: Elsevier; 2017:359.)

$$P = 2T/R$$

P = pressure within a sphere, T = surface tension,
R = radius of the sphere

Anatomy

At birth the neonatal larynx is small compared with the mouth and pharynx. The epiglottis is short and small, and the vallecula is shallow so that the tongue approximates the epiglottis. The larynx is pointed toward the nasopharynx, facilitating nasal breathing. The arytenoids are large in proportion to the lumen of the larynx. The

subglottic region is smaller than the glottic opening, with the cartilages telescoping into one another, forming a conical shape.¹¹ The cricoid cartilage is the narrowest portion of the airway, and the cricoid lumen is not a round but mostly an ellipsoid structure. It is lined with a pseudostratified epithelium that can be easily injured during laryngoscopy and can result in airway edema, stridor and bleeding. The pediatric airway is more cylindrical than funnel shaped.¹² The implication for clinical practice is that an endotracheal tube that may pass through the vocal cords during insertion may not be able to be advanced due to the narrowed cricoid cartilage.

The newborn tongue is large and difficult to manipulate because of the position of the hyoid. In addition, a smaller potential submental space is present, in which it is possible to displace the tongue during laryngoscopy. The anterior position of the larynx and the large tongue can increase the potential for airway obstruction and the difficulty of mask ventilation.

The larynx is located more cephalad and anterior, extending from the second to the fourth cervical vertebrae (C2 to C4). The anesthetic implication of the more cephalad location is that placing a neonate in the “sniffing position” for laryngoscopy and intubation will only move the larynx in an anterior direction, potentially increasing the difficulty of intubation.

The occiput of the newborn's head is large and prominent in relation to the size of their body. The placement of a rolled towel under the shoulders aids in the visual alignment of the oral, pharyngeal, and laryngeal axes during laryngoscopy ([Fig. 52.3](#) and [Table 52.3](#)).

FIGURE 52.3 Alignments of visual, oral, and laryngeal axes during laryngoscopy.

TABLE 52.3

Differences: Adult Airway and Pediatric Airway

	Pediatric	Adult
Laryngeal location	C2–C4	C3–C6
Narrowest location of airway	Cricoid cartilage	Glottis
Shape of epiglottis	Longer, more narrow	V-shaped
Right mainstem bronchus	Less vertical	More vertical

Mechanics of Breathing

The neonate's chest wall is pliable because of a lack of developed musculature and a skeletal structure primarily composed of cartilage. The ribs are horizontal in orientation, providing minimal assistance in the expansion of the chest wall with inspiration. During inspiration the compliant chest wall is noted to collapse inward during respiration (paradoxical breathing). To maintain negative intrathoracic pressure despite having a compliant chest wall, the neonate and infant actively recruit accessory muscles of

respiration (i.e., intercostal muscles). Additionally, exhalation is limited by the adductor muscles of the larynx, which contract and serve as an expiratory valve or brake to maintain end-expiratory pressure. These structural differences are responsible for the decrease in functional residual capacity (FRC) with administration of general anesthesia in the neonate and infant. The previously cited muscular activity responsible for maintaining FRC is diminished with the administration of sedatives, inhalation anesthetics, and neuromuscular relaxants. Rapid hypoxemia can occur with the loss of FRC. FRC may be restored with the application of CPAP or controlled ventilation. The premature infant has even more of a pliable chest wall, and paradoxical chest movement may occur with breathing during rest.

The diaphragm contributes to the differences in respiratory function of the neonate and infant. Unlike the adult diaphragm, which is dome shaped, the diaphragm of the neonate and infant is relatively flat. Accordingly, its anterior insertion on the chest wall fails to contribute any mechanical advantage with contraction. Primarily the diaphragm and, to a lesser extent, the intercostal muscles allow for expansion of the thoracic cavity and the associated increase in negative intrathoracic pressure. As a result, during inspiration, air is drawn into the lungs, and with relaxation of these muscles, air passively exits the lungs due to the elastic recoil. Two types of muscle fibers are present in muscle tissue: specifically, the diaphragm and intercostals. Type 1 muscle fibers are slow twitch muscle fibers and are resistant to fatigue. These fibers are essential for sustained ventilatory activity. Type 2 muscle fibers, also known as *fast twitch* muscle fibers, are fast twitch but fatigue rapidly. A newborn infant's diaphragm is composed of 25% type 1 muscle fibers as compared to 55% type 1 muscle fibers in the adult diaphragm. In addition, type 2 muscle fibers are predominant within the intercostals. Therefore, newborns and young infants are at risk of muscle fatigue, respiratory distress, and respiratory arrest. The anesthetist must assess for airway obstruction and respiratory compromise resulting from the depressant effects of residual anesthetic agents, airway obstruction, and postoperative pain. Assisting with respirations and relieving airway obstruction during the perioperative period will promote adequate gas exchange and

decrease the degree of atelectasis.

Control of Breathing

The control of breathing is dependent on the PaO_2 sensed via the peripheral chemoreceptors (carotid and aortic bodies), the partial pressure of arterial CO_2 (PaCO_2), and pH, which influence the central chemoreceptors within the respiratory control center of the medulla. Increases in PaCO_2 produce corresponding increases in tidal volume and respiratory rate, although this response is not as vigorous as in the adult. Increases in PaO_2 will depress the ventilatory response in the newborn, whereas a decreased PaO_2 will increase the ventilatory response. The ventilatory response to hypoxemia produces two distinctly different responses. Initially hypoxemia stimulates an increase in ventilation for the first minute but produces ventilatory depression for the next 3 to 5 minutes. Due to the newborn's lack of ability to compensate for physiologic stress, rapid ventilatory depression and arrest are distinctly possible if hypothermia, acidosis, or hypercarbia occurs.

Respiratory depression and/or apnea may develop in the newborn after stimulation of the carina and/or the superior laryngeal nerve, following upper airway obstruction or following sustained lung inflation (Hering-Breuer reflex). The newborn may exhibit periodic breathing with inspiratory pauses lasting 10 seconds, followed by abrupt increases in ventilation. Periodic breathing is more common in the premature infant and occurs more often during rapid eye movement sleep. Apneic episodes are not uncommon in the premature infant; such episodes can produce rapid arterial desaturation. If apnea is not rapidly resolved, bradycardia and cardiac arrest may occur. The suspected causes of apnea in premature infants include immature responses of the respiratory control center to hypercarbia or hypoxic stimuli and respiratory fatigue.

Lung Volumes

The mean values for pulmonary function in the newborn and adult are shown in [Table 52.4](#). The infant's metabolic rate and oxygen

consumption are approximately twice that of the adult. The decreased reservoir for oxygen (decreased FRC), coupled with the increased demand for oxygen (increased metabolic rate), results in rapid desaturation when ventilation is interrupted. Airway closure produces a mismatching of ventilation and perfusion. The volume of these poorly ventilated alveoli that contribute to intrapulmonary shunting is greater in neonates than in adults. In addition, increased pulmonary vascular resistance can produce a right-to-left shunt through the FO or a patent DA, resulting in the rapid development of hypoxemia.

TABLE 52.4

Mean Values for Normal Pulmonary Function in the Newborn and the Adult

	Newborn	Adult
Body weight (kg)	3	70
Tidal volume (mL/kg)	6	6
Respiratory rate (bpm)	35	15
Alveolar ventilation (mL/kg per min)	130	60
Oxygen consumption (mL/kg per min)	6.4	3.5
Total lung capacity (mL/kg)	63	86
Functional residual capacity (mL/kg)	30	34
Vital capacity (mL/kg)	35	70
Residual volume (mL/kg)	23	16
Closing capacity (mL/kg)	35	23
Arterial pH	7.38–7.41	7.35–7.45
PaCO ₂ (mm Hg)	30–35	35–45
PaO ₂ (mm Hg)	60–90	90–100
SaO ₂ (%)	95–100	95–100

Paco₂, Partial pressure of arterial carbon dioxide; *Pao₂*, partial pressure of arterial oxygen; *Sao₂*, oxygen saturation.

Airway Dynamics

Airway resistance is greater in neonates and declines markedly with growth from 19 to 28 cm H₂O/L per sec to less than 2 cm H₂O/L per sec in adults.^{13–15} According to Poiseuille's law, airway resistance is inversely proportional to the fourth power of the radius of the airway during laminar flow. A neonate must overcome the resistance to airflow, as well as the elastic recoil of the lungs and chest wall. The rate of ventilation that uses the least

amount of muscular energy and generates a satisfactory minute ventilation has been found to be 37 breaths per minute in the healthy newborn.

The metabolic energy expenditure of breathing in the neonate is similar to in an adult, approximately 0.5 mL per 0.5 L of ventilation. This is equivalent to 1% of their metabolic energy. The premature neonate's metabolic cost of breathing is 0.9 mL/0.5 L, almost double the metabolic price. If the neonate has pulmonary problems, the cost could go even higher.¹⁶

Airway resistance changes with age. Although the larger airway resistance remains constant, airway resistance in the smaller airways is increased. The increase in airway resistance increases the work of breathing in the neonate. Small airway disease (e.g., pneumonia) produces additional increases in the work of breathing. Due to stiff and noncompliant lungs, increased airway resistance from small distal airways, increased propensity of ventilation perfusion mismatch and high metabolic rate, barotrauma and hypoxemia can rapidly occur. Ventilation strategies utilizing pressure-limited ventilation and volume-targeted ventilation in preterm and term infants have shown to be effective at avoiding these complications.¹⁷

Nervous System

The central nervous system in the newborn differs from the older child in relation to the degree of myelination, muscle tone and reflexes, and development of the cerebral cortex. In the peripheral nervous system, myelination begins in the motor roots and progresses to the sensory roots. In contrast, the myelination in the cerebral sensory systems precedes that of the central motor systems. This incomplete myelination is associated with those reflexes that are used to measure neural development, the Moro and grasp reflexes. Myelination of the nervous system is not complete until approximately age 3.

Development of Neuromuscular Junction

The neuromuscular junction (NMJ) undergoes developmental changes during the first 2 months of life. During the maturation

process, the NMJ differs in several ways. There is a difference in the maturity, density, sensitivity, and distribution of the postsynaptic acetylcholine (ACh) receptors; in the rapidity of neuromuscular transmission; and in muscle fiber type.¹⁸ The functional difference between immature ACh receptors as compared to those that are fully developed is a prolonged opening of the ionic channels. This prolonged channel opening allows the immature muscles to be more easily depolarized. These ACh receptors also have a greater affinity for depolarizing agents and a lower affinity for nondepolarizing muscle relaxants (NDMRs). The clinical implication of these maturational changes is that neonates can have a greater variability in response to NDMRs. Monitoring for neuromuscular function after NDMR administration via a peripheral nerve stimulator is critical. Neuromuscular immaturity may be demonstrated with the appearance of fade after tetanic stimulation in the absence of neuromuscular blocking drugs. It is also worth noting that the type I fibers are more sensitive to NDMRs when compared with type II fibers. The clinical relevance of this difference is that the diaphragm of a neonate has fewer type I fibers as compared to the diaphragm of a toddler or an adult. This makes the diaphragm of a neonate more responsive to NDMRs than his or her peripheral musculature.¹⁹ The use of intermediate acting neuromuscular blocking agents during anesthesia has been associated with an increased risk of clinically significant postoperative respiratory complications.²⁰ It has not been scientifically determined if assessment of neuromuscular blockade via an accelerometer is a more effective measure of residual neuromuscular blockade in pediatric patients.

Pain Sensitivity

Pathways required for pain perception can be traced from sensory receptors in the skin to sensory areas in the cerebral cortex of newborn infants. These pain pathways have been demonstrated in the perioral area as early as 7 weeks' gestation. With positron emission tomography scans, neonates demonstrate maximal metabolic activity in the regions associated with sensory perception, such as the cortex, thalamus, and midbrain-brainstem regions. Neonatal anesthetists have seen newborns exhibit signs of

increased sympathetic activity (e.g. tachycardia and hypertension) in response to surgical stimulation with inadequate anesthesia. The risks associated with inadequate or absent pain control expose the neonate to noxious stimulation that can have significant physiologic consequences. Those consequences in the presence of abnormal cerebral autoregulation could result in intraventricular hemorrhage and pulmonary hypertension.²¹

Lack of development of inhibitory tracts may actually increase the intensity and duration of the painful stimulus. It has been suggested that newborn infants may develop prolonged responses to painful procedures that far outlast the stimuli by hours or days. This is illustrated by several examples. Premature infants mount a metabolic stress response that can be blocked with opioids, increased crying, and interrupted sleep patterns; behavioral changes have been shown to occur for days after circumcision,²² and with repeated heel lancing, there appears to be a hyperalgesic response to injury.²³ Other physiologic alterations that have been demonstrated are increased right-to-left shunting, hypoxemia, acidosis, and intraventricular hemorrhage.²¹

Sensory nerve distribution is formed by 20 weeks' gestational age. Pain pathways and receptors are present within the central nervous system at birth. Physiologic stimulation from anesthesia management and surgery dramatically increase circulating catecholamines and other stress hormones. As in adults, during the perioperative experience, pediatric patients exhibit tachycardia and hypertension if light anesthesia is coupled with significant surgical stimulation. Due to the lack of cerebral vascular autoregulation, increased blood pressure can cause intracerebral bleeding, especially in premature neonates. The pain threshold for infants and children may be lower than in older children and adults, possibly because of increased pain sensitivity, behavioral factors, or both. Preoperative and postoperative signs of pain in patients that are preverbal include tachycardia, elevated blood pressure, crying, restlessness, and grimacing.

In recent years, the safety of anesthetic medications and their effect on the developing brain have been questioned. In animal studies, agents that either antagonize N-methyl-D-aspartate (NMDA) receptors or potentiate the neurotransmission of γ -

aminobutyric acid (GABA) agents have been implicated, and no safe doses or durations of exposure of these agents have been defined.²⁴ One proposed mechanism of action for these effects is by inhibition of brain-derived neurotrophic factor, which stimulates neural development.²⁵ Neurotoxicity resulting in neuroapoptosis, interference with nerve pathway, and nerve cell development can result in long-term neurocognitive deficits.^{24,26-28} Most damage occurs during maturation periods when synaptogenesis rapidly occurs.²⁹ The Food and Drug Administration (FDA) is addressing this issue by forming a public-private partnership with the International Anesthesia Research Society called SmartTots (Strategies for Mitigating Anesthesia-Related Neuro-Toxicity in Tots). This partnership will seek to mobilize the scientific community, stimulate dialogue among thoughtful leaders in the anesthesia community, and work to raise funding for the necessary research.

Until the risks related to neurocognitive development and anesthetic agents are definitively determined, recommendations to minimize the potential for iatrogenic effects include attempting to minimize the duration of anesthesia and surgery, using short-acting drugs and/or a combination of general anesthesia and multimodal pain therapy including systemic analgesics, and local or regional anesthesia, to reduce the overall drug dosage.^{30,31} For an in depth discussion of pediatric pain and its management, refer to [Chapter 56](#).

Cranium and Spinal Column

The most significant neurologic growth and development occurs in utero. The neural tube is nearly completely formed by 3 to 4 weeks' gestational age. It further differentiates over the next 4 to 12 weeks to create other anatomic structures that include the forebrain, facial bones, and spinal cord. Neurogenesis proceeds during weeks 12 to 20, followed by synaptogenesis and increased myelination. Increased density of synaptic connections and glial cells continues to develop until 2 years of age and is estimated to be 50% greater than in the adult brain.³²

After birth, there is continued rapid functional and structural brain development. The brain doubles in weight within the first 6

months of life and triples in weight within 1 year. At 1 year of age, maturation of the cerebral cortex and brainstem is nearly complete. Myelination of nerve cells continues until 3 years of age. By age 2 years, the child's brain is 80% of the adult weight and 90% by age 5 years. Due to the rapid neuronal development growth, fontanelles and supple cranial bones allow the skull to accommodate for this increased cerebral volume without increasing intracranial pressure (ICP). There are two major fontanelles, anterior and posterior, as shown in [Fig. 52.4](#). In 96% of children, the anterior fontanelle closes by 2 years of age. The posterior fontanelle closes at approximately 4 months. The anterior fontanelle can be used to assess increased ICP (bulging anterior fontanelle) and also dehydration (sunken anterior fontanelle). The blood-brain barrier (BBB) is immature until approximately 1 year of age. Therefore, higher concentrations of medications and toxins that would be impermeable to the adult brain can result in higher cerebral concentrations throughout infancy.³³ Nerve cells within the spinal cord mature until completion at 6 to 7 years of age. As the pediatric patient grows, the conus medullaris and the dural sac migrates cephalad. Although the exact vertebral level of these structures varies slightly, the conus medullaris terminates between L2 and L3 in neonates. The dural sac ends between S2 and S3 until approximately 6 years of age. Being mindful of this information is imperative to providing safe anesthesia during placement of a spinal or caudal anesthetic. By age 8, the spinal cord approximates the adult and ends at L1.³³ [Fig. 52.5](#) illustrates the comparison between the adult and infant spinal anatomy.

Cerebral Metabolic Requirement

Due to the rapid maturation of the central nervous system (CNS) during infancy and childhood, proper nutrition is essential to ensure normal development. With maturation, there is an increase in the metabolic demands of the CNS. The primary fuel for the brain is glucose, and in the neonate, there are decreased stores of glycogen, making hypoglycemia a major source of morbidity causing apnea, hypotension, bradycardia, convulsions, and brain injury.

Cerebral Blood Flow

Cerebral blood flow (CBF) is closely coupled with cerebral metabolic rate of oxygen consumption ($CMRO_2$). CBF in the premature infant is 40 mL/100 g per minute, and in older children approaches the adult level of 100 mL/100 g per minute. Autoregulation of CBF refers to the ability of the CNS to regulate CBF over a wide range of cerebral perfusion pressures. CBF autoregulation is thought to take place in the neonate, but the specific limits are unknown. Complete loss of cerebral autoregulation may occur with hypoxia, severe hypercapnia (greater than 80 mm Hg), blood brain barrier disruption after head trauma, subarachnoid or intracerebral hemorrhage, or cerebral ischemia, or after the administration of high concentrations of potent inhalation anesthetics and vasodilators (nitroprusside). Changes in CBF will parallel changes in cerebral blood volume, except when cerebral perfusion decreases and autoregulation produces vasodilation to maintain a constant flow. The cerebral vessels are very fragile in preterm and low-birth-weight (LBW) infants. This fragility predisposes neonates to intracranial hemorrhage. Intracranial hemorrhage may be precipitated by hypoxia, hypercarbia, hyperglycemia, hypoglycemia, hypernatremia, and wide swings in arterial or venous pressure. The intravenous administration of hypertonic solutions may damage

these fragile vessels. Therefore, concentrations of sodium bicarbonate that would be administered to an adult should not be administered to neonates.

Autonomic Nervous System Immaturity

At birth, the autonomic nervous system is developed but not mature as in an adult. The sympathetic nervous system innervation to the heart and vasculature is less responsive compared with parasympathetic nervous system innervation. As a result, physiologic stress can cause severe and rapid cardiovascular collapse. As the pediatric patient ages, the child's sympathetic responsiveness becomes pronounced, and the child is able to compensate for stress by increasing heart rate and blood pressure. If bradycardia occurs, the anesthetist should focus first on hypoxia as possible cause. Rapid assessment and treatment is essential. Specific causes that could lead to bradycardia and cardiac arrest are

Box 52.3 in [Box 52.3](#).³

Causes of Neonatal Bradycardia and Cardiac Arrest

Respiratory (any cause resulting in hypoxia)

- Airway obstruction (laryngospasm, postextubation croup)
- Bronchospasm
- Pulmonary aspiration
- Inadequate oxygen delivery system
- Pneumothorax

Pharmacologic

- Inhalation anesthetics
- Succinylcholine

- Anticholinesterases

Neurogenic

- Celiac reflex
- Oculocardiac reflex
- Superior/recurrent nerve stimulation (during intubation, airway manipulation)

Metabolic

- Hypoglycemia
- Anemia
- Hypothermia
- Acidosis

Renal System

In utero, fluid and electrolytes equilibrate across the placenta in response to fetal growth and metabolic demands. The fetal kidneys make urine that passes into the amniotic cavity to compose one half of the amniotic fluid, which is then swallowed and absorbed in the gut. Structurally, the kidney is different in the neonate. Nephrons are still being formed at up to 35 weeks' gestation. The resulting glomerular filtration rate (GFR) is much lower in a preterm (0.55 mL/min per kg) than a full-term baby (up to 1.6 mL/min per kg) or a 2-year-old child (2 mL/min per kg). Decreased systemic arterial pressure, increased renal vascular resistance, and decreased permeability of the glomerular capillaries contribute to the low GFR. In addition to the stiff, noncompliant myocardium, the neonate is unable to tolerate fluid overload because of the lower GFR. GFR reaches adult levels by 6 to 12 months of age. The renal medulla is not completely mature, and the potential effect of antidiuretic hormone (ADH) is diminished. However, all of the

hormones that affect the kidney are active even in a very immature infant, albeit with reduced potency. Neonates are called *obligate sodium excretors* because of their inability to conserve sodium, even in cases of severe sodium depletion. The renin-angiotensin-aldosterone system acts to reduce sodium loss from the distal tubule, but the immature renal tubules fail to respond as in a child or an adult. In addition, the renal tubules have a limited ability to reabsorb glucose. Increasing plasma glucose concentrations may elicit osmotic diuresis, depleting intravascular volume. [Table 52.5](#) lists the daily electrolyte requirements for the newborn. Renal tubular function is immature until the age of 2 to 3 years. The neonate has a limited ability to concentrate urine compared with an adult (700 vs 1200 mOsm/L). Atrial natriuretic peptide is present, but its effects are blunted. In effect, the neonatal kidney is able to excrete water and sodium but cannot conserve these electrolytes as well as the kidney of an older child.³⁴ By the end of the first month of life, renal function is approximately 70% of adult levels and by the end of the first year, renal function reaches adult levels.

TABLE 52.5

Daily Electrolyte Requirements of the Newborn

Electrolyte	Daily Requirement
Sodium	2–3 mEq/kg
Potassium	1–2 mEq/kg
Calcium	149–200 mg/kg

Fluid Balance

Due to their high metabolic rate and increased composition of body water as compared to a child, a neonate's fluid requirements are substantial. After the first week of life, a neonate requires 150 mL/kg per day of fluid (equivalent to 20 pints a day for an adult). Neonates also have high insensible losses, particularly from evaporation, as a result of a high surface area/body-weight ratio (four times higher than an adult) and immature skin. These problems are accentuated for the preterm baby. Thirst mechanisms are poorly developed and are affected by sepsis or respiratory distress syndrome. Also, a surge of ADH at birth causes oliguria

over the first few days. [Table 52.6](#) summarizes indicators of fluid balance.

TABLE 52.6

Indicators of Fluid Balance

Parameter	Normal Range
Sodium	133–144 mmol/L
Body weight	Should fall by up to 10% below birth by 1 week, then increase
Hematocrit	Increases (without transfusion) suggest dehydration
Creatinine	Should fall from maternal levels to less than 50 $\mu\text{mol/L}$ after 5 days

Hepatic System

The liver begins to develop at 10 weeks' gestation, and by 12 weeks' gestation, it has already begun to function. Gluconeogenesis and protein synthesis are under way, and by 14 weeks' gestation glycogen is found in liver cells. The fetal liver has the ability to synthesize glycogen. Glycogen storage capacity is greatly increased just before birth. Approximately 98% of this stored glycogen is released from the liver within the first 48 hours of life, and glycogen levels are not restored to adult levels until the third week of life. Glycogen stores are not as large in preterm or small-for-gestational-age (SGA) infants. Therefore preterm and SGA infants should be monitored for hypoglycemia.

The function of the liver is decreased, and the capability for biotransformation is decreased, with oxidative activities approximately one-quarter to one-half of adult values.³⁵ The capacity to enzymatically break down proteins is depressed at birth as a result of a decrement in quantity and quality of hepatic enzymes. Albumin, an essential protein that regulates colloidal osmotic pressure, is produced beginning at 3 to 4 months of gestation, approaching 75% to 80% of adult levels at the time of birth. Plasma concentrations of albumin (which predominately binds acidic drugs) and alpha acid glycoprotein (AAG) (which predominately binds basic drugs) are lower in newborns and even lower in premature infants. The lower ability of the newborn to bind drug to plasma proteins results in greater levels of free drug. At approximately 1 year of age, the concentrations of plasma

proteins approximate adult levels.

Glucuronyl transferase activity within the neonatal liver is depressed as compared to a child. This enzyme is responsible for the metabolic breakdown of bilirubin. Hyperbilirubinemia may develop in term infants within the first days of life. Bilirubin production as a result of the breakdown of RBCs and enterohepatic circulation is increased because of the aforementioned depressed activity of glucuronyl transferase that is required for hepatic conjugation. Bilirubin levels of 6 to 8 mg/100 mL are not uncommon in term infants. However, premature infants may have levels as high as 10 to 12 mg/mL on the third day of life. Phototherapy and, in rare cases, exchange transfusion are used to avoid the development of encephalopathy (kernicterus). In infants with hyperbilirubinemia, it is imperative that a determination of physiologic versus pathologic jaundice be determined.

Concentrations of clotting factors in the premature infant and the newborn are low; however, hepatic synthesis of essential clotting factors reaches adult levels during the first week after birth. In utero, the liver is the organ responsible for hematopoiesis, but by 4 to 6 weeks after birth, this function is assumed by the bone marrow.

Temperature Regulation

The neonate lacks the ability to precisely regulate its body temperature. Large surface area, lack of subcutaneous tissue as an insulator, and the inability to shiver all contribute to inadequate thermoregulation.

The neonate has minimal ability to shiver, so sympathetic nervous system stimulation enhances the metabolism of brown fat to increase heat production, a process known as *non-shivering thermogenesis* (NST). It is metabolically driven heat production that does not involve muscular work. Brown fat stores located in the scapulae, axillae, the mediastinum, and in the retroperitoneal space surrounding the kidneys are metabolically active and contain a high density of mitochondria. Hypothermia stimulates the release of norepinephrine, which acts on brown fat to uncouple oxidative phosphorylation.³⁶ Heat production follows an increase in the basal metabolic rate stimulated through the release of anterior pituitary hormones. The result of NST is not only heat production but also

the metabolic biproducts of brown fat metabolism namely acetone, acetoacetic and β -hydroxybutyric acid. Metabolic acidosis can rapidly lead to bradycardia, and cardiac arrest in a neonate. Therefore, it is especially important to maintain body temperature during surgery and anesthesia in pediatric patients.

Perioperative hypothermia has many contributing causes, including a cold operating room environment, anesthetic-induced vasodilation, the infusion of room-temperature intravenous fluids, evaporative heat loss from opened body cavities, use of cool irrigating solutions, and the inspiration of cool/dry anesthetic gases. During laparoscopic surgery, the temperature of the carbon dioxide gas used for insufflation is 21°C. So despite having less direct exposure of the intraabdominal cavity to the environment, patients remain at risk for developing hypothermia.

It is well recognized that the thermoregulatory response is inhibited by anesthetic agents. Core body temperature may decrease by as much as 1°C to 3°C. Heat loss occurs as a result of the internal redistribution of heat, reduced metabolism and heat production, increased heat loss to the environment, and the effects of anesthetic agents on thermoregulatory control. Heat loss occurs more rapidly in neonates because of their increased body surface/body weight ratio. The skin (particularly of the premature neonate) is thinner and has less subcutaneous tissue, increasing the rate of evaporative heat loss.³⁷⁻⁴⁰

Radiant heat loss is responsible for the majority of heat loss.³⁴ It occurs with the transfer of heat to the environment and is dependent on the temperature differences between the neonate and the environment. Radiant heat loss may be minimized by wrapping the neonate in a warm blanket and isolating the skin from the cold operating table, effectively decreasing the transfer of heat. Radiant heat lamps may be used to maintain temperature during surgical positioning and preparation. Radiant heat lamps increase the temperature of the air between the neonate and the lamps, thereby minimizing radiant heat loss. However, radiant heat lamps are ineffective when operating room personnel or large objects are placed between the lamp and the patient. In addition, the placement of a radiant heat lamp in close proximity to the neonate may produce thermal injury.

An example of *conductive heat loss* includes placing the neonate on a cold operating table, resulting in heat transfer from the neonate to the table and thereby causing a decrease in core body temperature. Conductive heat loss is minimized with the use of warmed irrigating solutions, the use of warm blankets or heated forced-air blankets to cover the non-operative areas of the patient, and the preoperative warming of the operating room. Covering the head with a stockinet or reflective cap dramatically decreases conductive heat loss. The neonate's head may account for up to 60% of the total heat loss during the perioperative period.

Convective heat loss is precipitated by moving air currents. The operating room air circulation is changed 6 to 12 times per hour and, in conjunction with cool ambient temperatures, increases heat loss. The air surrounding the body is warmed and subsequently rises, being replaced by the cooler ambient air. To minimize convective heat loss, the ambient air temperature must be increased. Prudent practice is to preheat the operating room to 26°C for premature and neonatal surgical patients. The premature infant or neonate arrives in the operating room in a heated Isolette and is immediately covered with a warm blanket before being transferred to the operating table. Convective heat loss may be increased when wet cloth is in contact with the infant. Wet diapers and blankets soiled with preparation solutions must be replaced and not allowed to remain in contact with the skin.

Evaporative heat loss occurs through the vaporization of liquid from body cavities and the respiratory tract. Evaporative heat loss is either sensible loss (the evaporation of sweat) or insensible loss (the evaporation of water through the skin). The thin-skinned premature infant is particularly susceptible to insensible evaporative heat loss. Sensible evaporative heat loss may be prevented by removing wet clothing or blankets and thoroughly drying the neonate. Insensible evaporative heat loss may be mitigated by increasing the relative humidity of the operating room, covering the patient with a plastic barrier, and using warmed irrigating solutions. Insensible respiratory tract evaporative heat loss may be prevented with humidification of the inspired gases, which requires attentive temperature monitoring to avoid superheating of airway gases and subsequent airway burns. The

addition of in-line humidifiers to the patient breathing circuit adds to the complexity and weight, perhaps increasing the likelihood of unintended tracheal extubation. These humidifiers also may contribute to unintended increases in core body temperature during lengthy surgical procedures. The use of a passive heat and moisture exchanger, added between the patient circuit and endotracheal tube, has been of questionable efficacy.^{41,42}

Iatrogenic increases in core body temperature may occur. Attentiveness to the patient's core temperature is essential. Covering the neonate may result in progressive increases in core temperature during prolonged surgical procedures. These steady increases in core temperature may be aggravated by the previous administration of atropine.

Anesthetic Pharmacologic Considerations in the Neonate

Physiologic characteristics that modify the pharmacokinetic and pharmacodynamic activity in the neonate include differences in total body water (TBW) composition; immaturity of metabolic degradation pathways; reduced protein binding; immaturity of the BBB; greater proportion of blood flow to the brain, heart, liver, and lungs; reduced glomerular filtration; smaller functional residual capacity; and increased minute ventilation.

Pharmacokinetics

Several age-related differences in absorption, distribution, metabolism, and elimination effect pharmacologic responses in the neonate. Absorption and distribution are increased via an increased cardiac output per kilogram of body weight, protein concentration and binding capabilities, body composition, and the immaturity of the BBB. Elimination is decreased due to immature metabolic pathways and renal immaturity.

Cardiac Output

Resting cardiac output in the neonate at birth is approximately 400 mL/kg per min, in the infant is 200 mL/kg per min and in the adolescent is 100 mL/kg per min. Therefore, the circulation time in neonates and infants is faster as compared to the adult. For this reason, after hepatic and renal maturity occurs, drug delivery and metabolism of medications from their sites of action are at a more rapid rate as compared to the adult.

Body Composition

Total body water and extracellular fluid (ECF) are increased in neonates and fall proportionately with postnatal age. The percentage of body weight contributed by fat is 3% in a 1.5-kg premature neonate, and 12% in a term neonate. The proportion of

fat further doubles by 4 to 5 months of age. These body component changes affect volumes of distribution of drugs. Water-soluble drugs such as neuromuscular blocking drugs (NMBDs) distribute rapidly into the ECF, but enter cells more slowly. The initial dose of water-soluble drugs is consequently higher in the neonate than in the child or adult. Delayed awakening occurs because CNS concentration remains higher than that observed in older children as a consequence of this reduced redistribution.⁴³ Table 52.7 illustrates the changes in TBW, intracellular fluid, and ECF during stages of maturation.

TABLE 52.7
Fluid Compartment Volumes

	Premature	Infant	Child	Adult
Total body water (TBW)	80%–90%	75%	65%–70%	55%–60%
Extracellular fluid (ECF)	50%–60%	40%	30%	20%
Intracellular fluid (ICF)	60%	35%	40%	40%

Protein Binding

Protein binding of parenterally administered drugs are diminished in the neonate. Drugs that are normally highly protein bound can have a greater free fraction of the drug and therefore a greater pharmacologic effect. Albumin and AAG concentrations are reduced in neonates, but are similar to those in adults by 5 to 6 months. Plasma albumin concentrations approximate adult values by 5 months of age and are lowest in preterm neonates. Binding capacity approaches adult values by 1 year of age.

Blood-Brain Barrier

The BBB restricts diffusion of compounds between blood and brain. It is immature in neonates, which can have clinical consequences. Small molecules access the fetal and neonatal brain more easily than adult brains. BBB function improves gradually, possibly reaching maturity at term. Drugs bound to plasma proteins will not normally cross the BBB. However, the unbound lipophilic drugs passively diffuse across the BBB to achieve rapid equilibrium. This

may contribute to the tendency of drugs such as local anesthetics to produce seizures in neonates. Specific active transport systems across the BBB can be affected by CNS pathology, thereby changing the clinical effects of opioids and other compounds.^{43,44}

Metabolism

Generally, due to a large proportion of the cardiac output that traverses the liver in the pediatric patient, there is a more rapid clearance of drugs. However, phase I cytochrome P-450 (CYP) dependent reactions (e.g., oxidation, reduction, hydrolysis) are not fully developed during the neonatal and early infancy periods thereby decreasing metabolism of anesthetic drugs that are dependent on hepatic metabolism. These processes begin to mature within the first week of life, with remaining cytochrome-dependent metabolic pathways continuing to increase during the first 3 months of life.⁴⁵ Phase II reactions (conjugation reactions) increase water solubility to promote renal excretion, and this process is underdeveloped in neonates. Some cytochrome-dependent reactions can be induced prior to delivery when the mother is exposed to certain drugs and cigarette smoke.^{46,47}

The neonate lacks the capacity to effectively conjugate bilirubin (decreased glucuronyl transferase activity) and metabolize medications such as acetaminophen, chloramphenicol, and sulfonamides. Although the necessary enzyme systems are present at birth, enzyme activity is reduced, increasing drug elimination half-lives.⁴⁸⁻⁵²

Excretion

Most anesthesia-related drugs are eliminated by the kidney. In the neonate, GFR and tubular function is reduced, particularly in those infants born at less than 34 weeks. However, renal function reaches adult levels by 8 to 12 months of age. Healthy preterm and full-term neonates have relatively normal renal drug clearance by 3 to 4 weeks of age.

Pharmacodynamics

Pharmacodynamics describes how the pharmacological actions of drugs affect human physiology. The actions of a drug and its receptor are influenced by the number and type of receptors present and the action of the drug in the receptor population. Neonates can have significant differences in their dynamic response to drugs as compared with adults.

Nicotinic Acetylcholine Receptor

In its fetal form, the nicotinic acetylcholine receptor remains open longer after binding acetylcholine, protecting or increasing the safety factor of neuromuscular transmission, and this could account for the neonate's resistance to muscle relaxants.⁵³ As it transitions into its adult form, the duration that the receptor remains open is decreased after binding, resulting in less propensity for generation of an action potential, manifesting as less resistance to muscle relaxants. There is also a reduction in acetylcholine release in the neuromuscular junction in the neonate, which could account for the increased sensitivity to NDMRs.⁵⁴ These opposing factors make a neonate's response to a neuromuscular blocking agent unpredictable.

Opioid Receptors

The mu (μ) and kappa (κ) receptors are responsible for the respiratory depression associated with opioids. In the neonate, changes in the number and affinity of these receptors may account for the increased respiratory depression that results when opioids are used.

γ -Aminobutyric Acid Receptor

The action of general anesthetics may be associated with activation of GABA receptors.^{55,56} The number of GABA_A receptors in the neonate are only one-third that of the adult, and half of these receptors have a high affinity for binding with benzodiazepines and other anesthetics.⁵⁷ The potency of anesthetics and benzodiazepines in neonates could be explained by the high affinity of these receptors.

Drugs Used to Provide Neonatal Anesthesia

Inhalation Agents

Inhaled anesthetic agents equilibrate more rapidly in neonates due to increased minute ventilation, increased cardiac output, which is directed mainly to the vessel-rich group of tissues, and reduced solubility of the inhaled anesthetics in blood. In addition, their decreased distribution of adipose tissue and decreased muscle mass affect the rate of equilibration among the alveoli, blood, and brain. The minimum alveolar concentration (MAC) of the inhalation anesthetics is less in neonates than in infants. Neonates have a somewhat lower MAC, which peaks at approximately 30 days of age and decreases thereafter (Fig. 52.6). The anesthetic implication is that induction is more rapid and the development of cardiovascular side effects can occur more often. The margin of safety between adequate anesthesia and significant cardiopulmonary depression is very narrow. Elimination of inhalation agents, and therefore recovery, is also rapid, provided that cardiopulmonary function is not depressed.

FIGURE 52.6 Effect of age on minimum alveolar concentration (MAC) of anesthetic gases. MAC is higher at birth than in adults and increases until peaking at 3 to 6 months. The values at 1 year of age are closer to the adult values. (From Greeley WJ. Pediatric anesthesia. In Miller RD, ed. *Atlas of Anesthesia*. Vol 7. Philadelphia: Elsevier; 1999:55.)

In the neonatal period during transitional circulation both left-to-right and right-to-left intracardiac shunting occurs. In the presence of a left-to-right shunt, there is a minimal increase in inhalation anesthetic uptake. However, when there is a right-to-left shunt, there is a slowing of the rate of rise of the alveolar concentration of inhaled agent due to the decrease in the anesthetic concentration in arterial blood of the arterial system. The clinical implication of a right-to-left intracardiac shunt is that inhalation induction can require more time prior to loss of consciousness.

Potent inhalation agents depress ventilation in a dose-dependent manner and increase the risk of apnea. Likewise, they readily depress the myocardium and blood pressure because of immature compensatory mechanisms.

Intravenous Agents

Neonates and infants have a higher proportion of cardiac output delivered to vessel-rich tissues (i.e., heart, brain, kidneys, and liver). Intravenous anesthetic agents are readily taken up by these tissues and are subsequently redistributed to tissues less well perfused (muscle and fat). Intravenously administered drugs may have a prolonged duration of action in neonates and infants because of decreased percentages of muscle and fat. The CNS effects of opioids may also be prolonged because of the immaturity of the BBB.⁵⁰ Anesthetists have historically been hesitant to use opioids because of their perceived toxicity profile in neonates, particularly morphine. Fentanyl is well tolerated even in the most critical neonates. It is now understood that appropriate anesthetic drugs are necessary for neonatal procedures.⁵⁸ Significant amounts of anesthetic drugs may be required for complex neonatal procedures.^{59,60} Although some pharmacodynamic evidence suggests that intravenously administered anesthetic doses should be reduced, one must also recall the effect of increased body water. Increased doses of propofol are required, because of increased metabolic rate and a greater volume of distribution.^{43,44,61} In most circumstances, when a neonate requires a surgical intervention, intravenous access is established prior to arrival in the operating room.

Neuromuscular Blocking Drugs

Neonates have an increased sensitivity to the effects of NMBDs. The reason is the result of varied pharmacokinetic and pharmacodynamics profiles as compared to the adult. The increased volume of distribution causes a single dose of NMBD for a neonate that is the same as for the older infant, but due to reduced clearance and increased sensitivity prolong duration. NMBDs are highly ionized and have a low lipophilicity, which limits their ability to cross the BBB. This pharmacologic property restricts the distribution of NMBDs to the ECF compartment, which is larger in the neonate and infant than in the child and adult (see [Table 52.7](#)). Increases in ECF volume and the ongoing maturation of neonatal skeletal muscle and acetylcholine receptors affect the pharmacokinetics and pharmacodynamics of neuromuscular blockers. [Table 52.8](#) references the effective doses of NMBDs in

various age groups.

TABLE 52.8

Effective Doses (ED₉₅) of Clinical Neuromuscular Blocking Drugs (mcg/kg)

Neuromuscular Blocking Drugs	Neonate	Infant	Child	Adult
Succinylcholine*	620	729	423	290
Atracurium	120	156–175	170–350	110–280
Cisatracurium	—	43	41	50
Vecuronium	47	42–47	56–80	27–56
Rocuronium	600	600	600	300
Pancuronium	—	55	55–81	49–70

*Should only be used for emergency airway stabilization in children younger than 8 years. Not for routine intubation.

The neuromuscular junction is incompletely developed at birth. The presynaptic release of acetylcholine is slowed at birth compared with that in the adult, which explains the decreased margin of safety for neuromuscular transmission in the neonate. The acetylcholine receptors of the newborn are anatomically different from the adult receptors, which may explain the sensitivity of the neonate to NMBDs.

Neonates are more resistant to the effects of succinylcholine as compared to children and adults. This is illustrated by the intravenous effective dose (ED)₉₅ for neonates (620 mcg/kg), infants (729 mcg/kg), children (423 mcg/kg), and adults (290 mcg/kg) (see [Table 52.8](#)). The increase in dose requirement is in part a result of the increased volume of distribution within the large extracellular compartment. Plasma cholinesterase activity is reduced in neonates; however, the duration of action after a single dose of succinylcholine is 6 to 10 minutes in duration. A prolonged duration of action after a single bolus dose of succinylcholine would suggest the presence of an inherited deficiency of plasma cholinesterase activity. The FDA recommends that the use of succinylcholine in pediatric patients be limited to airway emergencies due to the increased risk of severe hyperkalemia in patients with undiagnosed myopathies.⁶² Succinylcholine induced hyperkalemia is more frequent in males and in children who are less than 8 years old.

The selection of a NMBD should take into consideration the desired degree and duration of skeletal muscle paralysis, the immaturity of organ systems, and the associated side effects of the selected relaxant. The variability in response to these drugs is significant, particularly in premature infants and neonates. Monitoring of neuromuscular function must be used to guide repeated administration of these drugs in all neonatal patients, just as it should be used in any patient requiring neuromuscular blockade.

Reversal of Neuromuscular Blockade

The neonate is extremely vulnerable to rapid hypoxemia if respiration is impaired due to residual muscle weakness caused by paralytic agents. Neuromuscular blockade should always be reversed unless mechanical ventilation in the postoperative period is planned. The safest treatment of prolonged muscle weakness is to provide sedation and controlled ventilation until the neuromuscular blocker is eliminated.

It can be difficult to determine the adequacy of reversal in neonates. Observing flexion of the elbows and hips, knee to chest movements, return of abdominal muscle tone, and presence of facial grimacing are important signs. Another measurement is the ability to generate a maximum negative inspiratory force (MIF) greater than -25 cm H₂O or a crying capacity of more than 15 mL/kg.⁶³ Neonates are capable of generating an MIF of -70 cm H₂O with the first few breaths after birth.⁶⁴ An MIF of at least -32 cm H₂O has been found to correspond with leg lift, which is indicative of the adequacy of ventilatory reserve required before tracheal extubation.⁶⁵ If a peripheral nerve stimulator is used, the train-of-four should demonstrate the standard 90% recovery.⁶⁶

The two anticholinesterase drugs used for reversal of neuromuscular blockade are neostigmine (0.05–0.07 mg/kg) and edrophonium (0.5–1.0 mg/kg). Neostigmine is routinely administered as it is more potent and, therefore, it has a greater efficacy for inhibiting cholinesterase. An anticholinergic agent, atropine (0.02 mg/kg) or glycopyrrolate (0.01 mg/kg), should be given prior to the anticholinesterase in neonates to prevent

cholinergic side effects such as bradycardia and bronchospasm. Due to similarities in time to onset and duration of action, glycopyrrolate is usually combined with neostigmine and atropine with edrophonium. The selective muscle relaxant binding agent Sugammadex (Bridion) has not currently received FDA approval for administration to patients less than 18 years old.

Drug Preservatives

Premature neonates have a reduced ability to metabolize the preservatives benzyl alcohol and sodium benzoate. Numerous anesthetic and nonanesthetic medications contain preservatives such as benzyl alcohol. This accumulation of benzoic acid can result in benzyl alcohol gasping syndrome, and can manifest as gasping respirations, metabolic acidosis and multiple organ system failure. These agents can produce severe CNS toxicity, seizures, and permanent brain damage. The use of preservative-free drugs and solutions is essential when possible.⁶⁷

Fluid Management

Neonatal fluid management varies based on gestational age, birth weight, rate of caloric expenditure and growth, ratio of evaporative surface area to body weight, the degree of renal functional maturation and reserve, and the TBW.⁶⁸ Total body water accounts for approximately 75% of body weight in term neonate and 90% in preterm neonates. This high percentage of TBW results from expansion of the ECF compartment, which may account for 50% of the TBW. In the first few days of life, a term neonate can lose 5% to 15% of its body weight. Urine output is low, and if the neonate is kept warm, fluid requirements are relatively low, as little as 40 to 60 mL/kg per day.^{69,70} Box 52.4 shows the common electrolyte

requirements in the newborn.

Common Intravenous Fluid and Electrolyte Requirements in the Newborn

Glucose

- Most newborns require 2–4 mg/kg per min.
- SGA/LGA infants may require greater than 15 mg/kg per min on days 1 to 3 of life.
- Glucose tolerance may fluctuate significantly in very low- and extremely low-birth-weight (VLBW and ELBW) infants.

Sodium

- Most neonates require no sodium for the first 24 hours of life.
- On day 2 and beyond, most newborns receive 2 to 4 mEq/kg per day.
- Sodium requirement may change dramatically in response to gastrointestinal, genitourinary, or transcutaneous losses or drug or metabolic effects.

- The ELBW infant may have huge transcutaneous losses, requiring meticulous monitoring and replacement.

Potassium

- Requirements for potassium are minimal for the first 24 to 48 hours of life.
- Subsequently, maintenance delivery is approximately 1 to 3 mEq/kg per day, always in the presence of a normal urine output.
- Serum levels in the newborn, especially VLBW and ELBW, are higher than in older infants.
- Replace gastrointestinal, genitourinary, or iatrogenic losses cautiously.

Calcium

- Requirements for calcium range between 200 and 400 mg/kg per day (calcium gluconate).
- Requirements for calcium vary with gestational age, history of asphyxia, and growth disturbances (e.g., SGA, LGA).
- Serum levels can be obtained for total Ca^{2+} and/or ionized Ca^{2+} .

LGA, Large for gestational age; *SGA*, small for gestational age.

From Gregory GA, Brett C. Neonatology for anesthesiologists. In Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia: Elsevier; 2017:517.

Assessing Fluid Requirements

In the neonatal period, several physiologic and physical factors can affect fluid requirements. The smaller the infant, the larger the percentage of body water to total body weight. With the smaller amount of body fat, the major part of body weight is water. The combination of renal loss and a large insensible water loss makes the neonate prone to dehydration and hemodynamic instability.

There are physical observations that can assist in estimating the fluid status of the pediatric patient, as shown in [Table 52.9](#).⁷¹

TABLE 52.9

Clinical Signs and Symptoms for Estimation of Severity of Dehydration in Infants

Clinical Signs	Degree of Dehydration		
	Mild	Moderate	Severe
Weight loss (%)	5	10	15
Behavior	Normal	Irritable	Hyperirritable to lethargic
Thirst	Slight	Moderate	Intense
Mucous membranes	May be normal	Dry	Parched
Tears	Present	±	Absent
Anterior fontanelle	Flat	±	Sunken
Skin turgor	Normal	±	Increased

From McClain CD, McManus ML. Fluid management. In Cote CJ, et al, eds. *A Practice of Anesthesia for Infants and Children*. 5th ed. Philadelphia: Elsevier; 2013:170.

Anesthesia and surgery have a significant effect on fluid homeostasis and renal function. The combination of vasodilation and myocardial depression, may result in blood pressure fluctuation that alters fluid compartment dynamics, vascular capacitance, and/or organ blood flow. The renin-angiotensin system is inhibited as a result of anesthesia.

Water Requirements

Holliday published a seminal work identifying caloric requirements of the “average” hospitalized infant based on body weight.⁶⁹ A secondary finding was that the water requirement in milliliters was equivalent to the total energy expended in calories. [Table 52.10](#) gives the water requirements of newborns.

TABLE 52.10

Water Requirements of Newborns

Birth Weight (g)	Water Requirement (mL/kg per 24 hr) by Age		
	1–2 Days Old	3–7 Days Old	7–30 Days Old
< 750	100–250	149–300	120–180
749–1000	80–150	100–150	120–180

1000–1500	60–100	80–150	120–180
> 1500	60–80	100–150	120–180

From Merves MH. Neonatology. In Tschudy MM, Arcara KM, eds. *The Harriet Lane Handbook*. 19th ed. Philadelphia: Elsevier; 2012:455–475.

Several considerations in planning the fluid management in the neonatal surgical patient are warranted:

- Degree of dehydration present before preoperative *nil per os* (NPO) guidelines
- Fluid deficit due to NPO guidelines
- Maintenance requirements during anesthesia/surgery
- Estimated third-space loss
- Alterations in body temperature

Due to the nature of the surgical interventions required by neonates, most will have had their fluid status managed in a neonatal unit. If that is not the case, during the time of preoperative evaluation, deficits should be determined and dehydration or electrolyte imbalance should be reversed. Other issues, such as acidosis, low hemoglobin, poor urine output, and poor perfusion should be resolved.²¹

There is no evidence that children who are denied oral fluids for more than 6 hours preoperatively benefit in terms of decreased intraoperative gastric volume and gastric acidity as compared with children permitted unlimited fluids up to 2 hours preoperatively. Children permitted fluids have a more comfortable preoperative experience in terms of thirst and hunger.

Current guidelines for healthy infants (younger than 2 years), children (2–16 years), and adults, should continue fasting from the intake of clear liquids at least 2 hours before elective procedures requiring general anesthesia, regional anesthesia, or sedation/analgesia (i.e., monitored anesthesia care) should be maintained. Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. The volume of liquid ingested is less important than the type of liquid ingested. It is appropriate to fast from intake of breast milk at least 4 hours and infant formula at least 6 hours before elective procedures. Fasting from intake of a light meal or nonhuman milk should be 6 hours or more. Fried or fatty foods or

meat may prolong gastric emptying time. Additional fasting time (e.g., 8 hours or more) may be needed in these cases. Both the amount and type of food ingested must be considered when determining an appropriate fasting period^{72,73} (see [Table 42.2](#) NPO guidelines).

Knowledge of the caloric requirements for a neonate can be used to estimate the maintenance fluid requirements. The classic “4-2-1” rule takes the caloric expenditure into consideration because it is calculated by body weight. A neonate weighing less than 10 kg will require 100 mL/kg per day or 4 mL/kg per hr.

Fluid deficits are a result of preoperative fasting or excessive gastrointestinal (GI) losses. Neonates receiving adequate preoperative maintenance will have no deficit and will require no deficit replacement calculated into the fluid management plan. If there has not been adequate maintenance, the fluid deficit can be calculated by multiplying the hourly maintenance rate by the number of hours without feeding. Total deficit restoration may require several hours or even days in the smallest babies. Current Pediatric Advanced Life Support guidelines recommend an isotonic crystalloid fluid bolus of 10 to 20 ml/kg for severe hypovolemia. The goal is to restore and preserve the cardiovascular stability and renal perfusion.

If total parenteral nutrition (TPN) is being administered, the amount of glucose/kg per min, as well as other components such as sodium, potassium, and calcium currently being administered, should be noted. If at all possible, the TPN should be maintained without interruption. If it must be discontinued, glucose must be monitored vigilantly and dextrose added to the fluid management plan as acute hypoglycemia can occur.

Third-space losses need to be replaced with a solution that does not contain glucose (e.g., normal saline, lactated Ringer's, or Plasma-Lyte). In those patients with abdominal lesions such as gastroschisis or NEC, the third-space losses can be very large. These patients may need as much as 25 to 100 mL/kg per hr to replace fluid loss.

Urine osmolality and specific gravity and serum osmolality are important indices in managing intraoperative fluids in neonates. They provide information as to the need for fluid, solute, and

electrolyte replacement. Normal urine osmolality in the neonate ranges from 49 to 800 mOsm/L, with an average of 270 mOsm/L. Osmolality should be maintained between 200 and 400 mOsm/L and specific gravity between 1.006 and 1.012. Serum osmolality ranges between 270 and 280 mOsm/kg.⁷⁴ Hyperosmolar states can result in intraventricular hemorrhage or kidney damage.

Fluid Management of the Premature Infant

Proper fluid management of the premature neonate requires an understanding of several variables: the extensive variability in body fluid composition, renal maturation, neuroendocrine control of intravascular fluid status, and insensible fluid loss with age.⁷⁵ Renal tubular function develops after week 24 of gestation, and nephrons mature by week 36.⁶⁸ The premature infant has a lower GFR and immature tubular function. The immature kidneys are unable to excrete sodium and excess fluid. The inability to concentrate urine secondary to the inability to reabsorb sodium leads to the excretion of large quantities of dilute urine. Therefore, underestimation of fluid requirements may lead to more serious consequences than overestimation of fluid requirements.^{70,76}

Blood glucose can be highly variable in the premature neonate. Hypoglycemia can be attributed to inadequate glycogen stores and the inability of the immature liver to perform gluconeogenesis. Symptoms of hypoglycemia are jitteriness, cyanosis, apnea, lethargy, hypotonia, and seizures. If not treated rapidly, hypoglycemia in the preterm neonate can lead to neurologic damage. Preterm and SGA neonates can have a glucose requirement of 8 to 10 mg/kg per min to prevent hypoglycemia. Glucose as a D₅ or D₁₀ solution followed by a 10% to 15% dextrose solution can be titrated to maintain a serum glucose level greater than 40 mg/dL.²¹ It is as important to avoid hyperglycemia, which can result in intraventricular hemorrhage, osmotic diuresis, dehydration, and release of insulin, leading to hypoglycemia.

Electrolyte abnormalities are often seen in preterm neonates. Hyponatremia may result if water loss is greater than sodium depletion combined with abnormal renal tubular function. Hypokalemia can result from respiratory alkalosis or aggressive

diuresis. Hyperkalemia can be caused by infusion of large amounts of potassium-containing fluids.

Blood Replacement

Over the first 6 months of life, many physiologic changes are occurring that can complicate the decision to replace blood in the neonatal surgical patient. Fetal hemoglobin (HgbF), which has a higher affinity for oxygen than adult hemoglobin, can range from 70% to 80% of the neonate's total hemoglobin at birth. It can be as high as 97% in the preterm infant.⁷⁷ The clinical implication is that the younger the patient, the higher the fraction of HgbF and thus the lower the oxygen-carrying capacity and oxygen delivery to the tissues.

Replacement of blood loss is critical in the surgical neonate, especially the preterm infant. Their blood volume is very small (85 to 100 mL/kg), and a loss of 10 mL could be approximately 10% of total blood volume. The clinical indication for blood administration should not be based on a predetermined percentage of total blood volume. Maintaining oxygen-carrying capacity and oxygen delivery to peripheral tissues and improving coagulation are the primary concerns. The transfusion trigger in this age group will need to be at higher hemoglobin levels than the older infant or child. Rapid blood loss in neonates can result in cardiovascular complications quicker than in the adult; therefore, transfusion may be required sooner. Low Hgb values at birth (< 12g/dL) was significantly associated with mortality in preterm infants born at or before 32 weeks' gestation.⁷⁸ The decision to transfuse should be based on the underlying and current cardiorespiratory status, ongoing blood loss, anticipated further blood loss, and baseline hemoglobin. Another concern is the presence of congenital heart disease or lung disease, resulting in a decreased ability to oxygenate blood.

The accurate measurement of blood loss in neonates and infants is crucial to any replacement regimen. The margin of safety is reduced in the neonate, and because the oxygen consumption is twice that of the adult, a smaller percentage of blood loss will result in cardiovascular instability. A major cause of cardiac arrest in pediatric surgical patient's results from hypovolemia from blood loss and hyperkalemia from transfusion of stored blood.⁷⁹ It is

mandatory to monitor loss by the weighing of sponges, the use of small calibrated suction containers, and vigilant visual estimation of ongoing blood loss. When saturated, every four inch by four inch surgical sponge is equal to approximately 10 mL of blood loss.

As noted earlier, VE in neonates or infants during anesthesia may lead to fluid overload and can be difficult to assess. New techniques to evaluate transfusion effects include the use of transesophageal Doppler (TED), a noninvasive cardiac output monitoring technique, which can provide a comprehensive estimation of the volume status. TED-derived indexed SV measurement is useful to predict and follow VE responsiveness in neonates and infants without myocardial dysfunction.⁸⁰

Estimating Allowable Blood Loss

The estimated blood volume (EBV) and allowable blood loss (ABL) must be calculated prior to induction of anesthesia for any procedure in which blood loss is expected. EBV is calculated based on age and body weight (see [Table 52.2](#)).

A predetermined acceptable low hematocrit is identified based on the clinical situation and the baby's health. Maximum allowable blood loss (MABL) can be calculated with the following formula in which Hct_0 is the original hematocrit, Hct_1 is the lowest acceptable hematocrit, and Hct_a is the average hematocrit, $(Hct_0 + Hct_1)/2$:

$$MABL = wt \text{ (kg)} \times EBV \times (Hct_0 - Hct_1) / Hct_a$$

Example: A surgical neonate who weighs 4 kg is going to have an abdominal procedure. Beginning hematocrit is 42%. The lowest acceptable hematocrit is 30%. The MABL for this patient is 106 mL.

$$MABL = 4 \times 320 \times (42 - 30) / (42 + 30) / 2 = 106$$

When the blood loss equals or exceeds the calculated allowable loss, transfusion should be considered. The volume of packed RBCs to be infused may be determined by the following formula:

$$\text{Packed RBCs (mL)} = \frac{(\text{Blood loss} - \text{ABL}) \times \text{Desired hematocrit (30\%)}}{\text{Hematocrit of PRBCs (75\%)}}$$

Using the previous example of a 4-kg infant, with a total blood loss of 100 mL, the volume of packed RBCs (PRBCs) would be $175 - 106 \times 30/75 = 27.6$ mL.

The administration of PRBCs can lead to a significant increase in the plasma potassium and cardiac arrest. Hyperkalemia associated with massive transfusion has been reported to be the most common cause of arrest in noncardiac procedures.⁸¹ Rapid administration of PRBCs stored for less than 2 weeks via handheld syringes and small-gauge catheters (23-gauge or smaller) has also been reported to result in hyperkalemia.⁸² Hypocalcemia and cardiovascular instability can result from the rapid administration of blood due to the amount of citrate contained in the stored blood. Whole blood should not be used, and irradiated blood should be given only to immunocompromised patients. Irradiation accelerates the leakage of potassium from RBCs into serum. To reduce the risk of hyperkalemia, washed or fresh (i.e., less than 7 days old) PRBCs should be used.⁷⁷

Anesthetic Equipment

Anatomic differences in the face and upper airway of neonates affect the design of the masks, laryngoscopes, and tracheal tubes. Physiologically, the need to minimize the resistance and dead space has design implications for breathing systems, connectors, and tubes. Disposable, humidified pediatric circle systems are more commonly used in neonates for some important reasons. These systems have low compliance, are lightweight, and, with the addition of plastic valves, have eliminated the high resistance associated with older systems. They also offer a more reliable method of monitoring end-tidal carbon dioxide. Ventilation is most often controlled in these patients, reducing the deleterious effects of the work of breathing in the spontaneously ventilating baby.

The anesthesia machine should be equipped to deliver air when nitrous oxide is not desirable, for example, in the neonate undergoing an abdominal procedure or when it is necessary to reduce the inspired oxygen concentration to avoid the potential for retinopathy of prematurity (ROP), or when maintenance of fetal circulation is desirable (e.g., unrepaired cardiac defects). The newest anesthesia machines have ventilators designed to deliver pressure ventilation modes that are reflective of the tidal volume that is desired. It is also possible to adapt and use the ventilators used in the neonatal intensive care units (NICUs). However, this is not the most desirable method of mechanical ventilation in the operating room. In some pediatric centers, with the most critically ill neonates, certain operative procedures are performed in the NICU to avoid disturbing the delicately balanced ventilation patterns and to preserve cardiorespiratory stability.

Due to the stiff epiglottis and short neck, a straight blade may be preferable. However, in one study in children aged from 1 to 24 months, the Miller and the Macintosh blades provided similar laryngoscopic views and intubating conditions.⁸³ The blade is placed along the right side of the mouth, sweeping the tongue to the left. With a straight laryngoscope blade, the epiglottis is lifted with the tip of the blade and the tracheal inlet exposed. The tube is inserted with the convex side to the left. The advantage of one over

another is the characteristic that allows the large tongue of the neonate to be manipulated out of the visual field. There are also modifications of straight blades that allow insufflation of oxygen into the pharynx during intubation. The use of video laryngoscopy for pediatric patients has become popular especially in those patients who are suspected of a difficult airway. Presently, there is no evidence to suggest that video laryngoscopy is superior or inferior to tradition laryngoscopy.⁸⁴

Oral endotracheal tube (OET) size for neonates cannot be calculated by formula because of the rapid growth during the immediate postnatal period. It can be determined from a table based on kilogram weight (Table 52.11). It is common for the full-term neonate to accommodate a 3.0-mm OET and a premature infant (less than 2 kg) to need a 2.5-mm OET. It is wise to select a tube that will result in an air leak at 20 to 30 cm H₂O pressure to avoid post extubation airway edema.

TABLE 52.11
Recommended Endotracheal Tube Sizes

Neonatal Age	Endotracheal Tube Size
Preterm neonate	2.0–3.0
Full-term neonate	3.0–3.5
3 months to 1 year of age	4.0

The length of the trachea (vocal cords to carina) in neonates and infants up to 1 year varies from 5 cm to 9 cm. Insertion distance of an oral endotracheal tube should be less than 10 cm, falling within the 8 cm to 10 cm range.

Traditionally, the use of an uncuffed endotracheal tube was the accepted method for endotracheal airway management in pediatric patients younger than 8 years old, primarily due to a perceived decrease in the incidence of post-extubation croup. The standard practice in neonatal anesthesia has been the use of uncuffed endotracheal tubes for reasons of airway resistance and tracheal damage from inflated cuffs. The proper use of specially made cuffed endotracheal tubes under certain clinical situations is considered acceptable. Indications include the use of a cuffed OET in certain thoracic or abdominal procedures or when high-pressure or complex ventilator modes are planned. The advantages include

decreased operating room contamination with the inhalation anesthetic agent, the use of lower fresh gas flow rates (more economical), the possible avoidance of repeated laryngoscopy and intubation to assess and seal leaks, more accurate capnography readings, and better control of ventilation.⁸⁵⁻⁸⁷

Monitoring of the neonate during anesthesia is important in detecting those small changes that can be very significant because of their smaller physiologic margin of safety. The precordial or esophageal stethoscope, as the case allows, is a simple means of assessing heart rate, rhythm, and sound, and secondarily extrapolating vascular volume. Continuous ECG monitoring is used for monitoring of not only heart rate but also for detection of arrhythmias, particularly in the baby that has electrolyte imbalances. Pulse oximetry is the standard of care for all patients in a critical care or surgical environment. The other standard monitoring parameters are blood pressure; inspired oxygen concentration; end-tidal carbon dioxide and inhalation agent concentration; and peak airway and end-expiratory pressure monitoring. Neuromuscular monitoring is technically difficult in the neonate, particularly preterm and very low-birth-weight (VLBW) babies, owing to their small muscle mass. Monitoring urine output is difficult due to technical problems of size of the catheters and accessibility of the patient.

Preoperative Assessment

The perioperative management of any neonate is determined by the nature of the surgical procedure, the gestational age at birth, postgestational age at surgery, and associated medical conditions. A comprehensive preanesthetic assessment is essential to competently determine a specific plan of care. Increased perioperative mortality associated with pediatric anesthesia include; children less than 1-year-old, increased American Society of Anesthesiologists (ASA) physical status (III-V), emergency surgery, cardiac or vascular surgeries, and multiple surgeries performed under the same anesthetic technique.⁸⁸

Gestational Age and Postgestational Age at Surgery

The gestational age, postgestational age, and birth weight are critical to the determination of the physiologic development of the neonate. The history of the delivery and the immediate postdelivery course can influence the choice of anesthetic technique and assist in anticipating possible postoperative complications.

Preterm neonates are classified as *borderline preterm* (36 to 37 weeks' gestation), *moderately preterm* (31 to 36 weeks' gestation), and *severely preterm* (24 to 30 weeks' gestation).⁸⁹ Neonates can be classified according to their weight, as well as their gestational age. Full term is considered to be 37 to 42 weeks' gestation. Large for gestational age (LGA) is defined as weight above the 90th percentile at gestational age. SGA refers to weight below the 10th percentile at gestational age. LBW is a weight below 2500 g, VLBW is a weight below 1500 g, and extremely low-birth-weight (ELBW) is below 1000 g. Full-term neonates that are SGA often present with conditions requiring surgical intervention. SGA neonates have different pathophysiologic problems as compared to preterm infants (less than 37 weeks' gestation) of the same weight.⁹⁰ Immaturity as determined by gestational age increases the potential for neonatal pathology. Maternal health problems also can have significant implications for all neonates. [Table 52.12](#) lists several

common maternal problems and the possible associated neonatal sequelae.

TABLE 52.12

Maternal History With Commonly Associated Neonatal Problems

Maternal History	Anticipated Neonatal Sequelae
Rh-ABO incompatibility	Hemolytic anemia, hyperbilirubinemia, kernicterus
Toxemia	Small for gestational age and its associated problems. Muscle relaxant interaction after magnesium therapy
Hypertension	Small for gestational age and its associated problems
Drug addiction	Withdrawal and small for gestational age
Infection	Sepsis, thrombocytopenia, viral infection
Hemorrhage	Anemia, shock
Diabetes	Hypoglycemia, birth trauma, large or small for gestational age and associated problems
Polyhydramnios	TE fistula, anencephaly, multiple anomalies
Oligohydramnios	Renal hypoplasia, pulmonary hypoplasia
Cephalopelvic disproportion	Birth trauma, hyperbilirubinemia, fractures
Alcoholism	Hypoglycemia, congenital malformation, fetal alcohol syndrome, small for gestational age and associated problems

TE, Transesophageal.

Prematurity

Due to the advances in neonatal medicine, many preterm babies born at exceptionally early gestational age and ELBWs are surviving to be challenged with a plethora of unique diseases that pose anesthetic challenges. Prematurity presents its own set of complications, including anemia, intraventricular hemorrhage, periodic apnea accompanied by bradycardia, and chronic respiratory dysfunction. It is beyond the scope of this chapter to address all pathologic conditions regarding preterm neonates and anesthetic implications.

Premature neonates are challenging to evaluate, and considerable controversy exists regarding the appropriateness of elective surgical intervention and proper postoperative care. Post gestational age (gestational age + postnatal age) should be determined at the time

of the anesthetic evaluation. Premature infants of less than 60 weeks' post gestational age have the greatest risk of experiencing post anesthetic complications. The manifestations of prematurity are thought to occur as a result of the inability of the neonate to adequately compensate during periods of physiologic stress. Inadequate development of respiratory drive and immature cardiovascular responses to hypoxia and hypercapnia have been implicated. Therefore, premature infants have a significant risk of postoperative apnea and bradycardia during the first 24 hours after general anesthesia.⁹¹⁻⁹³ **Box 52.5** lists contributing factors that may **Box 52.5** influence the occurrence of apnea in premature infants.

Factors Contributing to Increased Incidence of Apnea in the Premature Infant

Physiologic Contributors

- Inadequate development of respiratory centers
- Incomplete myelination of central nervous system
- Incomplete cardiovascular development leading to altered responses to stress

Metabolic Contributors

- Hypothermia
- Hypoglycemia
- Hypocalcemia
- Acidosis
- Respiratory instability

Anesthetic Contributors

- Residual anesthetics, opiates, relaxants, sedatives
- Prolonged intubation and ventilation

Apnea in the Premature Infant

Apnea of prematurity (AOP) is a significant clinical problem manifested by an unstable respiratory rhythm reflecting the immaturity of respiratory control systems. The ventilatory response to hypoxia and hypercarbia are impaired and inhibitory respiratory reflexes are exaggerated in the neonate. Treatment strategies attempt to stabilize the respiratory rhythm. Caffeine and CPAP remain the primary treatment modalities; methylxanthines such as caffeine are presumed to work through blockade of adenosine receptors. AOP typically resolves with maturation suggesting increased myelination of the brainstem.^{94,95}

Apnea occurs in 7% of babies born between 34 and 35 weeks' gestation, 14% born between 32 and 33 weeks, 54% between 30 and 31 weeks, and in 80% of neonates born earlier than 30 weeks' gestation. Although most apneas resolve by the time the infant reaches 37 weeks' postconceptional age, 80% of VLBW infants, in one study, still had significant apneas at 37 weeks. There are a variety of conditions that predispose an infant to apnea, including CNS lesions, infections and sepsis, ambient temperature fluctuations, cardiac abnormalities, metabolic derangements, anemia, upper airway structural abnormalities, NEC, drug administration (including opiates and general anesthetics), and possibly gastroesophageal reflux. Various monitoring techniques are used to detect apneic episodes, although pulse oximetry and abdominal-pressure transduction are the most common. As noted previously, standard therapy is with caffeine 5 to 10 mg/kg.⁹⁴⁻⁹⁶

Preventing and Treating Apnea.

Anesthesia and surgery for neonates is indicated only when significant pathology exists; then general anesthesia and airway management is most often used. General anesthesia with desflurane (maintenance only) or sevoflurane is preferred due to the rapid emergence. To reduce the risk of perioperative complications related to inadequate ventilation, the use of nonopioid medications

such as ketorolac and acetaminophen are preferable. Spinal or caudal anesthesia can also be performed. Transversus abdominis plane (TAP) blocks can be used safely to decrease the incidence of postoperative pain and decrease the postoperative need for opioids.⁹⁷ Due to the decreased hepatic metabolism and renal excretion of intravenous medication in the neonate, the dose of local anesthetic administered must be calculated to avoid local anesthetic toxicity. There is a risk of local anesthetic toxicity in neonates after a TAP block.⁹⁸

Intubation provides the safest airway control. Extubation should occur when the infant is awake, and shows adequate respiratory effort, with vigorous purposeful movement. All infants under 62 weeks' postmenstrual age (PMA) should be monitored postoperatively with an oxygen saturation monitor and an abdominal pressure transducer. Infants over 62 weeks' PMA with a significant history of apnea or respiratory disease also should be monitored. Infants over 62 weeks' PMA can be discharged following minor surgery after an appropriate period of recovery (minimum 4 hours) if they are stable and otherwise healthy. Higher-risk infants require 24 hours of monitoring.^{94-96,99}

Preanesthetic Assessment and Neonatal Anesthetic Implications

The information gathered during the preoperative assessment will allow the anesthetist to develop an individualized anesthetic plan based on the patient's pathology and the surgical and anesthetic implications. [Table 52.13](#) gives the characteristics of the body system and the anesthetic implications. A thorough review of the birth history such as gestational hypertension, preeclampsia, or gestational diabetes is important. Maternal use of cigarettes, alcohol, or drugs use should also be ascertained.

TABLE 52.13

Preanesthetic Assessment and Neonatal Anesthetic Implications

System	Characteristics	Anesthetic Implications

Central Nervous System	Incomplete myelination	Judicious use of muscle relaxants
	Lack of cerebral autoregulation	Cerebral perfusion pressure control
	Cortical activity	Pain relief/adequate level of anesthesia
	Retinopathy of prematurity (ROP)	Oxygen saturation (94%–98%)
	Birth history	A review of the pregnancy, including complications such as pregnancy-induced hypertension, preeclampsia, gestational diabetes, vaginal bleeding, infections, and falls; also any cigarette, alcohol, or drug (prescription, herbal, illicit) use
Respiratory		
Birth History		Weeks of gestation, neonatal intensive care unit admission, history of intubation or oxygen requirement, maternal complications including infection with herpes simplex virus (HSV) or HIV, and prenatal smoke exposure
Mechanical	↓ Lung compliance	Assist or control ventilation during general anesthesia
	↓ Elastic recoil	
	↓ Rigidity of chest wall	
	↓ V/Q due to lung fluid	
	↑ Fatigue of respiratory muscles	
	↓ Coordination, nose/mouth breathing	
Anatomic	Large tongue	
	Position of larynx, epiglottis, vocal folds, subglottic region	
Biochemical	Response to hypercapnia not potentiated by hypoxia	Avoid hypoxia Maintain normothermia
Reflex	Hering-Breuer reflex	Apnea/no desaturation/stimulation
	Periodic breathing	Stimulation/airway support
	Apnea	
Cardiovascular	↓ Myocardial contractility/↓ myocardial compliance	Maintain adequate intravascular volume Maintain heart rate
	CO rate dependent	Use vagolytic agents
	Vagotonic	
	Limited sympathetic innervation	
	Reactive pulmonary vasculature	Avoid hypoxemia resulting in ↓ PBF and possible shunting
	PDA/FO shunting	

Renal	↓ GFR	Maintain intravascular volume/CO
	↓ Tubular function	Avoid overhydration
	Low glucose threshold	Avoid excess glucose (0.5–1.0 g/kg)
Hepatic	Depressed hepatic enzymes	Judicious use of drugs metabolized by liver
	↓ Metabolism and clearance of drugs	
	Decreased protein (albumin, alpha-acid glycoprotein)	
	Hypoglycemia due to ↓ glycogen stores	
	Low prothrombin levels	Vitamin K (1 mg) before surgery
Hematologic	Fetal hemoglobin (does not readily release O ₂ to tissues)	Avoid hypoxia
	Oxyhemoglobin dissociation curve shifted left
